Carbon isotopes are measured alongside oxygen isotopes in every stalagmite record, but have been more complex to interpret because the influences of regional vegetation and climate are often difficult to distinguish from speleothem specific-in cave effects from degassing and prior calcite precipitation (PCP). The effect of PCP on carbon isotopes are simulated by increasingly sophisticated process models. Here, we present the feasibility, advantages, and disadvantages of using trace element ratios and $\delta^{44}Ca$ to remove the overprinting effect of PCP on measured $\delta^{13}C$ to infer the temporal variations in the initial

$\delta^{13}C$ of dripwater which are set by soil and epikarst processes. In 8 examined stalagmites, the most widely utilized PCP indicators Mg/Ca and $\delta^{44}Ca$ covary as expected, and mutually consistent estimates of f_{Ca}, fraction of initial Ca remaining at the deposition of the stalagmite layer, can be derived from fossil stalagmites even when initial dripwater composition cannot be sampled. Published estimates of the effective slope for the evolution of $\delta^{13}C$ during degassing and precipitation allow estimation of the initial $\delta^{13}C$, from the calculated fCa and measured $\delta^{13}C$ for each sample. We show that in coeval stalagmites from the same cave spanning the 94 to 82 ka interval, trends in calculated initial $\delta^{13}C$ are more similar than those in measured $\delta^{13}C$, and reveal a common positive anomaly in initial $\delta^{13}C$ during a stadial cooling event, as expected from the temperature response of vegetation and soil respiration rates. During deglaciations, the trend of greater respiration rates and higher soil CO_2 is captured in the calculated initial $\delta^{13}C$, despite the tendency of higher interglacial dripwater situation to favor more extensive PCP. These results suggest that the calculated initial $\delta^{13}C$ may be a more readily interpretable proxy variable in many climate settings, especially mid and high latitudes where temperature effects on soil and vegetation are significant and not necessarily coupled with changes in effective moisture and drip rate.

Deciphering climate variability by studying Late Pleistocene cave infillings. Case study: Muierilor Cave, Romania

Dr. Ionut-Cornel Mirea [1]***, Dr. Marius Robu*** [1]***, Dr. Alexandru Petculescu*** [1]***, Dr. Luchiana Faur*** [1]***, Dr. Silviu Constantin*** [1]

1. *Emil Racoviță Institute of Speleology, Romanian Academy, Bucharest*

This study presents data on the complex evolution of the Muierilor Cave system, in the Romanian Carpathian Mountains during the Late Pleistocene. The research included paleontological excavations coupled with sedimentological and geomorphological studies and dated through a combination of U/Th, OSL, and radiocarbon techniques. Studied deposits includes fossil remains, speleothems, and cave sediments and encompass a time range between ~120 ka through Holocene. Within this period, we have identified several evolutive stages of the cave and a succession of paleofloods most likely related to regional climatic changes. As a result, a rich fossil deposit accumulated that includes Upper Pleistocene fauna typical for the MIS 3-2 suggesting that the Southern Carpathians may had constitute a glacial refugia for the LGM great mammals. The taphonomical study combined with dating of speleothems from stratigraphically-relevant positions indicate that significant sediment inflow in the underground occurred between *c.* 22.5-14.5 ka. This suggests a deglaciation on the southern slopes of the Southern Carpathians that occurred earlier than previously known.

This research was supported by a grant of the Ministry of Research, Innovation and Digitization, CNCS - UEFISCDI, project number PN-III-P1-1.1-PD-2021-0262 (ICM) and PN-III-P1-1.1-TE-2021-0187 (to MR), within PNCDI III and further on was supported by KARSTHIVES2 to S. Constantin and RU-TE 2301/2014 (PALEOCLIM) to A. Petculescu.

Implications of modern pollen records on bat guano to paleoecological studies in southeastern Amazonia

Dr. Luiza Reis [1], *Mrs. Cecília de Sá* [1], *Ms. Fernanda Landim* [1], *Prof. Paulo De Oliveira* [2]

1. University of Sao Paulo, 2. Universidade de São Paulo

The rich diversity of bat feeding habits, from species that feed on insects and arthropods to those that feed on fruits, nectar, and flowers, leads to ecological interactions potentially archived in guano deposits. However, although bat guano provides important records about the evolution of the landscape and vegetation around the caves, they are largely neglected in Brazil, especially in southeastern Amazonia where over 1,500 cavities have already been identified. Our study aims to evaluate the pollen signal of guano deposits preserved inside the caves in relation to the surrounding vegetation. For that, bat guano surface samples were collected in five different caves located within the Carajás National Forest and Campos Ferruginosos National Park, in southeastern Amazonia. Our pollen data reveal a high diversity of very well-preserved palynomorphs. The presence of evergreen and forest patches taxa such as Tapirira, Ceiba, Parkia, Caryocar villosum, Alchornea, and Solanum in the pollen assemblage is strongly indicative of the local and regional vegetation cover. The recovery of fern and fungal spores in the pollen assemblage also reflects the warm and humid climate conditions in this region. The pollen data recovered from bat guano reveal that cave deposits in Amazonia provide a reliable substrate to understand the modern pollen and vegetation relationship. Where heavy rainfall and soil erosion occur and there is a paucity of lake, wetland, and swamp habitats, bat guano deposits can naturally be applied as a baseline for paleoenvironment reconstruction and paleoecology studies at both local and regional scales.

Palaeoenvironmental significance of hiatuses in speleothems

Prof. Michal Gradzinski [1], **Mr. Przemysław Sala** [2]

1. Institute of Geological Sciences, Jagiellonian University, Kraków, Poland, e-mail: michal.gradzinski@uj.edu.pl, 2. Instutute of Geological Sciences, Jagiellonian University, Kraków

Speleothems are now widely studied since they are a reliable archive that provides unrivalled record of the past climate changes. However, the speleothems are densely punctuated by hiatuses whose true significance and palaeoenvironmental meaning remain poorly understood. The hiatuses can provide invaluable insights into the periods that are otherwise not archived in spelean carbonates. The study of modern corrosion of speleothems and hiatuses in speleothem sections is still being conducted to unravel the processes which led to hiatus formation. A literature review and the studies carried out so-far enable to group hiatuses in speleothems into four below-mentioned types.

1. Corrosion of speleothems manifested by dissolution features are straightforward indicators of a hiatus surface. Such a kind of hiatus is characterized by irregular relief of the dissolved surface, which may support the deposition of detrital sediments, commonly of residual character, in the irregular voids thus formed. Several environmental factors can cause such type of a hiatus namely: (i) a quick inflow of aggressive percolation of water from the epikarst zone during humid conditions, (ii) episodes of flooding by an underground river, (iii) activity of bats in caves, (iv) condensation corrosion.

2. The presence of a lamina rich in non-carbonate clastic material serves as a significant indicator of the hiatus in a speleothem. Renewal of speleothem growth over such a hiatus is manifested by the re-nucleation of calcite crystals. The deposition of non-carbonate clastics is not always associated with corrosion of older parts of a speleothem. The non-carbonate material associated with a hiatus may also contain soot from fires in caves resulting in black colouration of speleothems.

3. The hiatus associated with the cessation of crystallization, but without any destruction of the formerly originated speleothem is a subtle feature since the younger overgrowth is often of epitaxial type.

4. Mechanical disintegration of a speleothem. The hiatus surfaces are sharp and irregular; they discordantly cut the speleothem. The breakage of speleothems can result from various factors (e.g., seismic shock, frost weathering, instability of surface at which speleothems grew, human activity).

The study is financed by the Polish National Science Centre grant no 2019/35/B/ST10/04397.

A Late Holocene climatic record for the Southwestern USA based on perennial cave ice

Ms. Laura Calabrò [1]***, Mr. Quinton Vitelli-Hawkins*** [1]***, Dr. Viorel Atudorei*** [2]***, Mr. Eric Weaver*** [3]***, Mr. Steve Baumann*** [4]***, Prof. Bogdan P. Onac*** [1]

1. University of South Florida, 2. Earth and Planetary Sciences, University of New Mexico, Albuquerque, 3. National Park Service, El Malpais and El Morro National Monuments, Grants, 4. National Park Service, El Malpais and El Morro National Monuments

A handful of caves and lava tubes worldwide host perennial ice deposits, which are the lesser-investigated members of the *cryosphere.* These deposits occur at elevations well below those of mountain glaciers and in areas outside the permafrost climatic belt, where no surface glaciation exists. These settings make any of the ice deposits in caves or lava tubes particularly susceptible to the current warming trend, leading to the imminent loss of some untapped cryospheric paleoenvironmental archives. Here, we present the results of a paleoclimate study based on an ice deposit accumulated within a lava tube in El Malpais National Monument (western New Mexico). The ice core spans the period 3828.5 to 1001 cal BP and its chronology is based on ^{14}C-dated charcoal present in some ice layers and volcanic reference horizons identified by means of non-sea salt sulfate peaks. The 110-cm-long ice core exhibits oxygen isotopic (δ^{18}O) values varying from −11.78 to −3.54‰. These values are influenced by composition of summer and winter precipitation which, in turn, can be affected by the source of precipitation (Gulf of Mexico versus Pacific). Therefore, the isotopic signal transferred from the atmosphere into the cave ice enables us to trace what main climatic systems affected its accumulation. The wide oscillation of this proxy suggests that several large-scale atmospheric circulation patterns, such as ENSO, the Pacific/North American pattern, the location of the ITCZ, and the North American Monsoon, significantly influence the region. The latter plays a critical role in increasing the isotopic values, showing the strength of summer rainfall over the record, particularly for the intervals 3828.5 to 3600, 2900 to 2400 (especially on 2800 to 2680 and 2650 to 2570), and 1900 to 1700 cal BP. The ice core also provides evidence for periods of prolonged drought, documented by the presence of 5 layers containing charcoal pieces. These are the product of man-made fires that occurred within the lava tube and date back to ~1017, 1121, 1203, 1582, and 1776 cal BP. Prolonged droughts correspond to La Niña phases characterized by weak North American Monsoon; this is especially true for the two oldest events.

Key considerations in developing precisely dated uranium-thorium chronologies from speleothems

Dr. Ellen Corrick [1], ***Dr. John Hellstrom*** [2], ***Prof. Russell Drysdale*** [2]

A key strength of speleothem palaeoclimate records is the accurate and precise uranium-thorium chronologies that underpin them. Uranium-thorium age determinations can be made back to at least 500,000 years, with relative uncertainties typically smaller than 0.5% (2-sigma), reaching 0.1% (2-sigma) in state-of-the-art studies of the late Pleistocene. The ability to be both accurately and precisely dated, in combination with their multiple proxies, has positioned speleothems as a critical archive for constraining the timing of climate events such as Dansgaard-Oeschger events, the Younger Dryas and glacial terminations. However, there are a number of important considerations that arise in the process of developing speleothem uranium-thorium chronologies that can potentially affect both the precision and accuracy of the final chronology. These considerations include: selection of the dating sample location; correction of ages for initial thorium activity (^{230}Th/^{232}Th); outlier identification and resolution; sample depth uncertainty; and interpolation uncertainty in the age model algorithm used. There is currently little guidance in the literature on how to manage these issues. Here we run a number of simulations to explore the potential effects these factors have on the accuracy and precision of speleothem age models. We also identify a set of best practices for producing accurate and precise uranium-thorium based chronologies across climate events, within the constraints of limited age determinations.

Abrupt paleoenvironmental changes during the Terminal Classic Period (800–1000 AD), as indicated by speleothem data from the northern Yucatán Peninsula

The causes for the political collapse of the Classic Maya civilization in Mesoamerica during the Terminal Classic Period (TCP, c. 800–1000 AD) are heavily debated and discussions include the impact of both natural (e.g., droughts) and social disasters (e.g., warfare and unsustainable economy). An increasing number of records from various paleoclimatic archives (e.g., lake sediments or speleothems) points to recurrent multi-year droughts that coincide with the end of monumental construction, abandonment of cities and political disintegration during that period.
Here we present a multi-tracer speleothem record from Áaktun Kóopo cave near Valladolid on the northern Yucatán Peninsula. High-precision ^{230}Th/U dating shows that this stalagmite grew during the last 1400 years. The stable isotope record (δ^{18}O and δ^{13}C values) has an average temporal resolution of 2–3 years per sample, while the laser ablation ICP-MS trace element record (e.g., Mg/Ca, U/Ca, …) reaches sub-annual resolution.
δ^{18}O values show pronounced variability on the inter-annual to sub-decadal scale and increase to peak values of around −4‰ during the TCP, which we interpret as a continuous increase in arid climatic conditions. Around 850–900 AD, i.e. during the TCP, speleothem U/Ca ratios and δ^{13}C values show a pronounced shift, indicating major changes in aquifer recharge and vegetation/soil system. δ^{13}C values drop from an average of −8‰ (~600–850 AD) to values of −11‰ (~900–1700 AD). This shift may have resulted from a change in the vegetation and soil zone above the cave due to an abandonment of the area and a subsequent return to natural tropical forest. In addition, U/Ca ratios increase by a factor of two in the following period (~900–1700 AD), which may be linked to increased soil activity during this time. Ongoing work includes the incorporation of other hydroclimate-sensitive trace elements such as Mg/Ca and Sr/Ca to disentangle local and regional hydrological processes, as well as radiocarbon analysis (dead carbon fraction) to constrain changes in soil turnover times and host rock dissolution. This speleothem record may thus allow to investigate the local and regional climatic forcing as well as the environmental response to the collapse of the Maya civilization on the northern Yucatán Peninsula.

Hydroclimate variability in the Caribbean during the Last Glacial Period

We provide a speleothem record spanning 98.7-84.9 ka BP from western Cuba. During 85–87.6 and 90.2–93.1 ka BP, our record reveals two different periods of high $\delta^{18}O$ corresponding to dry and/or cold periods, coinciding with Heinrich events 8 and 9. (H8 and H9). Thus, we present the first proxy evidence of the local climatic response to H8 and H9 in the Caribbean. Intriguingly, H8 is more apparent than H9, which may represent a local reaction to lower temperatures in the North Atlantic resulting in a weak AMOC and less deep water formation, therefore a greater southward shift of the ITCZ. Our results supplement existing speleothem records from western Cuba, which combined offer a virtually continuous paleoclimate time-series covering the past 100 ka BP and indicate a persistent response to millennial-scale episodes as dry and/or colder conditions. A study of regional paleoclimate data indicates an anti-phased link between the Caribbean and South America, induced by the southward migration of the ITCZ during millennia-scale occurrences, which resulted in drier conditions in the Caribbean and a more robust South American Monsoon System.

The spatiotemporal extent of the Green Sahara: A multi-proxy speleothem record from NW Africa

Dr. Yassine Ait Brahim [1]***, Dr. Lijuan Sha*** [2]***, Dr. Jasper Wassenburg*** [3]***, Prof. Hai Cheng*** [2]***, Dr. lhoussaine Bouchaou*** [4]***, Dr. Francisco Cruz*** [5]

The Sahara Desert, one of the world's most hostile ecosystems, has seen times of increased precipitation during which prehistoric people were able to survive. As a result of the paucity of paleoclimate data, the date and moisture sources of the Green Sahara remain unknown. We report a multi-proxy ($\delta^{18}O$, $\delta^{13}C$, $\delta^{17}O$, and trace elements) climatic record from NW Africa based on speleothems. During MIS5a and the Early to Middle Holocene, our data reveal two Green Sahara eras. The constancy of paleoclimate records throughout North Africa illustrates the east-west breadth of the Green Sahara, while millennia-scale cooling episodes in the North Atlantic have repeatedly led to drier conditions. We show that an increase in winter precipitation coming from the west during MIS5a led to favourable climatic circumstances for human population survival. The dramatic climatic degradation and decrease in human population density in the Sahara during the transition from MIS5 to MIS4 are indicative of climate-driven dispersals of local populations, which may have had ramifications for migratory routes out of Africa.

Improving Heinrich 1 chronology through Iberian speleothems

Mrs. Laura Endres [1], ***Prof. Heather Stoll*** [2]

1. *Geological Institute, ETH Zürich,* ***2.*** *(5) Department of Earth Sciences, ETH Zürich, Zürich, Switzerland*

Past changes in the Atlantic meridional overturning circulation (AMOC) represent a meaningful test case for abrupt climate events, given the multiple cascading feedbacks in the involved climate components such as ice sheets, ocean currents and shifts in atmospheric patterns. Multiproxy data ($\delta^{13}C$, $\delta^{18}O$, trace elements) from the Northwest Iberian speleothem archive (NISA) have recently shown to be highly sensitive to changes in salinity and sea surface temperature in the North Atlantic. This archive has a) the advantage of featuring the North Atlantic as the only moisture source, and b) provides simultaneous records of temperature and salinity changes in a single specimen. However, speleothems provide irregular time series and changes in growth rates over time occur regularly. To quantify rates of centennial to millennial change in AMOC from these records – crucially needed for modelling – a focus needs to be on deriving accurate age models and associated age uncertainties. We present here thoughts and approaches from the proxy side, with first results from a case study covering Heinrich stadial 1. We compare the similarity of two NISA speleothems over this period featuring several abrupt changes in isotopes and trace elements, but also a relatively slow growth (2-10 µm). Because of the large sample size needed for U-Th dating, a decent amount of mixing between growth layers occurs, limiting the accuracy of the estimated rates of changes. We address this challenge by tailored new U-Th dating, based on confocal microscopic images and prior isotopic measurements to constrain the main transitions in more detail. Additionally, age model reliability is improved by detecting changes in growth rates through higher resolution ^{14}C measurements. For ^{14}C, we assess the radiocarbon reservoir effect through coupled U-Th and ^{14}C measurements. If present, fluorescent layers or trace element cycles are additionally used as floating chronologies, anchored by the U-Th dates.

High-elevation speleothems suggest close coupling between North Atlantic millennial-scale variability and Alpine glacier dynamics during Marine Isotope Stage 8

Bundesamt für Strahlenschutz (BfS), GFZ - German Research Centre for Geosciences, Section 4.3 Climate Dynamics and Landscape Evolution, Potsdam, Germany

Processes triggering abrupt climate transitions during glacial periods are still not fully understood. Most research has focused on the last glacial cycle, limiting our test bed for studying the occurrence and absence of millennial-scale variability and, thus, our understanding of these large-scale reorganisations of the climate system under different background conditions.

Here, we present new stalagmite oxygen and carbon data from high-elevation caves in central Switzerland covering the period from ~300 to 200 ka. We demonstrate that millennial-scale variability recorded by these speleothems is representative of Northern Hemisphere interstadial-stadial variability. We use isotope-enabled fully-coupled ocean-atmosphere model simulations to show that the $\delta^{18}O$ value of meteoric precipitation was higher by ~1 ‰ during interstadials compared to stadials. This agrees with interstadial-stadial amplitudes of the last glacial cycle recorded by stalagmites from other caves in the Alps and is likely the result of North Atlantic seawater $\delta^{18}O$ millennial-scale variability.

We find that the effect of prior carbonate precipitation (PCP) is superimposed on the meteoric $\delta^{18}O$ signal, amplifying the isotope signal captured by Alpine speleothems on interstadial-stadial timescales. We propose that PCP variability provides a new proxy for milllennial-scale dynamics of warm-based paleoglaciers above these caves.

Seasonal climate conditions during the Penultimate Interglacial-Glacial Periods as recorded in speleothems from midcontinent North America

Ms. Melissa Reusche [1], ***Dr. Cameron Batchelor*** [2], ***Dr. Ian Orland*** [1], ***Prof. R. Lawrence Edwards*** [3], ***Dr. Feng He*** [4], ***Dr. Shaun Marcott*** [1]

1. *Department of Geosciences, University of Wisconsin- Madison,* ***2.*** *Department of Earth, Atmosphere, and Planetary Sciences, Massachusetts Institute of Technology,* ***3.*** *Department of Earth Sciences, University of Minnesota,* ***4.*** *Center for Climatic Research, University of Wisconsin-Madison, WI 53706, USA;*

Terrestrial climate records that include the Penultimate Interglaciation (PIG) and Glaciation (PG) are rare, and often suffer from larger geochronological uncertainties. This temporal data gap is more apparent when considering seasonally resolved climate archives. The PIG and PG archives that do exist generally are from lower latitudes, and thus are not representative of the atmospheric and climatic conditions of midcontinents, particularly in North America. Here we produce a seasonally resolved record of PIG and PG climate in midcontinental North America by combining microscopic imaging and micro-scale oxygen isotope ($\delta^{18}O$) measurements by ion microprobe from two speleothems that grew at the Cave of the Mounds in southern Wisconsin (USA). This cave was proximal to the margin of the Laurentide Ice Sheet during the PG. Prior work at this location demonstrated an increase in winter precipitation during the late Holocene, but relatively dry winters during the Last Interglacial Period. We further investigate climate conditions at Cave of the Mounds by applying both high resolution measurements and isotope-enabled climate modeling to compare seasonal variations in $\delta^{18}O$ during the PIG and the PG to resolve changing seasonality across climate mean states.

High resolution hyperspectral and discrete analysis of Adamello glacier ice-core sections from the ADA270 drilling project

Dr. Deborah Fiorini [1], ***Prof. Barbara Delmonte*** [1], ***Prof. Valter Maggi*** [1], ***Dr. Biagio Di Mauro*** [2], ***Prof. Roberto Colombo*** [1], ***Dr. Roberto Garzonio*** [1]

1. *University of Milano-Bicocca,* **2.** *Institute of Polar Sciences, National Research Council (ISP-CNR))*

Paleoclimatic information recorded in polar and mountain glaciers are very important to study climate and environmental changes, telling a story about the ancient past and the ongoing cryosphere response to the anthropogenic impact. In this contest, a new high spatial resolution ice-core analysis has been done using a hyperspectral system, which allows to detect ice characteristics related to paleoclimatic information in a new non-destructive way. This improves the accuracy of measurements and the preservation of samples. The hyperspectral analysis has been applied on sections from the ADA270 ice core project, drilled in 2021 at the Adamello-Mandrone glacial group (Pian di Neve, Eastern Alps, Italy). The optical method acquires reflectance images collecting spectral radiance in 840 bands in visible and NIR wavelengths (400-1000 nm). Different optical descriptors have been computed from all reflectance spectra to measure variations due to ice features and impurities encloses in ice layers. In particular, we considered the surface albedo and two spectral indices: Snow Darkening Index (SDI) and Impurity Index (II). From such descriptors continuous records along the core, in particular Albedo and SDI, samples are accurately selected and melted to make a discrete analysis with a Coulter Counter Beckman Multisizer 4e to make a calibration. Analyzed features are ice lenses, visible air bubbles, medium supposed dust concentration and high content of visible materials. The discrete data have been matched with SDI values for all analyzed sections to apply a regression model. A calibrated curve for impurities concentration has been created, providing a very important tool to not systematically apply destructive measurements in all ice-core sections. For a depth ranging from 14 m to around 35 m, many high concentration peaks (to a maximum of 30-35 ppm) have been identified and associated to visible impurities layers. The rest of the curve, highlights concentrations lower than 5-6 ppm. We have great confidence that the analysis of ice trough hyperspectral imaging has a great potential for improving the analysis of ice cores, guaranteeing the preservation of pristine cryosphere records over time.

Evolution of the Critical Zone environment in the Forni Glacier forefield, European Alps: a top-down approach based on key environmental factors after glacier retreat

Prof. Giovanni Leonelli [1], ***Dr. Anna Masseroli*** [2], ***Prof. Luca Trombino*** [2], ***Prof. Eric Verrecchia*** [3], ***Dr. David Sebag*** [4], ***Dr. Alessio Golzio*** [5], ***Mr. Adalberto Bonetti*** [6], ***Prof. Valter Maggi*** [7], ***Prof. Manuela Pelfini*** [2]

1. *Università di Parma,* ***2.*** *Università di Milano,* ***3.*** *University of Lausanne,* ***4.*** *IFP Energies Nouvelles, Rueil-Malmaison,* ***5.*** *Università di Torino,* ***6.*** *School,* ***7.*** *Università di Milano-Bicocca*

Glacier retreat, mainly driven by the ongoing warming of the atmosphere, is globally exposing forefields that if found at lower altitudes than the species limits, rapidly undergo colonization from the ecosystem, thus giving place to pedogeneis and to the development of a fully functioning Critical Zone (CZ) environment. By assuming a top-down approach from the top of tree canopies to soil, we analysed key environmental factors from the air, forest, water, and soil sectors, for describing and reconstructing pace and timings of the environmental and landscape changes occurred in the Forni Glacier forefield since the end of the Little Ice Age. The most evident landscape change is the forest growth and trees advance in the forefield: here trees taller than 2m high form a Glacier Forefield Treeline (GFT). Below and behind the GFT, a fully functioning Critical Zone (CZ) environment exists. Here, the lag time between surface exposure after glacier retreat and the successful tree establishment (i.e. the trees' minimum ecesis interval) reaches a median value of 38yr and generally shows decreasing values towards the glacier front. Above the GFT, in the proglacial area where an incipient CZ exists, the ecesis shows a median value of 8yr and reaches the minimum value of 1yr. The early stages of the CZ development in the proglacial area resulted strongly influenced by poor soil conditions and by the katabatic winds influencing the colonisation patterns of saplings and young trees. Soil moisture potential, assessed by means of a topographic wetness index, showed a dependence on past glacier positions up to the Last Glacial Maximum. In the valley floor the different moisture conditions were associated to type of flows and to different water isotopic signatures found in summer 2016 in the different geomorphological contexts of the CZ environment: running waters (δ^2H = -36.17‰ and δ^{18}O = -4.74‰ wrt. the local rain); alongside the stream (or in topographic depressions); in the valley floor, lateral valleys, concave slopes (δ^2H = +29.44‰ and δ^{18}O = +1.58‰ wrt. tlr.); in the reliefs, ridges, convex or steep slopes.

Assessing glacier surface reduction and recent climatic variations within small glacial catchments – The Fumo Valley case study (Southern Rhaetian Alps, Italy)

Dr. Manuel La Licata [1]

1. *University of Pavia*

The assessment of climate change impacts within small Alpine catchments is essential for evaluating specific mitigation responses, predisposing environmental conservation strategies and planning a sustainable watershed management. In this study, glacier surface reduction from Little Ice Age to present and recent climatic variations were assessed in the Fumo Valley (Adamello Group, Southern Rhaetian Alps, Italy), which is a natural protected area with a high scientific-cultural value providing several ecosystem and socio-economic services (e.g., water resources for hydroelectric power generation).

Sentinel-2 multispectral satellite images were used to elaborate a present-state glacier inventory through a combination of remote sensing techniques, which was compared to previous published glacier inventories in order to assess numerical and geometrical surface variations. Also, two temperature data series related to different thirty-years periods were analysed to assess air temperature variation.

The results highlight a total surface loss of 5.99 km^2 (-71.0%) from 1850 to 1958. Between 1958 and 2022 a total area reduction of 0.87 km^2 (-35.5%) has been observed, which is comparable to other studies carried out at national scales. However, a marked progression phase has been observed between 1958 and 1981 (+76.3%), which is partially imputable to the glacial readvance episode occurred between the 1970s and the 1980s in the European Alps. After this phase, glaciers have been declined by 63.4% (1981-2022), with an accelerated regression phase between 2015 and 2022 (i.e., higher annual rate of variation, formation of ice-contact lakes, tongue separation and severe glacier fragmentation). The mean annual air temperature rose of 0.6°C between 1971-2000 and 1991-2020 periods, with a greater variation recorded for the mean annual maximum temperature (+1°C) if compared to the mean annual minimum temperature variation (+0.1°C) and a higher average temperature increase during spring and summer than in autumn and winter.

The results of this study can be interpreted as clear indicators of the impact of climatic change on local scale, highlighting the vulnerability of the study area with respect of the predicted future climatic scenarios. The climate change impacts are expected to intensify in the next decades, with significant implications for hydrological cycle, geomorphological hazards, landscape evolution and ecosystems.

Mediterranean to Hemispheric circulation influence on African mineral dust in ice cores of the European Alps

Prof. Valter Maggi [1]***, Prof. Barbara Delmonte*** [1]***, Dr. Giovanni Baccolo*** [2]***, Dr. Massimiliano Clemenza*** [3]***, Dr. Elena Di Stefano*** [4]***, Prof. Giovanni Leonelli*** [5]

Alpine ice core records are typically restricted to a regional scale and to relatively short timescales, allowing for detailed reconstructions of the European atmospheric and climatic history of the last centuries. Thanks to their position in the middle of Europe, ice cores drilled in the Alps have allowed to extensively investigate the impact of climatic changes and environmental activities on glaciochemistry and to assess the role of the Saharan mineral dust deposited in Southern Europe. The analyses highlight [gl1] a link between the atmospheric mineral dust records from the Colle del Lys ice core and the NAO variations. In fact, the two opposing Azores high and Icelandic low pressure centers not only control the trajectory of cyclones and therefore very long-range transports, but also the turbulence over North Africa, which determines the injection of dust into the atmosphere. The observed robust similarity between the Colle del Lys dust record and the Sahel Precipitation Anomaly indicates that there is a relationship between events in the Sahel, normally correlated to monsoons in the Indian Ocean, and dust transport events in the Mediterranean area. The correlation between the Sahel and the ENSO events has been already observed in the past, but this is the first time that it is possible to observe the effect of this mechanism in the European Alps.

A gradual-rather-than-abrupt mechanism caused the Mid-Pleistocene Transition

Mr. Etienne Legrain [1]***, Dr. Frédéric Parrenin*** [2]***, Dr. Emilie Capron*** [2]

1. *Institut des Geosciences de l'Environnement (IGE), CNRS,* ***2.*** *Université Grenoble Alpes, CNRS, IRD, Grenoble INP, IGE*

The Mid-Pleistocene Transition (MPT, ~1.2-0.8 Ma) corresponds to a time interval when high amplitude ~100 ka glacial-interglacial cycles replaced the more subdued ~40 ka glacial-interglacial cycles. Whether the MPT was triggered by physical processes affecting the climate system at a specific time interval or more gradually over the course of the Pleistocene, is still an open question. In this study, we use an original approach based on conceptual modeling to identify the temporal structure of the MPT controlling factors. We present a new conceptual model which quantifies the global ice volume over the past 2 Ma. Our model switches between two states, a glaciation state and a deglaciation one, following a threshold mechanism related to the input parameters and the modelled ice volume itself.

Orbital-only, gradual and abrupt forcing hypotheses are tested using three simulations of our conceptual model in order to compare the relevance of each mechanism. The first one named the "ORB simulation", uses only orbital parameters as forcing inputs. In addition to accounting for the orbital forcing, the second simulation referred to as "ABR simulation" hereafter, includes a time-determined abrupt change that makes it more difficult afterwards to trigger a deglaciation. In the third simulation called "GRAD simulation", the initiation of a deglaciation is modulated by a continuous trend throughout the Pleistocene, while the orbital forcing is still considered too.

Our results show that the GRAD simulation best reproduces the change in frequency and amplitude of glacial-interglacial cycles observed during the MPT in the global ice volume reconstruction. Still, the good model-data comparison obtained using the ORB simulation suggests that the orbital forcing must be at least partly responsible for the MPT. In contrast, the results obtained with the ABR simulation are less relevant. Therefore, we propose that the MPT was due to the combination of the orbital forcing with an additional forcing characterized by a gradual change across the past 2 Ma. Our results support the hypothesis that a progressive decrease in atmospheric CO_2 concentrations throughout the Pleistocene played a key role in triggering the MPT.

Trace metal analysis of LEG 138 through the Pliocene-Pleistocene Transition

Mr. Oriol Teruel [1]

1. Intitute Of Environmental Science and Technology

Mineral dust aerosol is a main part of the climate system. Apart from sea salt, it is the most abundant primary aerosol and influences the radiative energy budget of the atmosphere. Aeolian mineral dust can intensify primary marine productivity and can be important for pedogenesis in distant areas. Trace metal can be a good proxy of the mineral dust deposition in the ocean. To understand the climate changes of the past it is required to have a precise reconstruction of the past atmospheric dust load and aeolian dust fluxes. Global climate change of the past 4 million years includes the end of the Pliocene warm period (5-3 Myr ago), the intensification of the Northern Hemisphere glaciation (2.75 Myr ago) and the emerge of the 100-kyr ice age cycles between 1.2 and 0.8 Ma ago. Therefore, Walker circulation seemed to be weaker during the warm Pliocene period.
Here, we present the results of the analysis of major trace metals of the IODP expedition LEG138, sites 848 to 854, a North (11.22ºN) – South (2.99ºS) transect through the meridian 110,00ºW situated at the Eastern Equatorial Pacific, of the last 4 million years. We analyze the data to infer changes in the atmospheric circulation on orbital scales, and to assess its meridional and zonal response during major climate transitions since the Pliocene.

Orbital forcing modulation of Indo-Pacific teleconnections during the past 2 million years

Mrs. Isma Abdelkader Di Carlo [1], ***Dr. Pascale Braconnot*** [1], ***Prof. Axel Timmerman*** [2], ***Prof. Mary Elliot*** [3], ***Dr. Olivier Marti*** [1]

1. *LSCE-IPSL, Laboratoire des Sciences du Climat et de l'Environnement (CEA-CNRS-UVSQ), Paris-Saclay,* ***2.*** *IBS Center for Climate Physics, Pusan National University,* ***3.*** *Laboratoire de Planétologie et Géosciences, UMR 6112, CNRS, Nantes Université, 2 rue de la Houssinière, BP 92208, 44322 Nantes CEDEX 3*

Understanding the teleconnections between the Indian and Pacific oceans is key to better mitigating climatic impacts in the future. This often translates into studying the linkage between their dominant modes of interannual variability, respectively, the Indian Ocean Dipole (IOD) and El Niño-Southern Oscillation (ENSO). Positive phases of the IOD have been shown to correlate with positive phases of ENSO in present times, indicating a positive relationship between the two. A new type of positive IOD has been observed in recent decades that develops and terminates earlier than usual. In the past, some paleo records suggest that the Indian ocean's variability has changed with time, including the emergence of a so-called "equatorial mode." Also, results of the Holocene show that seasonal changes in the mean state resemble that of an IOD pattern in boreal autumn and that the ENSO-IOD teleconnection was affected by insolation forcing. Thus, several effects must be considered in these IOD-ENSO modulations, including seasonal changes that affect variability and teleconnections. Here, we use an accelerated transient Coupled General Circulation Model (CGCM) simulation covering the last 2 million years. This allows us to systematically identify how the changes in seasonality and the variation of the Asian monsoon alter the Indo-Pacific relationship. A focus will the on the analyses of the respective role of the atmospheric and oceanic bridges in shaping the equatorial sea surface temperature variations.

Characterizing AMOC multi-stability on glacial-interglacial time scales in an Earth system Model of Intermediate Complexity

Dr. Markus Adloff [1], ***Dr. Frerk Pöppelmeier*** [2], ***Dr. Aurich Jeltsch-Thömmes*** [3], ***Prof. Thomas Stocker*** [2], ***Prof. Fortunat Joos*** [3]

***1.** Institute of Geological Sciences and Oeschger Centre of Climate Change Research, University of Bern, Switzerland,* ***2.** Climate and Environmental Physics and Oeschger Centre for Climate Change Research, University of Bern, Switzerland,* ***3.** Climate and Environmental Physics and Oeschger Centre for Climate Change Research, University of Bern*

Variations of the Atlantic meridional overturning circulation (AMOC) are associated with Northern Hemisphere and global climatic shifts throughout the Quaternary. Hysteresis behaviour of the AMOC has been found in a hierachy of numerical circulation models, suggesting that tipping points might exist at which small perturbations can cause disproportionately large circulation and hence climatic changes. We discovered such tipping points in simulations with an intermediate complexity Earth system model, which is fast enough to study this non-linear behaviour systematically over entire glacial cycles with varying boundary conditions. The simulations revealed that the glacial AMOC is more stable than the interglacial one, and that several stable circulation states between the interglacial and glacial end-members exist. We present the circulation and sea ice patterns that characterise the stable circulation states between which the model alternates during a glacial cycle, and the influence of radiative forcing and orbital constellation on the timing of the shifts. Our simulations also show how the sudden circulation changes affect the regional and global climate. When increasing the radiative forcing beyond levels characteristic of Quaternary interglacials, the temporal variability of the interglacial AMOC increases but our model does not tip into another stable AMOC state.

Constrain the latest Pleistocene climate changes in Lanzarote deposit using calcretes and insect nests.

Lanzarote, the easternmost island of the Canary Archipelago, represents an interesting study area to define the late Quaternary past climate changes occurred in extreme environments.

Mostly recent works have been addressed to palaeosoils formed as consequence of the dust storms coming from the close Sahara Desert; few have been addressed to calcretes (hardpan) and associated insect fossil nests -called "oothecae". Fossil nests are normally found in situ in 10 to 15 cm thick calcrete layers.

They occur in the NE part of the island where Late Quaternary deposit fill the El Jable plain. This is characterised by Late Pleistocene alluvial-fan systems merging into a wide central aeolian dunefield. Deposits are soils and calcretes alternated with dunes. The former are associated to humid-warm climate phases, the latter to cold-dry that alternate during the last 125 ky.

Our work concentrated on the upper 5 m thick sedimentary deposits of the Muñique quarry where 25-centimetre thick aeolian sandstones alternate with 1-5-centimetres thick hardpan interested by oothecae nests occur. Alluvial deposits appear at the bottom and top.

Eight *Hemycicla sp* samples for ^{14}C dating have been collected from different layers of hardpan and from the bottom and top deposits. The bottom has been dated at 30677 ± 319 cal BP, whereas the top at 12730±23.5 cal BP. Ages encompass the latest Marine Isotope Stages 3 (MIS3) and MIS2, specifically, the top matches the last-Pleistocene cold phase known as "Younger Dryas Stadial".

Although no precise information on the species is yet known, it is a fact that oothecae were built in situ by insects that did not dig in hard soils but only in soft, moist soils. It is reasonable to assume that they nested in a favourable humid environment.

The presence of hardpan with associated oothecae could be interpreted as damp moment as a result of climatic fluctuations in arid and semiarid regions. It is known that warm-cold high frequency millennium scale alternation known as Dansgaard-Oeschger (D-O) occurred during the last glacial time, particularly during the MIS3. We claim that hardpan and oothecae developed during the wet, humid phases associated with D-O stadial events.

Simulations reveal causes of inter-regional differences in Pliocene climatic periodicity

Dr. Xiaofang Huang [1]***, Prof. Shiling Yang*** [1]***, Prof. Alan Haywood*** [2]***, Dr. Julia Tindall*** [2]***, Prof. Dabang Jiang*** [3]***, Dr. Yongda Wang*** [1]***, Ms. Minmin Sun*** [1]***, Mr. Shihao Zhang*** [1]

1. *Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences,* ***2.*** *School of Earth and Environment, University of Leeds,* ***3.*** *Institute of Atmospheric Physics, Chinese Academy of Sciences*

The Pliocene Epoch (5.33-2.58 Ma) is a generally warmer interval with atmospheric CO_2 concentrations at or slightly above modern levels. Many geological records show dominant periodicities of about 41 ka and/or 21 ka during the Pliocene and have been ascribed to variations in Earth's orbital parameters. However, the mechanism for inter-regional differences in climatic cycle remains unclear. Here we perform four idealized experiments of orbit parameter's extremes, using a sophisticated coupled ocean–atmosphere global climate model, HadCM3. Our results show that changes in temperature induced by obliquity are large (>5 ℃) over high latitudes and relatively small (~0-2 ℃) over low latitudes, whereas those induced by precession or eccentricity are comparatively small (~0-3 ℃) worldwide. In contrast, precipitation changes driven by obliquity, precession, and eccentricity are all very small (~0.5 mm day^{-1}) over high latitudes, while over low latitudes, precession-induced changes in precipitation are dramatic (>2 mm day^{-1}) and those induced by obliquity or eccentricity are significant (~0-1 mm day^{-1}). These results indicate that the most notable effect of obliquity on climate occurs over high latitudes, whereas precession affects the climate mainly at low latitudes. Our findings reasonably explain not only the predominant 41 ka climatic periodicity at high latitudes and in marine oxygen isotope records regulated by high-latitude ice volume, but also the dominant 21 ka climatic cycle over low latitudes and the Mediterranean region.

Response of the Indian vegetation and monsoon changes during contrasting glacial periods: the MIS 14, 10, 6 and 4-2

Dr. Coralie Zorzi [1], ***Dr. Stéphanie Desprat*** [1], ***Mrs. Clara Boutreux*** [2], ***Mrs. Pomeline Chuet*** [2], ***Dr. Dulce Oliveira*** [3], ***Ms. Charlotte Clément*** [1], ***Prof. Philippe Martinez*** [1]

The Indian Summer Monsoon (ISM) appears particularly sensitive to ongoing climate change and its variability could have been a threat to freshwater availability, as well to sustainable agriculture in India in the near future. Despite intensification of monsoon rainfall suggested by the numerical models, severe droughts were recently recorded in India having dramatic consequences for the population and economy of the country. Hence, past ISM collapses have led to water scarcity and severe famines that were unfavorable to the long-term stability of societies such as for the Harrapan Civilization.

In order to better understand environmental changes and climatic mechanisms leading to catastrophic weak monsoon intervals in India, we aim at documenting the ISM variability during four glacial periods characterized by distinctive boundary conditions, namely the MIS 14 (~560-535 ka), 10 (~370-335 ka), 6 (~190-130 ka) and 4-2 (~80-20 ka). This study is based on an original approach that consists of pollen analysis of marine sediments drilled at IODP Site U1446, which gives an integrated image of the vegetation from the Mahanadi hydrological basin, and therefore of climate within the Indian core monsoon zone.

Low tropical tree percentages associated to grassland (Poaceae) expansions are recorded during all glacial maxima of the four studied periods revealing reduced hydrological cycle. In opposite, maximal development of tropical trees is recorded during the early MIS 14 when percentages of Combretaceae/Melatomataceae, *Glochidion*, *Mallotus*, *Hopea*/*Shorea* and *Tectona*, reach late Holocene values suggesting the highest ISM rainfall of the four glacial periods. A progressive change from a wooded savannah to an open environment composed by a varying proportion of grasslands, arid (Amaranthaceae and *Ephedra*) and semi-arid herbs (*Artemisia*) is also recorded during the MIS 10, 6 and 4-2. Therefore, a similar pattern displays in glacial vegetation records, in which a decrease in tropical trees and associated herb expansions, reflect a long-term ISM decrease during the four studied intervals. Herein, we suggest that the glacial aridification mirrors the global ice volume, although distinctive composition of the vegetation may also reveal a modulated response of the ISM to different factors such as sea-surface temperatures, ice-sheet distribution and/or orbital forcing (obliquity).

Bølling-Allerød warming as a part of climate internal self-oscillation

Dr. Yuchen Sun [1]***, Prof. Xu Zhang*** [2]***, Dr. Gregor Knorr*** [1]***, Dr. Martin Werner*** [1]***, Prof. Gerrit Lohmann*** [1]

1. *Helmholtz Centre Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany,* ***2.*** *State Key Laboratory of Tibetan Plateau Earth System, Resources and Environment (TPESRE), Chinese Academy of Sciences (CAS)*

Millennial-scale abrupt climate change events frequently occurred during the Late Pleistocene. Bølling/Allerød (B/A) event, which is the latest abrupt warming event, complicates understanding its occurrence due to the accompanying drastic climate background shift. Here we carried out a set of transient experiments during the B/A period under the PMIP4 protocol. The highlight is that a more realistic distribution of meltwater flux is applied in the experiments. We found that the intensity of the Atlantic Meridional overturning circulation (AMOC) is significantly modulated by the geographic distribution of freshwater injection. Considering only this distribution change without its temporal variation, our model shows a cold stadial climate during Heinrich Stadial 1 (HS1) and captures the B/A-like AMOC recovery. This B/A-like behavior is characterized by the self-oscillation of the AMOC and is mainly associated with a gradual change in the orbital parameters. The ice-sheet decline after the abrupt change attenuates the North Atlantic Deep Water (NADW) production, and the accelerated melting of the ice sheet after 14.5 ka (thousand calendar years before present) can develop this process, eventually moving the system out of this self-oscillation regime. The rise in atmospheric CO_2 does not offset this trend due to ice sheet retreat.

Comparing two similar extreme SST cooling events under different boundary conditions within MIS 8 and MIS 34 in the Iberian Margin

In the last 1.5 Myr, the Earth was marked by abrupt climate instabilities on millennial time scales superimposed on the global variations in the ice volume. The timing, duration, and amplitude of major glacial-interglacial cycles have been modulated by changes in the Earth’s orbit. In particular, the Early Pleistocene symmetrical, low-amplitude, and high-frequency (41 ky obliquity) climate cycles were gradually replaced by the Middle Pleistocene asymmetrical, high-amplitude and low-frequency and quasi-periodic 100 ky cycles. However major climatic shifts, including glacial climate instabilities, are not explained by the orbital forcing theory. The long Sea surface Temperature record of IODP Site U1385 (the “Shackleton Site”) from southwestern Iberian Margin (IB-$U^{k'}_{37}$-SST) reveals a continuous millennially-resolved record for the last 1.5 Myr. Our results show warm interglacials over the entire record and a persistent feature of Millennial Climate Variability (MCV) mainly during glacial inceptions and deglaciations. During glacials, the MCV is punctuated by extreme cooling episodes after reaching the maximum ice volume and modulated by different boundary conditions. Here we present two strong stadial events that occurred under different orbital-induced forcings but with similar impacts on the surface water conditions at the North Atlantic mid-latitudes. The extreme climate events occurred in the mid-glacial of MIS 8 at ~270 ka and in the terminal stadial event of MIS 34 at ~1125 ka. Both episodes are marked by substantial changes in the surface-water density, forced by freshwater fluxes from the melting ice and changes in the deep-water ventilation, suggesting a similar trigger mechanism for these extreme cooling events in the Iberian Margin.

Synchronization theory of glacial-interglacial cycles in the Quaternary

Dr. Takahito Mitsui [1], *Dr. Matteo Willeit* [2], *Prof. Niklas Boers* [1]

1. Technical University of Munich, 2. Potsdam Institute for Climate Impact Research

The dominant periodicity of glacial-interglacial cycles changed from 41 kiloyears (kyr) to roughly 100 kyr around 1 million years ago, which is called the Mid-Pleistocene Transition (MPT). Mechanisms generating these periodicities are still elusive. In this study we propose a synchronization theory of glacial cycles based on an Earth system model of intermediate complexity (CLIMBER-2), which is previously shown to simulate the MPT under a gradual decrease of volcanic CO2 outgassing rate and a shrinking area of regolith over the last three million years (Willeit et al. 2019). We show that the model exhibits self-sustained oscillations even in the absence of the astronomical forcing. Before the MPT, the glacial cycles synchronize with the 41-kyr obliquity cycles since the internal self-sustained oscillations have periodicity close to 41 kyr. After the MPT the time scale of internal oscillations becomes too long to follow every 41-kyr obliquity cycle, and the glacial cycles tend to synchronize with ~100-kyr eccentricity cycles which modulate the amplitude of climatic precession. The 41-kyr obliquity forcing however helps the synchronization with the ~100-kyr eccentricity cycles, through a nonlinear mechanism, which we call the vibration-enhanced synchronization.

Nature of cooling events on the southern Iberian margin points to extreme contraction of the North Atlantic's subtropical gyre during the early Pleistocene

Dr. Antje Voelker [1]***, Ms. Aline Mega*** [1]***, Ms. Monica Duque Castaño*** [1]***, Dr. Emilia Salgueiro*** [1]***, Dr. Teresa Rodrigues*** [2]

1. *Divisão de Geologia e Georecursos Marinhos, Instituto Português do Mar e da Atmosfera, Rua Alfredo Magalhães Ramalho, 6, Lisboa, and Centro de Ciências do Mar (CCMAR), Universidade do Algarve, Campus de Gambelas, Faro, Portugal,* ***2.*** *Portuguese Institute for Sea and Atmosphere (IPMA), Lisboa, Portugal.*

The Gulf of Cadiz on the western side of the Strait of Gibraltar marks the transitional zone between the North Atlantic and the Mediterranean Sea and is nowadays influenced by North Atlantic subtropical gyre waters. Studies on deep-sea cores from that region have shown that during the Heinrich events of the last glacial cycle colder surface waters penetrated into those southern mid-latitudes, but with reduced intensity. Making use of the centennial-scale paleoclimate records from IODP Site U1387 (36°48´N 7°43´W; 559 m water depth), which cover the early to middle Pleistocene interval of Marine Isotope Stage (MIS) 16 to MIS 52 (0.65 – 1.51 Ma), we are exploring the nature of cooling events during the Early to Middle Pleistocene transition (EMPT). Terminal stadial events during abrupt glacial/interglacial transitions, for example MIS 20/19, MIS 22/21, MIS 26/25 or MIS 48/47, recorded periods of extreme surface water cooling with annual sea-surface temperatures dropping below 15°C and the abundance of polar planktonic foraminifera species *N. pachyderma* increasing above 40% indicating the influx of subpolar surface waters into the southern mid-latitudes of the Northeast Atlantic. Those events can be related to disintegration of circum-North Atlantic continental ice sheets and their impact on the Atlantic Meridional Overturning Circulation (AMOC), similar to the impacts of Heinrich events. Additional stadial events with similar characteristics are also observed during early MIS 22, MIS 32 and MIS 38. The cooling on the Algarve margin during those EMPT events was, however, more intense than during Heinrich events 1 to 6 pointing to an extreme contraction of the North Atlantic's subtropical gyre during the EMPT. Duration of the cooling events varied between 1000 and 3000 years with a cumulation within MIS 22 with its two extended phases of extreme cooling. Prevalence of subtropical surface waters after the cooling event occurred generally within 1500 years, independent of the duration of the preceding cooling event, pointing to common processes leading to reestablishment of a strong AMOC. The IODP Site U1387 data reveals cooling events were a regular feature, but were, unexpectedly, more intense during the EMPT than during the late Pleistocene.

About the Mid-Brunhes interval and the role of the enigmatic coccolithophore Gephyrocapsa complex

Dr. Alba González-Lanchas [1]***, Dr. Rosalind E.M. Rickaby*** [1]***, Prof. FRANCISCO SIERRO*** [2]***, Dr. Andrés S. Rigual-Hernández*** [3]***, Dr. Montserrat Alonso-Garcia*** [4]***, Dr. Jose-Abel Flores*** [3]

1. *University of Oxford,* ***2.*** *Universidad de Salamanca,* ***3.*** *University of Salamanca,* ***4.*** *Universidad de Salamanca, Geology Department, Pza de los Caídos s/n, 37008 Salamanca, Spain*

Noëlaerhabdaceae coccolithophores contributed to modulate the global carbon cycle by increasing carbonate export and burial rates due to recurrent enhanced production at low eccentricity scenarios with an ~ 400 kyr cyclicity during the Pleistocene. If this variability also entailed a change in the degree of coccolithophore calcification is unknown, but plausible since regulation in the carbon cycle at this scale necessarily involve deep changes in the state of ocean carbonate chemistry.

We analyzed the morphometries (size and mass) of the dominant *Gephyrocapsa* complex during the last eccentricity minimum episode 400 kyr ago, encompassing the Mid-Brunhes event, at a wide range of latitudinal environments across the North Atlantic region and the Mediterranean Sea. We capture an enhancement in *Gephyrocapsa* calcification coeval to high coccolithophore production lead by mid-sized *Gephyrocapsa* specimens. Analysis of diversity on the *Gephyrocapsa* complex allows us to determine an increased calcification expressed by an array of morphotypes at the different sites. Such widespread enhanced calcification across the *Gephyrocapsa* complex supports the existence of a common trigger for a higher degree of calcification of a range of *Gephyrocapsa* during the Mid-Brunhes. This feature is plausibly related to changes in seawater chemistry, e.g., HCO_3^- increase, that could explain the response of *Gephyrocapsa* calcification observed at all sites.

This perspective critically underscores that the nature of the stimulus mediating orbital forcing and long-term phytoplankton evolution or adaptation could be embellished by changes in seawater carbonate chemistry as a critical component.

A new reconstruction of CO2 oscillations through the study of marine fossil records during the mid-Pleistocene transition: Boron isotopes in planktonic Foraminifera as a tracer for paleo-pH and pCO2.

Ms. Monica Pernice [1], ***Prof. Antonio Caruso*** [2], ***Prof. Fabrizio Lirer*** [3], ***Dr. Leopoldo Pena*** [4], ***Dr. Eduardo Paredes*** [4], ***Prof. Isabel Cacho*** [5], ***Prof. Luca Maria Foresi*** [6]

The mid-Pleistocene transition (MPT) marked a fundamental change in the dominant period of Pleistocene glacial cycles, from 41-kyr to 100-kyr cycles. The reasons are yet unknown, since the transition occurred in the absence of any significant change in orbital forcing. Most hypotheses invoke a decreasing atmospheric carbon dioxide as the trigger of the MPT origin, even if it has not yet been fully demonstrated. To validate the suggestion that a long-term drawdown of atmospheric CO_2 was the main cause of the climate transition, we present a new high-resolution 1.9-myr atmospheric pCO_2 and sea surface temperature (SST°) reconstruction, based respectively on boron isotopic composition of *Trilobatus sacculifer* and Mg/Ca ratio in *Globigerinoides ruber* (s.s.).

Assessing large scale ecological responses to climatic change of Central Mediterranean area in the last 2000 years

Mr. Haidra SALEH [1], ***Dr. Amalia Spina*** [2], ***Prof. Barry Lomax*** [3], ***Prof. Donatella Magri*** [4], ***Dr. Giulia Margaritelli*** [5], ***Dr. Federico Di Rita*** [4]

This PhD project is focused on the investigation of ecological dynamics across the Central Mediterranean area from a marine sedimentary record in Gulf of Gaeta. The geographic location and the semi-enclosed geometrical configuration of this area make it a vulnerable and sensitive region to modern and past climate changes. Multi-proxy approach is used to reconstruct the paleo-floral dynamics. This will enable relationships within and between ecosystems, as well as periods of stability and periods of changes. The method mainly consisted of the traditional pollen analysis - to reconstruct the vegetational palaeo-community, and chemical palynology – chemical signature of pollen – to reconstruct the past solar irradiance at the local, habitat scale. Specifically, ultraviolet radiation B which act as a biotic stressor and has the capacity to affect the eco and environmental systems.

Holocene hydroclimatic variability at the southern margin of the South American Monsoon System recorded by high-resolution sediment data from Lagoa Dourada, Brazil

Prof. Bernd Zolitschka [1], *Dr. An-Sheng Lee* [2], *Dr. Daniela Piraquive-Bermúdez* [3], *Dr. Thomas Giesecke* [3]

1. University of Bremen, Institute of Geography, Geopolar, Germany, 2. Department of Geosciences, National Taiwan University, 3. University of Goettingen

High-resolution and well-dated multidisciplinary data from the lacustrine sediment record of Lagoa Dourada (South Brazil) are presented and linked to long-term shifts in atmospheric circulation patterns of the Southern Hemisphere, which are mainly dependent on the spatial and temporal distribution of precipitation and climatologically controlled by the South American Monsoon System (SAMS).

Based on statistical analyses, four different sediment sources are characterized geochemically and related to lacustrine organic productivity, underground karst runoff, river flooding and cultural soil erosion. Thus, our multiproxy dataset provides a handle on lacustrine and catchment-related processes reflecting environmental responses to hydroclimatic fluctuations during the Holocene and to human activities.

Four distinctly different depositional conditions are determined: (1) Suspension fallout of fine-grained minerogenic particles transferred via fluvial activity during the Early Holocene and related to open grassland in the catchment area; (2) Activation of the karst hydrological system with deposition of sand layers indicating increased precipitation at the onset of the Middle Holocene; (3) Minerogenic sediments are replaced by organic deposition due to wetter climatic conditions with expansion of woodlands and release of nutrients due to enhanced pedogenesis during the Middle to Late Holocene; (4) Human-induced land-use changes caused destabilization of soils in the catchment area as well as cultural soil erosion since AD 1800.

The climatic development from a warm and dry Early Holocene to a warm and wet Middle and Late Holocene is in response to a strengthening of the SAMS. In addition to this general trend, our sediment record documents three of the two most prominent Holocene climatic events: the 8.2 ka event, the 4.2 ka event and the Little Ice Age. For Lagoa Dourada, these reflect several century-long increases in rainfall with complex responses of the environmental system – a result that favorably agrees with the climatic signal preserved by the speleothem record from Caverna Botuverá located ca. 250 km SSE of Lagoa Dourada.

Pollen preservation evidence from southern Patagonia (52°-54°S): Old methods, new insights into past changes in the Southern Hemisphere westerly Winds.

Dr. Robert McCulloch [1]***, Dr. Mary McCulloch*** [2]

1. *Centro de Investigación en Ecosistemas de la Patagonia (CIEP), Coyhaique, Chile.,* ***2.*** *The Glasgow School of Art, Glasgow, G3 6RQ, Scotland*

The vegetation cover of Patagonia is tightly controlled by the distribution of precipitation delivered by the Southern Hemisphere westerly winds. Pollen analysis (palynology) continues to be the most successful technique for exploring vegetation history from which we can infer climate change. No other technique provides the two key elements of being able to synthesize the changing patterns of vegetation in space and time. However, pollen data (percentages, concentrations, and influx) can only tell part of the story and regional patterns may be blurred by local site-specific factors (microclimate, basin hydrology, catchment) and differing ecological responses to climate (extinction, migration, adaptation). Inferences based on palaeoecological data may be supported by other lines of evidence of environmental change; sediment chemistry, plant macrofossils, a range of other micro fossils (diatoms, testate amoebae) as depositional environments allow. Here we demonstrate the utility of analysing the preservation status of pollen grains which to-date has been largely overlooked in Patagonian pollen records. Well preserved pollen are indicative of quick deposition in a stable anaerobic environment, such as a wet peat bog or small closed lake basin. Deteriorated pollen occur along a spectrum from broken or crumpled (mechanical damage) pollen grains, which tend to reflect more energetic transport (fluvial or aeolian processes) to corroded and degraded (chemical damage) grains that indicate more aerobic conditions (i.e. reduced mire surface wetness) at the point of deposition. Here we describe a simplified (5 category) method with examples and present a synthesis of six Late glacial-Holocene pollen records obtained from peat bogs from Fuego-Patagonia (52°-54°S). Comparison with the pollen assemblage data highlights a high degree of resilience in the vegetation, particularly the dominant arboreal taxa of the subgenus *Nothofagus* (southern beech), which leads to asynchronous responses to climate change. Our evidence suggests chemical damage is a particularly sensitive indicator of changes in mire surface wetness from which changes in precipitation can be inferred. This evidence has important implications for understanding the nature and timing of changes in the Southern Hemisphere westerly winds in southern Patagonia during the Late glacial and Holocene.

Tree-ring δ18OTRC variations in South American Nothofagus species record common large-scale climatic signals

Ms. Pamela Soto-Rogel [1]***, Dr. Juan-Carlos Aravena*** [2]***, Dr. Ricardo Villalba*** [3]***, Dr. Wolfgang Jens-Henrik Meier*** [1]***, Dr. Jussi Griessinger*** [4]

1. Institute of Geography, Friedrich-Alexander-Universität Erlangen-Nürnberg, Wetterkreuz 15, 91058 Erlangen, 2. Universidad de Magallanes, 3. Southernmost South America (SSA; 50-56°S) has recently experienced accelerated warming, decreased precipitation, reduced snow cover, and increased heat waves. These climate changes are related to variations in atmospheric circulation affecting SSA at different temporal scales. Since meteorological records are short with frequent gaps, long-term studies intended to properly identify changes in the dominant atmospheric circulation patterns in SSA are rare. Previous studies in SSA based on oxygen isotopes from tree-ring cellulose ($\delta^{18}O_{TRC}$) have shown the potential to extend local climate and atmospheric circulation records. Here, we studied two contrasting *Nothofagus* forests located in i) the deciduous *N. pumilio* forest in the transition to the steppe close to Punta Arenas (SKI site) and ii) the humid evergreen *N. betuloides* forest (NC site) in the Navarino Island. To investigate the potential for reconstructing past climate variability, $\delta^{18}O_{TRC}$ variations in tree rings from both species were compared over the last 60 years with local climates, as well as regional (Amundsen Sea Low, ASL) and hemispheric (Antarctic Oscillation, AAO) atmospheric patterns. The *N. betuloides* (NC) $\delta^{18}O_{TRC}$ variations showed an overall positive trend, indicating an isotopic enrichment during the last 60 years, whereas no trend was recorded in the *N. pumilio* (SKI) record. The strongest relationships with climate, which also showing the widest spatial representativeness, occurred for the NC chronology during the growing season (spring to austral summer) and extended spatially from mid to high latitudes. In contrast, the sensitivity of the SKI isotopic records was limited to summer months, and the spatial correlations were much more limited. In addition, the NC record showed greater potential for reconstructing local climate features such as soil water ($r = -0.76$), wind speed ($r = 0.69$) and precipitation ($r = -0.66$), as well as regional (ASL, $r = -0.80$) and hemispheric (AAO, $r = 0.77$) patterns of extratropical atmospheric circulation. Overall, weaker relationships between the isotopic *N. pumilio* record at SKI with local climate and large-scale circulation patterns were observed. Thus, we conclude that the isotopic *N. betuloides* record represents one of the most valuable tree-ring proxies for climate reconstructions in southernmost South America over the past centuries.

A chironomid inferred temperature reconstruction of the last glacial-interglacial transition for Fuego-Patagonia, southern South America.

Dr. Eileen Tisdall [1]***, Dr. Robert McCulloch*** [2]***, Dr. Stephen Roberts*** [3]***, Dr. Catherine Newman*** [4]

We present a record of climatic and environmental change for the southern hemisphere region of Patagonia in the vicinity of the Cordillera Darwin Icefield (~53°51'S) for the last glacial-interglacial transition. The palaeoclimatic history of southern South America is dominated by the strength and latitudinal position of the Southern Westerly storm tracks and the sub-Antarctic front. Patagonia lies along this zone of high precipitation and past migrations of these storm tracks can be tracked through fluctuations of the Patagonian ice fields and the response of the surrounding vegetation cover. Our current understanding of late Quaternary southern hemisphere ocean-atmosphere change is largely derived from reconstruction of glacier fluctuations during the Last Glacial / Interglacial transition (LGIT), but this provides an episodic view of the changing environment that may simply reflect the changing precipitation signal. In the northern hemisphere, the Greenland oxygen-isotope record shows that the LGIT was characterised by rapid high-magnitude climatic changes. However, the duration and magnitude of southern hemisphere climatic events, such as the Antarctic Cold Reversal (ACR), and their significance in driving Fuego-Patagonian glacial and vegetation change is unclear from pollen records obtained to-date. In this study, we present a sub-centennial record of chironomid inferred temperature change from a closed basin from Punta Yartou, western Tierra del Fuego. The climate record is further supported by sediment geochemistry, pollen analysis, and lithostratigraphic analyses, constrained by radiocarbon dating and tephrochronology. There is an apparent lag between climate change and the vegetation response, but we are unable to separate precipitation, and temperature from the pollen records alone. Here, we argue that the inferred chironomid temperature record is more sensitive to changes in regional climate, helping to circumscribe the timing and extent of temperature changes that drove the fluctuations of the Cordillera Darwin ice cap during the LGIT, and disentangle the role of shifts in the focus of the Southern Hemisphere westerly winds during the LGIT at a sub-centennial scale.

Unravelling the Holocene history of the Southern Westerlies: combined terrestrial (peat) and marine records from the South Indian Ocean

Dr. Nathalie Van der Putten [1]***, Dr. Elisabeth Michel*** [2]***, Prof. Cyriel Verbruggen*** [3]***, Prof. Svante Björck*** [4]***, Prof. Emmanuel Chapron*** [5]***, Prof. Jacques-Louis de Beaulieu*** [6]

The Southern Hemisphere (SH) plays a crucial, yet understudied, role in global climate. SH mid- to high latitude climate is dominated by the rain-bearing Southern Hemisphere Westerly winds (SHW). Changes in the intensity and position of the SHW and their impact on the oceanic Antarctic Circumpolar Current, affect both upwelling and uptake of CO_2 in the Southern Ocean (SO), an area on the planet where the deep ocean is well-connected to the atmosphere and where about 40% of the global oceanic uptake of anthropogenic CO_2 takes place. Furthermore, a poleward shift of the SHW during a number of successive austral winters recently caused severe drinking water shortages in Cape Town (South Africa), highlighting the societal impact of such changes. Understanding natural SHW variability is essential for further testing climate models, as these are not yet able to accurately simulate the position and strength of the modern SHW, hampering comprehensive future projections of SO behaviour. Here we present the results of a Holocene peat core from Kerguelen Islands (49°S) investigated using a multi-proxy approach: e.g. pollen analysis, geochemistry (XRF core-scanning) and biogenic silica content (reflecting diatom abundance). Accumulation rates are very low (~0.1 mm/yr) between 9 and 5.5 kyr BP (thousand years Before Present). From around 5.5 kyr BP and onwards, a change to more humid conditions caused renewed peat formation with relatively higher accumulation rates probably caused by increased SHW influence on Kerguelen Islands. We compare our long-term terrestrial data with marine SST records from down-wind core sites. Superimposed on this long-term trend, multi-centennial variability was found from about 4 kyr BP and onwards, showing periods of both (i) higher wind intensity (increased *Azorella selago* pollen and Ti content and (ii) increased humidity (increased *Botryococcus* sp. and BSi percentages) suggesting cyclic SHW intensity changes.

Paleoenvironmental and paleoclimate changes in the subtropical Andes for the last 15ka inferred from multiproxy records

Departamento de Geología, Facultad de Ciencias Físicas y Matemáticas, Universidad de Chile, Santiago, Chile, 7. Universidad de Chile, 8. Centro de Estudios Avanzados en Zonas Áridas (CEAZA)

Subtropical regions are characterized by being relatively arid environments compared to other zones, such as tropical or temperate zones, so the availability of lakes to take proper sedimentary records where to perform paleoclimate analysis is comparatively scarce. The subtropical Andes (30°-36°S) are not an exception and moreover, it is a highly sensitive region to current and past climate changes since it is located on the northern edge of the Southern Westerly Winds Belt. In order to establish the past environmental changes in the subtropical Andes since the Late Pleistocene, the multiproxy record of Laguna del Viento (LdV; 33°08'S; 70°25'W, 3160 masl), a high Andean lake located in Chile, was analyzed. The sedimentary, reflectance (VIS-RS), pollen, macro-charcoal particles, diatoms and chironomids records were jointly analyzed. The chronology of the LdV record based on 10 ^{14}C dates and a ^{210}Pb ages series for the top most part revealed that the LdV record encompasses the last ~15,800 cal yr BP. The pollen record shows the dominance of Poaceae and Ephedra along with Asteraceae and Geraniaceae during the end of Pleistocene. Between 12-10,5ka Poaceae increases suggesting more humid conditions and a temperature increase. Between 10,5-7ka the increase of *Arenaria* and Chenopodiaceae suggest the occurrence of the driest conditions for the whole record. Then gradual increase of Poaceae suggest an amelioration of dry conditions with wetter conditions peaking between 3-0,7ka. The macro-charcoal particles record shows the first occurrence of fires at 11ka with maximum fire magnitude around 10ka and 0,7ka. The sedimentary and reflectance records suggest the occurrence of cold phases between 2,4-2,1ka, 1,5-1,1ka and during the Little Ice Age. The diatom and chironomid records reflect lake changes that matches those inferred from the pollen, sedimentary and reflectance records. Changes suggested by the multiproxy record of Laguna del Viento are consistent with other records in the Subtropical Andes as Laguna Aculeo (34°S), Laguna Chepical (33°S) and Laguna del Maule (36°S) suggesting a regional climatic pattern associated to dynamic of winter precipitations associated to the Southern Westerlies Wind Belt dynamics.

Landscape evolution in the Mediterranean-Template forest transition of south-central Chile during the Late Holocene (37°S)

Dr. Juana Alejandra Martel-Cea [1], ***Dr. Ana M. Abarzua*** [2], ***Dr. Antonio Maldonado*** [3]

1. Centro de Estudios Avanzados en Zonas Áridas (CEAZA), 2. Universidad Austral de Chile, 3. Centro de Estudios Avanzados en Zonas Áridas (CEAZZA)

Recent climate change and anthropogenic pressure are becoming the main factor in the degradation of ecosystems in central-southern Chile, especially in the Mediterranean-temperate transition climate zone (35°-39°S). The rapid expansion of the forestry industry has displaced the last remnants of native forests to protected areas. The climate change scenarios of the 21st century are not encouraging either due to the projected dry and warm conditions. Several negative effects on those ecosystems have been proposed including the loss of services and functions, changes in spatial distributions, and extinction of species. Past environmental reconstructions can help to gather information about the occurrence of extreme climatic events, such as extensive droughts. To reconstruct the environmental changes related to the past soil erosion, vegetation, and fire regime, we obtained two sediment records using a Uwitec (1.2 m) and Livingstone piston (2.9 m) corers in the Laguna El Pillo (LEP, 37.27°S; 72.67°W, 64 m a.sl.) in September 2022. LEP is a small lake (0.1 km^2, 8 m depth) located in the transitional ecotone between the (deciduous) temperate and the Mediterranean sclerophyll-type forests, which is highly sensitive to rainfall changes related to Southern Westerlies wind dynamics and regional temperatures. Preliminary results related to the sedimentological characterization show that organic matter content (OM) is highly variable ranging between 10 to 50%. Also, massive laminations were detected visually and by X-ray imaging, which would correspond to changes in grain size linked to intercalations between fine sands and gittja. This process can be interpreted as an indicator of erosion since the soils of the study area corresponds to fine sands that were deposited by an alluvial cone during the late Quaternary from the Andes. The ongoing work and next steps for the LEP record include the deepening of sedimentological analysis, development of chronological control (210-lead and radiocarbon dating), as well, the analysis of biological proxies (pollen, macroscopic charcoal, and chironomid remains) to determine the influence of the regional paleoclimate and ultimately, human activity on those ecosystems. Dynamics of Brazil-Malvinas Confluence in western South Atlantic

Dr. Fang Gu [1]

1. *1. Department of Palynology and Climate Dynamics, University of Goettingen, Göttingen, Germany 2.School of Ocean Sciences, China University of Geosciences, Beijing 100083, China*

The Brazil-Malvinas Confluence (BMC) is a highly energetic convergence of surface currents in the southwestern South Atlantic. It has been detected that the BMC shifted southwards in the last decades. The transect study of the marine cores in the region of BMC indicates that the highly eutrophic sea surface condition occurred during the Last Glacial Maximum (LGM) was linked to the weak Brazil Current and intensified Malvinas Current, which refers to the northward shift of BMC. This study suggests that the latitude shifts of BMC plays an important role in controlling the heat transfer from the tropical South Atlantic to the Southern Ocean with the exchange of water masses.

The impacts of Southern Ocean changes on the tropical Pacific climate over the last 17,000 years

Dr. Paola Moffa-Sanchez [1], ***Prof. Yair Rosenthal*** [2]

1. Durham University, 2. Department of Marine and Coastal Science, Rutgers University, New Brunswick

Mode waters form around the Southern Ocean and spread northwards through the ocean's interior eventually surfacing in the tropics. As such, Southern Ocean circulation changes can be transmitted to the tropical Pacific impacting key climatic processes such as El Ninyo Southern Oscillation (ENSO). Yet, because of the mid-depth nature of these waters, there is a scarcity of high-resolution records of Southern Ocean derived intermediate and mode waters. It is for this reason that the exact linkages between high to low latitude Pacific Ocean over the last 17kyrs and its role on influencing tropical Pacific climate remain elusive. Temperature reconstructions from a sediment core recovered from the coast of Papua New Guinea show warming of the thermocline waters concomitant with southward shifts of the polar front and westerly winds around the Southern Ocean during the deglacial warming events. Across the Holocene, the data reveals a modified tropical Pacific thermocline structure highlighting the impact that changes in the Southern Ocean derived waters may have had on tropical sea surface temperatures and their respective atmospheric feedbacks.

Stable isotopes in lake water and precipitation along altitudinal/ latitudinal gradient and their potential for climate reconstruction in Central and South Chile

Dr. Denisse Alvarez [1], ***Dr. Pablo Pedreros*** [2], ***Dr. Francisco Fernandoy*** [3], ***Dr. Alberto Araneda*** [4], ***Mr. Ignacio Vega*** [4], ***Ms. Camila Santelices*** [4], ***Prof. Roberto Urrutia*** [5]

1. *Centro Bahía Lomas, Facultad de Ciencias, Universidad Santo Tomás,* ***2.*** *Centro de Ciencias Ambientales Eula, Universidad de Concepción,* ***3.*** *Universidad Andrés Bello, Viña del Mar, Quillota, Chile,* ***4.*** *Facultad de Ciencias Ambientales, Universidad de Concepción,* ***5.*** *Faculty of Environmental Sciences, EULA-Center, University of Concepción*

The use of stable isotopes has been extensive for climatic reconstructions in lake sediments mainly such as paleothermometers when the relationship with environmental conditions is well established. In South America, δ18O has been interpreted as a proxy for hydrologic balance related to westerly winds but assuming isotope oxygen signal in the lake is similar to the signal found in different organisms (e.g ostracods, diatoms, chironomids). Besides, recent studies on δ18O in lake water from different Chilean lakes compared Local Meteoric Water Line (LMWL) constructed with the few data from Global Network In Precipitation (GNIP) not finding evaporation evidence, although lakes show a notorious change in water level. The aim of this research was to identify the forcings and processes to affect isotope signal in precipitation in latitudinal and altitudinal gradients and establish the relationship with biological proxies to reconstruct temperatures y/o precipitation. We installed a rainwater collector between 34°S to 40°S and measured monthly δ18O and δD in precipitation, in addition, the same isotopes were analyzed in lake water and different water sources (groundwaters, rivers) and in-situ physicochemical parameters. The continuous air temperature was recorded with data loggers. To identify biological proxies for isotope analyses, we retrieved sediment cores. We found spatial differences in isotope signals for the rain precipitation confirming the continental effect. A good relationship was found with accumulated precipitation and a weak relationship with air temperature. LMWL constructed here showed different trends with LMWL – GNIP and the isotope signals of the lakes were located under the LMWL demonstrating the evaporation effect. The geochronology of the sediment cores permitted to cover at least the two millennials, and the main change in sedimentological analyses could response to the global climate event type- Little Ice Age, then chironomids were the only potential proxy due to the continuous record in sediment cores. Although the measurements of stable isotopes in chironomids are not easy due high quantity of material and possible vital effect, is necessary to evaluate their potential as a proxy for paleoprecipitation. This research is financed by the ANID/Fondecyt projects N°11201231, N°1201277 and CRHIAM/Fondap 15130015.

Investigation of Active Tectonics of the Mahi Basin, Western India: Use of Geomorphic Indices and Seismic Data

***Ms. Gitanjali Bramhankar* [1], *Prof. Pramodkumar Hire* [1]**

1. *Department of Geography, HPT Arts and RYK Science College, Nashik – 422005 (India)*

Investigation of active tectonics of the Mahi Basin is based on geomorphic methods and seismic data. The geomorphic indices that have been most successful are related to erosional and depositional processes associated with fluvial systems. The hypsometric curve and hypsometric integral (HI), drainage basin asymmetry factor (AF), stream length-gradient index (SL index), mountain front sinuosity (Smf index) and the ratio of valley floor width to valley height (Vf index) are used for identifying a level of tectonic activity of the Mahi Basin and its sub-basins namely Som, Anas, Jakham, Panam, Chap, Erau and Bhadar. Furthermore, indices are applied to identify areas experiencing rapid tectonic deformation within the basin. The results of several of the indices are combined to produce tectonic activity classes, which are broad-based assessments of the 'relative degree of tectonic activity in the Mahi Basin'. The results of the geomorphic indices show that the tectonic activity is greater in the northern, north-western, central parts and near the mouth of the river. Moreover, tectonic activities are greatly associated with major faults and lineaments such as Great Boundary Fault (N-S), Udaipur-Sardarpur Lineament (SE-NW), Rakhabdev (SE-NW) and Jaisalmer-Barwani Lineament (SE-NW), Kadana-Bhadar Strike-slip Fault (SE-NW-E), Mahi-Panam-Narmada Fault (SW-NW-W), Cambay Graben fault (SE-NW), etc. The anomalous values of the indices are associated with 35 historic as well as recent earthquakes occurred within and adjacent basins from 1967 to 2021. The magnitudes of the earthquakes range between 3.84 and 5.45 MW. Thus, the investigation signifies that the basin is tectonically active and a regional evaluation of the mountains in the basin suggests that detailed studies along the western and eastern fronts of the range as well as the Kadana folded mountain ranges (Southernmost part of the Aravalli Mountain Ranges) have the best chance of yielding rate of vertical tectonic (uplift), slip rate along active Kadana-Bhadar strike-slip fault, Mahi-Panam-Narmada fault and numerous active faults along the Mahi, Som, Jakham, Erau and Bhadar Rivers.

Quaternary landscape evolution as a proxy for understanding the tectonically driven uplift history of southwestern Sicily (Italy)

Dr. Nicolò Parrino [1], *Prof. Attilio Sulli* [2], *Dr. Maurizio Gasparo Morticelli* [2], *Prof. Alessandro Incarbona* [3], *Prof. Cipriano Di Maggio* [2], *Prof. Mauro Agate* [2], *Dr. Alessandro Bonfardeci* [2], *Dr. Pierfrancesco Burrato* [4]

1. *Dipartimento di Scienze della Terra e del Mare, Università di Palermo, Italy,* **2.** *Dipartimento di Scienze della Terra e del Mare, Università degli Studi di Palermo,* **3.** *University of Palermo,* **4.** *Istituto Nazionale di Geofisica e Vulcanologia, Rome (Italy)*

Although the late Pleistocene coastal landscape of south-western Sicily between Capo Lilibeo and Capo Bianco was shaped by a uniform climatic forcing, it shows significantly different landforms in different sectors. Its western portion hosts a roughly 100 km long, gently sloping Quaternary polycyclic surface known in the scientific literature as the Grande Terrazzo Superiore (GTS). Such peculiar landform abruptly terminates east of Sciacca, where numerous, deeply incised, V-shaped valleys separate the remnants of a 20 km long flight of late Pleistocene paleoshorelines.

The southwestern Sicily coastal sector hosts the frontal structures of the Sicilian Fold and Thrust Belt as part of the collisional African-European plate boundary in the central Mediterranean. The Plio-Quaternary frontal fold and thrust system developed primarily inland with an average WNW-ESE trend and is presently active as testified by seismological, geological and morphotectonic evidence. East of Sciacca, this system crosses the coastline and in the Sicily Channel offshore follows a NNW-SSE trend, being known as the Gela Thrust Front (GTF). Although the seismotectonic framework of the area was widely studied through oil exploration data, the geometry and location of the GTF along the coastline are still a matter of debate.

This work is based on the ongoing 1/50k geological mapping of the Foglio n. 628 (CARG Project) that includes the on/off-shore transition of the GTF. Our goal is to disentangle the contribution to the landscape evolution of the regional monocline from that of the local source of deformation, i.e. shallow individual thrust faults. To do that, we aim to decipher how marine and fluvial geomorphic markers recorded the regional tectonic signal across the GTF. We also use GNSS data and on- and off-shore seismic reflection lines to constrain the active deformation and the geometry of the deep tectonic structures.

The outcomes of this research will provide new constraints on the structural and seismotectonic framework of the area.

A new radiometric oriented, sub pixel resolution shoreline extraction method using satellite images in sandy beaches

Mr. Francesco Caldareri [1]***, Dr. Nicolò Parrino*** [1]***, Dr. Antonino Maltese*** [2]***, Prof. Gino Dardanelli*** [2]***, Dr. Simona Todaro*** [3]***, Prof. Attilio Sulli*** [3]

1. *Dipartimento di Scienze della Terra e del Mare, Università di Palermo, Italy,* ***2.*** *Dipartimento di Ingegneria, Università degli Studi di Palermo,* ***3.*** *Dipartimento di Scienze della Terra e del Mare, Università degli Studi di Palermo*

Shoreline variations drive the coastal landscape evolution over multiple spatial and temporal scales triggered by climate change, sea level variations and tectonic differential vertical movements. Sandy coasts are the most sensitive to coastal erosion and accretion processes, and, at the same time, these coasts frequently host valuable anthropogenic assets. For this reason, many different remotely sensed shoreline extraction techniques have been proposed in the literature, providing valuable tools for improving coastal management. Despite this broad interest, the water/sediment interface definition is still poorly investigated from a radiometric point of view. Moreover, most of the methodologies used by the scientific community are based on a pixel-bounded approach whose outcomes must follow the pixel geometry and resolution.

We identified the coastline signature from a radiometric beach profile and proposed a time-saving, sub-pixel resolution approach for the shoreline extraction capable of robust performance with freely satellite images as input data through an interpolation method. We explored the limits and strengths of our approach comparing achieved results with outcomes from one of the most used pixel-bounded methods, that adopt a thresholding approach, and a validation performed with a GNSS-detected shorelines from field surveys on three sandy beaches in Sicily (Central Mediterranean). We used satellite images with different pixel-size resolutions to demonstrate that in sandy coastlines, even with low-resolution satellite images, we reached an accuracy of up to 95% with respect to the GNSS-detected shoreline.

The proposed shoreline extraction method could represent a valuable tool for coastal management and coastal erosion risk detection and mitigation. Moreover, such a method could be used for the shoreline evolution time-series extraction, which could be treated as proxies to study the climate forcing on the coastal landscape evolution.

Evidence of tectonic activity from river terraces and alluvial fan surfaces from Kachchh: A stable cratonic region in NW India

Mr. Eshaan Srivastava [1], ***Prof. Javed Malik*** [1], ***Dr. Nicolò Parrino*** [2], ***Dr. Pierfrancesco Burrato*** [3], ***Mr. Nayan Sharma*** [1], ***Mr. Mitthu Dhali*** [1], ***Dr. Mahendrasinh Gadhavi*** [4], ***Prof. Attilio Sulli*** [5], ***Prof. Cipriano Di Maggio*** [5]

1. *Department of Earth Sciences, Indian Institute of Technology Kanpur,* **2.** *Dipartimento di Scienze della Terra e del Mare, Università di Palermo, Italy,* **3.** *Istituto Nazionale di Geofisica e Vulcanologia, Rome (Italy),* **4.** *L. D. College of Engineering,* **5.** *Dipartimento di Scienze della Terra e del Mare, Università degli Studi di Palermo*

In the last few thousand years, the coast of the Kachchh Upland (KU) region in northwest India went from being a shallow marine gulf to being an intertidal/continental environment (1 to 4 meters above sea level) and a salty desert called the Banni plain. In this area, which is bounded to the south by the Northern Hill Range (NHR, a series of outcropping fault propagation folds), the interaction of tectonics and climate caused the sea level to slowly go down from a peak of 2-4 m (around 6000 to 2000 BP) to its stable level today. During the time when the sea level went down, a pattern of ancient rivers caused a delta area to form. This delta area was controlled by the tides until the river network disappeared around 2000–3000 years ago because of tectonic activity and a dry climate. Subsequently, sedimentation from seasonal rivers formed a conspicuous deltaic-alluvial fan alignment in front of the NHR, suggesting that the emerging Kachchh Upland's tectonic activity is one of the leading causes of such a fast Landscape Evolution (LE). Preliminary findings of the fault scarplets analysis near the Jhura dome, the highest anticline in KU, support that such activity drove the LE but the pattern and rates of such tectonic forcing remain still not understood. To provide new constraints useful for the comprhension of the tectonic forcing on the LE of this area, morphometric and geochronologic studies of the sedimentary sequences were carried out from river terraces and alluvial fans. The findings of our study aim to improve the knowledge of the uplift history of the Jhura dome and the seismotectonic framework of a region that has experienced numerous earthquakes within a 500 years.

The Quaternary uplift of the Tyrrhenian side of the Central Apennines: insights from the Middle-Upper Aniene River Valley

Dr. Andrea Sembroni [1], *Prof. Paola Molin* [2], *Dr. David Scaccia* [2], *Dr. Michele Soligo* [3]

1. *Roma tre University,* **2.** *Department of Science, Roma Tre University,* **3.** *Università Roma Tre*

The central Apennines is a Neogene NE-verging thrust-and-fold belt developed as a consequence of the convergence between Eurasia and Adria-Africa plates. The Plio-Quaternary evolution of this portion of the Apennines is characterized by the last Pliocene compressive phases, the subsequent extensional tectonics, and the regional uplift that shows an increase since the end of lower Pleistocene. Compared with the Adriatic flank, the Tyrrhenian one is displaced by extensional tectonics which, interacting with regional uplift, climate, and bedrock configuration, makes the comprehension of the landscape evolution more complex.

The Middle-Upper Aniene R. Valley is located on the Tyrrenian flank of central Apennines. Due to the presence of abundant Quaternary deposits such as terraced fluvial deposits and calcareous tufa, it represents an optimal case study to investigate the Quaternary evolution of this portion of the Apennines. However, despite the abundance of these deposits, the recent evolution of this area has been poorly studied.

In this work we investigated the hydrography (river longitudinal profiles and χ-z plot) and topography (swath profile, slope, and local relief) of the Aniene R. basin coupling these data with field observations and geochronological analysis on the calcareous tufa outcropping in several locations along the valley. Finally, a river longitudinal profile inverse model was applied to unravel the recent uplift history of the area.

The results allowed to trace the Quaternary evolution of the Middle-Upper Aniene R. Valley. In particular, the study of the geometries, extension and thickness of the deposits as well as the dating of the calcareous tufa deposits, provided a mean incision rate comparable with the uplift rates obtained from the inversion model and with the values calculated elsewhere in the central Apennines. The inversion of the Aniene longitudinal profile indicates that a capture event ruled the recent evolution of the valley.

The determination of the age of calcareous tufa deposits has also shown how, in the Aniene R. Valley, the deposition of these deposits occurred only in cold periods (MIS 3, MIS 4 and MIS 6), suggesting that this process was mainly related to river dynamics (i.e. presence of knickpoints) and tectonics rather than temperature.

Loess is like hot sauce

Dr. Randall Schaetzl [1], ***Dr. Andrew Finley*** [1], ***Dr. Christopher Baish*** [1]
1. *Michigan State University*

Early definitions and descriptions of loess defined/described it as eolian silt. But as loess became more widely studied, and especially as it became mapped in detail across Europe, it became increasingly evident that a wide variety of fine- and medium-textured eolian sediments occur in nature. Cover sands grade into sandy loess which grades into silty loess, and all manner of “in-betweens”. No longer can we say that loess is simply eolian silt. Like hot sauce, which in the USA used to be dominated by only one brand (Tabasco Brand Pepper Sauce) but which now can be found a dozens of flavors, colrs, and degree of “hotness”, loess is now viewed as a rich and texturally diverse eolian sediment. In this talk, I bring forward a variety of detailed grain-size curves from loess deposits across Wisconsin and Michigan – states in the Great Lakes region of the United States. Much of the loess here has bimodal grain-size curves. Some of the bimodality is associated with mixing of sand into silty loess, both syndepositionally and post-depositionally. But other loess deposits have a more complicated and elusive genesis. Even among the silt-dominated loess deposits, the wide range of grain-sizes provides opportunities to evaluate paleoenvironments of deposition. Indeed, loess IS like hot sauce – it comes in all flavors.

Investigating and reconstructing complex sedimentary histories from loess – the Slivata story continued

Dr. Kaja Fenn [1] ***, Dr. Daniel Veres*** [2] ***, Prof. Simon Underdown*** [3] ***, Mr. Harry McDonnell*** [1] ***, Dr. Grace Skirrow*** [1]

1. *University of Liverpool,* ***2.*** *Romanian Academy,* ***3.*** *School of Social Sciences, Oxford Brookes University*

Loess-palaeosol sequences often provide one of the few long term, spatially extensive terrestrial archives of Quaternary environmental change. Many profiles in Central and Eastern Europe suggest almost continuous deposition responding to orbital scale drivers. However, there are growing numbers of studies that demonstrate hiatuses (either erosional or paucity of deposition) and influences of more regional and localised factors in sequence development.

Loess records along the Lower Danube have been relatively well studied, however a majority of the focus has been centred on Dobrogea and sites along the Danube up to the Olt tributary. In the upper sections of the Lower Danube, and in proximity to the Iron Gate, there are only a handful of archives that provide high-resolution records extending beyond deglaciation. At the same time the influence of competing air masses, distance from any major ice sheets, proximity to the Carpathian Mountains, and potential discontinuous permafrost influence resulted in a very dynamic and highly complex sedimentary sequence.

Here we build on our recent work that aimed to reconcile signals preserved at two loess-palaeosol profiles at Slivata (Fenn et al 2021). The top six meters of the Slivata 2 profile were sampled at a 2 cm resolution for sedimentary proxies and eight new luminescence samples collected. We present 16 new OSL (4-11 µm quartz) ages that extend the chronologies for both sites and provide a higher resolution record of environmental change over the last 50 ka in North Bulgaria. Additionally, the results of grain size, grain shape, grain sphericity, magnetic susceptibility, and colour analysis are presented for the Slivata 2 profile. The addition of geochemical analysis at 4cm resolution aims to support other proxies in disentangling regional influences on the development of the Slivata 2 loess-palaeosol profile from global ones.

Mid-Brunhes Climate Transition and millennial-timescale climate change preserved in a 800 kyrs loess-paleosol sequence from the Suhia Kladenetz quarry (Pleven, Bulgaria): a multidisciplinary study

Mr. Christian Laag [1], Dr. France Lagroix [2], Dr. Yohan Guyodo [1], Prof. Diana Jordanova [3], Dr. Neli Jordanova [3], Mr. Daniel Ishlyamski [3], Mrs. Bozhurka Georgieva [3], Mrs. Segolene Saulnier-Copard [4], Mr. Stoil Chapkanski [5], Dr. Olivier Moine [6], Dr. Pierre Antoine [4]

__1.__ Université Paris Cité, Institut de Physique du Globe de Paris, CNRS, Paris, 75005, France, __2.__ CNRS, IPG Paris, __3.__ National Institute of Geophysics, Geodesy and Geography, Bulgarian Academy of Sciences, __4.__ CNRS, Universite Paris1, __5.__ Laboratoire de Géographie Physique: Environnements quaternaires et actuels (LGP), UMR 8591 CNRS - Université Paris 1 - UPEC, Thiais, France, __6.__ CNRS, Laboratoire de Géographie Physique: Environnements Quaternaires et Actuels, Thiais, France

Eastern European loess-paleosol sequences (LPS) are excellent archives of past climate change. Millennial-timescale climate change is evidenced in loess of the last and penultimate glacial periods. In older glacial loess, observations of climate change on millennial timescales are very scarce because of various factors related to study design and geological considerations (scarcity of deposits, sedimentation rate, alterations).
The Suhia Kladenetz (SK) 27 m long profile was sampled continuously at a 2 cm resolution for bulk sediment. Magnetic and colorimetric measurements were performed on all 1336 samples. Mid-infrared spectrometry (ATR-FTIR; 719 samples) and granulometric measurements (249 samples) were acquired continuously at a lower depth resolution. Altogether, the multidisciplinary data reveal millennial-timescale climate change in the last and penultimate glacials (MIS 4-2, MIS 6), as previously reported. In addition, the data provide the first evidence, in an Eastern European LPS, of millennial-timescale climate change preserved in an earlier glacial period (MIS 12) from short term cyclicity observed in various proxies stemming from magnetic, colorimetric and ATR-FTIR data. We evaluate the observed short-term cyclicity against well-established marine paleoclimate archives (e.g. Ionian sea KC01B planktic foraminifera composition, EPICA δD records) as well as speleothems (e.g. Sofular Cave δ^{13}C paleo-precipitation record).
Combining observations from mineral magnetic and ATR-FTIR analyses, we reliably characterize the occurrence of tephra material. The SK LPS has one outcropping tephra. Further, the data suggest the presence of several crypto-tephra layers of which five are observed in other LPSs from the region at similar stratigraphic positions. The stratigraphic positions of the other crypto-tephras undetected in the regional terrestrial archives so far, appear to agree with macroscopic tephra layers preserved in the Lake Ohrid sedimentary record. The observation of millennial-timescale paleoclimate cyclicity in LPS multidisciplinary proxy data and the identification of cryptotephras within the same record provides a unique opportunity to tune the stratigraphic position of the crypto-tephras to ages of reliably dated (^{39}Ar/^{40}Ar) tephrochronological records; thus increasing the importance of terrestrial paleoclimate archives.
Finally, insights into long-term (post-and pre- Mid Brunhes Transition) climate change are sharpened from the multidisciplinary data and evidence the impact of competing Mediterranean versus prevailing continental climate regimes.

Inconsistent variations of biomarkers in loess-paleosol sequences across Eurasia

Prof. Liping Zhou [1], ***Dr. Shangzhe Zhou*** [1]

1. *Peking University*

We present results of a comparative study of biomarkers on loess-paleosol sequences in different climatic regions within the Eurasian loess belt. The original aim of this study was to obtain information of biogenic remains for paleoenvironmental reconstruction in these regions. The chosen sites include southeastern Poland with distinct periglacial features, southern Russia to the northeast of the Azov Sea with possible fluvial input, southern Tajikistan in the highland of Central Asia and Xinjiang in northwestern China under the influence of the mid-latitude westerly circulation, as well as those from southern, central and western Chinese Loess Plateau. The measured biomarkers include mainly *n*-alkanes, *n*-alkanols, *n*-fatty acids and fatty acid amides. The most surprising observation of the study is the lack of systematic differentiation between loess and paleosol for samples from Poland, Russia and Tajikistan. This is in contrast to the clear relationship between biomarkers and lithology for the loess and paleosol stratigraphic units documented previously and here in samples from Chinese Loess Plateau. The distribution patterns of *n*-alkanes in loess and paleosol samples from Europe and central Asia are characterized by the dominance of low carbon number, again different from those with high carbon number for the samples of Chinese Loess Plateau. Several factors may cause the discrepancies described above, which include the source of biological materials, e.g. types of plants, climatic conditions, sedimentary and post-depositional environments, as well as microbial activities. We examined fatty acid amides, the nitrogen-containing biomarkers, in the samples and revealed their different distribution patterns among the studied sections. An attempt was made to develop new indexes of fatty acid amides for reconstructing regional paleoenvironments using biomarkers in the European loess. However, interpretation of the experimental results is far from straightforward and requires further investigation. This study highlights the complications in the biomarker signals from the loess and paleosol sequences in Eurasia and calls for caution in the use of climate proxies for paleoenvironmental reconstructions.

Impact of analytical approaches on geochemical composition: Implication for palaeoenvironmental studies of loess

Dr. Jacek Skurzyński [1], *Dr. Kaja Fenn* [2]
1. University of Wrocław, 2. University of Liverpool

The features of environment in which loess had been formed can be reconstructed on the basis of a variety of proxies. In particularly research focused on geochemical approaches has increased exponentially in the recent years in loess literature. However, there are several methodological approaches available for obtaining elemental composition of samples and to date these approaches have not been cross-verified in context of the palaeoenvironmental interpretation of the results. Therefore any studies using published datasets assume the results from various methods are comparable.

To test for the results and their impact on environmental interpretation 10 loess samples from different locations were analysed using the three research methods; two Inductively Coupled Plasma (ICP) analysis with different preparation method and XRF. To dissolve samples for ICP analysis one preparation involved among others HF as the main acid treatment, and second used fusion of bulk sample by high temperature in the presence of flux (lithium borate), and subsequent dissolution of the consolidated alloy in the nitric acid. Additionally for all approaches grain size influence on final chemical makeup was also tested with samples analysed as bulk and <63 μm fraction.

The research shows both ICP approaches provide comparable results in the scope of major elements (especially the mobile ones), except e.g. TiO_2. The XRF results are typically offset which can in particular affect CIA (Chemical Index of Alteration) calculations. Further differences can be observed for trace elements which is linked to the only partial digestion of some more resistant mineral phases by “HF-based digestion”, in comparison to the “lithium borate fusion”. These results demonstrate that different ICP preparation methods are strongly not comparable when investigating trace and REE elements as the would lead to different paleoenvironmental and provenance interpretations. Finally, removal of coarser material only increases the share of some elements (especially REE) without affecting the trend of UCC-normalized plots.

This research was funded by the National Science Centre, Poland project No. 2017/27/N/ST10/01208, UK Natural Environmental Research Council (grant: NE/L002612/1), and Manchester Geographical Society.

Fault displacement hazard from distributed faulting during normal and reverse earthquakes

Dr. Francesco Visini [1], ***Prof. Paolo Boncio*** [2], ***Dr. Oona Scotti*** [3], ***Dr. Stephane Baize*** [4], ***Prof. Bruno Pace*** [5]

1. *Istituto Nazionale di Geofisica e Vulcanologia (INGV),* ***2.*** *Università "G. d'Annunzio" Chieti-Pescara,* ***3.*** *Institut de Radioprotection et de Sûreté Nucléaire, Fontenay-aux-Roses Cedex,* ***4.*** *Institut de Radioprotection et de Sûreté Nucléaire,* ***5.*** *Università degli Studi "Gabriele d'Annunzio" Chieti-Pescara*

During surface faulting earthquakes, displacement on secondary faults or factures may occur off the trace of the principal fault (PF), in the vicinity of the PF or up to many kilometres away. They are called distributed ruptures (DR). Though DRs are discontinuous in nature and characterized by lesser amount of displacement compared to the PF, their occurrence may threaten structures the safety and functionality of which are sensible to low levels of permanent ground displacement, such as critical infrastructure. Often DRs occur in unpredictable locations, without previous geologic evidence, making the assessment of fault displacement hazard from DR challenging. In this work we explore the characteristic of DRs from the analysis of numerous historical reverse and normal surface ruptures contained in a new release of the 'SUrface Ruptures due to Earthquake (SURE)' database (SURE 2.0, Nurminen et al., 2022). The database contains slip measurements and mapped traces of 50 historical surface ruptures of global, dip-slip and strike-slip earthquakes occurred between 1872 and 2019. The novelty of the SURE 2.0 database compared to the previous version is a ranking scheme which categorize the ruptures on the basis of geological information. In this work we analyse the distance-frequency and displacement distributions of reverse and normal events using the ranking information. The results have implications for deriving regressions that can be used in probabilistic analysis of fault displacement hazard.

A first comparison of instrumental European Grand Motion Service by Copernicus data with short and long term geological vertical movements for the Italian coasts

***Dr. Fabrizio Antonioli* [1], *Dr. Giovanni Barreca* [2], *Dr. Giovanni Cardello* [3], *Prof. Carmelo Monaco* [2]**

***1.** CNR IGAG, **2.** Università di Catania, **3.** Università di Sassari*

Space geodetic data from the Sentinel-5 satellite released by the Copernicus European Ground Motion Service have been analyzed in the 2016-2020-time range. In the digital platform (https://egms.land.copernicus.eu/), the preponderance of the data suggests that the Mediterranean region is stable to slightly subsides, while Fennoscandia and Iceland appear to uplift (up to 7-10 cm/yr) possibly as result of long-term glacial isostatic rebound. To test the geological significance of the coastal smaller-scale variations in the Mediterranean region, we take Italy as example for constraining the subsidence components. To do that, we have compared the vertical component of the Sentinel data with movements calculated from the long- (MIS 5.5, 119 ka BP), and short-term Holocene (last 5 ka) geological record, and GPS instrumental movements. We have also chosen MIS 5.5 and Holocene on some coastal areas. Geological, GPS and Sentinel data have been found to be coherent in uplifting volcanoes such as Etna and Campi Flegrei. In the latter, a significant uplift (averaging 8 cm/yr) occurs at Pozzuoli. At Ustica volcano subsidence is consistent with GPS data but mismatch with slight uplifts indicated by both MIS 5.5 and Holocene evidence Sentinel data are consistent with geological and GPS data even in "virtually stable" areas of Sardinia, where a 119-ka fossil tidal notch is found at altitudes between 4 and 8 meters. Elsewhere, Sentinel data appear to indicate also fault-related differential subsidence (up to 2 mm/yr) such as in between the Piana Pontina and the Volsci Range. At Venice, the geological and tide gauge data indicate subsidence in agreement with Sentinel data. Generally, long and short-term subsidence in the Po, Pontina and Volturno coastal plains are also in line with Sentinel data due to the local interaction between sediment compaction and regional to local long term tectonics. In more active tectonic areas with both long and short-term uplift, such as southern Calabria and eastern Sicily, where both Sentinel and GPS data indicate a slight subsidence, inconsistency has been observed at a local scale, where more transtensive and transpressive faulting may more effectively contribute with very short-term vertical deformation.

Building the paleo-seismic history of Allah-Bund fault, Great Rann of Kachchh, Western India

Mr. Nayan Sharma [1], *Prof. Javed Malik* [1], *Mr. Eshaan Srivastava* [1], *Dr. Mahendrasinh Gadhavi* [2], *Mr. Mitthu Dhali* [1]

1. Department of Earth Sciences, Indian Institute of Technology Kanpur, 2. L. D. College of Engineering

During the early Jurassic, the peri-cratonic Kachchh basin formed. After the Himalayan collision (40 Ma), the Mesozoic active rifting of this basin that occurred between 245 and 66 Ma was interrupted, which caused the stress to switch from extension to compression. Western India's Kachchh, which is regarded as a Stable Continental Region (SCR), has recently seen multiple earthquakes of a considerable magnitude, including those in 1668 CE (Mw 7.0), 1819 CE (Mw 7.8), 1845 CE (Mw 6.3), 1956 CE (Mw 6.0), and 2001 CE (Mw 7.7). Since the 17th century, the Kachchh region has hosted at least four destructive moderate to large magnitude of earthquakes. Except for the Allah Bund earthquake in 1819, none of these earthquakes had a surface rupture. Despite being the second-largest earthquake in the stable continental region (SCR), this event has not been examined from the perspective of current knowledge of earthquake seismology. A 90 km long scarp was created by the 1819 Allah Bund earthquake, limiting the flow of rivers that had previously flowed through the Great Rann of Kachchh (GRK) region and discharged into the Arabian Sea. The tectonic forcings present in the area and the paleo-seismic signatures will be the main focus of this investigation. A detailed tectono-geomorphic map was prepared using the remote sensing dataset, and the geomorphic markers were identified. We have excavated the Nara River section where the primary deformation due to the earthquake events can be seen and collected 8 OSL samples from the section. Before this study, the primary deformation had not been reported yet due to this event. This study will suggest whether the Allah-Bund scarp has resulted from a single 1819 event or multiple past seismic events.

First evidences of tilted MIS 5.5 tidal notches: new insight for the Late Quaternary tectonic evolution at Capo Rama (NW Sicily, Italy)

***Mr. Francesco Caldareri* [1], *Prof. Mauro Agate* [2], *Dr. Fabrizio Antonioli* [3], *Dr. Maurizio Gasparo Morticelli* [2], *Prof. Attilio Sulli* [2], *Dr. Nicolò Parrino* [1], *Dr. Stefano Devoto* [4], *Prof. Stefano Furlani* [4]**

1. Dipartimento di Scienze della Terra e del Mare, Università di Palermo, Italy, 2. Dipartimento di Scienze della Terra e del Mare, Università degli Studi di Palermo, 3. CNR IGAG, 4. Department of Mathematics and Geosciences - University of Trieste, Trieste

In the frame of the "Geoswim Programme developed and described in many recent papers, a geomorphological survey along a stretch of the Gulf of Castellammare eastern coast, south of the "Riserva Naturale Capo Rama" (NW Sicily, Italy), has been recently accomplished.

The survey was carried out by combining snorkeling swim technique, which provided rough measures of lateral variations in geomorphological and geological features and ecological and hydrological parameters, with classic field geologic-geomorphological survey. The investigated area consists of a rocky cliff, about 7 km long and up to 30 m high, which displays a fairly straight NNW-SSE trend. It is shaped in a Meso-Cenozoic shallow water carbonates with a limited outcrop of Tertiary clays. At the top of the cliff there is a wide marine terrace across which stepped landforms, such as a widely extended small terraces, can be recognize.

During the swim survey we observed the present-day tidal notch which shows typical morphometric parameters: it is well carved on both fine limestones and coarse carbonate breccias and it displays a depth up to 4 m long at fresh water springs.. The depth at the toe of plunging cliff ranges from 15 to 40 m. Moreover, we observed some fossil tidal notches, which are carved only on high resistant limestones„ such as sea-caves or sites covered by breccias deposits, at elevation ranging from 1.9 to 15 m a.s.l. moving southwards. The inner margin detected across the marine terrace has an elevation ranging from 52 to 80 m a.s.l. moving in the same direction.

We assume a MIS 5.5 age for the fossil tidal notch, based on radiometric U/Th and OSL analysis of fossil shells on coastal deposits outcropping about 1 km far from the southernmost fossil tidal notch detected. Furthermore, a Middle-Late Pleistocene age can be attributed to the inner margin, by applying the same tilting rate calculated for the fossil tidal notch.

In this work we illustrate first evidences of paleo sea-level indicators, detected along this 10 km long surveyed coastal area, that could be useful for better understand the Late Quaternary tectonic evolution of this coastal sector.

Late Pleistocene caves and their importance in the Mexican paleoenvironmental reconstruction with microvertebrates.

***Dr. José Alberto Cruz-Silva* [1], *Dr. Joaquin Arroyo-Cabrales* [1]**

***1.** Instituto Nacional de Antropologia e Historia*

Mexican Pleistocene paleoenvironmental (including paleoclimate) quantitative reconstruction with vertebrates are very recent. The first and most ecometrics used in Mexican vertebrates are stable isotopes on megafaunal remains; however, the paleoenvironmental reconstruction are usual very similar: some mammals present grazer diets, others browser, diets and still others are mixed feeder, inferring a grassland with open forests. The question is what kind of forests were those open forest and what was the paleoclimate? To answer this question, microvertebrates animals such as amphibians, reptiles, and small mammals are excellent proxies to reconstruct de environments in the past, and the caves are an excellent place for their preservation. In Mexico there have been more than 20 caves excavations, but very few had a controlled stratigraphy, dates, and small vertebrate studies. We present the inferred paleoenvironmental and paleoclimatic information from Loltún Cave, San Josecito Cave, and Huautla Caves System, in Southern, Northern, and Central Mexico, respectively. We use the Ecogeographical Mutual Range, the Habitat Weighting, and Ecological Niche Models methods to infer the paleoclimate of the different caves using the climatic niche and biogeography data from the nearest living relative of identified fossil taxa. Loltún Cave has an assemblage of amphibians and reptiles that infers a cooler and wetter paleoclimate between 40 000 – 30 000 years BP. In San Josecito Cave the assemblage of reptiles, small mammals and birds infers a warmer and drier paleoclimate for 34 892 ± 4077 years BP. For Huautla Caves System the presence of amphibians, reptiles and bats infer a paleoclimate similar to today during the 12,431–12,692 years BP. The paleoclimatic inferences for the three caves are consistent with other proxies such as pollen, diatoms, and speleothems in near paleontological sites. We emphasize the importance of the caves, the microvertebrates studies and the use of new methods for paleoenvironmental reconstruction to better understand the climate of the past and their effect in the biogeographic changes of the organisms.

Geomorphological evidence of active tectonics in northwestern Albania

Dr. Pio Di Manna [1]***, Dr. Luigi Piccardi*** [2]***, Dr. Eutizio Vittori*** [3]***, Dr. Anna Maria Blumetti*** [4]***, Dr. Valerio Comerci*** [4]***, Dr. Dashamir Gega*** [5]***, Dr. Rrezart Bozo*** [6]***, Dr. Olgert Gjuzi*** [6]***, Prof. Ismail Hoxha*** [6]***, Dr. Petraq Naco*** [6]***, Prof. Rrapo Ormeni*** [6]

1. *Geological Survey of Italy – ISPRA, Rome,* ***2.*** *Institute of Geosciences and Earth Resources – CNR, Florence,* ***3.*** *Institute for Geosciences and Georesources, CNR, Florence,* ***4.*** *Geological Survey of Italy - ISPRA, Rome,* ***5.*** *Geological Survey of Albania, Tirana,* ***6.*** *Institute of Geosciences – Polytechnic University of Tirana*

Albania is a very seismic country as confirmed by historical and recent earthquakes, including the Mw 6.4 November 26, 2019. This earthquake hit northwest Albania, opening the question on the level of seismic hazard in this region of important industrial, commercial and touristic growth, where major cities (Tirana, Kruja and Durrës) lie, with their historical centres and the densely populated extensive areas of new urban sprawl.
Starting from the survey of the effects induced by the 2019 earthquake, we carried out the analysis of the main tectonic features in the epicentral and surrounding areas, through field observations and remote sensing investigations, integrated with the analysis of historical and instrumental seismicity. The study is addressed to identify the active faults and folds able to produce deformation and/or rupturing at or near the surface in NW Albania.
Seismic data confirm the compressional regime acting in this region and morphotectonic evidence clearly show that the growing of the fault and fold systems influences the local morphology and the drainage pattern. Very steep and rectilinear fault scarps are associated with the major NW-SE striking thrusts and back-thrusts running with lengths reaching 50 km along the Kruja mountain front and the edges of the Durrës and Vora Hills. Fluvial diversions and wind gaps are clear evidence of the ongoing compressional regime and the associated thrusting and folding processes that control the landscape evolution between the Kruja thrust front and the coastline. At the same time, the activity of the major deep-seated geological structures, highlighted by geophysical investigations, induces the passive movement of the skin-deep structures and, controlling the regional uplift rate, it influences at large scale the landscape morphology. All the collected data suggest that the November, 2019 seismic event is not representative of the maximum seismic and surface faulting hazard in NW Albania. More detailed studies on active tectonics and palaeoseismological investigation are in process to better characterize the seismogenic sources and to define the precise location of the capable structures and the associated surface faulting potential, in the perspective to mitigate the risks due to the maximum expected earthquake in this region.

High-latitude Northern Hemisphere forcing of the Intertropical Convergence Zone in the tropical Atlantic - South American sector

***Dr. Veronica Ramirez* [1], *Dr. Francisco Cruz* [1], *Dr. Mathias Vuille* [2], *Dr. Valdir Novello* [3], *Prof. Hai Cheng* [4], *Dr. Juan Pablo Bernal* [5], *Ms. Angela Ampuero* [6], *Dr. Michael Deininger* [7]**

1. Universidade de São Paulo, 2. Department of Atmospheric and Environmental Sciences, University at Albany, 3. Geo- and Environmental Research Center, University of Tübingen, 4. Johannes Gutenberg University Mainz, Institute for Geosciences, Mainz, Germany

A major paradigm in paleoclimatology holds that shifts in the mean position of the Intertropical Convergence Zone were the dominant climatic mechanism controlling rainfall in the tropics during the last glacial period. Here we present a new paleo-rainfall reconstruction based on a high-resolution speleothem d 18 O record from north eastern Colombia, which spans most of the last glacial cycle. Our results suggest that the strength and positioning of the ITCZ over northern South America was more strongly affected by summer insolation at high northern latitudes than by local insolation during the last glacial cycle. Colder temperatures and ice sheet growth in the Northern Hemisphere (NH) displaced the ITCZ southward, increasing rainfall over Colombia, and resulting in an antiphased relationship with the Cariaco basin record in response to orbital forcing. This new record provides a better understanding of the forcings associated with ITCZ rainfall, which are in part different from those that control the South American Summer Monsoon (SASM). High-latitude Northern Hemisphere summer insolation was the dominant factor modulating the positioning of the ITCZ in the Atlantic-South America sector during millennial-scale events, such as Greenland Interstadials, Greenland Stadials and Heinrich Stadials.

Assessing neotectonic deformation through high resolution DEM Analysis. La Rinconada Fault, Eastern Precordillera. Argentina.

***Dr. Andres Richard* [1], *Ms. Lucía Jagoe* [2], *Mr. Rodrigo Quiroga* [3], *Dr. Carlos Costa* [4], *Ms. Victoria Alvarellos* [2]**

1. *CONICET-Departamento de Geología, Universidad Nacional de San Luis, San Luis,* ***2.*** *IDEAN - Instituto de Estudios Andinos Don Pablo Groeber - Universidad de Buenos Aires - CONICET,* ***3.*** *Instituto Argentino de Nivología, Glaciología y Ciencias Ambientales (IANIGLA-CONICET), Mendoza, ARGENTINA.,* ***4.*** *Universidad Nacional de San Luis*

The Andean orogenic front in Central Western Argentina (31º–32º S), is located at the foothills of Precordillera, and evidenced by Quaternary-active contractional structures, concentration of instrumental seismicity and destructive historical earthquakes. Quaternary alluvium deformed by faulting and folding along the La Rinconada fault provides excellent examples of active tectonic and climatic interplay, which is poorly understood. Our work aims to critically analyze the sensitivity of specific morphometric parameters obtained through DEM analysis to identify or suspect quaternary deformation, where the geomorphic imprint of neotectonic deformation is subtle or absent. Drainage network gradient and normalized steepness index (Ksn) were calculated to identify sectors where the erosion or uplift rates are more important. Longitudinal river profiles and knickpoints were also used to evaluate the equilibrium state of the drainage. Detailed mapping alluvial terraces was the cartographic base to understand how the Quaternary deformation is distributed.

We found evidence of drainage disequilibrium shown by several scattered knickpoints associated with high Ksn values. Concentration of these knickpoints are related to the hanging wall of the La Rinconada fault, mainly in areas where Paleozoic limestones crop-out. In outcrops of softer Neogene rocks a smaller number of knickpoints were determined, which could be linked to different factors. These heterogeneities evidence that careful field controls are necessary to link these parameters to subtle features of Quaternary deformation. However, detailed topographic analyses are promising to recognize meaningful trends in heights and gradients in different terrace levels, to quantify the geometry of faults and folds at the sub metric level. The development and improvement of these techniques will allow a better quantification of Quaternary deformation and to improve subsurface modeling for Seismic Hazard Assessment.

The earthquake ground effects accompanying the November 12, 2017, Sarpol-e-Zahab earthquake and ESI 2007 intensity, and extract locations with evidence of Quaternary paleo-earthquakes

***Dr. Hamideh Amini* [1], *Prof. Alessandro Michetti* [2]**

***1.** Department of Seismology, Institute of Geophysics, University of Tehran, Tehran, **2.** Università degli Studi dell'Insubria; INGV OV*

Sarpol-e-Zahab earthquake, November 12, 2017, Mw 7.3, occurred in Iran near the Iran-Iraq border, is the largest instrumental and historical seismic event recorded around this region. It was felt over an area of more than 800,000 km^2 with no reports of the surface faulting. The affected fault zone of this strong seismic event is located between the Mountain Front Fault and High Zagros Fault of main Zagros structures both striking NW-SE, closer to each other in northern west part of the region. Heavy building damage and numerous related environmental effects were caused by this earthquake. We assessed the macroseimic intensity of this earthquake using its available descriptions of the environmental effects and the building damage. According to the largest earthquakes reported around this region (such the ones occurred in 958AD and 1150AD both with reported magnitude 6.4), more investigation is needed to find more relevant information of the region seismicity, paleoearthquakes and seismic hazard. In this study, using the remote sensing and the satellite images, we start to analyze this region by concentrating on the environmental effects to find the last earthquake evidence. These effects can consist of rock-falls, liquefactions, ground features, and others, especially the triggered landslides; then, the intensity values can be assessed based on ESI07 macroseismic intensity scale. Therefore, in this study, we also try to find the suitable locations for sampling and dating the earthquake evidence to identify the region Quaternary paleo-earthquakes.

Environmental DNA in the tsunami deposits of the 2018 Palu-Donggala event

***Dr. Wenshu Yap* [1], *Prof. Adam Switzer* [1], *Dr. Jędrzej Majewski* [1], *Ms. Winona Wijyaya* [2], *Prof. Benjamin Horton* [1], *Dr. Federico Lauro* [2]**

1. *Earth Observatory of Singapore, Nanyang Technological University Singapore,* ***2.*** *Asian School of the Enironment, Nanyang Technological University*

Landslide-triggered tsunamis, although relatively rare, can have catastrophic effects on coastal communities. Their geological and hydrodynamic characteristics remain difficult to constrain due to limited number of studied examples. The palaeotsunami records of these events are rare and the mechanism which caused the tsunami is often unambiguously assigned. Here, we analyzed environmental DNA extracted from sediment samples emplaced on three sites in Palu Bay, Sulawesi, Indonesia, by the 2018 Palu-Donggala tsunami, which is known to be caused by landslides after the earthquake. This work applies a novel approach to understanding microbial impact of landslide-triggered tsunamis on coastal environments. Environmental DNA analysis is a promising approach to enhance the current multi-proxy framework when other evidence is variable.
Our results show that the environmental DNA in the tsunami-deposited sand differs significantly from the underlying non-tsunami-derived sediments and soil. A multivariate analysis shows that microbial communities in the tsunami deposits of all three sites are significantly different from those in the pre-tsunami layers (p-value = 0.0003). Notably, the difference in environmental DNA was still present at a site with limited grain size evidence between the tsunami and non-tsunami sediments. The study of the Palu-Donggala event shows that this microbial community difference between tsunami deposits and the underlying sediments and soil is impacted by tsunami disturbance, and this change in microbial communities detected using molecular techniques can be utilized to improve the reconstruction of geohazards in coastal environments.

Previously undocumented early-Holocene activity of Mount Edgecumbe, Sitka region, Alaska

Mr. Shaun H. Woudstra [1], Dr. Britta J.L. Jensen [1], Dr. James F. Baichtal [2], Ms. Katherine (K.K.) Prussian [3], Dr. Elizabeth Thomas [4], Dr. Jason P. Briner [4]

1. University of Alberta, 2. Blackpowder Consulting, Alaska, 3. Tongass National Forest Watershed Program, 4. University at Buffalo

The Mount Edgecumbe Volcanic Field (MEVF) is located on Kruzof Island, 16 km west of the town of Sitka, Alaska, USA. In April 2022, the previously dormant MEVF showed renewed seismic activity, and retrospective study revealed steady inflation has been occurring at the volcano since August 2018. Previous to this unrest, local mapping and documentation of tephras in marine cores have shown a major burst of activity of the MEVF in the late Pleistocene, likely related to deglaciation of the region. These eruptions deposited several metres of tephra in and around Sitka, and 15-20 cm in the Juneau region about 160 km to the NE. However, there is little understanding of the eruptive activity during the Holocene, with only two reported tephras and a pyroclastic flow identified on Kruzof Island. Our initial research and oral history of the indigenous Tlingit people suggest that it has been more active than previously thought.

We mapped a previously undescribed tephra sequence that contains 5-7 individual depositional units on Biorka Island, 17 km to the south of the volcanic field. Initial radiocarbon dates from below the sequence (9820-10180 cal yr BP) and mid-sequence (8200-8380 cal yr BP) suggest that these tephras were deposited during the early and middle Holocene. We successfully obtained glass geochemistry from seven of eight samples, with results geochemically consistent with MEVF tephras found in marine cores across Sitka Sound. To further clarify this potential Holocene sequence, we returned to the tephra sequence on Biorka Island in summer 2022. We collected new samples to expand the geochemical and radiocarbon dataset, mapped other exposures, and extracted new peat cores from Biorka Island and elsewhere around Sitka. These findings will aid the pressing need to better map, establish the eruptive history, and adjust hazard assessments of the newly-active Mount Edgecumbe.

Interplay of anthropogenic landscape shaping and fluvial dynamics

Dr. Philipp Schulte [1], ***Prof. Frank Lehmkuhl*** [1]

1. *RWTH Aachen University*

Land rehabilitation is a strategy for restoring near-natural landscape systems in anthropogenically influenced environments. Especially in post-mining landscapes after open-pit mining, land rehabilitation gives opportunities and potential for near-natural landscape modeling. To evaluate its success, biological monitoring approaches with a focus on biodiversity are common. However, the loss of natural soils, which are the result of long-term formation, is an irreversible damage to the pedosphere. The natural soil functions must be completely re-established and it is difficult to examine its success.
Our study area is located in the Inde River catchment (North Rhine-Westphalia, Western Germany), which is part of the international River Basin District Meuse. Due to the progress of the open-pit lignite mining, a 5 km long river course had to be relocated. To create a near-natural landscape and an appropriate development corridor for the river, a 12 km long river relocation was designed. The artificial river section “Neue Inde” is still geomorphologically “naive” and characterized by temporary, highly energetic morphodynamic processes resulting in strong erosion processes in the river bed and the surrounding area. Our study investigated initial soil formation in a morphodynamically active artificial river valley, constructed with a restoration substrate called “Forstkies”.
To characterize morphodynamics and to detect initial soil formation processes, we analyzed a transect of seven soil profiles. It includes floodplains and slope areas further away from the river. Allochthonous flood sediments can be differentiated from the underlying artificial restoration substrate by inherited enrichment of the heavy metals Pb, Zn, and Cu. First initial post-sedimentary alterations are detected employing common soil parameters (grain size, $CaCO_3$, total organic carbon and pH value) and geochemical weathering indices. The quality of the soils is appropriate to the state of development. The results obtained can be helpful for the planning of future restoration in post-mining landscapes.

Development of Holocene terraces along the Tsailiao River in the Western Foothills, southwest Taiwan

Mr. Kodai Iwasaki [1], ***Dr. Haengyoong Kim*** [2], ***Dr. Ai Kawamura*** [3], ***Dr. Yoshinari Kawamura*** [4], ***Prof. Chun-Hsiang Chang*** [5], ***Prof. Muneki Mitamura*** [6]

1. *Osaka City University,* **2.** *Nagoya University,* **3.** *University of Toyama,* **4.** *Osaka Museum of Natural History,* **5.** *National Museum of Natural Science,* **6.** *Osaka Metropolitan University*

Topographical and geological researches into fluvial terraces can reconstruct paleoenvironmental and sea-level changes caused by climate changes and crustal deformation. The island of Taiwan has been formed by the collision between the Philippine Sea plate and the Chinese continental margin of the Eurasian plate. The Western Foothills between the Central Range on the east and the Coastal Plain on the west defines the frontal zone of this collisional belt. Fluvial terraces are well developed along the Tsailiao River which flows through the Western Foothills. The surfaces of the terraces have been uplifting and deforming due to the activity of the zone. However, the developmental process of the terraces has not been clarified because previous researches are insufficient for accurate distribution and of the terraces, as well as lithological and chronological descriptions of their deposits. In this study, we have investigated the detailed distribution of the terraces, and discuss the forming process, chronology, climatic backgrounds, and tectonics on the terraces on the basis of the analysis using DEM, field works and radiocarbon dating. As a result, the terraces have been divided into three categories by the heights from the present-day riverbed and by the degree of dissection of the terrace surfaces. All the deposits of the terraces are composed of channel infill and overlying flood-plain deposits. These three terraces were formed in the early (Younger Dryas), middle and late Holocene for the higher, middle, and lower terraces, respectively, by climate warming and crustal uplifting. The terrace deposits have yielded marine invertebrate and land mammal fossils, but they had been derived from underlying sediments of Early and Middle Pleistocene in age.

Anthropogenically driven sinuosity variations on the channel of the lower Rio Grande, Texas, USA

***Mr. Edoardo Davila* [1], *Dr. Juan Gonzalez* [2], *Mrs. Sarah Hardage* [2]**

***1.** Texas Commission on Environmental Quality, **2.** The University of Texas Rio Grande Valley*

Large-scale dam building and river diversions on the Rio Grande over the last one hundred years, have reduced its discharge to 18% of pre-dam-building values, and have nearly eliminated the suspended sediment load. Present day suspended sediment concentration delivery to the Gulf of Mexico is 1% of pre-dam-building values. These new anthropogenic conditions have forced the river to adopt morphological changes. Here we explore how the river has adjusted the sinuosity of its channel on the delta, where the river gradient is 8 $cmkm^{-1}$ and the valley length is 88 km. We compare pre-dam sinuosity using the 1:10,000 scale International Boundary & Water Commission map of 1912, with that of 2014, using satellite imagery from the US Department of Agriculture, National Agriculture Imagery Program, with 1-meter pixel resolution. ArcGIS software was used to geo-reference the 1912 map, and to precisely measure channel length on both data sets. Our findings show that in response to the new conditions the river reduced its channel length by 10 km, from 202.35 to 192.31 km, which resulted in a sinuosity reduction from 2.3 to 2.2. This seemingly small change is the river's way to adjust its gradient to more efficiently discharge its load to the Gulf of Mexico. The sinuosity change occurred through lateral migration of the meandering channel. Worth noting is the observation that the position of the mouth of the river remained fixed for the 102-year period cover in this study. Two unexpected results are, 1- the international boundary shifted as the channel migrated laterally, and consequently the United States gained 4 km^2 of land, and Mexico lost the same amount, and 2- in the delta there are segments of the channel with sinuosities of 2.5, these are among the highest reported for any river channel.

Lower Meuse Holocene overbank deposition: persistent climate forcing and growing human impact

Dr. Willem Toonen [1]***, Mr. Tim Dorrestein*** [1]***, Mrs. Marjolein van Noord*** [1]***, Dr. Harm Jan Pierik*** [2]***, Dr. Hessel Woolderink*** [3]***, Dr. Kees Kasse*** [1]

1. *Earth Sciences, Vrije Universiteit Amsterdam,* ***2.*** *Cultural Heritage Agency of the Netherlands,* ***3.*** *Wageningen Environmental Research, Wageningen University*

For the Meuse River, located in the Netherlands, a dataset of 427 radiometric dates derived from its fluvial setting was compiled from existing literature. A cumulative probability density function (CPDF) was deployed to reconstruct the phasing in fluvial activity throughout the Holocene. Wavelet analysis was used to identify persistent periodicities in deposition or non-deposition (stability). It was found that particularly centennial-scale periodicities correlate to known episodes and modes of variability of the Atlantic climate system and solar activity – particularly that of the Gleissberg solar cycle. Major changes in overbank deposition closely followed North Atlantic climate anomalies and periods of rapid climate change, suggesting that the Lower Meuse's flooding regime is highly sensitive to such perturbations.

In addition, the CPDF results show a rise in the amplitude of overbank deposition in the last few millennia, which coincides with increasing human influence on land cover and an associated increase in sediment input from the hinterland. Whereas initial Neolithic farming societies seem to have had a limited direct impact, there are notable increases in overbank deposition during the middle Bronze Age (1800-1100 BC), the late Iron Age (250-12 BC) and particularly the Medieval period (AD 450-1500). Such periods are associated with enhanced pressure on arable lands due to agricultural innovations and increases in population density. The resulting fluvial responses in flood regime and overbank deposition did, reversely, affect cultural dynamics in the alluvial valley. Periods of increased fluvial activity coincide with a shift in occupation to higher grounds, while periods of relative stability are characterized by increased human activity in the low-lying floodplain areas.

Based on these results, it is argued that CPDFs can be a useful tool to understand flood regime changes, and to identify the impacts of climate and human forcings. This can be considered as important baseline information for current and future flood risk mitigation efforts, as they allow to establish the 'rhythm of the river' and its sensitivity to external punctuated and long-term perturbations.

Leipzig, city in a state of flux. Urban-fluvial symbiosis in a long-term perspective

Dr. Johannes Schmidt [1] ***, Prof. Julia Schmidt-Funke*** [2] ***, Prof. Matthias Hardt*** [3]

1. *Institute of Geography, Leipzig University,* ***2.*** *Historical Seminar, Leipzig University,* ***3.*** *Department "Humans and Environment", Leibniz Centre for History and Culture of Eastern Europe (GWZO)*

Leipzig, today a metropolis with 600.000 inhabitants, originated in the Middle Ages at the edge of the Pleiße and Weiße Elster floodplain. The place gave the city its name, which derives from Indo-European *Leibh-, meaning watery, slippery, loamy area. At least since the 12th century, Leipzig's inhabitants engaged in water engineering methods in order to secure water provisioning and allow for the use of water power and waterways. This led to an anthropogenic transformation of the existing waterbodies and related fluvial landscapes, which shaped the city for centuries. While the close connection between city and water tended to disappear in the 20th century, it is being rediscovered today through town planning, tourism and nature conservation. With its varied water history, Leipzig is a particularly well-suited case study for investigating the interdependencies between humans and water in the sense of a "fluvial anthroposphere". The city is characterised by a dense network of smaller water courses, a still-existing riparian forest, and a high density of archival sources, provided by both cultural and natural archives. The project takes a long-term perspective, investigating the period between 1000 and 1800, and combines historical, archaeological and geoscientific analyses. Its main objectives are (1) hydrological dynamics and city politics, (2) floods and droughts as social-natural events, (3) urban water pollution and (4) floodplain economies. The project stands for a decisive urban approach that provides the basis for drawing out the specifics of an urban-fluvial anthroposphere. Beside the conceptual idea, we will focus our presentation on the sedimentary reconstruction of Late Holocene fluvial and alluvial boundary conditions of the Weiße Elster, Pleiße and Parthe floodplains before and after passing Leipzig.

Geoarchaeological and stratigraphic investigations on the alluvial fan of the Riana Stream (Vedeggio valley, Southern Switzerland)

Ms. Dorota Czerski [1], ***Mrs. Maruska Federici-Schenardi*** [2], ***Mr. Mattia Gillioz*** [2], ***Prof. Cristian Scapozza*** [1]

1. University of Applied Sciences and Arts of Southern Switzerland, 2. Briva Sagl, Via Pedemonte 28A, 6500 Bellinzona

The alluvial fan of the Riana stream lies at the foot of the right side of the Vedeggio valley, in Canton Ticino (Southern Switzerland). The fan is densely built today, and recent archaeological discoveries revealed the frequentation and presence of human settlements in the area as early as the Roman Epoch.

The activity and position of the Riana stream deeply affected human activity on the fan. The archaeological remains are observed between 5 and 0.5 m depth, with three different levels of anthropic occupation. The first level shows evidence of artisanal iron mining activities, with the presence of an ore reduction furnace. Following a major flood event, the site changed function, making way for a necropolis characterized by six infant and two adult graves. These graves are located around a mound built with large stone boulders and with an observed extent of 10 m. After these two occupation phases attributed to the Roman Epoch, the area was also occupied during the Middle Ages and the Modern Epoch, when several terraces and a massive wall are built, most likely for agricultural purposes.

The alluvial fan deposits crosscut the anthropic levels observed. These deposits consist mainly of sands and gravels, clast-supported (fluvial active band), and matrix-supported silty sands for calmer phases of hydro-sedimentary activity. Destruction phases with a reworking of anthropogenic structures and finer layers (paleosoils in terrace fill) were also observed. Remains of charcoals were sampled for radiocarbon dating; this together with the archaeological observations will provide a detailed chronological analysis of the alluvial sequence.

These discoveries are unique in the area and reveal new insights into the human colonization history of Southern Switzerland. In recent years, many investigations were carried out in Canton Ticino, providing a nice overview of the human settlements and their link to the evolution of the hydro-sedimentary activity of Alpine rivers during the Holocene. The present contribution allows us to study the historical river dynamics of the Vedeggio valley and discover complementary evidence on the palaeoclimatic and palaeoenvironmental conditions, as well as the impacts of these rivers on humans as a resource and/or natural risk.

The Holocene record of the Galera River in the Guadix-Baza Basin (SE-Spain)

Dr. Daniel Wolf [1]***, Prof. Francisco Juan García Tortosa*** [2]***, Dr. Christiane Richter*** [3]***, Dr. Julie Dabkowski*** [4]***, Mr. Quentin Wackenheim*** [5]***, Dr. Christopher-Bastian Roettig*** [1]***, Prof. Dominik Faust*** [1]

The Guadix-Baza Basin (GGB) that also includes the Granada UNESCO Geopark constitutes a unique archive of Quaternary landscape formation. As the largest late Neogene Inland basin of the Betic Cordillera that was captured not earlier than during the middle Quaternary, it hosts a spectacular erosion landscape formed by the incision of the Guadiana Menor River and its drainage system. However, due to ongoing erosion dynamics since the middle Pleistocene, highly resolved sediment records documenting palaeoenvironmental conditions are very rare. Here we present an outstanding fluvial sediment record of the Galera River within the Baza Basin, the eastern sub-basin of the GGB that provides detailed insights into early to middle Holocene landscape dynamics. The up to 15 meters thick sediment sequence contains several meters of palustrine tufa deposits indicating more humid conditions after 8.2 ka cal. BP. After 6 ka, sedimentary features suggest an increasing aridification. In a period following 4.5 ka that relates to utmost aridity in several regional environmental archives, the Galera River system switched towards strong incision that contradicts general concepts of fluvial reactions on climatic impacts. The fluvial sequence of the Galera River record, together with various proxy information provides interesting new insights into Holocene environmental dynamics in a highly erosive marl landscape. Nevertheless, there remain some open questions regarding the interpretation of fluvial behaviour that might be strongly affected by geological substratum, tectonic impacts and particular relief conditions.

The Baer knolls as a landscape that served to reconstruct the palaeodelta of the Volga in the Late Pleistocene

Ms. Daria Lobacheva [1]***, Dr. Ekaterina Badyukova*** [1]***, Mr. Radik Makshaev*** [1]

1. *Independent Researcher*

Many geological sections in the ledge of the Lower Volga valley have been actively studied since the end of the 19th century. Results many years of field work showed that in all the studied quaternary sections along the Lower Volga valley alluvial sediments of the Khvalynian time (end of the late Pleistocene - early Holocene) are absent.

Numerous literatures, descriptions of wells, maps were used as research methods. We conduct geomophological mapping out in Arcgis using the SRTM DEM and studied many outcrops along Volga valley and in the Baer knolls – gyant underwater dunes of the Northern Caspian.

We consider the Volga River probably did not flow at the site of its present position in the Khvalynian time. In this regard, the question arises of where the Volga channel was located in the North-Western Caspian in the Khvalynian time. Thus, we propose the extreme western branch of the Volga ran along the foot of the Eastern Ergeni slopes, eroded the surface of the marine plain, as a result of which the Sarpinsko-Davanskaya hollow was formed, the eastern branches of the delta flowed into the Kha-ki saline. Which was one of the estuaries of the Northern Caspian, where the waters of one of the extreme eastern channels of the PaleoVolga stream probably flowed into.

In the Khvalynian time, the Volga channel in the lower reaches had multiple terminal distributary channels at different scales. Where were arcuate fluvial-dominated delta much larger (200-210 km wide) than the modern delta and somewhat reminiscent of the modern Lena delta in size. In the location of the modern Volga-Akhtuba floodplain there was probably a small central branch, in the west there was a Sarpinsky branch, and in the east, there was an Elton-Khaki branch. They were interconnected by an extensive system of branches, the relief of which is still preserved.

At the very end of the late Khvalynian time, the Sarpa and Khaki branches began to die off, and most of the water began to rush along the central branch, forming the modern Volga-Akhtuba valley.

Tectonics and climate events at the eastern flank of the Jordan Rift between the Late Pliocene and the Early Pleistocene

***Mr. João Carlos Cerqueira* [1], *Dr. Giancarlo Scardia* [2], *Prof. Fabio Parenti* [3], *Mrs. Simone Belarmino* [3]**

***1.** Universidade Estadual Paulista UNESP, **2.** Universidade do Estado de São Paulo, **3.** Universidade Federal do Paraná*

The Zarqa Valley is a remarkable morphological feature infilled by basalt flows interbedded with artifact-bearing fluvial deposits, about 40 km east of the Jordan River. Based on a review of the stratigraphy and geomorphology it has been possible to document major phases of erosion and aggradation in the last 5 million years, possibly related to the Jordan Rift tectonics and climatic evolution of the Levant. Chronologic constraints of the Zarqa Valley infill have been provided by paleomagnetic and geochronologic analyses of basalts and sediments. After the former valley formation, the first infilling phase is documented by a ca. 150 m-thick succession of basalt flows (Lower Basalt) accumulated at 5.82-5.51 Ma and now constituting the maximum aggradation surface at 550 m above the sea level. Our study documented 3 million years of erosion until a new cycle of aggradation took place at the end of the Pliocene. We sampled the lowermost stratigraphic beds of the Dulayl Fm. (40 m thick), where we could identify a geomagnetic polarity reversal from normal (at the base) to reverse magnetization (at the top). Since the Dulayl Fm is covered by a 2.52 Ma basalt flow (Upper Basalt) this magnetic reversal is interpreted as the Gauss-Matuyama boundary at 2.58 Ma. This implies that at least 30 m of Dulayl Fm deposited in ~60 kyr, a fast sediment accumulation rate of 50 cm/ky. The data also indicates that the Late Miocene Lower Basalt (5.82□5.51 Ma), was slowly eroded during the Pliocene at a rate of 3.6 cm/ky.

We interpret the erosion phase during the Pliocene associated with the progressive lowering of the base level in the Jordan Valley. Palynological records from several boreholes drilled throughout the Jordan Valley, show that the Levant had a humid and warm temperate climate provided by colder polar air from the north at the end of the Pliocene, providing an aggradation phase around the Plio-Pleistocene boundary by the increasing precipitation. This event on one side could have triggered higher sediment discharge in the Zarqa Valley and on the other side higher accommodation space for lacustrine transgression in the endorheic Jordan Basin.

Facies architecture and aggradation rates of periglacial alluvial fans: control by autogenic processes or high-frequency climatic osciallations?

Prof. Jutta Winsemann [1]***, Mr. Tim Hartmann*** [2]***, Dr. Jörg Lang*** [2]***, Ms. Runa Fälber*** [2]***, Dr. Tobias Lauer*** [3]

1. *Institut für Geologie, Leibniz Universität Hannover,* ***2.*** *Leibniz Universität Hannover,* ***3.*** *University of Tübingen*

Quaternary alluvial systems reveal a complex history of incision and aggradation responding to climatic forcing. However, the depositional architecture and geomorphology of alluvial fans that have evolved in response to similar regional environmental conditions can differ strongly, implying that autogenic processes may play an important role and lead to similar cycles of fan aggradation and incision that may be difficult to be distinguished from the effects of tectonics or climate change. Here, we present data from two different Late Pleistocene (MIS 3-2) alluvial fan systems in Germany. The selected fan systems formed under similar climatic and tectonic conditions, but differ in size, type, and drainage area allowing to estimate the role of climate and autogenic controls on flow processes, facies architecture, and fan-stacking patterns.

Luminescence dating is used to determine the timing of fan onset and aggradation rates. Fan onset occurred in response to climate change at the end of MIS 3 when temperatures decreased and periglacial climate conditions were established in northern central Europe. A related increase in sediment supply and strongly variable precipitation patterns probably promoted fan formation. The major period of fan aggradation was approximately between 33-18 ka, followed by fan inactivity, abandonment, and incision during the Lateglacial. The highest aggradation rates occurred during the early stage of fan building.

Sand-rich, sheetflood-dominated fans are related to larger, low-gradient fan catchments. Steep depositional fan slopes (5°-17°) favored supercritical flow conditions. Steep, dip-slope catchments enhanced stream gradients and promoted the transport of coarser-grained sediments. These fans have lower gradient slopes (2-6°) and are dominated by channelized flows, alternating with periods of unconfined sheetfloods. Meter-scale coarsening-upward successions, characterized by sandy sheetflood deposits at the base, overlain by multilateral or smaller single-story gravelly channel fills may be related to high-frequency climatic fluctuations or seasonal fluctuations in water and sediment supply. These coarsening-upward successions are commonly bounded by a paleo-active layer, from which ice-wedge casts penetrate downwards. The recurrent pattern of multistory, multilateral and single-story channel bodies with a lateral offset to vertical stacking pattern most probably was controlled by autogenic switch in avulsion-dominated systems.

River terrace formation in the Granada UNESCO Geopark (Spain): Timing and dynamics

Mrs. Laura Kögler [1], ***Dr. Daniel Wolf*** [2], ***Prof. Dominik Faust*** [2], ***Prof. Markus Fuchs*** [1], ***Dr. Christopher-Bastian Roettig*** [2], ***Dr. Thomas Kolb*** [1]

1. *JLU Giessen University,* ***2.*** *TU Dresden University*

River terrace formations are widespread geomorphological features all over the world. The complex interplay of erosion and accumulation processes and their triggering environmental conditions, which control the dynamics and timing of river terrace formation is only one of numerous questions related to fluvial terraces that have not yet been adequately answered.

The Baza/Guadix Basin, which is part of the Granada UNESCO Geopark, located in northeastern Andalusia, provides ideal conditions to investigate the dynamics of river terrace formation. Starting in the Pliocene and persisting until the middle/late Pleistocene, the basin was a vast drainage-free depression that was continuously filled with sediments of all grain sizes originating from the surrounding mountains. At a so far unknown time during the middle or late Pleistocene, this endorheic basin was captured by a source river of the Rio Guadalquivir, and a new river system was established, cutting into the original basin sediments and leaving deeply incised valleys with several generations of fluvial terraces. At several locations, the river terraces are coupled with travertine and sinter formations. The terrace deposits as well as the tufa and travertine formations occurring in the basin are to be systematically documented, mapped, and dated.

The DFG-funded project presented here aims to investigate the evolution of this newly established drainage network. Based on luminescence dating of river terrace sediments and supported by U/Th-dating of tufa and travertine formations, we will establish a regional chronostratigraphic framework, which will provide information on the dynamics of the fluvial landscape evolution in the Basin ever since the capturing event. We expect our results to allow us to approximate the velocity of backward erosion and to determine typical incision rates for the local rivers.

Our poster gives an overview of the goals the project is aiming at, provides information on the methods applied, and presents some first geochronological results.

Pliocene-Quaternary landscape evolution of the Krško Basin (south-eastern Alpine foreland, Slovenia) based on sedimentological, geomorphological, and chronological data

***Dr. Eva Mencin Gale* [1], *Dr. Jure Atanackov* [1], *Dr. Ana Novak* [1], *Dr. Petra Jamšek Rupnik* [1], *Dr. Kristina Ivančič* [1], *Dr. Mirka Trajanova* [1], *Dr. Luka Gale* [2], *Mrs. Aleksandra Trenchovska* [1], *Dr. Miloš Bartol* [1], *Mr. Miha Marinšek* [1], *Dr. Petra Gostinčar* [1], *Mr. Blaž Milanič* [1], *Mr. Anže Markelj* [1], *Mrs. Aleša Uršič Arko* [1], *Dr. Klemen Teran* [1], *Dr. Milos Bavec* [1], *Dr. Stephanie Neuhuber* [3], *Dr. Sandra M. Braumann* [3], *Mr. Alexander Wieser* [4], *Mr. Oscar Marchhart* [4]**

***1.** Geological Survey of Slovenia; Dimičeva 14, 1000 Ljubljana, Slovenia, **2.** University of Ljubljana, Faculty of Natural Sciences and Engineering, Department of Geology, Aškerčeva 12, 1000 Ljubljana, Slovenia, **3.** University of Natural Resources and Life Sciences, Department of Civil Engineering and Natural Hazards, Institute of Applied Geology; Peter Jordan Strasse 82, 1190 Wien, **4.** University of Vienna, Faculty of Physics, Isotope Physics, Währinger Strasse 17, 1090 Vienna, Austria*

This study focuses on the Pliocene-Quaternary landscape evolution of the Krško Basin located in the south-eastern Alpine foreland, Slovenia. The basin covers an area of approximately 280 km^2 and is elongated in the west-southwest to east-northeast direction with its main tributaries Sava, Krka, and Sotla Rivers. The formation of the Krško Basin is related to the Krško Syncline which was formed by the north-northwest to south-southeast compression that started at the end of the Miocene and continues to the present day. The base of the syncline, consisting of Mesozoic sedimentary rocks is overlain by the Neogene marine and terrestrial succession followed by terrestrial Pliocene-Quaternary sediments. The latter were the main focus of our study which aimed to define the morphostratigraphy, composition, provenance, sedimentary environment, and time of deposition of these sediments. Facies analysis revealed that the Pliocene-Quaternary sediments were deposited in fluvial and alluvial/colluvial fan environments. The sediments are preserved in terrace staircase sequences, which are controlled by folding caused by the compressive tectonic regime. We conducted geomorphological mapping which was based on combining existing data, geomorphological analysis (analysis of topographic profiles and GIS-based shaded relief, elevation, slope-inclination, slope-aspect maps, and relative elevation model), ground truthing, clast lithological analysis and the evaluation of subsurface data. Based on geomorphological analyses and age dating with terrestrial cosmogenic nuclides, eight levels of Pliocene-Quaternary terraces were constrained. Clast lithological analysis revealed not just local but also distal provenance of the Pliocene-Quaternary sediments. Local character is deduced from the Triassic volcanic, clastic and carbonate rocks since all of the mentioned lithotypes are outcropping in the vicinity of the basin. However, metamorphic rocks from Pohorje Massif and Permian carbonate rocks are indicating distal provenance. Considering present exposures of identified rock formations, the main transport path was along the Savinja River.

A response of fluvial systems of different size on climate changes during the Last Glaciation in Polish Lowlands area

1. *University of Gdańsk,* **2.** *Silesian University of Technology,* **3.** *Maria Curie-Skłodowska University in Lublin,* **4.** *University of Wrocław,* **5.** *Maria Curie Skłodowska University, Institute of Earth and Environmental Sciences, Lublin,* **6.** *Polish Geological Institute – National Research Institute*

Fluvial systems with different catchment sizes and discharge rates respond differently to climate change. It is assumed that large river systems (the size of the Vistula or the Rhine Rivers) are characterised by a high response inertia, while smaller rivers respond more quickly and to smaller-scale climate fluctuations. Therefore, 2 river systems were selected that operated during the Weichselian glaciation in the extraglacial zone to testify this assumption. The first example is the middle section of the Vistula River valley, which represents the main fluvial system of the Polish Lowlands. The second study area is the lower part of the Prosna River valley, a tributary of the Warta River. The sediments building the fluvial terraces of both valleys were studied on the basis of lithofacial analysis. Analysis of periglacial structures and textural features of the sediments was used to reconstruct climatic conditions during sediment accumulation. Optically stimulated luminescence (OSL) and the radiocarbon method were used to determine the age of the studied sediments.

The results obtained indicate that the river systems of the Prosna and Vistula Rivers responded differently. In the middle section of the Vistula River valley, two main periods of deposition were identified. They took place during the Late Vistulian and at the end of the last glaciation. On the other hand, in the Prosna River valley, 4 erosion-deposition cycles were distinguished during the Middle and Upper Vistulian. At the end of the Late Pleniglacial, there was a deep erosional incision in the Prosna River valley and a change in the river type from braided to meandering (a system of large meanders). In the Vistula River valley, on the other hand, erosional incision presumably took place just after the Last Glacial Maximum. Beginning at the end of the Late Pleniglacial, sediment aggradation in the Vistula valley was dominated by a braided river type.

It can be concluded that the Prosna fluvial system was characterised by high sensitivity to climate change, whereas the Vistula fluvial system responded only to major changes in environmental conditions.

Alluvial fans as an indicator of Quaternary climate change

Prof. Frank Lehmkuhl [1]***, Dr. Lewis Owen*** [2]***, Dr. Janek Walk*** [1]

1. *Department of Geography, RWTH Aachen University,* ***2.*** *North Carolina State University*

Past research suggests that alluvial fans are, due to their direct coupling to the source area, sensitive to Quaternary environmental change and, thus, provide essential archives for paleoenvironmental conditions, notably climate, hydrology, and tectonics. Although they have been studied for many decades across the globe, there is no unifying scheme to view their variety in relation to the formative geomorphological regimes. The spatial and temporal approach in geomorphology indicates that the development of landforms is a function of size and time. While small-scale landforms are created by short-term events, mesoscale and macroscale landforms develop within a period of 10^4 to 10^5 years. A conceptual model for the formation of alluvial fans is developed, and their implication for Quaternary climate change is assessed, using a review of their global range and data from selected key dryland regions. We propose three main depositional regimes for alluvial fan development: i) Mountain alluvial fans, small in size and extent; ii) mesoscale pediments and bajada of (semi-) arid regions; and iii) mega fans mainly associated with Cenozoic mountain building.

Mountain alluvial fans are governed by cryogenic and nival processes, closely linked to climate change, tectonic processes such as earthquake-triggered landslides, and are often also modified by anthropogenic intervention. In drylands, mesoscale pediments and bajadas are one of the most common fluvial systems and landform features, where they are frequently associated with steep mountain fronts, closely related, and often modified by active tectonics. The formation of mesoscale alluvial fans occurs in different settings characterized by distinct relationships between sediment production and transport capacity. Although governed primarily by the climatic setting, bedrock geology can be the dominating factor, especially for sediment production. Alluvial fans in the drylands of the western United States, Mongolia, Chile, and Namibia illustrate the links to climate variability by glacial-interglacial cycles or expressed in late Quaternary pulses of increased humidity. Furthermore, mesoscale alluvial fans are common in glaciofluvial and periglacial settings, where streams have high bedload and transport capacity depending on a sediment supply especially due to frost weathering and discharge by snow and ice dynamics.

Complex fluvial archives of varied types: erosional and depositional evidence from the River Trent, Midland England

Prof. David Bridgland [1], ***Dr. Andy Howard*** [2], ***Dr. James Innes*** [1], ***Prof. Danielle Schreve*** [3], ***Prof. Mark White*** [1], ***Dr. Tom White*** [4]

1. *Durham University,* ***2.*** *Landscape Research & Management,* ***3.*** *Royal Holloway, University of London,* ***4.*** *Natural History Museum*

Fluvial archives can take a variety of forms, both depositional and erosional, the latter invariably of a geomorphological nature (although there can have been subsequent burial); sedimentary and geomorphic evidence are optimally combined in river-terrace sequences. The record from the Trent, combines all these types of data. There is a sequence of terraces in the Middle Trent that has been researched over many years and was extended into the lower reaches by the Geological Survey late in the last century. The river has excavated gorge reaches of various lengths through resistant bedrock strata, interpretation of which is fundamental to unravelling its evolution. The latter has involved multiple diversion events associated with glaciation on three separate occasions. There are sporadic but important remnants of fossiliferous interglacial sediment that provide pinning points for deciphering the complex evolution of the system.

The story of the Trent began with the River Bytham, which drained from the West Midlands to East Anglia along an alignment several kilometres south of the valley axis of the modern Trent. That system was destroyed by the Anglian (MIS 12) glaciation, although various reaches became parts of later drainage, in some cases reversed. Anglian deglaciation saw the emergence of a Derwent-Soar system, derived from the Bytham but flowing into the North Sea through the newly (glacially) excavated Wash basin, crossing the Jurassic escarpment at Lincoln (giving rise to the Lincoln Gap). The constricted gorge-like course of the Trent between Nottingham and Newark was adopted at this time, although its excavation has required progressive downcutting throughout the subsequent Pleistocene, keeping pace with the lowering of the river recorded by its terraces. There is no sedimentary record in the lower valley older than MIS 8, but deposits of the Wragby (MIS 8) glaciation fill a subsurface feature interpreted as the MIS 12–8 palaeo-Trent valley. The Wragby glaciation coincided with the west-east course of the Trent between Derby and Nottingham becoming established. The Trent flowed to the Wash until deglaciation of the Devensian (MIS 2) ice sheet that had blocked and ponded the Ouse-Humber system (which drained the eastern Pennines further north).

Late Neogene-Quaternary Andean foreland basin evolution of the depositional system of the Salado-Juramento fluvial megafan, South America

Dr. Bélen Thalmeier [1], ***Dr. Ernesto Brunetto*** [1], ***Mrs. Cecilia Zalazar*** [2], ***Mr. Oscar Pedersen*** [2], ***Mr. Javier Soffiantini*** [1], ***Dr. Daniela KROHLING*** [3]

***1.** CICyTTP (CONICET-Entre Ríos Prov.-UADER), **2.** FCYT-UADER, Universidad Autónoma de Entre Ríos, **3.** CONICET and Universidad Nacional del Litoral*

Strata in foreland basins record are the result of periods of deformation, climatic change, changes in thrust rates, and source rock variation, among others. In underfilled basins, the forebulge remains a topographic high as observed in the middle part of the Salado-Juramento fluvial megafan-SJFM in the modern Andean and Pampean foreland basin in South America (26°-30°S). The interaction between tectonics and sedimentation in the foreland basin, whose evolution is related to normal dipping slab subduction (>30°) and flat slab subduction transition, was analyzed by a sedimentary record from 42 deep boreholes. Constraining, the geometry of the basin from the Anta and Paraná formations, the evolution of the Late Miocene-Quaternary foreland basin was interpreted. The Bermejo DFS cross-section, situated along the long axe, showed a classical foreland profile produced from flexural loads originated by the Sub-Andean fold-thrust belt. It controls the synorogenic sedimentation mainly in the foredeep zone. In the NW-SE section of the SJFM, the major sedimentation occurs in the foredeep zone. The forebulge is interpreted as the Otumpa Hill-OH which could indicate an uplift stage due to flexural loads and faulting reactivation over the Late Cenozoic. The back-bulge zone is represented by a large plain, limited in the E by the Vera Block-VB. VB corresponds to ancient zones of basement weakness that were reactivated, generating a tectonic style of blocks with differential vertical movements. Presently, sedimentation rates do not exceed the uplift rates that occur in the mid-distal foreland basin in SJFM and generate differences with the other Chaco DFSs. A tectonostratigraphic model of the evolution of a DFS in a modern underfilled basin may be interpreted from vertical grain-size trends in the SJFM. Basal sandy or conglomeratic fining upward sequences are associated with higher sediment supply and higher accommodation spaces at the first stages. These sequences could be related to periods of higher tectonic activity in the northeastern Pampean Ranges, in addition to the climatic control. The top fine sandy–silty sequences indicate a foreland basin stage characterized by lesser accommodation space and higher sediment transport rates. Lateral grain-size variations also can be observed inside these major sequences.

Development and evolution of the Maggia river delta in Lago Maggiore since the deglaciation (Southern Swiss Alps)

Prof. Cristian Scapozza [1], ***Ms. Dorota Czerski*** [1]

1. University of Applied Sciences and Arts of Southern Switzerland

The delta of the Maggia river between Locarno and Ascona (Canton of Ticino, Southern Switzerland), with its typical fan shape prograding into the upper Lago Maggiore, is one of the most emblematic fluvio-deltaic landforms of the entire Alpine domain. This site is located at the crossroads between the wide and deep water-filled valley trough, which penetrates deeply into the Alpine chain, and the upper Southern Alpine valleys, which enable reaching and crossing the Alpine divide.

The compilation, harmonization, and contextualization of the regional chronostratigraphic framework, combined with the analysis and interpretation of unpublished radiocarbon ages, allowed for the determination of a new chronology and the diachronic paleogeographical reconstruction of the development and evolution of the Maggia river delta. In particular, the geomorphological history of upper Lago Maggiore is assessed, highlighting the timing of deglaciation after the Last Glacial Maximum, the reconstruction of the mean lacustrine level, and the progradation rates of the Maggia river delta during the Late Glacial (19.9–11.7 ka b2) and the Lower (11.7–8.24 ka b2k) and Middle (8.24–4.25 ka b2k) Holocene.

Thanks to the sedimentological and paleoenvironmental observations carried out in four archaeological sites on the Maggia river delta, a particular focus is done on the morphoclimatic and environmental evolution during the Upper Holocene (4.25–0 ka b2k), by evaluating the variation of the Lago Maggiore mean level and the hydrosedimentary activity of the watercourses that contribute to feeding the delta.

Understanding the timing of development and the environmental evolution of an Alpine delta, contribute to raising knowledge about the mountain geomorphological systems' response to the climate oscillations after the Last Glacial Maximum. This assessment is necessary to compare a system controlled only by natural factors, dominated by paraglacial and paraperiglacial erosion models, and a system where increasing human activity modifies the environment. In the Southern Swiss Alps, anthropogenic factors start playing a role since the frequentation of the valley bottoms and the main Alpine passes during the Middle Mesolithic (10.0–9.0 ka b2k). This role increased significantly since the Neolithic (7.5–5.4 ka b2k), with the first permanent settlements.

Geomorphology and stratigraphic record of the Murinascia Grande delta in Lago Ritóm since the deglaciation (Piora Valley, Southern Swiss Alps)

***Ms. Chantal Del Siro** [1]**, Ms. Dorota Czerski** [1]**, Dr. Sandro Peduzzi** [2]**, Dr. Nicola Storelli** [3]**, Prof. Cristian Scapozza** [1]*

***1.** Institute of Earth Sciences, University of Applied Sciences and Arts of Southern Switzerland, **2.** Ufficio dei corsi d'acqua, Canton of Ticino, Switzerland, **3.** Institute of Microbiology, University of Applied Sciences and Arts of Southern Switzerland*

The Lago Ritóm is located in the Piora Valley at 1849 m a.s.l., on the southern side of the Swiss Alps, in a natural basin carved by ice during the Last Glacial Maximum. The natural dam of Lago Ritóm consists of a rock sill, whereas the artificial dam was built in 1917 for the construction of a hydroelectric power plant.
The construction of the dam led to an increase in the water level in the basin from 1828 m a.s.l. to a maximum elevation of 1850 m a.s.l., resulting in the flooding of the delta of the Murinascia Grande, the main lateral tributary located northeast of the basin. However, since the summer season of 2020, the water level decreased below 1827 m a.s.l. due to the maintenance of the hydroelectric dam, allowing the emersion of the Murinascia Grande delta. The subsequent fluvial erosion caused the exposure of the fluvio-deltaic sequence.
Approximately ten meters of alluvial deposits with layers of silts and organic muds, sands from finer to coarser, and gravels were observed and described on the field. The organic sediments together with pieces of wood were sampled for radiocarbon dating at different levels in the stratigraphy. This approach was combined with a detailed 3D photogrammetric model of the delta obtained through a drone survey.
Based on previous studies on palynological records, the development of the vegetation in the area was attested during the Lower Holocene at around 9 ka b2k. As a result, the radiocarbon dating on the delta deposits will probably provide a chronology covering a period included between the Middle to the Upper Holocene (8.24–0 ka b2k). The dating, together with the estimation of the volumes and thicknesses of the deposits from the digital terrain model, will allow tracing the variation of the sedimentation rate on the delta in time.
The results will provide information about the timing of development and the evolution of an Alpine delta during the Holocene, providing evidence on the response of the hydrosedimentary regime to the climate oscillations and therefore on the palaeoclimatic and palaeoenvironmental conditions on a regional scale.

New ESR Ti ages of the fluvial terraces of Arlanzón River (Sierra de Atapuerca, Duero basin, Spain)

Dr. Davinia Moreno [1]***, Mrs. isabel Hernando*** [2]***, Dr. Alfonso Benito-Calvo*** [1]***, Dr. Ana Isabel Ortega*** [3]***, Prof. Eudald Carbonell*** [4]***, Dr. José María Bermúdez de Castro*** [1]

1. *Centro Nacional de Investigación sobre la Evolución Humana (CENIEH),* ***2.*** *CENIEH,* ***3.*** *Fundación Atapuerca,* ***4.*** *IPHES-CERCA, Institut Catala de Paleoecologia Humana i Evolucio Social*

The Sierra de Atapuerca is a limestone range located in the NE Duero basin (Burgos, Spain), where a multilevel endokarst system containing the oldest fossil remains in Europe is located. Previous geomorphological studies have correlated the three cave levels of the Atapuerca karst with terraces between T2 (+82-91 m) and T6 (+44-46 m) of the Arlanzón River according to their altimetric position. Therefore, establishing an accurate chronological framework for the fourteen-stepped terrace system of the Arlanzón river is important to better understand the connection between the Atapuerca karst system and the Duero basin hydrographic incision.

Previous studies dated terraces T3 (+70-78 m), T4 (+60-67 m) and T5 (+50-58 m) by ESR to 1.24; 0.8-0.9 and 0.70-0.6 Ma respectively, in agreement with a paleomagnetism study that revealed normal polarity for terraces T5 (+50-58 m) and T3 (+70-78 m), and inverse polarity for T4 (+60-67 m). However, ESR ages were obtained from the Aluminum center whose results have recently been interpreted as maximum dates because the signal from this center does not bleach completely. In contrast, the Ti center has much faster bleaching kinetics, so it usually provides more coherent ages although it is more complicated to measure.

To complete the previous chronostratigraphic framework of the Arlanzón terraces, eight ESR samples were collected from T2 (+84-88m), T3 (+70-78 m), T4 (+60-67) and T5 (+50-54 m) to be dated using both the Al and Ti centers. Our first results suggest maximum Al ages of Lower Pleistocene for T2 (+84-88m) and T3 (+70-78 m), being impossible to obtain reliable Ti center ages from samples taken in both terraces. Lower Pleistocene terrace T4 (+60-67) was dated using both the Al and Ti center of more than 0.78 Ma. Finally, AZN1502 and AZN1503 from T5 (+50-54 m) yielded an approximate age of Middle Pleistocene. The results provided in this paper are in agreement with the geological context and the previous Al ESR ages for Arlanzón river terraces.

The Upper Volga River formation history reconstructed: a case study of Rybinsk-Plyos valley section

Ms. Anna Utkina [1]***, Prof. Andrey Panin*** [2]***, Dr. Redzhep Kurbanov*** [3]

1. *Institute,* ***2.*** *Institute of Geography, Russian Academy of Sciences,* ***3.*** *Institute of water problems, hydropower and ecology, TNAS, Dushanbe*

The Upper Volga – the upstream section of the Volga River – was always considered to have had a long and complex paleogeographical history. Given the extensive research that has been conducted in its valley since the 1930s, one would expect its evolution to be firmly established. Nevertheless, our recent studies prove that previous reconstructions were often operating popular, yet misleading misconceptions. One of such popular misconceptions was the formation of the Upper Volga River system of proglacial lakes during the LGM (MIS2). The Upper Volga valley was considered to have emerged only after this lake system was drained during Late MIS2. It was thought that the geological evidence of the lakes' existence was still preserved in the valley as terraces. To test this concept, we conducted field studies in the valley focusing on three key sites: incision valleys near Tutayev and Plyos (which were thought to have formed during the lake drainage), and the Rybinsk site. We discovered no geological evidence of the proglacial lakes' existence in the valley during MIS2. Instead, luminesce dating revealed that a lot of previously thought fluvial or limnoglacial terraces are in fact comprised of fluvioglacial sediments – we make this assumption since all the ages appear to be overestimated. The incision valleys also seem to have appeared a lot earlier than MIS2: we were able to locate the remnants of the river terrace in the Plyos incision valley dating back to MIS5e. An archive section near Rybinsk also showed that during that time the upstream part of this valley part was taken up by a lake. During Late MIS2, the Rybinsk-Plyos valley section had already existed as a fully functioning river, as indicated by MIS2 river terrace. All of this evidence combined with our assessment of the GIA influence on the Upper Volga valley during MIS2 indicates that 1) the minimum age of the valley formation is MIS6; 2) since MIS6, it was never fully occupied by proglacial lakes; 3) it incised after Late MIS2 and in Holocene, as found river terraces suggest.

New combined study of surface and subsurface maps of the Turin Plain (Po River)

Dr. Igor Marcelli [1], Prof. M. Gabriella Forno [2], Dr. Franco Gianotti [2], Dr. Andrea Irace [1], Dr. Gianfranco Fioraso [1]

1. CNR - Institute of Geosciences and Earth Resources, Torino, 2. UNITO - Department of Earth Sciences

Turin and suburbs (NW Italy) lie in the western sector of the Po Plain, between the Western Alps and the Turin Hill. The published data concern the marine and deltaic deformed Pliocene succession and the overlapped (in discordance) fluvial Quaternary sequence separately. The aim of this research is to combine the two information toghether to obtain a unique stratigraphic framework of the Turin subsurface, useful for any significant intervention in the area.
The Pliocene (Zanclean to Piacentian) succession (mailny observed in the lower stretch of some logs with depth between 150 and 16 m and through the geophysical survey) consists of bacinal/outer shelf Argille Azzurre, litoral Asti Sand and deltaic/fluvial Villafranchian sediments. Complex lateral stratigraphic relationships and time-trasgressive boundaries exist between these deposits.
The Pliocene succession setting, involved in the Turin Hill thrust propagation fault system and deformed until the Early Pleistocene, was evidenced by this recent reconstruction of the multilayer structure through the construction of a three-dimensional model based on a database.
The Quaternary sequence (observed in the upper stretch of all logs and by geological and geomorphological survey) lies on a sub-horizontal erosional surface shaped on the Pliocene succession and consists of a relatively thin cover (30-35 m) of outwash gravel, with local sand, forming the proglacial plain of the Rivoli-Avigliana end-moraine system fed by the Dora Riparia catchment basin (Susa Valley). This plain occupied the whole space between Alps and Turin Hill until the Upper Pleistocene, while the Po River was missing from the Turin area as it flowed south of Turin Hill. The new collected data allowed to distinguish two outwash units (Bennale and Turin), separated by a palaeosol and referred to pre-LGM and LGM by radiocarbon dating respectively. Subsequently, this plain was terraced by the Lateglacial-Holocene activity of the Po River and its tributaries (Dora Riparia, Stura di Lanzo and Sangone), that formed a set of entrenched fluvial terraces along this watercourse.
This work combines surface and subsurface cartographies. A new interpretation of the stratigraphic and tectonic relationships between the buried Langhian-Early Pleistocene sedimentary successions and the terraced fluvial deposits lying above them are shown.

Patterns, rates and controls on Quaternary foreland basin erosion along the Sahara Desert margins using fluvial-fan terrace markers

Dr. Martin Stokes [1], ***Prof. Anne Mather*** [1], ***Dr. Jesse Zondervan*** [2], ***Dr. Sarah Boulton*** [3], ***Prof. Alaeddine Belfoul*** [4]

1. School of Geography, Earth and Environmental Sciences, University of Plymouth, UK, 2. School of Earth Sciences, University of Bristol, 3. University of Plymouth, 4. Laboratory Structural Geology and Thematic Cartography (GESCAT) Department of Geology Faculty of Sciences Ibn Zohr University of Agadir

Foreland basins are subsidence zones that develop onto continental crust by flexural geodynamic processes linked to the growth and decay of collisional mountain belts. The sedimentary and geomorphic records of foreland basins can provide key insights into the patterns, rates and timing of long-term Quaternary landscape development and drivers.

Here, we use an inset sequence of fluvial-fan surfaces to document the long-term erosion of the Ouarzazate Basin (Morocco), a major foreland basin developed along the southern flanks of the Atlas orogenic system and the NW Sahara Desert margins. The basin is 150x40km, is infilled with > 1 km of Neogene-Quaternary sediment and covers an area of ~3200km^2. During the Plio-Quaternary, a switch from foreland sedimentation to erosion occurred leaving behind relict fan surfaces and river terraces formed primarily from streams draining the High Atlas orogen (north) and its Anti-Atlas forebulge (south) regions. The fan surfaces are dissected by ephemeral modern streams exiting the SW basin via a deeply incised canyon across Anti-Atlas basement.

The landform sequence comprises six levels (Q6 = highest, oldest; Q1 = lowest, youngest) spanning the Pleistocene, based on ^{10}Be cosmogenic dating of foreland fan surfaces (Arbolyea et al, Geol Soc.Lond. 2008) and OSL dating of fold-thrust belt fluvial terraces (Stokes et al., QSR 2017; Zondervan et al., Geomorphology 2022). These remnant fan surfaces cover some 1500km^2 (~50%) of the foreland basin area. Older levels (Q6-5) form minor components and are primarily preserved in the eastern basin region with Anti Atlas sources. Q4-Q2 dominate the landform record and reflect High Atlas sources. The youngest Q1 level forms a minor component, dominated by Anti Atlas sources.

Using an SRTM 1-arc second DEM, we interpolate the fan surfaces across the basin. We then use the interpolated surfaces to quantify erosion between different landform levels (sensu Stokes et al., Quaternary 2018). Erosion rates are then calculated using the published age data. We explore some technical aspects of the digital mapping and erosion quantification approaches used. Finally, we discuss the landform patterns, erosion rates and timing in the context of a post orogenic landscape affected by basin-scale river captures.

The subsurface geological map of the Turin metropolitan area (Western Po Plain)

Dr. Igor Marcelli [1]***, Dr. Andrea Irace*** [2]***, Dr. Gianfranco Fioraso*** [1]

1. *CNR - IGG,* ***2.*** *CNR - Institute of Geosciences and Earth Resources, Torino*

The 1:100,000 subsurface geological map of the Turin area is the cartographic output of a database-assisted 3D geological model, covering an area of about 890 km^2, between the western Alps and the Turin Hill reliefs. This sector is of strategic interest because it develops above one of the most significant structural elements of the northwestern Apennine - Po plain transition, i.e. the Turin Hill thrust front and associated folds system, whose late Miocene to early Pleistocene tectonic activity strongly influenced the geologic evolution of this region.

In the recent past, the geologic setting and the oldest (late Miocene) activity of the eastern, outcropping part of this tectonic belt were studied and mapped in detail in the Turin Hill. The general traits of the architecture and recent (Plio-Quaternary) activity of the western, buried counterpart of this belt were only partly illustrated by a few seismic reflection profiles. Furthermore, lower detail and scale geological maps of the subsoil of the central-eastern and northern portions of the study area have been provided. Therefore, a complete geological subsurface representation of the tectono-stratigraphic assemblage of the tectonic belt was still lacking.

In this perspective our map is a more detailed document, providing an updated representation of the stratigraphic and tectonic relationships between the buried Langhian - Lower Pleistocene sedimentary successions involved Turin Hill thrust-propagation folds system. The map is grounded on detailed stratigraphic log correlations along triangle meshes, combines subsurface and surface cartographies and includes a contour base map of terraced fluvial deposits (middle Pleistocene - Holocene).

The map illustrates for the first time all the lithostratigraphic units of the stratigraphic succession, their reciprocal conformal or non-conformal relationships and represents in greater detail the tectonic structures, providing new elements to discuss the tectonic evolution of the northwestern termination of the Apennine thrust-and-fold belt. In addition, it provides a reference model and a data infrastructure of the subsoil of the Turin plain, useful for various thematic research with application purposes.

Depositional Sequences of Pelotas Basin (southern Brazil): an accommodation succession view

Ms. Luísa Collischonn [1], ***Prof. Maria Luiza Correa Camara Rosa*** [1]

1. *Universidade Federal do Rio Grande do Sul (UFRGS)*

Pelotas Basin is located in the southernmost Brazilian Continental Margin. Its onshore portion corresponds to the Pelotas Basin Coastal Plain, which is composed of depositional sequences mainly controlled by glacioeustatic cycles of about 100 kyr, considered as high-frequency sequences. Studies of the Basin approach its filling from depositional sequences of longer period. Recently, a hierarchization was proposed for the sedimentary record of the Pelotas Basin, using the accommodation succession method.

The aim of this work was to complement the stratigraphic hierarchical framework of the Pelotas Basin with the inclusion of an intermediate scale depositional sequence. For this purpose, there were interpreted seismic sections, Ground Penetrating Radar (GPR), outcrops, well data and vertical electrical soundings (VES).

According to previous studies, four composite sequences were established for the Pelotas Basin. Each composite sequence is formed by three sequence sets, defined according to their stacking pattern as Progradational-Aggradational (PA), Retrogradational (R) and Aggradational-Progradational-Degradational (APD). Thus, 12 sequence sets compose the basin filling, and the last sequence set comprises eight depositional sequences. The depositional sequence here identified was correlated with the last depositional sequence present in the seismic sections (depositional sequence 43), with about 0.5 Ma, and is composed of lowstand, transgressive and highstand/falling stage systems tracts. A river mouth to the ocean was interpreted as part of the lowstand systems tract of the depositional sequence 43. With the development of the transgressive and highstand/falling stage systems tracts, this river system became internalized, forming a bayhead delta. The highstand/falling stage systems tract of this depositional sequence (43) comprises the four high-frequency sequences which outcrops in the coastal plain, corresponding to Quaternary barrier-lagoon systems. Each of the high-frequency sequences, in turn, can be subdivided into system tracts.

This study was funded by Conselho Nacional de Desenvolvimento Científico e Tecnológico – CNPq, Brazil (grant #132261/2019-7 for Luísa Collischonn and #PQ 307467/2019-8 for Maria Luiza Correa da Camara Rosa).

Sediment dynamics in a mesoscale catchment. Impacts of geology when using landscape evolution models. A modelling approach for the Northern Franconian Jura, Germany.

Mr. Bastian Ringleb [1]***, Mr. Raphael Steup*** [1]***, Dr. Katja Kothieringer*** [2]***, Dr. Timo Seregély*** [2]***, Prof. Markus Fuchs*** [1]

1. *Justus-Liebig-University Giessen, Department of Geography,* ***2.*** *University of Bamberg, Institute of Archaeology, Heritage Sciences and Art History*

Landscape Evolution Models simulate the transport of sediment over a landscape. Several parameters are used to describe the flow of water on a surface and thereby calculate a change in landscape. However, the transport of sediments in a catchment is a complex system and simplification is needed to keep computing powers reasonable. The CAESAR-Lisflood landscape evolution model simplifies the transition from precipitation to runoff with a cell storage-based system, where water is retained in each cell and released at later iterations, simulating infiltration and forming the hydrograph. This reduced complexity works well for surface processes but leads to problems in catchments, where ground water flow and infiltration are unknown parameters and an unknown proportion of sediment transport is connected to sub-surface processes.

The Weismain River catchment (~125 km^2) located in the Northern Franconian Jura, Germany, poses a particular challenge when modelling the sediment dynamics of the catchment. The Weismain river and its tributaries are deeply incised into a limestone plateau forming small, well-defined valleys opening to wider floodplains in the lower parts of the catchment, where sandstone is dominant. The karstic nature of the catchment and its resulting irregular groundwater flow complicates the model calibration and lowers confidence in model results. To get a better understanding of the sediment dynamics and the evolution of this catchment, we first need to determine the impact of the karstic geology on model results. Therefor we are using the CAESAR-Lisflood model not only with precipitation inputs but also with inputs from springs. We are now looking at the spatial distribution of alluvial sediments and how they are affected by differences in discharge calculations. This should give insight into the sediment dynamics of the catchment and should help gain confidence in future model results.

Evolution of the Vosgian fans in the Upper Rhine Graben during the Upper Pleistocene and the Holocene : an history controlled by pre-existing landforms, Rhine river and climate fluctuations

Antéa Archéologie & Laboratoire Image Ville Environnement, 5. CNRS, Laboratoire de Géographie Physique: Environnements Quaternaires et Actuels, Thiais, France

The Upper Rhine Graben is a large Cenozoic structure that is still active today and drained by the Rhine river along about 250 km of its course. Its margins are characterised by large alluvial fans, several tens of square kilometres in size, deposited by the rivers draining the bordering mountains (uplifted blocks), i.e. the Vosges (west) and the Black Forest (east). Composed of pebbles and sands, these fans were mapped in the southern quarter of the graben using aerial photographs and test pits during the production of geological maps in the 1960s and the 1970s. They were attributed to the Upper Pleistocene on the basis of their topographic position and the weathering degree of the coarse materials, but numerical age estimates were missing so far. It was therefore difficult to identify the drivers of their formation.

Here, thorough gearchaeological survey allowed exploiting numerous excavations dug in four large fans deposited by four main Vosgian rivers (i.e. Thur, Giessen, Bruche and Zorn) to reconstruct their evolution during the Upper Pleistocene and the Holocene. About twenty stratigraphic profiles (several metres long and up to four metres deep) have been dated by luminescence, radiocarbon and archaeological findings. Combined with the study of LiDAR-derived DEM, our results show that the formation of these fans is primarily controlled by the pre-existing landforms and by the lateral mobility space of the Rhine, which determines their maximum extension. The fans were mainly deposited during the first part of the last glacial period before being incised and covered by aeolian deposits, silts and sands. This points to a decrease in fluvial discharges and flow capacities after 22 ka. After coarse deposition attributed to the end of the Upper Pleistocene, a luvisol developed from the Lateglacial period onwards. From the 1st millennium BC onwards, this soil is truncated by locally coarse torrential deposits that have been so far wrongly attributed to the Weichselian. In the end, on a regional scale, fans evolution appears to be controlled by the climate and the relief. However, a better spatial resolution and deeper profiles are needed to re-evaluate the role of neotectonics.

Post-glacial fluvial evolution of the Cleurie Valley (Vosges Mountains, NE France): a complex story

Ms. Coraline Fuchs [1] ***, Mr. Timothée Jautzy*** [1] ***, Dr. Gilles Rixhon*** [1] ***, Dr. Claire Rambeau*** [1] ***, Mrs. Martine Trautmann*** [2]

1. *Laboratoire Image, Ville, Environnement (LIVE UMR 7362), Université de Strasbourg, 3 rue de l'Argonne, 67000 Strasbourg, France,* **2.** *Université de Strasbourg, Centre National de Recherche Scientifique CNRS, Laboratoire d'Analyses des Sols & Formations Superficielles EOST UMS 83, 3 Rue de l'Argonne, 67000 Strasbourg, France*

The Vosges Mountains are located in NE France and belong to the Variscan low-mountain ranges sprawling across the alpine foreland. Abundant and widespread glacial features imprint the landscape in the more elevated southern part, especially thick sedimentary sequences filling the deeply incised valleys. Located at the heart of the formerly glaciated area, the small Cleurie catchment (~80 km²) stands out because (i) it hosted a large (or several) palaeolake(s) (supposedly) during the peak of the last glaciation due to the singular convergence of three individual valley glaciers and (ii) ~40% of the catchment's surface is still covered by glacial-related deposits. Although several works previously investigated this advantageous but challenging setting, some of their results are outdated (e.g. geomorphological mapping) and, more importantly, none of them focused on the post-glacial landforms and provided chronological constraints.

This study thus aims to reconstruct the post-LGM evolution of this valley. It thus combines morphometrical analysis at the catchment scale with geomorphological, sedimentological and chronological analyses of the fluvial morpho-sedimentary units, including the modern riverbed, in the main valley. First, we took advantage of a 1m LiDAR-derived DEM and high-resolution geological mapping to produce updated geomorphological maps. Second, longitudinal analysis involved the extraction of river profiles and *in situ* grain-size measurements of the modern coarse bedload. Third, grain-size measurements and luminescence profiling via a portable reader on the fine-grained fraction of two representative profiles, along with radiocarbon dating of woody macro-remains (e.g. trunk), were performed. Geomorphological analysis highlights a system of two widespread terrace levels above the modern floodplain. Dating of the upper terrace, unconformably overlying lacustrine deposits, possibly allocates the first post-glacial aggradational event to the Bølling-Allerød or the Younger Dryas whereas floodplain formation can be assigned to the final part of the Holocene (Subatlantic). Moreover, (i) the Cleurie's long profile exhibits two major knickzones, (ii) tributaries' profiles are either concave, straight or convex, (iii) and the riverbed grain size increases downstream. These features together with post-glacial readjustments involving river incision and terrace formation point to a transient fluvial response in the catchment, which is unique at the massif scale.

A case study of effect of tectonic uplift and precipitation on the formation and evolution of alluvial fans at the northern foot of Qilian Mountains

Dr. Qiong Li [1]***, Ms. Jiaojiao Wang*** [1]

1. *MOE Key Laboratory of Western China's Environmental Systems, College of Earth and Environmental Sciences, Lanzhou University*

As an achieve for recording past regional environmental changes, alluvial fans have received widespread attention from the earth science community. Tectonic activity and climate change are generally considered to be the two main factors affecting the development of alluvial fans. The Qilian Mountains, located on the northeastern edge of the Tibetan Plateau, have experienced intense tectonic uplift since the Cenozoic. Mountain rivers flow down the great difference in elevation between the surrounding mountains and the Hexi Corridor and form a series of alluvial fans which can be studied comparatively in this region at the northern foothills of the Qilian Mountains. To explore the effects of precipitation and tectonic uplift on the formation and development of alluvial fans, a numerical model of the drainage-fan system was developed based on the stream power law and the diffusion equation. Simulations of the Xigou and Dayekou rivers and their alluvial fans in the Qilian Mountains were carried out using the above numerical model. The results show that changes in precipitation and uplift rate both affect the fan landform characteristics. Both an increase in uplift rate and a decrease in precipitation lead to an increase in fan slope and vice versa. The fan slope varies linearly with the uplift rate, while the effect of precipitation on the fan slope is relatively small. The response of catchment to tectonic activity and precipitation disturbances, as the change of sedimentary flux, is also in different patterns.

Architecture of Late Pleistocene to Holocene outwash plain and its environmental implications (the Tatry Mts., Slovakia)

Prof. Juraj janocko [1]**, *Dr. Marta Prekopova*** [1]**, *Prof. Helena Alexanderson*** [2]**, *Prof. Giorgio Basilici*** [3]**,**
Prof. Tapan Chakraborty [4]**, *Dr. Vladimir Budinsky*** [1]

__1.__ Institute of Geosciences, Faculty BERG, Technical University of Kosice, Letna 9, 040 11 Košice, Slovakia, __2.__ Department of Geology, Lund University, Sölvegatan 12, SE-223 62 Lund, Sweden, __3.__ Department of Geology and Natural Resources, Geosciences Institute, State University of Campínas, __4.__ Geological Studies Unit, Indian Statistical Institute, Kolkata

We have studied an areally restricted, gravelly outwash plain deposited in front of the Studena Valley (Tatra Mountains, Carpathians), which was glaciated during the Late Pleistocene. The plain deviates from common proposed models for outwash plains/fans by lacking proximal to distal trends of deposits and different architectural elements. The lower and middle part of the 9 m thick outwash succession is typified by high facies variability and only locally preserved small bedforms. The lower part of succession shows three cycles (units I-III) with OSL ages from 77.7±8.1 to 23.2±1.3 ka. Each cycle consists of channelized, upward-fining sediments at the base overlain by horizontal, low-angle or disorganized tabular gravelly beds. Occasional sand lenses show parallel lamination and antidune stratification. The cycles are overlain by disorganized gravel with locally preserved dune stratifications capped by massive sand and silty mud showing pedogenic modification (unit IV). Preliminary OSL data from the top of the unit yielded 13.6±1.0 ka. The overlying unit V consists of disorganized gravel with clusters of cobble- and boulder sized clasts and boulder-sized rip-up clasts. The boundary between units V and VI is dated by OSL and ^{14}C to 10.8±1.3 ka and 11.361 cal., respectively. The unit shows wide and shallow channels with lateral accretion packages suggesting meandering rivers. Vertically, and also laterally these channels pass to gravel filling small channels and sand lenses. The entire succession is capped by pebbly sand overlain by a Holocene palaeosoil and a current soil (unit VII).

The sediment architecture points to deposition by stream and hyperconcentrated flows at the base of each unit I-III (channelized geometry) passing to deposition by prevailingly hyperconcentrated flows (sheet geometry). The units contain supercritical flow structures suggesting a high discharge variability system. The interval of fine sand and mud at the top of unit IV preliminarily dated to 13.6 ka suggests calm deposition during warmer phase (Bölling/Alleröd?). Preliminary interpretation associates the areally extensive deposits of unit V to deposition by hyperconcentrated flows possibly triggered by sudden drainage of an ice-dammed lake. The occurrence of meandering rivers in unit VI indicates changed conditions at the onset of the Holocene.

Quaternary alluvial terraces identification and analysis in the central Marche region (central Italy) for climatic and tectonic signals detection purposes

Ms. Valeria Ruscitto **[1]*, Dr. Michele Delchiaro* [1]*, Prof. Marta Della Seta* [1]*, Dr. Giulia Iacobucci* [2]*, Prof. Daniela Piacentini* [1]*, Prof. Francesco Troiani* [1]**

1. *Department of Earth Sciences, Sapienza University of Rome,* **2.** *Dipartimento di Scienze della Terra, Università Sapienza di Roma*

River terraces, together with their deposits, can provide a great deal of information about the history of a drainage system, from a hydrological and sedimentological perspective. As such, they are functional to understand the influence of tectonics, varying climate and base level change on landscapes, and their relevance as geomorphic markers is widely recognized. Through the complete and accurate analysis by remote sensing and field work of the Marche drainage network, it has been possible to identify and reinterpret the main river terrace staircase and to map its remnants in detail, in the perspective of attempting the detection of the tectonic and climatic signals preserved in these geomorphological features.
The selected area is challenging from a geomorphological and geomorphometric standpoint because it is characterized by low-rate tectonic activity and well-preserved fill terraces, that developed from the Upper Pliocene-Lower Pleistocene, allowing to analyse these classic climatic signal-bearing forms in a tectonically active setting. The fill terraces will be measured and dated, and then the data will be interpreted with methodologies already implemented by other authors, that will accurately prevent eventual biases in the analysis. This work was based on a relatively innovative approach, that analyses Relative Elevation Models (REMs), converted from 1 m/pixel DEMs collected from a 1x1 LiDAR dataset, to better pinpoint river terraces through the identification of their surfaces with the SCM model. Further goal of the research is to verify if there is a possibility to isolate a clear climatic signal, despite the tectonic influence on the area.

Deciphering long-term river incision in the Middle Rhine Valley (Germany) by Electron Spin Resonance dating of quartz

Dr. Melanie Kranz (née Bartz) [1], *Dr. Mathieu Duval* [2], *Mrs. Maria Jesus Alonso Escarza* [2], *Dr. Gilles Rixhon* [3]

1. Institute of Earth Surface Dynamics, University of Lausanne, 2. CENIEH, 3. Laboratoire Image, Ville, Environnement (LIVE UMR 7362), Université de Strasbourg, 3 rue de l'Argonne, 67000 Strasbourg, France

Connecting the Alps with the North Sea, the Rhine river system represents one of the most complete sequences of fluvial archives at the continental scale. The Middle Rhine Valley (MRV) exhibits a well-preserved terrace flight that serves as an important record for studying the response of geological and sedimentary processes to the impact of changing environmental conditions. However, reconstructing rates of landscape evolution over the Late Cenozoic period remains challenging mainly due to difficulties in dating such ancient terrace sediments and the resulting lack of numerical age available. For the first time, we use electron spin resonance (ESR) to date quartz grains from three various localities corresponding to two key geomorphological markers in the MRV's staircase. They are the Kieseloolithe terrace, i.e. oldest level in the sequence (Ochtendung), and the upper and lower levels of the main terrace complex sampled at Kärlich and Kasbach-Ohlenberg, respectively. Based on these new ESR data derived from the Multiple Centre (Al & Ti centres) approach, we aim to (i) assess the time-varying incision rates over the Late Cenozoic, (ii) unravel the role of each driver responsible for the disequilibrium of the Rhine on these timescales, (iii) and discuss potential implications as far as early human occupations in the region.

Al and Ti ESR signals resulted in consistent equivalent dose (De) values, suggesting [MD1] complete bleaching (=signal reset) prior to deposition. First ESR age constraints are stratigraphically consistent for each terrace. The main terrace complex yield age estimates of ~1.3 Ma (older main terrace, Kärlich) and ~1.15 Ma (younger main terrace, Kasbach-Ohlenberg). In comparison, the Kieseloolithe terrace deposits at Ochtendung shows a much older age estimate of at least ~1.8 Ma, which is consistent with the existing geomorphological framework, although perhaps somewhat younger than the expected Pliocene chronology. Preliminary age constraints of the Middle Rhine terraces suggest low incision rates of <0.5 mm/yr for the period from the onset of the Quaternary. Finally, our results also indirectly provide additional chronological constraint to the deposits associated to the well-known Kärlich archaeological site, considered as one of the earliest evidence of human presence in western Germany.

The palaeoenvironmental evolution of Privlaka pedo-sedimentary complex on the Adriatic coast, Croatia – preliminary results

University of Zagreb, Faculty of Mining, Geology and Petroleum Engineering

The pedo-sedimentary complex of Privlaka is situated in the central part of the Eastern Adriatic coast, in Croatia. The investigated section is represented by a more than 12 m thick succession of glacio-fluvial deposits and palaeosols. During the Pleistocene sea-level low stands, the area of Privlaka was influenced by terrestrial and glacio-fluvial sedimentary processes presumably originating from the East. The investigated succession was divided into four different units. One is represented by palaeosol (the lowest unit), while the others are represented by glacio-fluvial deposits divided by an indication of sedimentation under different environmental conditions. Aiming at identifying and describing the palaeoenvironmental evolution of the abovementioned site, a detailed investigation is being carried out. The investigation of palaeoenvironmental changes on the Privlaka section is conducted by high-resolution analysis using a multi-proxy approach comprising chemical analysis, particle size analysis, modal analysis, pedological analysis, bulk and clay mineralogical XRD analysis, as well as micromorphological analysis of soil thin sections. The lateral extent of the described units was obtained by the application of geophysical methods and remote sensing techniques, while the chronological framework of the complex is established by optically stimulated luminescence (OSL) dating. This research is funded by the Croatian Science Foundation under the project ACCENT (IP-2020-02-3274).

Periglacial features and permafrost disappearance during MIS-2 in northern Poland and northeastern Germany

Dr. Andreas Boerner [1], ***Prof. Mirosław Błaszkiewicz*** [2]

1. *State Agency for Environment, Nature Conservation and Geology Mecklenburg-Vorpommern,* ***2.*** *Department of Environmental Resources and Geohazards, Institute of Geography and Spatial Organization, Polish Academy of Sciences, Toruń, Poland*

Some landscape features of lowlands in Northern Poland and Germany represent relicts of former periglacial activity. These features include ice wedge casts, polygons and other surface patterns, cryoturbation structures, pingo scars and thermokarst features. Recent studies of the areas covered by the last glaciation indicate that the disappearance of permafrost under the ice sheet was not complete, and even that it was limited only to the subglacial water circulation zones and the importance of subglacial permafrost in the formation of subglacial drainage and subglacial channels. The most important features include thermal contraction cracks, oriented kettle holes on outwash plains, permafrost-affected horizons in soil profiles, as well as the long-term preservation of buried dead ice blocks in depressions.

Three main lake generations of the appearance were recognized: 1. “early” pre-Allerød lakes, 2. lakes of the Bølling-Allerød period and 3. “late” Preboreal generation of lakes. In the context of the final permafrost decay, the lakes of the youngest, Preboreal generation are particularly important, since the lakes age differentiator was the varied length of preservation of lake basins by buried dead ice blocks, which in turn was dependent primarily on the conditions of surface drainage network. Under the permafrost conditions, full preservation of dead ice blocks took place when the mineral cover reached the thickness corresponding to the depth of the active layer. In this way, buried dead ice blocks became an essential element of the permafrost. Under thermokarst, at the places where dead ice blocks existed, quickly spreading taliks formed.

In the last glaciated area are some local evidences of periglacial features, like meso scaled ice wedges pseudomorphs and active layer based ball-and-pillow graviturbations, showing clearly the retreat of discontinious permafrost during Younger Dryas period. The preservation of dead-ice masses in some local depressions until the Preboreal leads to the conclusion that the ultimate disappearance of permafrost in the study area occurred at the beginning of the Holocene.

The research was supported by the National Science Centre of Poland NCU.

Digital terrain model DTM 5.0 usage in engineering geological mapping and analysing of the development of the landslide near Machnac Hill in Biele Karpaty Mts.

Mr. Robert Žjak [1]***, Dr. Pavel Liscak*** [1]***, Dr. Ivan Dananaj*** [1]***, Dr. Peter Paudits*** [1]***, Dr. Peter Ondrus*** [1]***, Mr. Matej Oros*** [2]***, Dr. Marek Frastia*** [3]

1. *State Geological Institute of Dionyz Stur,* ***2.*** *Geotronics Slovakia,* ***3.*** *Slovak University of Technology*

"Identification, inventory and engineering geological mapping of slope deformations", is geological task solved by the State Geological Institute of Dionyz Stur. In the scope of this project the digital terrain model DTM 5.0 generated from the airborne laser scanning in 2018 has been widely used. The LiDAR technology has significantly improved the quality of mapping of the slope failures and possibilities to precisely analyse terrain surface. Identified slope deformations are then verified and documented during field surveys.

During the field survey in May 2020 an active landslide situated northeast of the Machnac Hill in the Biele Karpaty Mts. was documented. This part of the mountain range is built of flysch rocks environment which is significantly endangered and affected by slope deformations. All morphological features characteristic for the surface of an active landslide area were documented at the site.

An unmanned aerial vehicle was used to create the second set of airborne laser scanning of the active landslide surroundings in November 2021 during leaf-off conditions. The scanning was realised in the cooperation with Geotronics Slovakia Ltd. and the Department of Surveying. This survey provided an updated DTM 5.0 model with a time gap of 3 years.

Interpolated LiDAR data comparison of the two differential digital terrain models via geometric analysis was used for the elevation change detection in a form of differential map. A colour scale was used to illustrate landform changes as the result of the mass movement. Depletion of material in the crown and its accumulation in landslide toe are clearly visible in difference map.

Post-Late Glacial Maximum costal evolution of the north Sardinia

The integrated use of Side Scan Sonar (SSS), Multibeam (MB) and ground truth points acquired with Remote Operating Vehicles (ROVs) are helpful tools to map and describe seabeds laying at different water depths. In this view, marine mapping can provide important information on the underwater sedimentary bodies deposited as consequence of past sea level changes.

According to this, latest Pleistocene beach ridges, if analized in term of spatial continuity, depth and age formation, may point out which have been the relative sea level rise steps occurred post Late Glacial Maximum. Beach ridges were therefore mapped in different areas of northern Sardinia, and their spatial distribution was reconstructed using the GIS (Geographic Information System).

In this work, we present the seabed map of the Tavolara Marine Protected Area (MPA). Using a marine mapping survey, we reconstructed the paleogeography of the area surrounding Tavolara Island during the interval from the Late Glacial Maximum (LGM, 20-19,000 y BP) to the Present. Paleoshorelines and associated beachrocks were identified at depths of -90, -70, and -50 m, along with the presence of interpreted paleo-rivers, paleo-lagoons and paleo-delta systems.

The reconstruction of the paleo-shorelines distribution let us to relate the beach ridges laying at -90 m, -70 m -50 m depth, respectively, to the relative sea level still stand occurred after the Melting Water Pulse (MWP) 1A (14,650 y BP), to the relative lowstand occurred during the cold Younger Dryas (between 12.900 and 11.700 y BP) and to the so-called “8.200-kiloyear cold event” following the MWP 1B.

The geological structure of Italian seas: a synthetic and up-to-date GIS representation of tectonic and volcanic features around Italy (Mediterranean Sea)

An updated structural map of Italian seas is represented at 1:1,250,000 scale. The map is the result of cooperation between marine geology researchers from different universities and research institutes coordinated by ISPRA-SGI, in the framework of the European Marine Observation and Data Network (EMODnet) Project Lot Geology. The map aims to present in a synthetic but exhaustive way the structural setting of Italian seas, a key region in the geological setting of Mediterranean Sea. This area, geologically very active, is dominated by the geodynamic process of convergence and collision between the European and African plates, which during the Quaternary recorded tectonic activity accompanied by seismic and volcanic events of great impact.

The map shows the geological expression of the seafloor surrounding the Italian region as revealed by the marine geological researches carried out during last thirty years that have benefited from the contribution of relevant technological innovations in the field of marine geological surveys (multibeam, sub-bottom CHIRP, high penetration seismic surveys).

The map contains structural data from original surveys as well as data from scientific literature or derived from strategic national research programs, properly integrated and validated in order to create a homogeneous data set for the mapped area.

A geodatabase is related to the Map, in which the structural and volcanic elements have been classified according to the EMODnet terminology (INSPIRE compliant) and characterized by geometric, kinematic and chronological parameters.

The tectonic structures and the volcanic elements are represented on a bathymetric DTM downloaded from the EMODnet Bathymetry portal and the tectonic topic is complemented by additional information on seismicity, heat flow, crustal thickness, thickness of the Plio-Quaternary deposits.

The map shows the current geological-structural setting of the Italian seas, the migration over time and space of the tectonic events, those features that have contributed mostly to the current conformation of the Italian seafloor and, among these, those that may originate geohazards.

Therefore, the map represents a solid base for more detailed studies of seismotectonics and applied geology for territorial management and spatial planning as well as for scientific dissemination which will benefit the new generations of marine geologists

The process of update of the structural map of Italian seas

The Geological Survey of Italy – ISPRA coordinates cooperation among marine geology researchers from different universities and research institutes, in the framework of the European Marine Observation and Data Network (EMODnet) Project Lot Geology.
The cooperation is aimed at providing products for the "Geological events and probabilities" layers of the Project including earthquakes, volcanoes, landslides, tectonics. Data gathered during this work allowed to realize an update of the structural map of Italian seas at 1:1,250,000 scale.
The map shows the geological expression of the seafloor surrounding the Italian region as revealed by the marine geological researches carried out during the last thirty years that have benefited from the contribution of relevant technological innovations in the field of marine geological surveys (multibeam, sub-bottom CHIRP, high penetration seismic surveys).
The map contains structural data from original surveys as well as data from scientific literature or derived from strategic national research programs, properly integrated and validated in order to create a harmonized data set.
Structural and volcanic elements, classified according to the EMODnet terminology (INSPIRE compliant), are characterized by geometric, kinematic and chronological parameters which are included in the geodatabase completing the map.
The tectonic structures and the volcanic elements are represented on the EMODnet Bathymetry DTM and are complemented by additional information on seismicity, heat flow, crustal thickness, thickness of the Plio-Quaternary deposits.
The map aims to present in a synthetic but exhaustive way the structural setting of Italian seas, a key region in the geologically very active Mediterranean Sea which is dominated by the geodynamic process of convergence and collision between the European and African plates.
The map shows the current geological-structural setting of Italian seas, the migration over time and space of the tectonic events, the features that have contributed mostly to the current conformation of the Italian seafloor and, among these, those that may originate geohazards.
The map represents a solid base for more detailed studies of seismotectonics and applied geology, for territorial management and spatial planning as well as for scientific dissemination.

Mapping Quaternary travertine of the Viterbo geothermal area

Dr. sergio madonna [1]***, Prof. Anna Gandin*** [2]***, Prof. Andrea Brogi*** [3]***, Prof. Enrico Capezzuoli*** [4]***, Dr. Francesco Gentili*** [1]

1. *Tuscia University,* ***2.*** *University of Siena,* ***3.*** *Dipartimento di Scienze della Terra e Geoambientali, Università degli Studi di Bari Aldo Moro; Istituto di Geoscienze e Georisorse, CNR-Pisa,* ***4.*** *Department of Earth Sciences, University of Florence*

The Viterbo thermal field (more than 50 small hydrothermal vents) corresponds to a deep uplifted calcareous structure (horst) bounded by a complex Plio-Quaternary extensional fault system. This area insists on a large volcanic plateau produced by the emplacement of eruptive deposits from three volcanic districts (Cimino, Vico and Volsini), active between 1,35 Ma e 90 ka. The volcanic and Quaternary sedimentary units rests on Pliocene clays and sands of the Tiber River graben and on Triassic-Eocene thrust folds units ("Tuscan ", "Umbrian", and "Ligurian"). The thermal mineralized water upwelling along the main structural discontinuities, (produced by polyphasic tectonics and by volcano-tectonic activity) built small, low relief bodies of rather compact, well-bedded porous carbonate rock mainly made of macro, micro crystalline and microbial facies. The macro crystalline carbonate commonly occurs surrounding the main spring vents (punctual venting shield/crater mounds, or fissure ridge, result from physico-chemical processes (cooling, evaporation, etc.). and flow velocity. Microbial laminites, result from biologically mediated processes developed by microbial communities, commonly spread on the thermal distal drainage system that is a complex environment comprising swamps/palustrine flats and slopes or shallow lakes filled with mixed ambient and thermal water. The morphological analysis of these bodies has been integrated with digital models of the terrain (DTM), historical topographic maps, aerial photos and high-precision photogrammetry models obtained from UAS flights (with the support of GNSS stations for a precise spatial location). To define the structure and morphology of these deposits and the organization of their depositional system, geological surveys and facies analysis have been combined with passive and active seismic techniques and other geophysical data directly or indirectly related to them. The data are organized in layers and integrated into a GIS project. The numerical cartography (CTRN) and the Geotopographic database (DGBT 2009-2014) of the Latium Region have been used as a basic map. All these data were integrated with other layers: geodetic and photogrammetric information location and chemical-physical characteristics of the thermal mineral springs; geological and structural data; borehole, etc. Finally, historical and archaeological data have also been considered since these springs were exploited since Roman and Etruscan times.

Quaternary map and evolution of the Tyrrhenian side of the Northern Apennines: preliminary results from the METIQ Project

__1.__ Geological Survey of Italy - ISPRA, Rome, __2.__ CNR IGAG, __3.__ Dipartimento di Scienze della Terra, Università degli Studi di Firenze, Via La Pira 4, I-50121 Firenze, Italy, __4.__ Istituto Superiore per la Protezione e la Ricerca Ambientale, __5.__ DST, Department for Earth Sciences, University of Pisa, __6.__ Dipartimento di Scienze della Terra, Università degli Studi di Torino, Italy, __7.__ Istituto Nazionale di Geofisica e Vulcanologia (INGV), __8.__ Department of Earth Science, University of Pisa, Italy

The METIQ Project aims to produce a 1:500.000 scale Quaternary Map of Italy, which synthesizes the Quaternary evolution of the Tyrrhenian side of the Northern-Central Apennines (Liguria, Tuscany, Umbria, Latium, and Abruzzi regions). The Quaternary Map is the result of the integration of different source data spanning from the 50.000 and 100.000 scale National Geological Maps of Italy, the 1:250.000 scale Geological Continuum project and, where available, the Regional Geological Maps at 1:10.000 scale. All these data were then compared to and harmonized with the geological maps available in the more recent scientific literature.

The Map includes the main lithological, chronological and paleoenvironmental evidence through the time of the Quaternary deposits reflecting the complex interaction between climate and tectonics. Quaternary sedimentation onset in an ongoing extensional regime in the inner (western) sector of the Apennines whereas the compressive fronts were active to the east. The distribution of Quaternary deposits on the Tyrrhenian side of the chain depicts this scenario meaningfully showing a succession of sedimentary basins from the coast to the axial part of the chain. The westernmost basins are characterized by several cycles of shallow-marine and continental deposition accommodated into extensional basins and, at least across a Tuscany transect, moving to the axial part of the chain, by continental deposition within intermontane basins that experienced the transition from compressional to the extensional regime with a progressive rejuvenation toward the east. In Latium-Abruzzi Apennines, the current extensional tectonics is clearly shown by the stack of Quaternary tectonic terraces and confirmed by strong historical and recent earthquakes.

The coastal area is dominated by large fluvial plains slightly subsiding and filled with alluvial deposits. The main features come from the interaction, during the Quaternary, between tectonics and isostatic and eustatic sea level variations, leading to the creation of marine terraces along the coast.

The coexistence of fully extensional sedimentary basins in the inner part of the chain and compressional-extensional basins in the axial part of the orogen is more evident across the southern part of Tuscany whereas to the north (Ligurian-Emilian Apennine) is less pronounced possibly reflecting a deep crustal discontinuity.

Mapping continental quaternary deposits of mountainous areas: the high Orta Valley (Central Apennines, Italy)

Dr. Marco Nocentini [1] ***, Dr. Giuseppe Nirta*** [1] ***, Dr. Edi Chiarini*** [1]

1. *Geological Survey of Italy – Institute for Environment Protection and Research (ISPRA), Rome*

The preliminary results of the Quaternary geological surveys performed along the high Orta Valley in the frame of the CARG – Project (Geological Map of Italy 1:50,000 Sheet 370-Guardiagrele) are here presented.

The high valley of the Orta River extends in the outermost sector of the Central Apennines, between Caramanico Terme to the north and San Leonardo pass to the south, within the UNESCO Maiella Geopark. It is a narrow depression, N-S trending, confined between the calcareous ridges of Mount Morrone to the west and of Maiella Massif to the east and floored by late Neogene siliciclastic foredeep deposits. The Quaternary valley infill consists of clastic deposits deriving from the erosion of the steep slopes of the Maiella and the Morrone.

The oldest continental deposits are diamicton containing metric boulders and abundant silty-sandy matrix (megabreccias) referable to catastrophic rock-slope failures, presumably occurred in the Early or early-Middle Pleistocene during the first stages of the Orta Valley development. These deposits, now forming isolated reliefs, were initially confined in valley trunks among siliciclastic lithotypes and were later exposed by erosion giving rise to a relief inversion.

The valley's eastern and western flanks are characterized by several generations of Middle to Late Pleistocene slope and proximal alluvial fan deposits, shaping wide piedmont wedges. These deposits comprise angular to sub-rounded clast-supported stratified breccias, usually well-cemented and open-work, often covered by Holocene colluvial and talus deposits.

In the axial sector of the valley two orders of fluvial terraces were recognized. The oldest one consists of well-cemented, clast-supported coarse grain gravels underlying a terraced surface 40-50 m above the current thalweg. The younger one is represented by an erosional surface 15-20 m above the valley floor, carved in both the Late Pleistocene slope deposits and the conglomerates of the first order fluvial terrace. They could be referred to the Late Pleistocene and Holocene, respectively.

In such a difficult context, characterized by few available chronological constraints, the integration of stratigraphic and facies analysis with geomorphological and topographic analysis allowed us to define the succession of sedimentary events and their possible correlations with past tectonic and climate conditions.

3D mapping in a 2D country: a new geological map of the Kingdom of the Netherlands

Dr. Jeroen Schokker [1], Dr. Marcel Bakker [1], Mr. Reinder Reindersma [1], Dr. Jan Stafleu [1], Mr. Nikki Trabucho Alexandre [1], Dr. Michiel van der Meulen [1], Dr. Sytze van-Heteren [1]

1. TNO - Geological Survey of the Netherlands

On the occasion of its centennial anniversary, the Geological Survey of the Netherlands created a new geological map of the Kingdom of the Netherlands. Unlike its predecessor from 1975, this map does not only include the onshore and offshore European Netherlands, but also the Caribbean part of the Kingdom (the islands Aruba, Bonaire, Curaçao, Saba, Statia, and St. Martin). Besides near-surface Quaternary deposits and older rocks, important fault lines and lines of maximum ice extent during glacial periods are shown. Four cross sections illustrate the relation between the shallow and deeper subsurface.

The map, on a scale of 1:600,000, summarises part of our present subsurface knowledge and aims to illustrate the rich geological history of the Kingdom to professionals and the general public alike. By applying a profile-type legend, describing unit sequences rather than just the top unit, we are able to show information from our 3D digital mapping programme on a 2D map. It gives maximum insight into the geological history of the country and clearly demonstrates the occurrence of similar deposits on both sides of the current coastline. One of our biggest challenges was to construct a harmonised legend respecting the diversity of the onshore and offshore geology, yet simple enough to be readily understandable.

From an applied perspective, the map highlights geological resources and geohazard potential. For example, it shows shallow marine sand and gravel resources necessary for offshore construction activities and coastal maintenance. From a geohazard viewpoint, two of the Caribbean islands are dominated by active volcanoes. Furthermore, all islands reside in a tectonically active area and are prone to coastal erosion, flooding and landslides.

The map forms the basis of the Dutch contribution to international projects like the International Quaternary Map of Europe (IQuaME 2500) and the European Marine Observation and Data network (EMODnet). It is also the starting point of renewed and intensified mapping of the Caribbean islands. Finally, this map -both available on paper and interactively online- helps the Geological Survey to market state-of-the-art digital subsurface models that might be very suitable for resource and risk analysis, but difficult to understand.

Mapping a complete silicic and effusive Quaternary volcano: Geo-volcanological map of Monte Amiata (Southern Tuscany, Italy)

Dr. CLaudia Principe [1]***, Prof. Luigina Vezzoli*** [2]***, Dr. Sonia La Felice*** [1]

1. *Istituto di Geoscienze e Georisorse, Consiglio Nazionale delle Ricerche, (IGG-CNR), Via G. Moruzzi 1, 56124, Pisa, Italy,* ***2.*** *Università degli Studi dell'Insubria, Como*

The poster presents the new map of Monte Amiata Volcano (305–231 ka; Italy), at the scale 1:25.000, that perfections the volcanological studies on this Quaternary volcano performed by the authors. Monte Amiata is a rare example of completely effusive silicic (trachydacite) composite volcano. As mapping procedure, we first used the lithostratigraphic units for the identification of the volcanic bodies and their cartographic representation. Subsequently, we applied the UBSU criteria to group lithostratigraphic units into synthems and subsynthems on the basis of the identification of significant unconformity within the stratigraphic sequence. We applied the Unconformity Bounded Stratigraphic Unit criteria, volcanic facies analysis, and structural survey to unravel Monte Amiata geological evolution and volcanic architecture, and to infer the interactions of the regional tectonics with the volcanic plumbing structure. Based on the occurrence of a first-order geological unconformity (representing an intravolcanic paleoweathering surface of regional paleoclimatic significance), we recognized and mapped two major volcanic stratigraphic units and seven phases of volcanic activity. The interpretation of the genetic and emplacement processes of the volcanic deposits is based on the description and distinction of the various volcanic lithofacies within the 40 identified and mapped lithostratigraphic units. Lithostratigraphic units often contain various members (different lithosomes, as lava flow succession, domes etc..) and were correlated across the volcano slopes on the basis of: (i) the observable lateral continuity of the lava flow horizons and bounding surfaces, (ii) the physical volcanology of lava flows (internal and surface structure, texture, geometry and architecture), and (iii) their specific petro-chemical composition. In addition, facies analysis and morphostructural features enabled us to suggest the source location. Based on these data, we have determined a relative chronology of the volcanic events and correlated the extrusive activity on the entire mapped volcanic edifice. As cartographic support we used the topographic map at the 1: 10,000 scale of the Technical Map of the Tuscany Region.

Quaternary glacial GIS database of the South-Eastern European Alps and Northern Dinaric Mountains

Dr. Manja Žebre [1]***, Dr. Petra Gostinčar*** [1]***, Dr. Petra Jamšek Rupnik*** [1]***, Dr. Eva Mencin Gale*** [2]***, Dr. Jernej Jež*** [1]***, Prof. Uroš Stepišnik*** [3]***, Dr. Jure Atanackov*** [1]***, Dr. Milos Bavec*** [1]

1. *Geological Survey of Slovenia; Dimičeva 14, 1000 Ljubljana, Slovenia,* ***2.*** *1Geological Survey of Slovenia; Dimičeva 14, 1000 Ljubljana, Slovenia,* ***3.*** *University of Ljubljana, Faculty of Arts, Department of Geography*

The glacial history of the South-Eastern European Alps and the neighbouring Northern Dinaric Mountains has been studied since the late nineteenth century. However, some discrepancies exist among palaeoglaciological data and maps of this area produced by different authors. Here presented GIS database of glacial evidence has been created with the aim of improving empirical palaeoglaciological reconstructions as well as chronological correlations across mountain glaciations in this region. This GIS database is a compilation of all published glacial and other relevant data in the South-Eastern Alps and Northern Dinaric Mountains in Slovenia, Italy and Croatia. The database contains the following elements: glacial landforms, non-glacial landforms relevant for the interpretation of the glacial environment, outcrop locations, geochronological data, and geophysical survey data. The attribute tables that accompany these elements provide more detailed information about each feature. This includes the type and description of a landform, its assumed age, reference, and relationship to other records in the database. The GIS database has been created in three steps. First, the data were digitised, georeferenced and cited accordingly. Second, the input data were revised in the field and, where necessary, topographically adjusted using a high-resolution lidar-based digital elevation model. Third, the GIS database was used to develop the web map viewer, which also displays empirically reconstructed ice limits for different time spans during the last glacial cycle. The data stored in the GIS database is available in ESRI shapefile format. Both the GIS database and the Web Map Viewer are freely accessible. The collected and generated data have the potential to be used for validation of numerically modelled glacier simulations and more generally for further reuse in the scientific community.

This work has received funding from the Slovenian Research Agency under project agreement J1-2479, “Past climate change and glaciation at the Alps-Dinarides junction project”.

Seawall impacts on vegetation and carbon sequestration at Gibraltar Point, UK

Dr. Kristen Beck [1], ***Dr. Mark Schuerch*** [1], ***Dr. Daniel Magnone*** [1]

1. University of Lincoln

Coastal salt marshes are important environments that provide vital ecosystem services such as carbon sequestration, coastal protection, and habitat provisioning. However, salt marshes are increasingly threatened by sea level rise, reduced sediment availability and anthropogenic activity (e.g. embankments). Gibraltar Point National Nature Reserve (GPNR), is a highly dynamic sand spit-enclosed coastal salt marsh that is expanding into new salt marsh areas. However, the installation of the sea defence “Bulldog Bank” in the late 19th century has disrupted salt marsh succession, and a freshwater marsh has developed behind this seawall. While the embankment has created diverse freshwater wildlife, seawalls such as this have detrimental effects on the coastal protection and carbon sequestration capacity of salt marshes. Therefore, this project aims to reconstruct the marsh development to determine the impacts of the seawall on vegetation and carbon sequestration. To address our research aims we collected sediment sequences from the Freshwater marsh and the Old salt marsh habitat and applied a multiproxy palaeoecological approach of grainsize to identify transitions in marsh formation and ontogeny, and pollen to reconstruct past vegetation, loss-on-ignition (LOI) and isotopic and elemental organic carbon and nitrogen to consider carbon sequestration and origins. The preliminary results from the Old salt marsh core show the expected developmental trajectory of a salt marsh habitat, dominated by classic salt marsh vegetation (Amaranthaceae taxa) and organic carbon sources of marine origin, as expected. The Freshwater marsh habitat developed into its modern state when cut off from tidal exchange due to the construction of Bulldog Bank. A decrease in grainsize fractions, stall in carbon sequestration, and increase in freshwater inputs of organic carbon are characteristic of isolation from seawater inundation. Prior to Bulldog Bank the habitat supported a mixture of freshwater (Cyperaceae) and salt marsh vegetation (Amaranthaceae) and organic carbon sources of both marine and fresh origin. Following the installation of Bulldog Bank, peaks in Amaranthaceae pollen suggest breaches in the sea wall. The creation of Bulldog Bank has decreased the influence of marine sources of carbon, sediment deposition, and salt marsh vegetation and thus threatens the coastal protection provided by this salt marsh system.

Recent increased loading of carbonaceous pollution from biomass burning in the Baltic Sea

Dr. Karl Ljung [1]***, Dr. Petra L Schoon*** [1]***, Mr. Marcus Rudolf*** [1]***, Dr. Laurie M Charrieau*** [2]***, Dr. Sha Ni*** [1]***, Prof. Helena Filipsson*** [1]

1. *Department of Geology, Lund University,* ***2.*** *Helmholtz Centre Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany*

Black carbon (BC), spheroidal carbonaceous particles (SCP), and polycyclic aromatic hydrocarbons (PAH) are carbonaceous pollutants affecting the climate, environment, and human health. International regulations limit their emissions, and the present emissions are followed by monitoring programs. However, the monitoring programs have limited spatio-temporal coverage and only span the last decades. We can extend the knowledge of historical emission rates by measuring pollution levels in radiometrically dated marine and lacustrine sediment sequences.

Here we present measurements of BC, SCP and PAH from a sediment sequence sampled in the Öresund strait, between Denmark and Sweden and dated back to CE 1850. Our data show a massive increase in the burial rates of all measured pollutants starting in the 1940s. The pollution deposition peaked in the 1970-the 1980s and declined through the 1990s. However, the declining trend was reversed in the 2000s. Source appointment of PAHs shows a relatively higher contribution of emissions from wood-burning since CE 2000. This coincides with a change towards increased use of biomass for both municipal and regional energy production in Scandinavian. In Sweden, biomass energy use increased massively in the 1990s and supplied 99PJ of energy in 2014, which accounted for about half of the total district heating energy use. Installation of domestic wood burning (pellets) stoves increased from 300 to 11000 per year between 1998 and 2004. Our results demonstrate that changes in energy production to increased reliance on biomass, particularly wood fuels in Sweden, have caused increased the delivery of carbonaceous pollution to marine environments. The increase in particle emissions from wood burning is potentially posing a future environmental and health risk.

Climate variability and anthropogenic impacts through a palaeo-morphological lens: an innovative microCT approach using Baltic Sea benthic foraminifera

Prof. Helena Filipsson [1], ***Dr. Constance Choquel*** [1], ***Mr. Jonas Donnenfield*** [2], ***Dr. Sha Ni*** [1], ***Prof. Gerhard Schmiedl*** [3], ***Dr. Dirk Müter*** [4], ***Dr. Behnaz Pirzamanbein*** [5]

Institute of Geology, University of Hamburg; Center for Earth System Research and Sustainability (CEN), University of Hamburg, 4. FORCE Technology, Brøndby, Denmark, 5. Department of Statistics, Lund University, Sweden

Human-induced impacts are increasing pressure on coastal ecosystems, particularly on benthic ecosystems in high-latitude regions. It has become evident that three of the greatest marine environmental challenges related to anthropogenic activity are warming, ocean acidification, and deoxygenation. The effect of these environmental changes on our uncertain future has created a need to understand their severity and potential outcomes, and geological records can provide a much-needed perspective of environmental processes extending beyond the instrumental period. Within palaeoceanography, marine microfossil species distribution and geochemistry have long been used as proxies for reconstructing environmental changes. Here, we explore an alternative avenue by using calcareous foraminiferal shell morphology (e.g., shell volume, shell thickness, pore density) to study past coastal environments. We have performed tomographic X-ray microcomputation analyses on foraminifera for three-dimensional (3D) shell reconstruction from different sites and periods (e.g., the last 200 years, and the last deglaciation from ~18 to ~11 ka BP into the Holocene) in the Baltic Sea region. These data are combined with conventional faunal analyses of the foraminiferal fauna. We will discuss the advantages, challenges, and future prospects of micro-computed tomography and 3D imaging, how the field has developed over time, and how to manage massive data in the environmental sciences.

Study of geomorphic change by understanding the spatial distribution of late Quaternary sediments using UAV-SfM method, Shichiri-Nagahama coast, northeastern Japan

Dr. Naoto Koiwa [1]***, Ms. Saki Kawamura*** [2]***, Dr. Mio TAKAHASHI*** [3]

1. Faculty of Education, Hirosaki University, 2. Katahira Elementary School, 3. Hirosaki Gakuin University

Shichiri-Nagahama coast in northeastern Japan has well-exposed sea cliffs with Tertiary and late Quaternary sediments because a harbor was built there in the 1990s, intercepting coastal drift sand. In this study, the spatial distribution of exposed sediments and contemporary landforms is analyzed by UAV-SfM method in order to reconstruct of the Mid Holocene sea-level and assess the process of sea cliff retreat. The sea cliffs in the study area are composed of unconsolidated sedimentary rocks, gravels and sands (marine terrace deposits), volcanic loess, black soils, and Holocene dune sands in ascending order. In the basement rock, the main recession factors in winter are not only erosion by storm waves, but also exfoliation of the bedrock due to freezing and thawing, and collapse of the convexity during the non-winter season formed by the exfoliation. The marine terrace deposits above the bedrock have experienced small-scale failures in unstable areas due to erosion of the basement rock, and the dune deposits have experienced small-scale arc-shaped landslides. These erosions are partially progressing at a rate of 1 m/year.

In this sea cliff, a buried wave-cut platform formed in the mid-Holocene sea-level highstand is exposed, with a shoreline angle of 3.5 m in elevation. Furthermore, there are two levels of wave-cut platforms that undergoing formation, with the higher level (elevation 2 m) having no sediments, and the lower level one covered by sand and gravel in winter, showing a shoreline angle of 0.7 m elevation. The buried wave-cut platform is covered by a marine sand and gravel layer, which is presumed to be similar to that found at the low level described above. The relative heights of the two shoreline angles suggest that the relative sea level in the study area at the Mid-Holocene sea-level highstand was about 2.8 m higher than present.

The impact of sea level rise on the development of the southern Tiber delta and Ostia lagoon as deduced from a Mid- to Late Holocene pollen record

Prof. William Gosling [1], ***Prof. Jan Sevink*** [1], ***Dr. Francesca Bulian*** [2]

1. *University of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics, Amsterdam, The Netherlands,* ***2.*** *Rijksuniversiteit Groningen*

A pollen record for a very precisely dated Mid- to Late Holocene lagoonal sequence from the former Ostia lagoon, in the southern extension of the Tiber delta in central Italy, demonstrates changes in local and regional vegetation. Combining these with results from other studies on environmental proxies (molluscs, foraminifers, ostracods), the record could be linked to changes in sedimentary facies in the lagoon. The sequence is from a tectonically stable area, with a subsoil that is not affected by Holocene subsidence due to sediment compaction, in contrast to the central and northern part of this delta, which is known for its massive subsidence. The changes in facies were used to reconstruct the sea level record for the Mid and Late Holocene and are compared to the existing curves for sea level change in this part of Central Tyrrhenian Italy. The record additionally allowed for a study of the potential impact of contemporary land use (notably salt production) on this environment.

Seamless marine and terrestrial topographic mapping from the seafloor to the intertidal zone and mountain slopes

Prof. Hironobu Kan [1]***, Mr. Seido Onishi*** [2]

1. *Kyushu University,* ***2.*** *Asia Air Survey Co., Ltd.*

Red soil run-off caused by agricultural and other land development is causing problems with the Ramsar Convention-listed wetlands and coastal coral reef environment. This problem is also occurring in Nagura Bay, Ishigaki Island, Japan, where submerged karst landforms and large living coral communities are found, and efforts are being sought to protect the environment. In order to visualise and monitoring these marine and terrestrial issues, topographic maps connecting land and seafloor are needed.

We produced high-resolution Digital Elevation Model (DEM) for an area of 58.2 square kilometers including the Nagura Bay of 5 kilometers in diameter and its surrounding tidal flats, sandbars, rivers and mountain slopes, by combining the results of bathymetric survey using the Multibeam Echo Sounder (MBES) and the Airborne LIDAR Bathymetry (ALB) survey from shallow water to terrestrial area.

Multibeam bathymetric surveys were conducted using Sonic 2022 (R2 Sonic, LLC) in a rectangular area spanning 1.85 × 2.7 km in the central part of Nagura Bay and a 1 m grid DEM was produced. ALB survey was conducted with Chiroptera II (Leica Geosystems Inc.) and a 2 m grid DEM was produced. The maximum depths of ALB bathymetry were 15 to 20 m at the bay head, ~30 m at the middle of the bay and ~40 m at the bay mouth. The depth of ALB bathymetry increases as seawater transparency increases. The accuracy of the ALB bathymetry was verified comparing with 135,065 MBES data points obtained at the same location, which showed very good agreement (r = 0.997).

Seamless land-sea topographic maps, such as the one produced in this study, will provide important basic information for understanding environmental change in coastal areas in the Anthropocene and for developing future environmental management plans.

Contemporary pollution of surface sediments from the Algarve shelf, Portugal

Dr. Piero Bellanova [1]***, Ms. Lisa Feist*** [1]***, Prof. Pedro JM Costa*** [2]***, Prof. Klaus Reicherter*** [1]***, Prof. Jan Schwarzbauer*** [3]

1. *Institute of Neotectonics and Natural Hazards, RWTH Aachen University,* ***2.*** *IDL – Instituto Dom Luíz, Faculdade de Ciências da Universidade de Lisboa,* ***3.*** *Institute of Geology and Geochemistry of Petroleum and Coal, RWTH Aachen University*

The present-day human footprint is traceable in all environments. Growing urban centers, tourism, agricultural and industrial activities in combination with fishery, aquacultures and intense naval traffic, result in a large output of pollutants onto coastal regions. The Algarve shelf (Portugal) is one exemplary highly affected coastal system. With this study the contemporary pollution was followed in eighteen offshore surface sediment samples.

Heavy metals (e.g., Cr, Pb, Cu, Hg) and organic contaminants, such as linear alkylbenzenes (LABs), dichlorodiphenyltrichloroethane metabolites (DDTs), polycyclic aromatic hydrocarbons (PAHs), and hopanes, have been identified and quantified, that pose hazardous effects on the marine environment and biota. This study correlates spatial distribution patterns with the pollutant composition, potential sources and pathways, each sample’s grain size, and local influences, such as discharging river systems and ocean currents.

Geoaccumulation of pollutants in the Algarve shelf surface sediments, controlled by sediment characteristics (grain size) and content of organic matter, threats marine environments. With considerable pollution, toxicity in marine environment is passed on into the food-chain through bioaccumulation posing long-term hazards for the marine ecosystem, aquacultures and fishery, and especially in the marine nature reserves.

This study presents a blueprint-study that allows the methodological adaption to new shelf systems with regionally different ocean current-driven distribution patterns of anthropogenic pollutants.

Risk assessment of land subsidence above sea cliff in Yonaguni Island, Japan

Mr. Hayate Kimura [1]***, Mr. Yasumasa Ichikawa*** [2]***, Prof. Hironobu Kan*** [1]

1. *Kyushu University,* ***2.*** *World Scan Project*

Sea cliffs are formed by wave-induced erosion and collapses, around which there is an increase use as buildings or roads. Although the disaster risk caused by cliff recession is widely recognized, the hazard of land subsidence above sea caves is less recognized. The aim of this study was to assess the risk of land subsidence above the sea cave by 3D surveying from the ground surface to the inside of the caves and analyzing the relationship between the two.
For the data acquisition, a RTK-UAV (DJI Phantom4 RTK) and multiple action cameras (GoPro Hero8) were used on the ground and in the caves, respectively. Accurate 3D models and very high spatial resolution DSMs (1~5 cm/pixel) were generated by data processing on the photogrammetry software Agisoft Metashape Professional. The study area is located in the south coast on Yonaguni Island, Japan. The sector around the two surveyed sea caves is mainly made up of Pleistocene limestone. The larger cave is 81m long and up to 62m wide, and the maximum elevation of dome-shaped ceiling is 27.5m. This study revealed that this cave extends under the road located about 50m inland from the cliff edge. The ceiling collapse occurred most commonly below the road and the difference in height between the ceiling and the road is 13.9m. The thickness of the boulders deposited on the cave floor was up to 5.3m. In addition, there were few continuous joints from the cave ceiling to the ground on the 3D model. Based on these findings, the next collapse is unlikely to cause the road to subsidence because the cave roof is thicker than a single collapse estimated from the boulder size broken down in the past. However, the future risk of subsidence could increase due to the expansion of the joints or destabilization accompanied by a single collapse.
Therefore, analyzing a 3D model from the surface to the cave allows us to assess the risk of land subsidence and conduct the follow-up research, such as investigation of cracks on the road above the cave and confirming the collapse of the cave ceiling.

The role of hyperpycnal flows on the burial of plastic in prodelta deposits: the case of the Gulf of Patti (Tyrrhenian Sea)

Dr. Martina Pierdomenico [1]***, Dr. Domenico Ridente*** [2]***, Prof. Daniele Casalbore*** [3]***, Prof. Letizia Di Bella*** [4]***, Prof. Salvatore Milli*** [3]***, Prof. Francesco Chiocci*** [5]

1. *Institute of Anthropic Impacts and Sustainability in marine environment, National Research Council (IAS-CNR), Italy,* ***2.*** *Institute of environmental geology and geoengineering, National Research Council (IGAG - CNR), Italy,* ***3.*** *Department of Earth Sciences, Sapienza University of Rome,* ***4.*** *Department of Earth Sciences, Sapienza University, Rome, Italy,* ***5.*** *university of Rome Sapienza*

Plastic contamination of seas is a global problem of growing concern, at present affecting every environmental compartment of all oceans from coastal surface waters to the water column and the seafloor. Despite the seafloor is recognized as the main accumulation area for anthropic debris and the sequestration of plastic within sediments is considered the ultimate long-term sink of this pollutant, the physical controls on its distribution and burial remain poorly known. In this work, we document the presence of deeply buried macroplastics in prodelta deposits at the mouth of the Mazzarrà River, a steep mountainous river flowing into the Tyrrhenian Sea in the Gulf of Patti (NE Sicily). This torrential river is able to carry a large amount of sediment during seasonal flash floods, which are able to generate hyperpycnal flows at sea, as witnessed by the widespread occurrence of erosional and depositional bedforms over the prodelta deposit. These bedforms include cross-shelf gullies and “dune-like” seafloor undulations. Two macroplastic items, consisting of a fragment of a “pasta” packaging bag and a semi-circular piece of synthetic rubber, have been retrieved within a sediment core collected at 38 m depth within a prodelta channel aligned with the mouth of the river. Grain-size analysis on the cored sediment showed the occurrence of decimetre-thick sandy intervals with sparse gravel alternating with more silty-clayey intervals. The plastic items were found at 68 and 255 cm below the core top (corresponding to the seafloor), enclosed in the coarse-grained intervals and associated with terrestrial plant debris, suggesting that they were deposited through hyperpycnal flows triggered by flood events. The trapping and burial of plastics in nearshore and prodelta environments are favored by the efficiency of rivers as conveyer and transporting agents of litter combined with the high sedimentation rates during single flood events. These findings testify the efficiency of sedimentary flows in burying plastic at depth below the seafloor, highlighting a clear need for assessing the magnitude of plastic storage in a variety of depositional settings.

Microplastic transport and accumulation in the land-sea continuum: Multi-year sediment trap monitoring at an estuary of the Baltic Sea

Dr. Saija Saarni [1], ***Mr. Tuomo Soininen*** [2], ***Dr. Emilia Uurasjärvi*** [2], ***Dr. Tom Jilbert*** [3], ***Mr. Antti Sainio*** [4], ***Dr. Arto Hiltunen*** [1], ***Dr. Jari Hänninen*** [1], ***Dr. Arto Koistinen*** [2]

1. *University of Turku*, **2.** *University of Eastern Finland*, **3.** *Department of Geosciences and Geography, University of Helsinki, Helsinki, Finland*, **4.** *Department of Geography and Geology, University of Turku*

Microplastics are shown to accumulate in aquatic environment posing ecological risks. Majority of the microplastics in the oceans are derived from land resulting from traffic, industry and insufficient waste management. Yet, the flux rates of microplastics from catchments to water bodies are poorly investigated. Estuaries are shown to efficiently trap nutrients and organic carbon through various processes involving flocculation and aggregation. Previously published laboratory experiments have shown that these processes can influence microplastic accumulation as well. Hence, estuaries have potential to act as microplastic filters decreasing their access from coastal areas to oceans. However, the estuaries are vulnerable key ecological environments suffering from multiple environmental problems, such as eutrophication and deoxygenation. In order to understand and predict the added environmental risk posed by microplastics in these sensitive systems, it is crucial to understand the flux rates and processes controlling microplastic accumulation in estuarine systems. Here we report first results from multi-year sediment trap campaign, where microplastic accumulation rates are investigated together with sediment composition (detrital supply, organic C, trace metals, and phosphorus loading) and seasonal hydroclimatic conditions. Large seasonal changes in the boreal estuary of Halikonlahti in the Finnish southwestern coast result strong climatic control on sediment supply, sources, accumulation rates, and sediment composition. While majority of microplastic particles were PE and PP, which are most commonly found materials in the sedimentary archives across the world, the microplastic fluxes show significant temporal and spatial variation.

Groundwater discharge and tidal flushing dynamics related to modern microbialite systems on a drought prone rocky coast

Mr. Tristin O'Connell [1], ***Prof. Thomas Bornman*** [2], ***Ms. Carla Dodd*** [3], ***Dr. Gavin Rishworth*** [4], ***Mr. Callum Anderson*** [1]

***1.** Department of Geosciences, Institute for Coastal and Marine Research (CMR), Nelson Mandela University, **2.** South African Environmental Observation Network, Elwandle Coastal Node, Nelson Mandela University, **3.** Department of Geosciences, Nelson Mandela University, Gqeberha 6031, South Africa, **4.** Department of Zoology & African Centre for Coastal Palaeoscience & DSI/NRF Research Chair: Shallow Water Ecosystems, Institute for Coastal and Marine Research (CMR), Nelson Mandela University, Gqeberha 6031, South Africa*

Extant microbialite systems precipitating in a hydrological environment formed by constant, fresh groundwater discharge and periodic marine water intrusion are known from global locations including Western Australia, the United Kingdom and South Africa. In semi-arid South Africa, these occur in the supratidal zone of rocky coasts and are especially numerous and well-developed in the Nelson Mandela Bay (NMB). Microbialites are layered organosedimentary deposits which form part of the longest uninterrupted geological record of life on Earth (3.4 bya). The layering of sediment and carbonates of modern microbialites potentially provides a window into historical environmental conditions. Rapid groundwater development in response to a severe regional drought has led to the exploration of the coastal aquifers on which the microbialite systems rely for groundwater inflow. This study provides insight into the current state of the coastal aquifers of NMB through the quantification of groundwater discharge via microbialite systems in terms of flow rate and volume. This is paired with *in situ* hourly microbialite pool water temperature and conductivity data to determine the effect of tidal flushing dynamics coupled to rainfall. Results indicate that in excess of 3.8 ML/d of groundwater is discharged to the NMB coast, with 78% of discharge points (xx per km) supporting active microbialite growth. Preliminary results suggest a seasonal variation in flow rate and tidal dynamics. This is the first spatial analysis of groundwater discharge volumes along the NMB coast and is especially timeous given the trend for groundwater development in the face of urban expansion and climate change linked to rising sea-level or storm surge prevalence and consequent increased saltwater intrusion into these microbialite pools.

Assessing tsunami susceptibility along the coasts of the Thermaikos Gulf, Northern Greece

Dr. Konstantinos Tsanakas [1], ***Mr. Dimitrios-Vasileios Batzakis*** [1], ***Prof. Efthimios Karymbalis*** [1]

1. Department of Geography, Harokopio University, GR-17671, Athens

The study investigates the tsunami susceptibility along the coastline of the Thermaikos Gulf. For this purpose, a series of simulations were conducted by manipulating the Community Model Interface for the Tsunami (ComMIT) software. Several offshore seismic faults of the North Aegean Sea were taken into consideration as potential tsunamigenic sources. The parameters of the focal mechanism of past seismic events that may trigger tsunamis were retrieved from earthquake catalogues. The results of the simulations revealed that tsunamis, triggered by submarine earthquakes, can cause an extended inundation in the coastal area of Thermaikos Gulf. In order to validate our results, detailed geomorphological mapping was conducted and two shallow boreholes were drilled at Alykes lagoon (western coast of the Thermaikos Gulf) in an attempt to recognize the late Holocene palaeoenvironmental changes. In total, 64 sediment samples collected from the cores, were granulometrically and palaeontologically analysed. Moreover, two shell samples were ^{14}C dated and provided the chronostratigraphy of the cores. Four biosedimentary units were identified corresponding to different depositional palaeoenvironments. A shallowing upwards sedimentary sequence was recorded indicating a shallow marine environment which progressively changed to a more protected lagoonal one, with restricted communication to the open sea. The fining upwards sequence of the sedimentary record of the cores was interrupted by a coarse-grained layer corresponding to a high energy marine inundation event attributed most likely to a palaeotsunami which occurred not long before 4330–3920 cal BP. A similar strong marine signal which is regarded as a sedimentary feature indicative of a tsunamite has been documented by other studies in the same region as well as at Cape Epanomi and Sozopoli at the eastern coast of the Gulf. This signal correlates well with the high energy marine inundation layer documented in our study validating the simulation results. Our study can provide decision makers with important information for land-use planning, determining safe and unsafe areas for urban development along the coasts of the Thermaikos Gulf.

Earthquake history of Northern Cyprus, implications from coastal geomorphology and geochronology

Prof. Cengiz Yildirim **[1]**, ***Dr. Daniel Melnick*** **[2]**, ***Prof. Okan Tüysüz*** **[1]**, ***Ms. Cevza Damla Altınbaş*** **[1]**, ***Prof. Julius Jara-Munoz*** **[3]**, ***Dr. Konstantinos Tsanakas*** **[4]**, ***Prof. Orkan Özcan*** **[1]**, ***Prof. Manfred R. Strecker*** **[5]**

Cyprus is an island located on a convergent plate boundary in the Eastern Mediterranean. The African Plate subducts and collides with Anatolian Plate along the Cyprus Arc. The distance between northern Cyprus's coasts and the plate boundary varies between 70 km and 3 km from west to east. Nevertheless, the offshore escarpment of northern Cyprus is delimited by a dip-slip fault with a strike-slip component. However, the seismicity during the instrumental period is very low along the northern shore. Our high-resolution geomorphic mapping of coseismically uplifted landforms and biological and archaeological markers (fish tank) reveal that the northern coast of the island was hit by several earthquakes nucleated by offshore faults capable of producing enough seismic energy to deform the shoreline. The radiocarbon 14C ages of the biological marker (algal rims etc.) reveal that the coseismic uplift of the shoreline starts from 4 ka to 1.2 ka BP. The number of paleo shorelines is three at some sites, and their elevations rise to 3 m above sea level, indicating multiple earthquakes along the same segments of the offshore faults. The spatial distribution of radiocarbon 14C ages displays that the ages are getting younger toward the east, which might indicate the migration of stress toward the east.

Quaternary Flexure and breaking of the African Plate along the Eastern Mediterranean Coasts: implications from deformed marine terraces

Prof. Cengiz Yildirim [1]

1. Istanbul Technical University, Eurasia Institute of Earth Sciences, 34469 Maslak, Istanbul

The African, Aegean and Anatolian plates converge in the Eastern Mediterranean Sea. The African Plate subducts beneath the Aegean and Anatolian plates along the Hellenic and Cyprus arcs, respectively. This subduction gives rise to the down-riding of the oceanic lithosphere under the Agean and Anatolian plates and the flexure of the African Plate. The coasts of eastern Libya (Cyrenaica) and western Egypt are among the best places to observe ongoing deformation on a down-riding plate in a subduction zone. Nevertheless, most of the efforts have focussed on the northern and eastern coast of the Eastern Mediterranean Region. Today, the southern coasts are low-strain regions, and the number of large-magnitude earthquakes is limited during the instrumental period. However, the coastal geomorphology reveals the presence of several uplifted marine terraces stretching hundreds of kilometres between Sirte Bay (Libya) and the Nile Delta, implying young deformation. Geomorphic mapping and morphometric analysis indicate that the shorelines of marine terraces are strongly deformed. The elevation of the same shorelines dramatically increases the along the strike of the shore. Their spatial distribution and geometries resemble a folding and, thus, flexing of the African Crust. The Marmarica Basin is located between deformed marine terrace regions and is characterised by several east-west striking en-echelon normal faults. They are the surface expression of the breaking of the flexured crust response to the down-riding of the African Plate. All these geomorphic markers reveal that the northern coast of Africa is strongly deformed in Quaternary and should be reassessed in terms of seismic hazard.

A new landslide inventory map in the Southern Swiss Alps

Mr. Alessandro De Pedrini [1], **Prof. Christian Ambrosi** [2]

1. SUPSI, Institute of Earth Sciences, IST, 2. SUPSI, Institute of Earth Sciences IST

Landslides in urbanized mountain environments often threaten the infrastructures and population settled near the slopes. In this context, detailed knowledge of the types of gravitational phenomena, their extension, and state of activity is fundamental for risk reduction. In this study, we revise the current landslide inventory map of Canton Ticino (Ambrosi and Czerski, 2016) and present a first landslide inventory of the Moesa Region of Canton Graubünden, Switzerland. This inventory consists of a mapping of the landslides classified according to Varnes (1978) and Hungr et al. (2014), which include phenomena as falls, flows, slides, and Deep Seated Gravitational Slope Deformation, DSGSD. In addition, we complemented the map with morpho-structures.

Mapping was carried out by interpreting hillshade views generated from high resolution digital terrain models, historical aerial photos, and images from aerial strips visualized by stereo-photogrammetric technology. An evaluation of the state of activity of the landslides was performed using the available data from geodetic monitoring and Interferometric Synthetic Aperture Radar (InSAR) through Permanent Scatterers (PS) and Interferometric Point Target Analysis (IPTA) techniques. The available InSAR data include the Sentinel-1 mission from 2014 to 2021, TerraSAR-X from 2014 to 2019, and RadarSAT from 2011 to 2018. The sensor of each satellite utilizes different acquisition parameters, thus can reveal the surface displacements with different accuracies, depending on the slope displacement magnitude, presence of vegetation, and slope orientation. The results of the mapping were statistically analyzed in relation to the relief topography, in order to understand the tendency of different morphological environments to favor or disfavor specific gravitational phenomena.

The new inventory provides a tool for local government to update hazard zoning, allowing them to limit construction, plan necessary technical protection measures, and manage emergencies in case of major events.

Geomorphological classification and hazard mapping considering both natural and anthropogenic landforms in Japan

Prof. Toshihiko Sugai [1]

1. *The University of Tokyo*

In this decade, a series of heavy rainfall events have led to frequent flood and sediment (e.g., slope failures, landslides, and debris flows) disasters in the Japanese archipelago, among them events in Hiroshima (2014), Kanto and Tohoku (2015), Northern Kyushu (2017), Western Japan (2018), Eastern Japan (2019 Typhoon), Kumamoto (2020), and Atami (2021), that have killed dozens of people every year. Over 10,000 slope failures and dozens of riverbank breaches have abruptly changed landforms, for example, by deepening upland valleys, forming alluvial cones and crevasse splays, changing river channels from meandering to braided, and shortening the courses of rivers. Concentrations of such sudden changes occur in geomorphic hot spots, sites where high volumes of water or sediment make short-term sedimentation or erosion events more likely. Photogrammetry conducted with unmanned aerial vehicles coupled with grain size and geochemical analyses of event sediments and 14C dating has revealed that geomorphic hot spots can be divided into two types: natural and anthropogenic. Natural hot spots are located at node points of sediment routing such as valley heads, river junctions, fan apexes, and avulsions; at such sites flooding and sediment events have occurred repeatedly during the Holocene. Anthropogenic hot spots are located where artificial landforms have been created, such as valley fills, terraces constructed on steep hillslopes for agriculture, and river channels modified by the elimination of meanders, the lowering of banks by removing dunes or not raising levees in low-lying areas, or the narrowing of channel cross sections by bridging or tree growth. Such local anthropogenic topographic changes may also trigger the regional geomorphic system to transition to a new equilibrium state. To reduce vulnerability to sediment and flood disasters in tectonically active and intensely denuded regions with a high population density such as Japan, it is crucial to distinguish between natural and anthropogenic geomorphic hot spots. Hazard maps should be based on a detailed geomorphological classification system that reflects both naturally developed Quaternary landforms and artificial landforms.

Geological and geomorphological features of landslides by August 2021 heavy rainfall at the foot of Mt. Mutsu-Hiuchidake, northern Honshu Island, Japan

Dr. Ching-Ying Tsou [1], Dr. Naoto Koiwa [2], Dr. Takahisa Furuichi [3], Dr. Toshiyuki Kon [4]

1. Faculty of Agriculture and Life Science, Hirosaki University, 2. Faculty of Education, Hirosaki University, 3. Forest Research and Management Organization, 4. Aomori Prefecture

Volcano-alluvial fans are comprised of unconsolidated material and steep faces can be created by erosion, forming favorable conditions for landslides. We investigated the geological and geomorphological features of landslides induced by heavy rainfall on 10 August 2021 along the coastal area at the foot of Mt. Mutsu-Hiuchidake, northern Honshu Island, Japan. The area received the maximum hourly rainfall intensity of 59 mm hr^{-1} and the cumulative rainfall in two days of 385 mm, which was about 2.6 times larger than the average rainfall in August in this area, resulting in one of the most major prefectural natural disasters of recent years. The bedrock in the study area is Miocene-Pliocene to Pleistocene in age and comprises, in ascending order, Ohata formation (pumiceous tuff, tuff-breccia, sandstone, and mudstone with basal conglomerate) and volcanic products of tuff-breccia. Field surveys showed that the fan surfaces mostly gentler than 15 degrees are distributed at about 50 m a.s.l and are surrounded by steeper slopes (of about 40 degrees) with well-defined slope breaks whereas old landslide scarps can be observed in many locations. Landslides by this rainfall event were mainly distributed on the steep slopes, along the slope breaks, and above the old landslide scarps. Besides, outcrops exposed by landslides suggested the bedrock is overlain by volcano-alluvial fan deposits of 3-10 m thick consist of matrix or clast-supported massive diamicton with muddy or sandy matrix and matrix-supported bedded diamicton with altered materials. Landslides occurred associated with the above materials generally had piping holes within the tops of the landslide scars, suggesting the locations of these landslides must be controlled by the concentration of groundwater in the volcano-alluvial fans.

Sediment sources and discharge as disaster and environmental risks in an upstream mountainous catchment in northwestern Vietnam

Dr. Takahisa Furuichi [1], ***Dr. Takuma Watakabe*** [2], ***Dr. Hikaru Osawa*** [3], ***Dr. Wataru Murakami*** [4], ***Dr. Katsuto Shimizu*** [5], ***Dr. Takashi Okamoto*** [6]

1. *1 Department of Disaster Prevention, Hydrology and Meteorology, Forestry and Forest Products Research Institute,* ***2.*** *2 Kansai Research Center, Forestry and Forest Products Research Institute,* ***3.*** *3 Department of Disaster Prevention, Hydrology and Meteorology, Forestry and Forest Products Research Institute,* ***4.*** *4 Department of Disaster Prevention, Hydrology and Meteorology, Forestry and Forest Products Research Institute,* ***5.*** *5 Department of Forest Management, Forestry and Forest Products Research Institute,* ***6.*** *6 Department of Disaster Prevention, Hydrology and Meteorology, Forestry and Forest Products Research Institute*

The northwestern region of Vietnam, the most mountainous area in the country, has suffered from frequent occurrence of mountain disasters caused by landslides, debris flows and river floods. The area has also long faced catchment-scale active sediment movement which involves various hillslope processes likely affected by land-uses. Our study aims at investigating important sources and processes of sediment movement and quantifying sediment discharge at a catchment-scale, in order to contribute to assessment of disaster and environmental risks in mainland Southeast Asia, where such risks have not yet been well documented.

Our study catchment, c.a. 200 km^2 in area and located in Yen Bai Province, northwestern Vietnam, is largely underlain by rhyolitic volcanic rocks and tuff, often intervened by shales. The catchment is at altitudes between approximately 900 m and 2000 m a.s.l. Deforested and terraced agricultural fields are extensively distributed on footslopes and middle slopes, while they are not observed on the slopes where soil layers are thin. Forest types vary, but extensively include highly degraded forest composed of regenerated shrubs and bush.

During the field survey in the 2022 rainy season, river water of the main stream of the catchment appeared highly turbid during a rainfall event; however, tributary river water was not equally turbid even though water levels looked higher than base flow, suggesting specific areas in the catchment were more contributing as sediment sources. A series of water samples collected through the sampling campaign along the main stream in a rainy-day, together with land-use and landform analysis using satellite images, revealed that erosion was occurring most distinctively in areas where artificial landform transformation took place. Infiltration tests on land surfaces under forest and degraded forest showed almost the same infiltration capacity, suggesting surface erosion would not be always critically accelerated by deforestation. However, the spatial distribution of landslides in the study area suggests deforestation likely increases the risk of shallow landslide, and former landslides (i.e. soils decomposed by landslides) were a major source of sediment in some of the tributary areas where highly concentrated suspended sediment flowed.

Mapping the subsidence susceptibility of the Ebro Delta from geological information

Dr. Miquel Vilà [1]***, Dr. Xavier Rodríguez*** [2]***, Ms. Roser Pi*** [1]***, Dr. Oscar Mora*** [1]***, Mr. Fernando Pérez*** [1]***, Mr. Jordi Marturià*** [1]

1. *Cartographic and Geological Institute of Catalonia,* ***2.*** *Institute of Geology, University of Hamburg*

Modern river delta plains in general are areas very susceptible to flooding because of their low elevation. This is the case of the Ebro Delta plain (northwest Mediterranean coast, 320 km^2), where more than 40% of its area is less than 50 cm above sea level. Aside from the sea level rising, the flooding hazard of delta plains can also increase because of subsidence (the absolute lowering of the ground surface elevation). In this context, we have developed a zonation of subsidence susceptibility on the Ebro Delta plain based on the analysis of the different relevant geological factors that influence it. To achieve it, firstly, a detailed geological characterization of the Holocene prism of the Ebro Delta has been carried out based on the compilation and analysis of new and pre-existing data.

The subsidence associated with natural mechanical compaction of Holocene delta deposits, has been estimated based on their 3D sedimentary architecture and their geomechanical properties. On the other hand, it was analyzed the contribution on subsidence of the flexure of the lithosphere related to the deposition of water and sediment in the Ebro margin since the Last Glacial Maximum, and the regional tilting of the Ebro shelf during the Quaternary. The subsidence estimates associated with these three factors are broadly coherent with the DInSAR subsidence measurements. In addition, other minor factors and features able to locally modify the Ebro Delta plain subsidence (e.g., recent sedimentary dynamics, the chemical and biological compaction of sediment, or the effects related to anthropogenic activities) were also qualitatively evaluated. The joint analysis of the different information sources allowed the composition of a subsidence susceptibility map, which indicates that the subsidence in the Ebro Delta plain ranges from <1 mm/year (in the inner delta plain) up to ~2.3 mm/year (in some parts of the outer delta plain). This methodology, fundamentally based on geological information and knowledge, is being implemented in the other main coastal plains of Catalonia to predict the subsidence distribution and to facilitate the management of these vulnerable areas.

Geostatistical approach of submarine landslides: new insights on mass wasting dynamics along the Italian continental margins

Dr. Marco Bianchini [1]***, Prof. Daniele Casalbore*** [2]***, Dr. Silvia Ceramicola*** [3]***, Prof. Francesco Chiocci*** [4]***, Dr. Daniele Spatola*** [5]

1. *Department of Earth Sciences, Sapienza University, Rome / National institute of Oceanography and applied Geophysics,* ***2.*** *Department of Earth Sciences, of Sapienza University of Rome,* ***3.*** *National Institute of Oceanography and Applied Geophysics OGS,* ***4.*** *university of Rome Sapienza,* ***5.*** *1. Department of Earth Sciences, Sapienza University, Rome, Italy*

Submarine landslides are usually very large events respect their terrestrial counterparts, are an important process for sediment transfer, can generate tsunamis and therefore represent a very relevant geohazard for marine and coastal infrastructures. They are globally reported along both active and passive margins and are often associated with specific submarine morphologies (e.g., canyons, pockmarks, seamounts).

Despite their frequency and relevance, submarine landslides are far harder to monitor and study than terrestrial landslides, and much greater uncertainty affects their preconditioning factors and triggers, and this has led to a huge disparity of knowledge between mass wasting in the two different environments and therefore a large uncertainty for geohazard assessment exists in the marine realm.

Marine observatories and long-term studies on marine landslide are very few as in situ measurements and monitoring are technologically challenging and economically demanding. On the other hand, in the last decades, the availability of very high-resolution sonar data (up to centimetres) allowed to observe morphologies never observed before, bringing new insight on their dynamics

The Italian continental margins provide an excellent playfield to study submarine mass wasting because of their different morpho-tectonic and sedimentary setting. Between the 2007 and 2013, a detailed regional mapping program of seafloor morphologies and features including mass wasting were funded by the Civil Protection (DPC) through the MaGIC project that gathered seven universities, three institutes of the National Research Council and the National Institute for Oceanography and Applied Geophysics (OGS), with the objective of providing the DPC with occurrence and distribution of geohazard-related features including submarine mass wasting and associated deposits.

In the framework of the PNNR Project GEOSCIENCES IR we propose to integrate all the existing data along the continental margins, indicative of mass wasting in a new well-constrained geodatabase. Such platform will allow to apply statistical methods to constrain better mass wasting dynamics in relation to different geological setting and to recognise the role played by predisposing and triggering factors.

Preliminary results on geomorphic and seismological analysis on earthquake and tsunami hazards in the inner Northern Apennines

Ms. Lauretta Kaerger [1], *Ms. Chiara Del Ventisette* [1], *Ms. Paola Vannucchi* [1], *Mr. Derek Keir* [1], *Ms. Carolina Pagli* [2], *Mr. Giancarlo Molli* [2]

1. *Department of Earth Sciences, University of Florence,* **2.** *Department of Earth Science, University of Pisa, Italy*

The inner Northern Apennines are considered as a region of only moderate to low seismic hazard, however recent findings suggest that the faults of the region might display a much greater threat than previously thought. Indeed, the faults might be able to cause not only larger (M>5-6) magnitude earthquakes but also tsunamis. Of our special interest is the 1846 ~M6 Orciano Pisano earthquake which caused major destructions at the time and, based on historic reports, is also suspected to have caused a tsunami. Despite the effects this event had on the region the location and source of the earthquake is still unknown and hence its seismological relevance remains unclear. Clarifying these issues is crucial as a similar event today would likely have devastating effects on the densely populated area.

So far, a new geomorphic analysis shows some indications of recent tectonic activity for the faults of the region whereas their large-scale architectural frame need to be better understood. In particular questions remain whether the N-S fault systems predominately recorded in the area are the only active systems, and what is the role of the E-W trending systems. To better understand fault activity, the seismicity of the area recorded by the INGV earthquake catalogue since 1985 has been analysed. Initial analysis shows continuos seismic activity over the past ~30 years with events magnitude as high as M 4.0 and a depth distribution in the upper crust down to ~20 km. Furthermore, the data set shows several interesting clusters and patterns in the region indicating activity along both the N-S striking faults as well as on the E-W striking structures in the area. The INGV catalogue has hypocentral errors of several km's due to the location methods used and the relatively modest density of seismic stations. In order to image the subsurface active fault planes and their kinematics reprocessing and relocation of past earthquake clusters will be done. In addition, a new temporary seismic network of 8 stations has been set up to densify the network to accurately locate current and future earthquakes.

The listric faults bounding the Dor Disturbance from the southeast: indications for recent major seabed ruptures

***Ms. May Laor* [1], Prof. Zohar Gvirtzman [1], Dr. Oded Katz [1], Mr. Omri Gadol [2], Prof. Yizhaq Makovsky [2]**

1. Geological Survey of Israel, 2. Dr. Moses Strauss Department of Marine Geosciences, University of Haifa

The thin-skinned faults crossed by the Leviathan gas pipeline, and bounding the Dor disturbance (offshore Israel) from the southeast are exceptional relative to other thin-skinned normal faults nearby. (1) Whereas most of the faults are aligned along the base of the continental slope, these faults are located on the upper slope. (2) Their dip angle is relatively small, beginning with about 45 degrees near the surface and gradually changing to 10 degrees at depth. (3) However, they stop above the base Pliocene and do not penetrate the top of the Messinian salt layer. (4) Their width is large relative to the faults developed above the salt wedge-out. (5) They produce large seabed scarps despite their location in a high sedimentation zone. In fact, the sedimentation rate at that location (~200 cm/ky) is four times larger than the displacement rate (~50 cm/ky), averaged at 350 ky. Allegedly, this observation indicates that either these faults creep faster than the sedimentation rate or they operate in rapid episodes or “slow earthquakes”. To better understand the formation of these listric faults and assess the hazard they pose, we performed a high-resolution, multi-channel, seismic reflection survey south of the Dor Disturbance. We map three unconformities on and off the shelf and date them using sequence stratigraphic principles and a global sea-level curve. Considering the dated seismic reflectors, we measure fault offsets and calculate the displacement rates throughout the history of the fault motion. Results show an acceleration of the moving during the last ~14 ky, with displacement rates of 2.5-3.5 m/ky. Also, the backward restoration shows quiet periods with no fault motion. In this talk, we will present the preliminary results and discuss their implications.

Reassessing fault activity over different time scales in the Lower Rhine Graben and the processes controlling scarp preservation, towards an improved fault database.

Dr. Marthe Lefevre [1], ***Dr. Kris Vanneste*** [1], ***Dr. Aurèlia Hubert*** [2], ***Dr. Alain Demoulin*** [2]
1. Royal Observatory of Belgium, 2. University of Liege

The Lower Rhine Graben is an area of slow intraplate extension (~0.1 +/- 0.03mm/yr) in northwestern Europe. The major active faults are well known, but the structures presenting limited surface deformation or the detailed fault geometry are often overlooked, mostly because such slow deformation produces weak tectonic signal, easily overprinted by other processes. We present, for the entire region, a revised and homogeneous fault map, based on morphological observations of fault scarps and offset alluvial terraces realized on a high-resolution Lidar-based DEM, complemented by external information from paleoseismological and geophysical surveys. We compiled our active faults model in a database, including several levels of fault mapping (traces, fault sections, faults), with indications about the certainty of the faults identification and location.
The eastern side of the graben exhibits clear scarps and sharp boundaries, while the western side presents smoother cumulative scarps, suggesting contrasting fault behavior across the graben. Moreover, the number of faults increase drastically southward pointing to a N-S contrast in terms of graben development. This map also points to variations of scarp preservation along the graben that are not related only to the local geology. We observe many small structures that are surprisingly well-preserved compared to their assumed rates of activity and recent landscape remodeling processes (climate, anthropogenic…), raising the question of the role of the periglacial condition in scarp preservation.
To better understand the sources of these variations, we refine the assessment of the fault activity through time and along strike. In the southern part of the graben, a well-developed terrace has been used to estimate the activity of most faults over the Quaternary. In addition, we use several 3D-geological models to retrieve the vertical offsets, and obtain the spatial slip distribution at different timescales. We observe that, along individual faults, the slip profile evolves laterally and in time, showing fault linkage, while at the scale of the graben borders the total slip is relatively homogenous. Moreover, in the northern part, although the surface-expression differs between the two sides of the graben, the total slip rates are fairly equivalent on both sides, suggesting a symmetrical extension.

Could phreatomagmatic eruptions trigger reverse faulting? A paleoseismic history and stress modelling at Antarctica

Dr. Raúl Pérez-López [1]***, Dr. Marta Béjar-Pizarro*** [1]***, Dr. Miguel Ángel Rodríguez-Pascua*** [1]***, Dr. Jose J. Martínez-Díaz*** [2]***, Dr. Jorge Luis Giner Robles*** [3]***, Prof. Pablo G. Silva*** [4]***, Dr. Javier Elez*** [4]

1. Instituto Geológico y Minero de España IGME-CSIC, 2. Universidad Complutense de Madrid, 3. Universidad Autónoma de Madrid, 4. Universidad de Salamanca

The relationships between earthquakes and volcanic eruptions have been studied as processes with the potential to trigger each other. Large earthquakes greater than M = 7 and subsequent significant eruptions can be related as a causative phenomenon in very active tectonic frames, such as subduction zones and mid-ocean ridges. Recently, large earthquakes activating stratovolcanoes have been described, although the underlying mechanisms are poorly constrained. However, no cases of volcanic and earthquake interactions have been described from volcanic eruptions triggering moderated-size earthquakes, this also showing geomorphological and paleoseismic evidence. In this work, we describe the paleoseismic record of reverse faulting triggered by a phreatomagmatic eruption in Deception Island (West Antarctica). A powerful phreatomagmatic eruption took place in the inner bay shoreline of the island in 1970, destroying the Chilean Antarctic Station and generating three WNW-ESE aligned craters, affecting an area of 380 x 184 meters. The analysis of aerial imagery before and after the eruption identifies an apparent E-W surface rupture with a reverse movement also revealed by paleoseismic trenches and geomorphic volcanic terraces. Moreover, we have studied the static stress changes induced by the phreatomagmatic eruption on the E-W fault, with the aim to connect paleoseismic observation, geomorphological analysis, and volcanic eruption. We propose three volcano-tectonic interactions models: (1) Reverse earthquake (5<M<6) triggered by the 1970‘s phreatomagmatic eruption; (2) Reactivation of a previous fault as a consequence of dike injection and/or magma migration in relationship with the eruptive process and (3) Aseismic fault creep activity post-volcanic eruption. Hence, this work represents a good opportunity for matching volcanic eruptions and earthquake faulting with surface rupture for opening a fruitful scientific discussion.

Interference among volcanism, faulting and Quaternary fluvial terraces in the Cabriel Valley (Valencia, East Spain).

Prof. Pablo G. Silva [1], ***Prof. Francisco-Jose Perez-Torrado*** [2], ***Dr. Javier Elez*** [1], ***Dr. Raúl Pérez-López*** [3], ***Dr. Elvira Roquero*** [4], ***Dr. Yolanda Sánchez Sánchez*** [1], ***Dr. Teresa Bardají*** [5]

1. *Universidad de Salamanca,* ***2.*** *Universidad de Las Palmas de Gran Canaria,* ***3.*** *Instituto Geológico y Minero de España IGME-CSIC,* ***4.*** *Universidad Politécnica de Madrid,* ***5.*** *Universidad de Alcalá*

This work analyses the Quaternary volcanic activity within the Cabriel Valley in the northern end of the N-S trending Ayora-Cofrentes graben (Valencia East Spain). Normal faulting facilitated Quaternary volcanic activity from subcrustal levels, geochemically characterized as olivinic nephelinites (limburgites) with olivine-piroxene phenocrystals.

The study identifies three independent volcanic outcrops recording different eruptive events: Agrás Volcano (AGV); Pico del Fraile (PDF) and Cofrentes Castle (CFC). The AGV is a small strombolian cone, 50 m high with 450x325 m dimensions with two original elongated craters evidencing different overlapped edifices, close in time. Volcanic activity intrudes, disrupts and embeds the oldest terrace of the Cabriel River (+130-135 m). The basal pyroclastic levels show abundant cauliflower-shaped bombs, lapilli and chilled rim pyroclasts supporting the presence of water during magma rise (hydrovolcanism). Towards the top of the volcano interbedded basaltic levels (8m thick) become abundant, indicating eventual lava-flow activity. Subvertical basaltic dikes, N-S to NNW-SSE, trend with the regional fault system. Paleomagnetic determinations using a portable fluxgate magnetometer consistently indicated reverse polarity (Matuyama) according to published K/Ar dating (2.0 – 1.4 Ma).

At the base of the AGV, the PDF materials show normal polarity (Brunhes) and disrupt and overlap the +50 (ESR: 370 ka) and +40m (OSL: 180 ka) terraces of the Cabriel River. The remnants of the edifice outline a crescent-shaped rim opened to the SSW facing to CFC outcrop in the opposite side of the valley. The rim preserves massive pyroclastic and peperite materials, with abundant clastic components in a palagonite-like matrix indicating explosive phreatomagmatic activity. Resurgent activity records pseudo-pillow lavas above the +40m fluvial level which also embed peperites. This assemblage indicates subaqueous volcanic activity contemporaneous to the formation of the +40 m terrace during the Middle Pleistocene (MIS 7).

The CFC outcrop record a basal mélange (20m thick) of volcanic materials with large blocks of the Neogene and Triassic substratum, topped by a pyroclastic deposit containing pervasive small-rounded fluvial gravels. This last outcrop is interpreted as the remnants of pyroclastic flow coming from the PDF blast. Hydrothermal activity around the area suggest some type of latent activity. FUNDED BY MINCIN-FEDER 2021-123510OB-I00

Structural control of rapid magma ascent during Cumbre Vieja eruption (La Palma, 2021): the role of fault intersection in dyke ascent

Dr. Raúl Pérez-López [1], ***Dr. Miguel Ángel Rodríguez-Pascua*** [1], ***Dr. Julio López-Gutierrez*** [1], ***Dr. Jose F. Mediato*** [1], ***Dr. David Sanz-Mangas*** [1], ***Dr. Rayco Marrero*** [1], ***Dr. Isabel Montoya*** [1], ***Dr. Inés Galindo*** [1], ***Dr. Nieves Sánchez*** [1], ***Dr. Marta Béjar-Pizarro*** [1], ***Dr. Gonzalo Lozano*** [1], ***Dr. Juan C. 1. *Instituto Geológico y Minero de España IGME-CSIC,* ***2.*** *(3) Dpto. de Geodinámica, Facultad de Ciencias Geológicas, Universidad Complutense de Madrid. 28040 Madrid*

On 11 September, a tecto-volcanic earthquake cluster started underneath La Palma (Canary Islands). Eight days later, a strong strombolian eruption began in the Cumbre Vieja volcanic ridge, located in the southern part of the island. As a consequence, the new scoria cone born and it was in the ongoing erupting mode for 85 days, with alternating ash columns up to 8 km height. Besides, the eruption emitted lava fields with a total land covering of ca 1100 Ha, and a huge volume of tephra with fine ash which covered the entire island and affected ordinary aerial traffic.

A vast quantity of magma was emplaced at 11 km depth at the beginning of the volcanic unrest, 11/09/2021. Four days later magma moved shallower and was emplaced between 6 and 2 km depth. Finally, on September 19, the eruption began. The rapid dyke ascent, was controlled by a previous pre-existing fault trending NW-SE. Several volcanic vents trending NW-SE emerged whereas the magma was moving along the fault, from SE to NW. Moreover, the presence of another previous fault trending ENE-WSW was also affected by the magma rising, and controlled the opening of new vents during the final volcanic stages. In total, more than thirty vents were opened been the most active the scoria cone on the intersection between those two previous faults, NW-SE and ENE-WSW, main and secondary respectively. Relocation of earthquakes shows a dyke ascent from southeast to northwest, between 20 km and 5 km depth and an average dip of 65°S. We suggest that the dyke reaches the fault intersection and ascends rapidly in a vertical mode filling the normal fault plane (NW-SE), and opening vents along 1.2 km length. When the NW-SE fault plane was totally full of magma, its overpressure reactivate the ENE-WSW and the magma moved through it, opening new vents from ENE to WSW during the last 15 days of the eruption. Therefore, the structural control of previous Quaternary faults under an extensional tectonic regime takes control of the rapid magma ascent and the spatial distribution of the vents.

Morpho-structural analysis of the active volcanic Ischia caldera using drone-based LiDAR: a new method to improve the spatial resolution of DTMs

Dr. Argelia Silva Fragoso [1], *Dr. Gianluca Norini* [2], *Prof. Alessandro Michetti* [3], *Dr. Rosa Nappi* [4], *Dr. Gianluca Groppelli* [5]

1. Università degli Studi dell'Insubria, Como, 2. CNR Istituto di Geologia Ambientale e Geoingegneria, Milano, Italy, 3. Università degli Studi dell'Insubria; INGV OV, 4. Istituto Nazionale di Geofisica e Vulcanologia, Sezione di Napoli Osservatorio Vesuviano, Naples, 5. CNR-IGAG, Milano

Ischia Island is an active volcano in the northern sector of the Gulf of Naples, which belongs to the Neapolitan volcanic system (southern Italy). The island represents an interesting case study of long-term resurgence and subsidence processes in active volcanic calderas. The final stage of the resurgence phase formed Mt. Epomeo (787 m elevation), the main morphological structure emerging nowadays, and bounded by NW-SE, E-W, and N-S normal faults. Early studies associated seismic activity with the E-W faulting system north of Mt. Epomeo. This is in fact the epicentral area of the July 28, 1883, earthquake, which completely destroyed Casamicciola Terme and caused ~2300 victims. The last moderate earthquake (M_d=4.0) occurred in the same epicentral area on August 21, 2017. Although much has been done so far, understanding the fault geometry and kinematics here is still debated. These are volcanotectonic seismic events with a very shallow hypocentral depth (1-2 km) and moderate-to-low magnitude (3<Mw<5). However, owing to extremely high exposure and vulnerability, the associated risk is very severe.

Analysis of the surface expression of volcanotectonic deformation allowed us to identify and constrain the structural architecture of this active volcanic and seismic area. Thus, we carried out a morpho-structural analysis (e.g.,lineaments, fault scarps, and slope maps) interpreted from shaded relief images processed from digital terrain models (DTMs) at 10 cm resolution. For obtaining accurate bare-earth elevation data and enhance its acquisition, we used a LiDAR sensor transported by the DJI-Matrice-600 drone. The drone-Lidar survey covered an area of 2.2 km^2 between Grande Sentinella horst and a normal master fault at the base of Mt. Epomeo. This tool represents the most advanced remote sensing technique for generating high-resolution digital elevation models.

In this study we present both the workflow and the methodological computing technique followed to generate the most precise high-resolution DTMs, removing the presence of vegetation and buildings. This technology showed a high potential for quantifying the deformation rate of the area by constraining the volcano-tectonic model. The results will be crucial for evaluating the dynamics of seismogenic structures in the framework of the proposed resurgence and subsidence activity in Ischia.

Travertine deposition and fissure ridge development in the geothermal field of Viterbo (Northern Latium, Italy)

Dr. sergio madonna [1]***, Prof. Anna Gandin*** [2]***, Prof. Andrea Brogi*** [3]***, Prof. Enrico Capezzuoli*** [4]

1. *Tuscia University,* ***2.*** *University of Siena,* ***3.*** *Dipartimento di Scienze della Terra e Geoambientali, Università degli Studi di Bari Aldo Moro; Istituto di Geoscienze e Georisorse, CNR-Pisa,* ***4.*** *Department of Earth Sciences, University of Florence*

Several thermal springs (52°C to 65°C) of sulphate-alkaline-earthy waters, used since Roman times, occur west of Viterbo (Latium, Italy) in an area of the large volcanic plateau covered by extensive travertine deposits. This area, with high heat-flow values (200-300 mW/m^2 up to 450 mW/m^2), corresponds to a buried structural high, mainly identified through geophysical data. It corresponds to a Plio-Quaternary horst in which early Miocene thrust and folds related to the Northern Apennine's tectonic evolution and affecting the Tuscan Units are preserved. The substrate of the travertine carbonates consists of a pyroclastic succession derived from three volcanic districts (Cimino, Vico and Volsini, active between 1,35 Ma e 90 ka), which buried the Tuscan Units. The thermal springs are located along the traces of the main oblique-slip and normal faults. Travertine bodies developed and are still developing around them, both for chemical or biological processes, forming shield/crater mounds (Piscine Carletti, Bullicame, Bagnaccio), mushroom-like domes (Paliano) and fissure ridge (Bacucco, Aeroporto, Asinello). The related distal thermal drainage system is characterized by carbonate bodies made of dominant microbial laminites, typical of swamps/palustrine environments and/or shallow lakes filled with mixed thermal and ambient water. Fissure ridges are built up by thin, subvertical crystalline crusts forming two symmetric laminated bodies separated by a longitudinal open fissure, locally filled by banded, onyx-like crystalline carbonate (aragonite and/or calcite). The feature of the flanks of the ridges reflects a sheet of water flowing on the flanks of the slope with laminar or turbulent flux and welling up from an open fracture now dried up for most of its length. The travertine deposition was and is still controlled by the combined effects of different leading processes reconciled in a geothermal setting with continuous tectonic activity.

The youngest Quaternary tectonic crustal stresses in the Bohemian Massif inferred from the faulted lava flow of Komorní Hůrka Volcano (1.1 Ma) (Czech Republic)

Dr. Miroslav Coubal [1], Dr. Martin Šťastný [2], Dr. Jakub Stemberk [1], Dr. Petra Štěpančíková [1], Dr. Jana Schweigstillová [1], Mrs. Dagmar Kořínková [2], Dr. Vladimír Prouza [3]

__1.__ Institute of Rock Structure and Mechanics, Prague, __2.__ Geological Institute, the Czech Academy of Sciences, __3.__ Czech Geological Survey

In order to expand the range of knowledge about the youngest Quaternary tectonic stresses that acted in the Bohemian Massif, the brittle deformation of the lava flow of one of its youngest volcano Komorní Hůrka (0.7 - 1.01 Ma) was studied. Komorní Hůrka Volcano is situated in the Cenozoic seismoactive Cheb basin in Western Bohemia (Czech Republic), which is famous by Pleistocene volcanism, mantle-derived CO_2 emanation and present day, probably fluid-driven earthquake swarms.

Within the observations and measurements on the lava flow, we have identified several generations of striations differing in their morphology, which were successively formed and superimposed one over the other during the last ca. 1 Ma. The measured heterogeneous set of fault slip data was separated into homogeneous sub-sets using an automatic procedure completed by a technique based on recording mutual superposition of striation populations. Both optical microscopy and SEM were used to estimate the original conditions of the individual populations of striations.

Three generations of striations were recognized. The oldest generation of striations (represented by two similar homogeneous sub-sets) were analyzed by optical and SEM microscopes, which revealed their abnormally plastic morphology as well as reduced content of Na, K, and increased content of SiO_2 in the outermost layer of slickensides. This implies that these slickensides were formed during high temperatures, which we interpret as a record of mutual collision of the semi-solidified blocks of the lava flow during the effusion process.

The younger generation of striations was produced in already solidified (hard) rocks by tectonic stress with parameters very close to the present crustal stress as identified from earthquake focal mechanisms in Western Bohemia.

The youngest homogeneous sub-set was reactivated by vertically oriented, nearly uniaxial compression. Due to the low number of assigned/analyzed fault-slip data, we only hypothesize it might be an indication of the action of pressurized fluids. This would imply for example possible dyke emplacement, which might have had also a causal relationship to documented large late Quaternary surface-rupturing earthquakes in the Cheb basin.

Active and capable faults (ACF) at Mt. Etna volcano (Italy): the contribution of field geologists for seismic microzonation analyses and territorial planning

Dr. Raffaele Azzaro [1], ***Prof. Stefano Catalano*** [2], ***Dr. Roberto De Franco*** [3], ***Dr. Edoardo Peronace*** [4], ***Dr. Antonio Torrisi*** [5]

__1.__ Istituto Nazionale di Geofisica e Vulcanologia (INGV) - Osservatorio Etneo, Catania, __2.__ Catania University, __3.__ CNR-IGAG, Milano, __4.__ Istituto di Geologia Ambientale e Geoingegneria (IGAG), Consiglio Nazionale delle Ricerche, Via Salaria km 29,300, Monterotondo Stazione, 00015 Rome, Italy, __5.__ Dipartimento Regionale della Protezione Civile, Regione Sicilia - Servizio Rischio Sismico e Vulcanico

Field evidence of active tectonics at Mt. Etna volcano (Italy) is a widespread and well-known feature since the mid-1800s. Here faults display two end-member modes of rupture mechanism, with different sections of the same fault governed by stick-slip (earthquake-related slip) or stable-sliding behaviour (aseismic creep). While coseismic displacements due to shallow small-size earthquakes (M < 5, depth < 2-3 km) can be impressive (max vertical offsets 90 cm, max strike-slip 50 cm), with end-to-end ruptures up to 8 km, near-continuous ground fracturing produced by fault creep is responsible for significant cumulative displacements in the long-term. Field observations indicate that both phenomena affect mainly the eastern flank of Etna (faults of the “Timpe” system) but also other sectors of the volcano host, although at a lesser extent, not negligible fault slips. Mapping distribution and characteristics of surface faulting in areas lacking of morphotectonic features, has also permitted to recognize hidden faults, i.e. surface breaking faults that do not exhibit a clear and permanent associated geomorphology. These concealed structures, buried by Holocene and historical lava flows, are not isolated but represent discrete segments of major, continuous fault zones. While from a purely scientific viewpoint, studies on surface faulting made possible to constrain seismotectonic models, to produce active fault maps as well as to understand local geodynamics, the impact of the effects produced by capable faults on local communities living on the urbanized flanks of the volcano, is still little investigated. To this end, the Department of Civil Protection of Sicily engaged the “Centro per la Microzonazione Sismica” (constituted by CNR and other research institutions and universities) for a project aimed at preventing and reducing seismic risk in the frame of the regional plan for seismic microzonation (26 municipalities in the Etna region). Here it is presented the task devoted to the characterization of the active and capable faults (ACF); the main activity steps are: 1) collection of literature data on ACF; 2) population of a GIS platform; 3) definition of study areas for geophysical/geotechnical surveys; 4) ACF guidelines for volcanic zones in the perspective of risk mitigation planning for the urban areas.

Surface ruptures accompanying the 2021 Cumbre Vieja volcanic eruption (La Palma, Canary Islands) and their possible relation with an early-stage flank instability

Dr. Giorgio Tringali [1]***, Ms. Marta Masserini*** [1]***, Dr. Raúl Pérez-López*** [2]***, Dr. Inés Galindo*** [2]***, Prof. Alessandro Michetti*** [3]

1. *Università degli Studi dell'Insubria, Como,* ***2.*** *Instituto Geológico y Minero de España IGME-CSIC,* ***3.*** *Università degli Studi dell'Insubria; INGV OV*

Flank instability is an important issue related to many volcanoes because it can lead to catastrophic flank collapses. The Cumbre Vieja 2021 volcanic eruption, started in September 2021, represents a significant event in the study the links between magmatic, volcano-tectonic, and gravitational processes. Between 25th November and 5th December 2021, during the final phase of the eruption, a complex network of fissures affected the NW flank of the volcano, with an "unexpected" trend almost perpendicular to the volcanic slope and to the coastline. Surface ruptures started at the southeastern edge of the main eruptive fissure. In July-August 2022 we mapped the ground ruptures affecting mostly buildings, paved roads but also the 2021 lava flow and volcanic fall-out deposit. We collected structural data along 63 surface ruptures observing mostly pure dilational with minor strike-slip components. The fractures strike is 275° on average with a WNW-ESE trend. We also observed hot gas emissions from some of the eastern ruptures closest to the lowest and late eruptive fissures. From the field observations analysis, it is possible to hypothesize the occurrence of an early-stage instability in the western flank of the Cumbre Vieja volcanic system with a slow sliding toward the sea. Dilational stresses along the instability zone can promote magmatic intrusions as demonstrated by the several eruptive vents aligned along the western flank of the Cumbre Vieja (NW-SE and WSW-ENE). A similar behavior has already been observed during the 1949 eruption where a NNW-SSE fault rupture occurred on the Cumbre Vieja western slope. We infer that the 2021 eruptive fissures and the surface ruptures could be the extension of the 1949 fault system with a propagation of the instability to the NW, that is toward the coastline. After the eruption, no reactivation of these fractures was observed, suggesting that the edifice is not close to collapse, but also the need of ground deformation monitoring. These results can lead to a better volcanic hazard assessment in La Palma Island and also promote in-depth studies on the possibility of flank collapse.

Reconstructing Holocene palaeoenvironmental conditions in the Egyptian Nile Valley using soil rhizoliths

Dr. Kathryn Adamson [1], ***Dr. Angus Graham*** [2], ***Dr. Jan Peeters*** [3], ***Prof. Melanie Leng*** [4], ***Dr. Willem Toonen*** [5], ***Dr. Benjamin Pennington*** [6], ***Dr. Julie Durcan*** [7]

1. *Manchester Metropolitan University,* ***2.*** *Department of Archaeology and Ancient History, Uppsala University, Uppsala, Sweden,* ***3.*** *University of Michigan,* ***4.*** *British Geological Survey,* ***5.*** *Vrije Universiteit Amsterdam,* ***6.*** *University of Southampton,* ***7.*** *School of Geography and the Environment, University of Oxford*

Recent morphosedimentary analysis in the Nile Valley at Luxor (Upper Egypt) shows major changes in River Nile behaviour in response to Holocene climate change. What is more, these large-scale alterations to the fluvial system may have influenced patterns of human activity on the Nile floodplain since the Egyptian Middle Kingdom.

However, palaeoclimate archives from this region are currently scarce, hindering more detailed reconstructions of past environmental change. Importantly, the Luxor alluvium is abundant in rhizoliths; secondary carbonates that form around plant roots. Their microstructures and stable isotopic composition capture environmental conditions at the time of formation, such as aridity and vegetation type. While secondary carbonates, including rhizoliths, have been widely used for arid zone palaeoenvironmental reconstruction elsewhere, their micromorphology has not yet been examined in detail in the Egyptian Nile Valley.

Sediment cores collected across the Luxor floodplain as part of the Theban Harbours and Waterscapes Survey (THaWS) are rich in rhizoliths. Borehole age-depth models are constrained by Optically Stimulated Luminescence (OSL) dates and archaeological analysis of ceramic-rich horizons, yielding basal ages of ~4 ka. These borehole records thus provide an unrivalled opportunity to examine River Nile activity and floodplain conditions in relatively high temporal resolution and in close stratigraphic association with archaeological finds.

Here, we present new insights into the morphology and stable isotopic composition ($\delta^{13}C$ and $\delta^{18}O$) of soil rhizoliths from Luxor in order to: 1) establish Holocene rhizolith formation and palaeoenvironmental conditions on the banks of the Nile, and 2) produce a morphological framework of rhizolith development, applicable in Egypt and elsewhere. Findings will enhance our understanding of Holocene palaeoenvironmental change and human-environment interactions in the Egyptian Nile Valley, and inform rhizolith studies in other arid and semi-arid environments.

Active faults in La Palma (Canary Islands, Spain)

Dr. Miguel Ángel Rodríguez-Pascua [1], Ms. Maria A. Perucha [1], Dr. Nieves Sánchez [1], Dr. Raúl Pérez-López [1], Dr. Inés Galindo [1], Dr. Julio López-Gutierrez [1], Dr. Gonzalo Lozano [1], Dr. Juana Vegas Salamanca [1], Dr. Jose F. During the 2021 La Palma fissural eruption, two faults were identified that controlled the distribution of earthquake hypocentres and lava emission centres. One of these faults has a NW-SE direction (Tazacorte Fault: FTZ) and the other one has an ENE-WSW trend (Mazo Fault: FMZ). Previous work of fault population analysis in La Palma (344 striated fault data distributed in 34 measurement stations; Rodríguez-Pascua et al., 2018 and 2019) indicated that the eruption zone was compatible with an extensional strain ellipsoid and normal-strike-slip directional faults, at the confluence of FTZ and FMZ. The fractures opened during the eruption were mapped in real time and there are more than 400 fracture data associated with the emission centres. Many of these fractures affect houses and studies carried out after the end of the eruption have shown that these two faults moved before, during and after the eruption. Some of the houses affected by the FTZ have been damaged 9 months after the eruption (these houses were not damaged during the eruption). These houses already had repairs made to the same fractures since 1980. The lack of seismicity after the eruption indicates that the movement of the faults is creep and that this was the type of movement they have had at least since 1980, with the exception of the eruptive process and the onset of seismic shocks in 2016. The mapping of these faults (FTZ and FMZ) is important in view of their application in the land use planning needed after the La Palma eruption of 2021.

Tectonic constraints as the origin of heterogeneity in seismic style: new analyses and simulations

Dr. Matteo Albano [1], ***Dr. Davide Zaccagnino*** [2], ***Prof. Carlo Doglioni*** [1]

1. *Istituto Nazionale di Geofisica e Vulcanologia (INGV),* ***2.*** *Department of Earth Sciences, Sapienza University of Rome*

Faults are the boundaries where the slip between contiguous crustal volumes happens. The energy is mainly accumulated in the brittle lithosphere because of the action of tectonic and gravitational forces and it is released according to optimal dissipation criteria. The unbalance of stress components in the Earth's crust, based on the relative motion of crustal volumes, produces a wide pattern of heterogeneities in local tectonics and seismic dynamics. Thrust faulting events, usually featured by dip angles ranging between 5°-30°, mostly take place along convergent plate boundaries and are caused by the elastic strain accumulation, which is released by multifaceted fault slip dynamics, ranging from almost periodic silent events to mega-quakes. Strike-slip-faulting earthquakes localize along steeply dipping faults (70°-90°) or transcurrent plate boundaries and transfer zones. Finally, normal faults develop along rift zones in extensional regimes having intermediate dip (45°-65°), with a dominant gravitational contribution to their energy budget. Structural, morphological, and geophysical differences have been highlighted among the three main tectonic settings. Normal faults cause fracturing mainly concentrated in the hanging walls and spaced clusters of parallel faults across rifting areas. Fractured volumes host complex fluid circulation during the seismic cycle. Intricate geometries are also typical of transcurrent regions, often accompanied by releasing and restraining bends or step-overs and other geological structures shedding light on complex spatial stress patterns. Conversely, thrust-faulting earthquakes usually involve geometrically simpler seismogenic sources. We propose a simple mechanism for faulting inspired by the physical properties of granular matter and optimization criteria to explain differences in seismic activity depending on the tectonic setting: while the dynamics of compressive and transcurrent zones is driven by elastic strain, seismic activity associated with normal faults is mainly fuelled by gravity. Computational simulations support our hypotheses.

Stepwise, earthquake‐driven coastal subsidence in the Ganges–Brahmaputra Delta (Sundarbans) since the eighth century deduced from submerged in situ kiln and mangrove remnants

Dr. Till Hanebuth [1]***, Prof. Hermann R. Kudrass*** [2]***, Dr. Anja Zander*** [3]***, Prof. Humayun S. Akhter*** [4]***, Dr. Anwar Zahid*** [5]

***1.** Department of Marine Science, Coastal Carolina University,* ***2.** MARUM–Center for Marine Environmental Sciences, University of Bremen,* ***3.** Institute of Geography, University of Cologne,* ***4.** Department of Geology, Dhaka University,* ***5.** Bangladesh Water Development Board, Dhaka*

This study reconstructs the coastal subsidence over the past 1,300 years in a mangrove region along the coast of the Ganges–Brahmaputra Delta, an area not affected by anthropogenic interference yet. The relative sea level (RSL) history is based on radiocarbon and luminescence ages measured on 108 submerged kilns and in situ mangrove stumps. While the regional, long-term average subsidence rate is calculated to be 2.7 ± 0.3 mm/yr, modern RSL (including eustasy, isostasy, ocean level, and subsidence) rises by 8.7 ± 0.4 mm/yr. This rate has been balanced by natural sediment accretion so far. A reduction in sediment supply by engineering projects along rivers and coasts may, however, accelerate coastal inundation and retreat. Subsidence has accelerated during specific episodes since the eighth century. A major land-sinking event happened in the eighteenth century, with a downward displacement of 1–2 m, depending on geographic area. We propose that the subduction related 1762 Arakan earthquake caused this sudden lowering. Prior to this event, RSL was nearly stable for 900 years. An earlier major subsidence event occurred around 900 CE, when the land suddenly sank by about 1 m, which also coincided with a major earthquake along the Arakan coast. Event-driven, sudden, significant subsidence, thus, needs to be considered a potential major hazard for coastal Bangladesh.

Plio- early Pleistocene re activation of Levant Fracture system. (Outer shelf,Offshore Lebanon)

Prof. David Iacopini [1]***, Mrs. Marina Dottore stagna*** [2]***, Prof. Stefano Tavani*** [3]***, Prof. Christian Gorini*** [4]***, Dr. Davide Oppo*** [5]***, Prof. Vittorio Maselli*** [2]

1. *DISTAR, Università di Napoli Federico II.,* **2.** *Department of Earth and Environmental Sciences, Dalhousie University,* **3.** *DISTAR, Universita di Napoli Federico II,* **4.** *Sorbonne Universitè, CNRS-INSU, Institut des Sciences de la terre de Paris,* **5.** *School of Geosciences, Louisiana State University at Lafayette*

The eastern Mediterranean Levant Basin is an area where the effect of an adjacent major strike-slip fault in a complex geodynamical context can be tested. In the Lebanese area we explore the offshore expression of the Levant Fracture System (LFS) which are flanking long left lateral transform fault linked to the Dead Sea fault system. By using high quality 3-D seismic dataset and grounding our observations on a detailed seismic mapping of the Messinian to Pleistocene units we produce evidence of the LFS across the shelf edge along the offshore Lebanon. We do show that in addition to the well-known salt tectonic structures, there are clear offshore expression of the LFS which are deforming the Neogene unit (Messinian to late Pleistocene?). The structures in part re activate well known Mesozoic structures and are represented by both anticline and inverted structures. They deform both the Messinian Units (laterally pinching out toward the shelf) and the post Messinian contourite and deep-water system units mapped across the shelf edge . The structures are partly coeval with but un-related to the salt tectonic activity observed in the slope basin offshore Lebanon. We do provide and discuss good examples for those Neogene-Quaternary structures pointing that the main regional tectonic activities persisted to the early Quaternary across the offshore Lebanon.

The peculiar phreato-magmatic "jarosite deposit" in the island of Vulcano (Southern Italy): a significant impact, in terms of volcanic hazard

Prof. Donatella Barca [1], ***Prof. Domenico Miriello*** [2], ***Prof. Gino Mirocle Crisci*** [2], ***Dr. Stefano Marabini*** [2]

1. Universita' della Calabria, 2. Università della Calabria

A very peculiar thin reddish brown layer (on average between 2 cm and 0.1 mm) has widespread mantled most of the island of Vulcano, in Southern Italy, indicatively 500-1500 years B.P. when it was pratically uninhabited. The optical and scanning electron microscopic analyses show that this thin layer coat tit is composed of finely laminated amorphous material alternated with thicker lens-shaped layers with massive structure. The finely laminated portion contains high concentrations of S, Fe, K and Si, while the massive one consists primarily of glass fragments and microphenocrystals.

This deposit is so reasonably related to an eruption of phreato-magmatic type probably caused by the interaction between a magma batch (belonging to the high potassium series) which produced glass fragments and minerals in the massive portion, and a geothermal brine responsible of the formation of the finely laminated portion.

It is suggested that the involvement of a high saline component in the eruptive process generated a particular type of eruption comparable at a "hot hurricane", which have been characterized by relatively small quantities of material with a very high ejection energy. The pyroclastic reddish brown deposit formed during this event has been named "jarosite deposit" because of its considerable jarosite – $KFe_3(SO_4)_2(OH)_6$ – content.

The study of this peculiar phreato-magmatic material, which in the case of the island of Vulcano suggests has been ejected from a vent located to the north of the crater named Fossa.

The repetition of these events, due to the particular eruption type, would have a relevant impact, in terms of volcanic risk. The specific knowledge of these phenomena allows to better characterize the modalities and timing of the risks in insular and coastal volcanic areas, especially in highly populated ones.

Poster - sessions 6, 33, 145, 156, 160, 183

The case study of Corvo Island (Azores Archipelago) as a key for undersanding the shelf formation of ocean volcanic islands.

1. *Instituto Dom Luiz - University of Lisbon,* ***2.*** *Instituto Hidrográfico,* ***3.*** *Department of Earth Sciences, Sapienza University of Rome,* ***4.*** *School of Earth and Environmental Sciences, Cardiff University,* ***5.*** *Department of Earth and Environmental Sciences, Columbia University*

Volcanic ocean islands are the present-day subaerial remains of much larger volcanic edifices that have grown from the ocean floor. Once the primary volcanic progradation is over, marine erosion (and mass-wasting) processes start dismantling the coastal areas and consequently form the island shelves. Shelf width and shelf edge depth can provide relative age constrains and eventual uplift or subsidence of the island. This work presents some quantitative preliminary results about the morphological evolution of Corvo Island (Azores Archipelago), through an integrated onshore/offshore approach. We interpreted data including subaerial (aerial photogrammetry, volcano-stratigraphy) and submarine datasets (multibeam bathymetry and high-resolution reflection seismics). This island basically consists on a main volcanic edifice so it can be considered a natural laboratory for understanding shelf evolution. The shelf surrounding Corvo is irregular both in width and edge, showing the widest and deepest erosive basement on its western side. A comparison between the assumed original volume of the subaerial edifice and its present volume allows estimating the total erosion on the island. Considering a maximum age of 1-1.5 Ma for Corvo, rough estimates of the erosional rates based on the shelf width were obtained. The Western shelf, being more exposed to waves, is wider than the remaining ones and so yields the highest values (1.87-2.80 mm/year). Differently, the analysis of cliffs erosion on the island of Corvo based on aerial orthophotos since 1955 till 2022, indicates values that are one order greater than the shelf rates. Once again, the western cliffs, being more exposed to marine erosion, are taller than the remaining ones and so yields the highest retreat (~0.9 cm/year). The comparison between short-time and long-time erosive rates is something that has never been done before. Therefore, these results will provide a more comprehensive understanding on the evolution of volcanic islands shelves.

Spatial variabily of nearshore clinoform bodies on the southern insular shelf of Madeira Island: the influence of sediment supply and inherited bathymetry.

Ms. VIVIANA BELVISI **[1]**, ***Dr. Rui Quartau*** **[2]**, ***Prof. Claudia Romagnoli*** **[3]**, ***Prof. José Madeira*** **[4]**, ***Dr. Aurora Bizarro*** **[2]**

1. *Istituto Dom Luiz - University of Lisbon,* ***2.*** *Instituto Hidrográfico,* ***3.*** *University of Bologna,* ***4.*** *Instituto Dom Luiz - University of Lisbon*

Nearshore clinoform bodies can be observed on the submarine parts of a variety of geological contexts such as continental margins and volcanic islands. These clinoforms have been suggested to form by wave action during storms that moves sediments from the nearshore and depositing them offshore where wave action falls behind the threshold of motion. On the bathymetry, clinoform bodies have a cross-shore sigmoidal geometry composed by a nearshore flat morphology (topset) separated from a steeper morphology (foreset) by a pronounced edge (rollover point). Further offshore, the steeper part of the clinoform gives place again to a flatter morphology (bottomset). On seismic profiles, their architecture is characterized by basinward surfaces that can either be obliqual or sigmoidal. The dimensions and shapes of clinoforms have been related with their depositional environments, including sediment supply, the energy of transport and grain sizes. Thus, their superficial and seismic characteristics allow understanding the hydrodynamism of the area where they developed. Madeira Island is an ocean volcanic island with a high relief and incised by a well-developed drainage mainly composed by torrential streams. Its southern shelf is not homogenous in what respects to its width, steepness and sediment grain-sizes. Although, the southern shelf is submitted to the same wave regime there is however, a great spatial variability of the nearshore clinoform bodies in what respects their dimensions, continuity, thickness and rollover point depths. The analysis of the bathymetry, seismic profiles and sediment grain-sizes, allowed the definition from west to east, of four different sectors, which are mainly controlled by sediment supply and the inherited topography, rather than wave energy.

Submarine sedimentary instabilities on the Palomares Continental Margin (W Mediterranean). Morphometry and distribution

The Palomares Continental Margin, located in the Iberian Mediterranean margin, encompasses a narrow continental shelf (down to 120m water depth), and a continental slope that extends down to 2500m water depth. Different tectonic and sedimentary features at various scales define the heterogeneous, abrupt and irregular physiography of the margin. The most important features are the morphological highs (Aguilas, Abubacer and Maimonides); prominent submarine canyons (Gata, Almanzora-Alias-Garrucha and Aguilas); morphosedimentary features associated with contour currents (mainly in the continental slope) and sedimentary instability deposits of different size distributed throughout the margin.

The analysis of medium and high resolution, 50m and 15 m respectively multibeam bathymetric data has allowed to build a regional inventory of 937 events of sedimentary instability, defined by their scars and head areas. Mass-wasting affect more than 821 km^2 and mobilize approximately 10.34 km^3 of sediment along the margin. Regional-instabilities inventories are very useful quantifying the role of these processes in the geomorphologic evolution of one area but also constitute a first step towards the assessment of landslide-related hazard. In addition to size, other morphometric parameters such as scar length and sinuosity, head area, regional gradient, scar height and scar gradient have been included in the inventory to have a good selection of variables that characterize the instability events.

Statistical analyses revealed that the cumulative distribution of the landslide area can be characterized both by inverse power and log-normal distributions. In the first case, a partial fit is achieved explaining two orders of magnitude (major events) of the whole dataset. The log-normal function is adjusted to the entire sample events. This fact would lead to define both a characteristic event size determined by the geomorphological conditions and a variance linked to the characteristics of the main triggers that in the area would be the earthquakes.

Liquefaction and evolution of the shallow Garrucha submarine canyon head

Dr. Jose Nespereira [1], Dr. David Casas [2], Dr. Mariano Yenes [1], Dr. Serafin Monterrubio [1], Prof. Daniele Casalbore [3], Ms. Nieves López-González [4], Dr. Belen Alonso [5], Ms. Maria Eugenia Martin [6], Mr. Ruben Ruiz [6], Mr. Angel Tijera [6], Dr. Sara Lafuerza [7], Dr. Jaume Llopart [5]

The aim of this work is to establish the role of liquefaction on the shallow Garrucha submarine canyon head, in the W Mediterranean Sea. A geotechnical approach has been used to determine the liquefaction potential, combining *in situ* CPTu data as well as undrained cyclic direct simple shear (UCDSS) laboratory tests on sediment cores. All the data have been analysed considering the simplified procedure for evaluating soil liquefaction potential. The use of both, laboratory and CPTu tests for liquefaction assessment increase clearly the confidence of the results obtained.

Sediments sampled around the canyon head are sands with a very low fine sediment and without plasticity. Three series of UCDSS tests were carried out under vertical loads equivalent to 1.8 m, 3.7 and 12.3 meters below sea floor (mbsf) and the results indicate that liquefaction is clearly possible in the area. On the other hand, the cyclic resistance ratio (CRR) provided by the CPTu tests for depths up to 20 mbsf confirmed the liquefiable character of the sediments in the area specially at depths of more than 3 m below seafloor and where low-permeability intervals intercalated are detected.

The high probability of triggering liquefaction processes highlights a phenomenon normally underestimated in submarine environments. This process may be associated to minor morphological effects or major morphosedimentary consequences that may be involved in the evolution of the canyon head as well as the downslope transport of sediment stored on the upper part of the canyon.

The results reported here are also significant in terms of the shallow environment studied and the proximity of coastal infrastructures such as the Garrucha harbour. This implies that any stability model for hazard and risk assessment must include the dynamic properties of the sediments.

Seismic stratigraphy and geological structure of the Plio-Quaternary deposits on the Korea Strait shelf, Korea: Implications for tectonic effects and sea-level changes

Dr. Dong-Geun Yoo [1], ***Ms. Bo-Ram Lee*** [2], ***Dr. Gwang-Soo Lee*** [1], ***Dr. Seok-Hwi Hong*** [1], ***Dr. Seong-Pil Kim*** [3], ***Dr. Gil Young Kim*** [1]

1. *Korea Institute of Geoscience and Mineral Resoiurces,* ***2.*** *Korea Institute of Geoscience and Mineral Resources (KIGAM)„* ***3.*** *Korea Institute of Geoscience and Mineral Resources (KIGAM)*

On the basis of high-resolution seismic data from the Korea Strait, the shelf sequence consists of four seismic units, namely, Pliocene (III), Lower Pleistocene (IIB), Upper Pleistocene (IIA), and Holocene (I), respectively. Vertically, with the exception of unit I, the units show a series of superimposed prograding wedges that thicken seaward. A structural high, including several faults and folds, occurred in the northern part of the Tsushima Island, extending northeastward to the Dolgorae Thrust Belt at the southern margin of the Ulleung Basin. In this study, we deduced that the deformed zone was formed due to compressional deformation associated with back-arc closure that occurred after the extension of the East Sea. Most of the faults and folds oriented in NE–SW or NNE–SSW directions mainly developed in the lower two units (III and IIB). The lower two units were also significantly deformed, whereas the two overlying units remained relatively undeformed. This indicated that, during the Pliocene and Lower Pleistocene (units III and IIB), sedimentation was mainly controlled by tectonic activities, whereas sedimentation after the Lower Pleistocene (units IIA and I) was mainly influenced by periodically repeated sea-level changes rather than tectonic effects.

A morphotectonic investigation targeting an onshore and offshore setting: methodologies and examples from a preliminary case study on the Maltese archipelago

Dr. Monica Giona Bucci [1], ***Prof. Aaron Micallef*** [1]

1. *University of Malta*

The last decade has seen a growing interest for the geomorphic research to integrate datasets from multidisciplinary and interdisciplinary techniques. This approach is particularly effective when working at the geomorphic evolution of coastal areas, Quaternary developments, and geohazard analysis. Our contribution reveals the first attempt of a tectono-geomorphic analysis for the areas onshore and offshore of the Maltese Islands, extending the use of common techniques for terrestrial morphometric analysis to the area offshore. For the offshore portion, a mosaic of three datasets was created and then resampled at the resolution of 30 m in order to increase the computational efficiency of our analysis. This dataset was obtained from a combination of surveys carried between 2012 and 2021 (including bathymetry retrieved from research cruises and airborne LiDAR). The dataset for the area onshore, originally at the resolution of 3 m, was also resampled at 10 m and then at 30 m, to guarantee consistency with the analysis of the dataset offshore. The morphometric analysis was performed at the resolution of the final dataset (30m) but also re-ran at finer resolution across those portions of the study area that allowed a higher resolution in data. The dataset obtained was refined for hydrological analysis by applying smoothing filters, voids fillings and artefacts removal. Our results revealed that the river organization appeared as dendritic for the onshore portion of the island of Gozo, while it turned to be trellis and oriented parallel to the strike (NNW/SSE) of the major structural feature of the offshore graben on the east side of the archipelago. In addition, the streamnet followed an E-W orientation across the onshore portion of the Island of Malta, in agreement with the predominant structural features observed. Low values of river steepness index (K_{sn} <10) for both the offshore and onshore areas are measured, while knickpoints are largely concentrated where high differences in the topographic gradient are recorded, in coincidence of lithological contacts, structural features and gullies erosion. This preliminary investigation links the drainage anomalies outlined by knickpoints and *Ksn* with a tectonic and/or climatic cause that could explain its neotectonic evolution.

Reconstruction of former landscapes and Late Quaternary sea level changes in the Krka River mouth area

1. *Croatian Geological Survey, Department of Mineral Resources,* **2.** *Laboratory of Marine Geology and Physical Oceanography, Department of Geology, University of Patras, 265 00 Rio Patras, Greece*

Most of the eastern Adriatic rivers have cut their rocky canyons for the last time during the Last Glacial Maximum (LGM). In that period the sea level was up to 130 m lower than today and karstic rivers originated as incised valleys, with a sediment bypass to the shelf and formation of a delta at their river mouths. The Krka River mouth on the eastern Adriatic Coast (EAC) went through intensive paleoenvironmental change since the LGM. The paleoenvironments evolved from an offshore extensive alluvial plain and a lowstand shelf-edge delta in the area between the island of Žirje and the mainland, to the present-day onshore salt-wedge karst estuary and the Skradinski buk tufa waterfalls. The architectural units and paleoenvironmental changes were studied by a multidisciplinary approach, combining multibeam, seismics and dated sediment cores.

In the area of lowstand alluvial plain and shelf-edge delta a total of 37 seismic profiles were recorded, while in the incised valley and present estuary a total of 119 seismic profiles were recorded and correlated with seven long sediment cores. The deltaic deposits consist of stacked progradational wedge-shaped units with penetration of acoustic signal up to 40 m.

Postglacial sea level rise (approx. 17000–7000 y BP) flooded a wide delta with a formation of shallow brackish environments and an early Holocene estuary between the island of Žirje and mainland. Furthermore, during that period favorable conditions were established for freshwater tufa barriers growth and the deposition of fluvio-lacustrine sediments in the onshore part (Prokljan Lake). In continuation of rapid sea level rise, the sea started to flood Prokljan Lake and the tufa waterfalls at the beginning of the Holocene with a formation of the salt-wedge estuary and deposition of marine/estuarine sediments at approx. 7000 ky BP.

This study highlights the complexity of investigated system which is under the control of several factors, mainly the sea level changes, climate, sediment supply and geomorphology and offers a valuable new results and information on sea level changes and paleoenvironmental variability along the EAC.

This work was supported by the Croatian Science Foundation project QMAD (HRZZ IP-04-2019-8505).

Insular shelves as proxy for reconstructing Late-Quaternary local sea-level and paleogeographical changes in volcanic islands

Prof. Claudia Romagnoli [1], ***Prof. Daniele Casalbore*** [2], ***Prof. Federico Lucchi*** [3], ***Dr. Rui Quartau*** [4], ***Dr. Alessandro Ricchi*** [3], ***Prof. Claudio Antonio Tranne*** [3]

1. *University of Bologna,* **2.** *Department of Earth Sciences, Sapienza University of Rome,* **3.** *Department of Biological, Geological and Environmental Sciences, University of Bologna,* **4.** *Instituto Hidrográfico*

Insular shelves on volcanic islands form essentially through marine erosion of edifices during stages of reduced or inactive volcanism, and are representative of their original extension. In particular, the shelf edge is a marker of the relative sea level at the moment of shelf formation, being a useful indicator of the interaction between tectonics, volcanism and sea level changes.

The distribution and morphological characteristics of the insular shelves around Salina Island (Aeolian Arc, Southern Italy) including the shelf-edge depth, are taken as a proxy for the relative age attribution of the volcanic edifices on which they were carved, giving insights on the chronological development and early emergence of the island. Larger and deeper shelves (shelf edges over 125 m depth) experienced wave erosion during successive sea-level fluctuations and subsidence after their formation, and are thus indicative of a relatively older age of the eroded volcanic edifices, largely dismantled and, in some cases, not more documented on land. Narrower shelves have a lower evolutionary maturity and formed where younger volcanic edifices are present. Their shelf edges, mostly lying at -110 m depth, suggest that these coastal sectors were relatively stable after erosion during the Last Glacial Maximum. By integrating these data with onshore geological field studies, we estimated relevant paleo sea level positions from i) the erosive shelf edges recognized offshore at different depths and ii) the raised terrace inner margins exposed subaerially at different elevations. Compared with the eustatic sea levels at the main highstands (for the raised terraces) and lowstands (for the submerged shelf edges) derived from the literature, these paleo sea level markers allowed us to quantify the pattern, magnitude and rates of vertical movements affecting the different sectors of Salina since the time of their formation. The crustal vertical deformation through time shows alternating uplift and subsidence, respectively outlined for the last 124 ka (MIS 5.5, Last Interglacial) and for the time interval between 465 ka (MIS 12) and 124 ka). This behaviour likely suggests a major tectonic and geodynamic change and variation of the stress regime acting on the Aeolian sub-volcanic basement.

Uranium series disequilibrium(238U-230Th) dating of zircon in trachyte from Jeju island, South Korea

Dr. Youn-Joong Jeong [1]

1. Korea Basic Science Institute

Uranium series disequilibrium dating (^{238}U-^{230}Th) has been considered an attractive tool for Quternary volcanic rocks dating. In Jeju Island, South Korea, there are many Quaternary volcanic rocks that can be used for uranium series disequilibrium dating. Among them, trachytic rocks are observed in Mosewat trachyte in the northwestern part of Backrokdam in Mt. Hallasan, Hangpaduri in the north of Jeju Island, and Jejigioreum volcanic cone in Bomok port, Seogwipo-si.

In this study, Cl imaging and uranium series disequilibrium dating of zircons mineralized from trachytic rocks collected from 6 areas in Jeju Island, including Mosewat trachyte, were performed using Laser Ablation Multi Collector Inductively Coupled Plasma Mass Spectrometer(LA-MC-ICPMS) of the Korea Basic Science Institute. The analysis conditions of LA-MC-ICPMS were 30 μm for beam size, and the analysis time was 30 sec. The analysis points of zircon grain ranged from 16 to 34 depending on the rock body.

Among the analyzed samples, trachyte rock with the oldest age, Jejigioreum showed an age of 296Ka, and Mosewat trachyte showed a younger age of 28.8Ka. Jeju Island is a volcanic island located at the southern edge of South Korea and represents a volcano located on the Eurasian continental margin. We will report the ^{238}U-^{230}Th age dating of zircons from the Middle Pleistocene to the Holocene and discuss their mineralization time scale and the formation history of volcanic stratigraphy.

Quaternary volcano-tectonic morphology in the lower slope of Canary Islands (Canary Basin)

Dr. Juan-Tomás Vázquez [1], ***Mr. Ricardo León*** [2], ***Dr. Olga Sánchez-Guillamón*** [1], ***Dr. Desirée Palomino*** [1], ***Ms. Teresa Medialdea*** [2], ***Mr. Luis Miguel Fernández-Salas*** [3], ***Mr. Luis Somoza*** [2]

__1.__ Instituto Español de Oceanografía (IEO, CSIC), Centro Oceanográfico de Málaga, __2.__ Instituto Geológico y Minero Español, CSIC, Madrid, __3.__ Instituto Español de Oceanografía (IEO, CSIC), Centro Oceanográfico de Cádiz

The eastern side of the Canary Basin (NE Atlantic Ocean) corresponds to the interference of the western Africa continental margin and a volcanic seamount-islands chain. The lower slope is developed to the west of the Canary Islands. This slope segment is characterized by the influence of several processes: tectonism, volcanism and mass transport deposition. It has been differentiated morphological elements of tectonic, volcano-tectonic, and volcanic origin controlling the current seafloor and the sedimentary flows of the lower slope.
Most of the differentiated structural features correspond to linear scarps and ridges following NNE-SSW trends. They are interpreted as subvertical faults, mostly normal, and subparallel anticline-syncline to monocline folds, respectively. In addition, pronounced escarpments and related wide linear depressions cross the area with WNW-ESE to W-E trends, which are formed concerning oceanic fracture zones. Volcano-tectonic reliefs include the Garoé bulge which is a kilometric-scale structure, 78 m high, with an elliptical shape that is crossed by normal faulted depressions in its summit and flanks; and subcircular to elongated domes are identified due to the merging of several structures, with predominant NE-SW trends. Both types of structures have been related to sills intrusions. Finally, volcanic edifices are constituted by hundred of mounds, hills and seamounts. Mounds are distributed in NNE-SSW trails although isolated edifices are also observed. Their shapes vary from subcircular cones to mostly irregular and elongated crests. Hills and seamounts are randomly distributed in the study area but they are WNW-ESE aligned in the Southern Canary Islands Volcanic Province. They have a great variety of shapes, mostly irregular and ellipsoidal although some elongated ones are also identified. They are built by magmatic and/or hydrothermal extrusion events.
The trends of these tectonic and volcanic reliefs matching with the oceanic fabric, NNE-SSW normal faults related to old ocean spreading axis, and WNW-ESE oceanic fracture zones evolved from transform faults. The current expression on the seafloor corresponds to a volcano-tectonic activity from the Middle-Late Miocene to the Quaternary. This morphological model is a study case for deeply slope areas controlled by tectonic deformation and volcanic activity during the Quaternary.

Geomorphology and sub-surface stratigraphy of a Mediterranean shelf receiving minor fluvial input: The imprint of relict landscapes

***1.** Instituto Andaluz de Ciencias de la Tierra (IACT), CISC-UGR,* ***2.** Instituto Andaluz de Ciencias de la Tierra (IACT), CSIC-Universidad de Granada,* ***3.** Departamento de Estratigrafía y Paleontología, Universidad de Granada,* ***4.** Instituto Español de Oceanografía (IEO, CSIC), Centro Oceanográfico de Málaga,* ***5.** Institut de Ciències del Mar (ICM CSIC), Barcelona, Spain,* ***6.** Instituto Español de Oceanografía (IEO, CSIC), Centro Oceanográfico de Cádiz,* ***7.** Department of Geoscience, Aarhus University,* ***8.** Departamento de Ciencias de la Tierra, Universidad de Cádiz,* ***9.** IOCAG, Universidad de Las Palmas de Gran Canaria*

Narrow continental shelves such as those surrounding the Mediterranean basin are usually dominated by active depositional features such as major prodeltaic wedges located off major rivers (e.g. the Gulf of Lions, the northern Adriatic Sea), or by infralittoral wedges in settings where fluvial supply is more limited and hydrodynamic regimes are more energetic. However, the knowledge of the geomorphological patterns of undernourished shelves remains much less documented. In this contribution, we aim to characterize the submarine geomorphology and the sub-surface sedimentary bodies of a shelf sector located west of the Guadalfeo River, a major regional source in the northern margin of the Alboran Sea, where fluvial supply is provided by small seasonal rivers. To reach those goals, we analysed a data base comprising multibeam bathymetric and backscatter data, seafloor video images and Parasound acoustic sections.

The studied shelf exhibits a distinctive zonation, where three major domains could be characterised. In the inner shelf, the most significant depositional bodies are composed by wedge-shaped deposits with limited lateral extent. Over the surface, several geomorphic indicators reveal the occurrence of high-energy processes in relation to the seasonal inputs of the Verde and Seco rivers. Recent to modern sedimentation seems to be much reduced distally. The middle shelf is marked by two main breaks of slopes, the surficial expression of highly reflective depositional bodies, likely marking the location of ancient paleo-shorelines and extensive development of paleo-coastal plains. The outer shelf is a flat domain covered by several elongated sedimentary bodies, which are disposed oblique to the middle shelf paleo-shorelines. Below those bodies, sub-surface architectures exhibit several unconformity-bounded regressive wedges.

We discuss the shelf zonation observed in the study area considering the confinement of recent infralittoral and prodeltaic wedges to the inner shelf, the preservation of ancient landscapes in the middle shelf, and the record of sediment transport dynamics during postglacial phases of shelf flooding in the outer shelf.

Insights into the 1977 Gioia Tauro Landslide: role of shelf indenting canyons and submarine depositional terraces.

***Dr. Angela Alla* [1], *Prof. Daniele Casalbore* [2], *Prof. Francesco Chiocci* [3]**

***1.** CNR-IGAG, **2.** Department of Earth Sciences, Sapienza University of Rome, **3.** university of Rome Sapienza*

Submarine landslides are a major threat for coastal infrastructures. A key example is the event occurred on 12th July 1977, when tsunami waves up to 5 meters high hit the coastline during the construction of the port of Gioia Tauro, (Southern Tyrrhenian Sea, Italy), causing severe structure damages. The event is still poorly understood because of lack of detailed data before the landslide and paucity of scientific studies afterwards. In this study we combined literature data, unpublished technical reports, detailed historical and present-day bathymetric analyses to achieve a better comprehension of the event dynamics.

Results show that: (1) a canyon head is present in front of the port and the seabed is, and was before the slide, characterized by the presence of a submarine depositional terrace (SDT) all along the coastline, made up of prograding sand and gravel; (2) before the failure event, a large amount of sediments derived from port excavation was progressively dumped within the canyon head and above the SDT. This generated a partial infilling of the canyon head and increased the progradation of the SDT; (3) the landslide caused both the collapse of dumped sediments, mainly within the canyon head, but also the failure of a ~2km stripe of SDT on the neighboring coastline; it is worth to notice that the failure affected not only the dumping but also the sediment pre-existing port construction. Therefore, we hypothesize that the Gioia Tauro event was a complex progressive submarine landslide starting at canyon head and propagating retrogressively toward the SDT. The landslide was probably triggered by the weight of the dumped material above the SDT that was present inside the canyon head. Then the failure affected the SDT outside the canyon and this probably played a key role in tsunami propagation. We conclude that submarine depositional terrace may play a relevant role in the generation and propagation of nearshore tsunamigenic landslides. Further studies on these sedimentary bodies are therefore extremely relevant for marine geohazard assessment.

Sedimentological and morphological expressions of glacial floods in the area of the Saalian Glaciation in Poland

Dr. Małgorzata Frydrych [1], ***Dr. Zbigniew Rdzany*** [1]
1. University of Lodz, Faculty of Geographical Sciences, Department of Physical Geography

Glacial floods constitute a very important factor in shaping the forelands of contemporary glaciers. They also had a large-scale impact on areas glaciated during the Pleistocene – both during the most recent glaciation (Weichselian, Vistulian), and – as indicated by the latest research in Poland – also in the area of the Saalian Glaciation.

The most typical sediments interpreted as traces of glacial flood in the analysed area include the following: massive gravels and boulders, gravels and boulders with normal and reverse grading, matrix-supported massive gravels, planar cross-stratified gravels with boulders, low-angle and horizontally stratified gravels and sands. These sediments fill, often completely, erosional channels. They also occur in the form of continuous fluvioglacial covers. Common, characteristic forms include gravel dunes of up to 2.5 m of height, usually buried. Coarse-grained flood sediments are often found near fine lacustrine sediments, resulting in density deformations. Morphological record of glacial floods in the study area is generally sparser than in the areas of the Weichselian Glaciation. It underwent considerably more prolonged modifications from various morphogenetic factors (fluvial and aeolian erosion and accumulation, processes related to the occurrence and degradation of long-term permafrost, denudation processes). The most distinct forms include erosional valleys, cut into end moraines and moraine plateaus, which carry off water in the glacier foreland, and which are contemporarily drained by disproportionately small watercourses. Their widths reach up to 2-5 km. The presence of erosional terraces and several generations of suspended cuts indicates that these runoff paths were used multiple times during flood events. Traces of a glacial flood in the outwash plain have been preserved in the form of numerous kettle holes left after melted blocks of dead ice, and indistinct dunes of 0.5-1 m of height with an amplitude of 60-70 m.

As follows from the research done by the authors in recent years, the impact of glacial floods in areas of the Saalian Glaciation in Poland was significant. The sedimentological record of these processes is very well preserved, whereas in relief it is varied as a result of various long-term destructive processes of the postglacial period.

Morphological characteristics of eskers in Poland

Dr. Małgorzata Frydrych [1]

1. *University of Lodz, Faculty of Geographical Sciences, Department of Physical Geography*

The purpose of the research is to conduct morphometric analysis of approximately 300 eskers in Poland, to the south of the Last Glacial Maximum. The analysed forms originated during the Saalian and Elsterian glaciations. There is still insufficient knowledge about eskers formed within the extent of ice sheets older than the Weichselian or Wisconsin Glaciation. Studies tend to focus on areas with a high density of eskers formed on hard bedrock. Eskers of the study area were formed on permeable, soft bed, composed of glacial and glaciofluvial sediments. The eskers were delineated on the basis of the Detailed Geological Map of Poland 1:50 000, topographic maps 1:10 000 and DEM 1m. The morphological analysis included their length, maximum width, elongation, fragmentation, sinuosity, orientation, presence of tributary ridges and their order. In the analysed area of Poland, eskers of 1-3 km in length prevail. The maximum length slightly exceeds 10 km. They are characterised by the average maximum width of 250 m and slight predominance of straight over sinuous forms. They are built of elongated ridges with only 15.5% of gaps in their total length. 35% of eskers have tributary ridges of maximally second order. The distribution and morphological characteristics of eskers of the study area were mainly influenced by the origination of forms on a permeable substrate. The eskers' features support the theory of predominance of the synchronous model of esker formation in this area. Morphological parameters depend on complex genesis of some eskers and superimposition of open crevasse sediments over the subglacial facies. The important factor is the formation of eskers during older glaciations (MIS6-12) and their subsequent transformation and erosion under variable climatic conditions. The presented study broadens the knowledge of eskers originated during older glaciations. It also provides new insights into the nature of esker formation and subglacial meltwater drainage in the area of soft bed.

Distribution and age of periglacial ramparted depressions in East Anglia, United Kingdom

Dr. Benjamin Boyes [1]***, Dr. Lorna Linch*** [2]

1. *Department of Geography, University of Sheffield,* ***2.*** *University of Brighton*

Relict periglacial ramparted depressions (PRDs), believed to be pingo scars, are mapped extensively across East Anglia (United Kingdom) using LiDAR and field surveys, and their topo-climatic origins, relative age, and evolution are examined.

Pingos are a type of ice-cored hill that develop in permafrost, i.e. perennially frozen ground. They are formed either where water is injected upwards under hydraulic pressure, or where water that is trapped between layers of frozen ground becomes pressurized and subsequently erupts upwards. PRDs are thawed products of ice-cored hills, and are characterised by ramparted, circular depressions. However, PRDs may be expressed in a variety of forms due to erosional/depositional histories – especially where agricultural practices have altered the landscape.

PRDs (~10-30 m diameter) are identified across East Anglia and can be used for reconstructing former permafrost environments and palaeoclimates. PRDs are concentrated in valleys and scattered across hillsides, suggesting pingo formation favoured wetter environment as expected in the valleys. Pingo formation is thought to have occurred during the Late Devensian (MIS 2) when the last British Ice Sheet flanked the East Anglian coastline; pingo degradation, and subsequent PRD formation, likely occurred during the Younger Dryas-Holocene transition (*c.* 11.7 ka) in response to climate warming.

This dataset of PRDs can also be used to better understand human-landscape interactions. Extant PRDs in coppiced woodland contain ephemeral ponds, suggesting that numerous pond environments may have existed across East Anglia throughout the Holocene. Archaeological remains such as heat crackled flint and bone found within and adjacent to PRDs suggests humans have utilised and/or infilled ramparted depressions across the landscape, perhaps for thousands of years.

New data about timing of late Weichselian Scandinavian Ice sheet (MIS-2) in northeastern Germany - lithostratigraphical investigations of tills and OSL-datings from a pipeline trench

Dr. Andreas Boerner [1], *Mr. Alexander Fülling* [2], *Mr. Ulrich Müller* [3]

1. State Agency for Environment, Nature Conservation and Geology Mecklenburg-Vorpommern, 2. Albert-Ludwigs-Universität Freiburg, 3. Schwerin

The NEL gas pipeline trench gave in 2012 excellent insights into the uppermost Quaternary sections. Several sites across the basin were sampled for lithostratigraphical investigations of uppermost till layers, local sedimentological investigations as well as dating by OSL.
According to several new published OSL results in Mecklenburg-Vorpommern at southwestern Baltic Sea coast the Scandinavian Ice Sheet (SIS) reached its Last Glacial Maximum (LGM) during Marine Isotope Stage 2 (Brandenburg-phase, MIS-2). In general the ice front retreated from this position, interrupted by several short periods of readvance or stillstand during e.g. the Frankfurt(Oder)-subphase or the transgressive Pomeranian phase (c. 20-19 ka). For till gravel composition and lithostratigraphy from uppermost till layer several samples has been taken for petrographical analysis of small gravel till clasts using former GDR standard TGL 25232 (1971, 1980). The majority of samples from upper till contains clasts from eastern Baltic region e.g. Palaeozoic limestones and to a minor extent of sandstones, quartzites ,and Palaeozoic shales (PS), and representing a typical till clast composition of tills of Late Weichselian glaciation (MIS 2).
Local results from 'Dobbiner Plage' indicate that during deglaciation of the Frankfurt(Oder)-subphase (W1F), a river system and a local ice-dammed lake existed in the glacigenic depression. The glaciofluvial phase of W1F-deglaciation is represented by cross bedded gravelly sand deposits and has been OSL dated to ~21 – 20 ka. On top of the glaciofluvial sequence, periglacial structures like meso-scale frost cracks and large-scale frost wedge pseudomorphs with maximum of 2 m depth were detected. The OSL dates suggest that cover sands (mainly aeolian) infilled the open ice wedges between 19.5 – 17.3 ka. The timing of periglacial encroachment with opening and filling of ice wedge polygons therefore well correlates with cooler period of Pomeranian ice transgression phase (W2) and the beginning deglaciation.
OSL measurements were performed on quartz of the fine to medium sand fraction (90-200 µm) using a standard SAR protocol on 2-millimeter aliquots. The OSL properties of the measured quartz were good and in most cases the grains were well bleached during the last sedimentation cycle as shown by the narrow paleodose distributions.

Ice buttressing controlled rock slope failure on a cirque headwall, English Lake District

Prof. Paul A. Carling [1], ***Dr. John D. Jansen*** [2], ***Dr. Teng Su*** [3], ***Dr. Jane Lund Andersen*** [4], ***Dr. Mads Knudsen*** [4]

1. University of Southampton, 2. Czech Academy of Science, 3. Chinese Academy of Sciences, 4. Department of Geoscience, Aarhus University

Rock slope failures in the English Lake District have been associated with deglacial processes after the Last Glacial Maximum, but controls and timing of failures remain poorly known. A cirque headwall failure was investigated to determine failure mechanisms and timing. The translated wedge of rock is thin, lies on a steep failure plane, and yet the friable strata were not disrupted by downslope movement. Fault lines and a failure surface, defining the wedge, were used as input to a numerical model of rock wedge stability. Various failure scenarios indicated that the slope would have failed catastrophically, if not supported by glacial ice. The amount of ice required is insubstantial, indicating likely failure during thinning of the cirque glacier. As ice retreated, the wedge was lowered slowly down the cirque headwall slowly exposing the failure plane. A ^{10}Be exposure age of 18.0 ± 1.2 ka from the outer surface of the wedge indicates late Devensian de-icing of the back wall of the cirque, with the upper portion of the failure plane exposed at 12.0 ± 0.8 ka. These dates suggests that a small buttressing ice mass lingered in the cirque for several millennia after general deglaciation of the area. The exposure age of 12.0 ± 0.8 ka represents a minimum age, as the highly-fractured failure plane likely experienced post-failure mass wasting. Considering the dates, it appears unlikely that the cirque was re-occupied by a substantial glacial ice mass during the Loch Lomond Re-advance or during the Younger Dryas Stadial.

Proglacial areas belong to one of the most dynamic landscapes and are important indicators of changes related to climate warming. Systematic observation of landforms in the glacier forelands, combined with measurements of changes in their volume, allows for estimating the rate of the changes taking place and a better understanding of the processes that generate these changes. In this study, short-term (2014, 2016, 2021, 2022) transformations of the proglacial landscape in front of Kvíárjökull, SE Vatnajökull, Iceland, were quantified using a time-series of unmanned aerial vehicle (UAV) surveys processed through structure-from-motion (SfM) workflow to produce digital elevation models (DEMs) and orthomosaics. We selected four areas representing different landform assemblages: kame terraces, outwash plain, ice-cored moraine complex, and ice-cored pushed moraine arc and calculated elevation and volumetric changes. Kame terraces between 2014 and 2022 and outwash plains between 2016 and 2022 were mainly stable, with 81% and 95% of their surfaces which did not undergo any changes. Ice-cored pushed moraine arc recorded a volume loss of 65 538 m^3 in 2016-2022, and maximum surface lowering was up to 8.8 m. The most dynamic was the ice-cored moraine complex, with transformation recorded for more than 87% of its area in 2014-2022. The surface of the ice-cored moraine complex lowered up to 19 m, and the total volume loss was 390 977 m^3. The most dramatic changes were related to the rapid degradation of dead ice blocks and, to a lesser extent, water erosion by small streams and mass movements. We also propose a conceptual model for the development of ice-cored moraine in a short time scale, pointing to possible end effects of its evolution.

This research was funded by the National Science Centre, Poland, Grant Number 2019/35/B/ST10/03928.

Glacial features map database of Finland produced using LiDAR data interpretation

***Dr. Jukka-Pekka Palmu* [1], *Dr. Niko Putkinen* [1], *Mr. Tapio Väänänen* [1], *Mrs. Satu Putkinen* [1], *Mr. Markus Valkama* [1], *Prof. Antti Ojala* [2]**

***1.** Geological Survey of Finland, **2.** University of Turku*

The glacial features map database workflow utilises LiDAR data produced by National Land Survey of Finland. The point cloud density is 0,5 points per square metre. The point cloud data was processed at the Geological Survey. In the interpretation work the main LiDAR data derivative used is the Multidirectional hillshade, but also slope is used. The primary DEM data is also used to visualise the height differences.

Additionally extensive other data is used in the interpretation: topographic data, aerial photos, earlier mapping (Quaternary geological maps 1:20 000, 1: 100 000, 1:200 000), Aggregate resources mapping data, field observations, borehole data, field geophysics (refraction seismics, GPR, and gravity profiles).
The map database format is ESRI geodatabase and the software used are ArcMap and ArcGIS Pro. Database main elements are the glaciofluvial and moraine deposits and the glacial lineations (over 330 000 lineation polylines). Additionally, for practical reasons the littoral (shoreline) deposits are included. Currently work is progress to produce the eolian deposits, mainly the dune fields.

For the glaciofluvial deposits (over 100 000 polygons) the main classes are the eskers and the ice-marginal deposits, but the extramarginal deposits are also included. Esker areas are further divided to subclasses, as are the ice-marginal deposits.
The moraines (diamicton-dominated deposits) (over 82 000 polygons) main classes are the ribbed moraines, and hummocky moraines. Hummocky moraines are further divided into subclasses, which include the subglacially formed and ice-contact hummocky moraines. De Geer moraines and other diamicton-dominated end moraines also have their classification system. Work has started to delineate the murtoo and pulju deposits.
The map database can be studied using the Geological Survey of Finland (Geologian tutkimuskeskus = GTK) map server, from the web address: https://gtkdata.gtk.fi/maankamara/ (in Finnish, look for Jäätikkösyntyiset maaperämuodostumat), there is additionally hillshading data you can combine with the Glacial Features data, it is Varjostettu korkeusmalli in the Table of Contents. You can also download the map database from the GTK Hakku service: https://hakku.gtk.fi/en/locations/search and search for Glacial features.

Iceberg ploughmarks on the Norwegian shelf

Dr. Dag Ottesen [1], _Prof. Julian Dowdeswell_ [2]

1. Geological Survey of Norway, 2. Scott Polar Research Institute, University of Cambridge

Inspection and mapping of large volumes of high-resolution multibeam echo-sounder data (30 000 km^2) on the Norwegian shelf have revealed many different types of iceberg ploughmark, illustrating several processes linked to both ocean currents and tidal influence. We have mapped the total population of iceberg ploughmarks in a number of areas and produced statistics on the size and direction of the individual ploughmarks. From this, the palaeo-current pattern from the last deglaciation of the Norwegian shelf has been reconstructed, c. 15 – 20 000 y BP. Many sets of single- and multi-keeled ploughmarks are presented from the Norwegian continental shelf and slope with the largest up to 2 km wide and with more than 10 protruding keels. Several iceberg ploughmarks with well-developed chains of regularly spaced pits have been mapped on the upper mid-Norwegian continental slope in 400-500 m water depths. The pits are interpreted to reflect a tidal imprint by the grounding of icebergs at successive low tides, allowing the drift velocity of the icebergs that formed the ploughmarks to be calculated. The distance between pits varies between 70 and 175 m giving an average drift velocity of between 5 and 15 m hr^{-1}. The pits are asymmetrical and often have a downstream berm, making it possible to determine the direction of iceberg drift and, thus, the current direction at the time of ploughmark formation. The general drift direction during deglaciation is similar to the direction of the modern North Atlantic Current. A large proportion of the ploughmarks on the continental slope of the mid-Norwegian shelf were probably produced by icebergs from the Norwegian Channel Ice Stream during deglaciation.

Inter-ice stream moraine belts: implications for Quaternary palaeoglaciology

Dr. David Evans [1], *Dr. Nigel Atkinson* [2], *Prof. Emrys Phillips* [3]

1. Durham University, 2. Alberta Geological Survey, 3. British Geological Survey

Expansive areas of complex glacial landform assemblages, dominated by glacitectonic compressional structures and hummocky terrain, constitute a long recognised landsystem signature of ice sheet recession on the North American prairies often generically labelled as "moraine belts". Such belts separate the more elongate and streamlined zones that constitute the footprints of the former palaeo-ice streams of the SW Laurentide Ice Sheet and hence have more recently been referred to as inter-ice stream regional moraine zones, constructed during regional deglaciation. These inter-ice stream moraines are characterised by: 1) spectacular glacitectonic compression of bedrock, cupola hill construction and mega raft displacement; 2) multi-phase stagnant ice melt-out related to partially overprinted surge lobes; 3) kame and kettle topography related to the development of glacier karst and the production of eskers contemporaneous with lobe overprinting; and 4) widespread enigmatic landforms such as prairie doughnuts, doughnut chains, artesian blow-out features and possible till eskers. The latter have traditionally been related generically to supraglacial processes but we propose that they are predominantly the product of groundwater pressure variability and potentially biogenic shallow gas escape driven by deglaciation of the low permeability Cretaceous bedrock, where ice flow was against an adverse bed slope. Landform patterns also indicate that larger areas of hummocky terrain are not chaotic but rather comprises hummock chains that parallel the receding ice sheet margin and hence are related to ice-marginal processes. Complex stratigraphies and landform palimpsests also indicate that the moraine belts may contain older marginal landform assemblages likely dating to more restricted ice sheet extents that pre date the last glaciation.

Using high resolution 3D morphometry to understand the spatiotemporal properties of de Geer moraines and evaluating their potential to refine palaeo-ice marginal reconstructions of the Fennoscandian Ice Sheet

Ms. Gwyneth Rivers [1] ***, Dr. Robert Storrar*** [2] ***, Dr. Naomi Holmes*** [2] ***, Mr. Andrew Jones*** [2] ***, Prof. Antti Ojala*** [3]

1. *Department of Natural & Built Environment, Sheffield Hallam University,* ***2.*** *Department of Natural and Built Environment, Sheffield Hallam University,* ***3.*** *Department of Geography and Geology, University of Turku*

De Geer moraines (DGMs) have the potential to generate very high-resolution, spatial and temporal, ice margin reconstructions (~annual in contrast to 100-500 years, the current state-of-the-art), however, formational processes remain poorly understood. Existing studies suggest that DGMs likely form annually, in association with the seasonal cycles of glacial advance/retreat. Specifically, it is suggested that formation occurs in a subaqueous, ice-marginal environment whereby basal sediments are advected and deposited at the grounding-line during seasonal advances. However, there have also been suggestions of a crevasse-fill origin that challenges this temporal regularity. Whilst the spatiotemporal properties of DGMs are disputed, the balance of evidence suggests an ice-marginal depositional environment with annual/seasonal regularities. This is critical, as it suggests that DGMs may be able to delineate ice-marginal retreat at unprecedented (potentially annual) resolutions. We attempt to constrain the spatiotemporal properties of DGMs by undertaking a highly detailed 3D transect-segmented morphometry study in the Fennoscandian Ice Sheet area. Here, we present the results of a high-resolution (2 m), large sample (n > 9,000) study of DGM morphometry across a study site located in SW Finland. This 3D transect-segmented morphometric approach provides a powerful method in which to analyse DGMs at large scales and in considerable detail. High resolution digitisation of DGM outlines and crestlines allows the quantification of several geometrical parameters including: length, width, height, volume, sinuosity, slope, and cross-sectional asymmetry. In addition, spatial distribution characteristics were assessed using a cluster analysis approach which allows for a deeper understanding of environmental prerequisites and formational controls. The results may be used to: 1) inform process models of DGM genesis, 2) provide a robust dataset which can be extrapolated for discriminative/classification studies against similar landforms (i.e., crevasse-squeeze ridges), and 3) evaluate DGM potential to refine palaeo-ice marginal reconstructions.

New metrics reveal the evolutionary continuum behind the morphological diversity of subglacial bedforms

Mr. Jean Vérité [1]***, Dr. Edouard Ravier*** [1]***, Dr. Olivier Bourgeois*** [2]***, Mr. Paul Bessin*** [1]***, Mr. Stéphane Pochat*** [2]

1. *Laboratoire de Planétologie et Géosciences, UMR 6112, CNRS, Le Mans Université, Avenue Olivier Messiaen, 72085 Le Mans CEDEX 9,* **2.** *Laboratoire de Planétologie et Géosciences, UMR 6112, CNRS, Nantes Université, 2 rue de la Houssinière, BP 92208, 44322 Nantes CEDEX 3*

Understanding the evolution of subglacial bedforms is critical to constrain ice-meltwater-bed interactions and the dynamics of past and present ice sheets. However, the difficulty to monitor active subglacial bedforms below present-day ice sheets implies that their evolution are essentially deduced from the inversion of morphological data from palaeo-subglacial bedforms. In this study, the morphological characteristics of subglacial bedforms are explored through a new approach based on the combination of three dimensionless morphometric indices i.e., circularity, sinuosity and oriented elongation.
From two selected portions of the Irish Ice Sheet and Laurentide Ice Sheet beds, we measure the spatial distribution of morphometric indices on an unpublished database composed of ~13 500 digitized subglacial bedforms considering (1) they were all formed under a single ice flow configuration in each region and (2) they may have developed either orthogonal, parallel, or oblique to ice displacement directions. Our results demonstrate the existence of a morphometric and spatial continuum of subglacial bedforms behing a larger morphological diversity than currently postulated in the litterature. In this continuum, ribbed bedforms – ranging from circular to elongated flow-transverse forms – are incipient bedforms that can evolve into transitional sinuous ribbed bedforms, then into predominantly flow-parallel sinuous bedforms, which progressively realign to form increasingly elongated streamlined bedforms. Considering the glaciological contexts of selected study areas, this continuum may provide new geomorphic criteria to constrain spatial variations in subglacial conditions (e.g. ice flow velocity, bedrock characteristics, meltwater pressure).

Chronology and morpho-climatic history of large rock slope failures in the Southern Swiss Alps

<u>Mr. Alessandro De Pedrini</u> [1], Prof. Cristian Scapozza [1], Ms. Chantal Del Siro [1], Prof. Christian Ambrosi [1]

1. SUPSI, Institute of Earth Sciences IST

Large rock slope failures in Alpine environment are influenced not only by structural weaknesses inherited from tectonics and lithological characteristics of slopes but also by the climate history. The glacial history plays a significant role in slope stability, as the glaciers' pressure exerts a variable load on the valley flanks and reduces the slope strength, often leading to rock slope failures.

In the Southern Swiss Alps, in the territory of the five valleys north of Bellinzona (Riviera, Valle Leventina and Valle di Blenio in Canton of Ticino, Val Calanca and Valle Mesolcina in Canton of Graubünden), several deposits of large rock slope failures can be observed. A detailed geochronological assessment of glacial retreat and the age of slope collapse is essential to understand the strong relationship between the two phenomena.

This research aims to define the exposure age of the rock slope failure deposits considered Prehistoric through Schmidt hammer exposure-age dating and analyze the achievements in relation to the collapse volume to assess their morpho-climatic evolution.

Exposure ages indicate collapses just a few centuries/millennia after the deglaciation (dated between 16.94 and 16.25/15.96 ka b2k for the lower and middle parts of Mesolcina, Blenio and Leventina valleys). Both deglaciation and dated rock slope failures occurred during the Greenland Stadial GS-2.1a of the INTIMATE event stratigraphy, dated between 17.48 and 14.69 ka b2k (Rasmussen et al. 2014, Quat. Sci. Rev. 106) or, at least, at the beginning of the Greenland Interstadial GI-1 (14.69–12.90 ka b2k), in particular during the events GI-1e (14.69–14.08 ka b2k), GI-1d (14.08–13.95 ka b2k) and GI-1c (13.95–13.31 ka b2k), characterized by the first significant temperature increase after the Last Glacial Maximum.

This chronological assessment highlights a lack of collapses between the end of the Late Glacial Interstadial and the historical times, suggesting slope stability during almost the entire Holocene and increased activity during the Little Ice Age.

Understanding the timing of rock slope failure collapses during paraglacial crisis helps to define future scenarios of slope collapse under a changing climate.

Late Pleistocene to Holocene glacial, periglacial and paraglacial geomorphology of the upper Río Limarí basin (30-31 ºS) in the Andes of central Chile.

***Ms. Javiera Carraha* [1], *Dr. Juan L. García* [1], *Mr. Hans Fernandez* [2], *Dr. Samuel Nussbaumer* [3]**

***1.** Pontificia Universidad Católica de Chile, Instituto de Geografía, Santiago, Chile, **2.** Pontificia Universidad Católica de Chile, **3.** University of Zurich, Department of Geography, Zürich, Switzerland*

The Andes of central Chile are a suitable region for assessing the geomorphic response of the mountain cryosphere to climate forcing. Despite this, detailed mapping of geo-cryoforms and last glaciation reconstructions in this region remain unresolved with few studies to date. Moreover, the region includes present-day different types of glaciers, with or without debris cover, as well as rock glaciers, suitably for studying present-day ice change in light of the paleo-glacier record. In this context, this research's purpose is to reconstruct the geomorphic imprint of the last glaciation and subsequent deglaciation in the Andean mountains of the Limarí basin, semiarid central Chile. For this, geomorphological maps of four formerly glaciated valleys in the head of two sub-basins of the Andean Limarí basin, namely Combarbalá and Río Hurtado, were built.

Field observations and the analysis of aerial photograph and satellite images allowed us to identify a mosaic of glacial, periglacial, and paraglacial landforms. Glacial landforms include a massive dead-ice moraine complex, with sinkholes and debris-filled stripes indicating former ice-cored moraine degradation, as well as landforms related to active ice processes such as glacial lineations and moraine ridges containing striated and faceted boulders. Current periglacial landforms such as rock glaciers, gelifluction tali, and protalus lobes occur in cirques and U-shaped valleys. Paraglacial processes are indicated by talus accumulation.

We suggest that glaciers, mostly without debris cover, expanded during the last glaciation in the upper Limarí basin. During deglaciation they would have been covered with debris in response to negative mass balance, evolving eventually to dead-ice moraines and extensive hummocky terrain at the end of the last glaciation. Moraine ridges and fluting punctuating the dead-ice moraine implies that the overall deglaciation process would have been interrupted by several glacial or post-glacial re-advances. Inactive rock glacier morphology converging with dead-ice moraines is evidence for the discussion of a potential evolution of the debris-covered glacier into a valley rock glacier. The transition from glacial to nonglacial environment has left detrital niches that behave as hosts for periglacial features such as cirque rock glaciers, gelifluction tali, and protalus lobes, which are responding to current climate changes.

Submarine glacial landforms in the southern part of the Baltic Sea Basin

Ms. Inese Grinbauma [1], ***Dr. Karol Tylmann*** [1], ***Prof. Jan Piotrowski*** [2], ***Dr. Sarah L. Greenwood*** [3]

1. *Faculty of Oceanography and Geography, University of Gdansk, Gdynia, 81-378,* ***2.*** *Department of Geoscience, Aarhus University, DK-8000 Aarhus C, Denmark,* ***3.*** *Department of Geological Sciences, Stockholm University, 10691 Stockholm, Sweden*

During the last glacial cycle, the Scandinavian Ice Sheet (SIS) was one of the Northern Hemisphere's largest ice sheets. The ice flow pattern of the last SIS was characterized by the occurrence of ice streams (corridors of fast-flowing ice). The Baltic Sea Basin hosted the Baltic Ice Stream complex, which was one of the main corridors of fast flowing ice within the SIS. This research offers a reconstruction of the last SIS dynamics in the southern part of the Baltic Sea Basin based mainly on the remote surveying of the seafloor relief and mapping glacial landforms.

Unravelling the puzzle of glacial processes operating within one of the most important palaeo-ice streams at the southern SIS sector will contribute to better understanding the dynamics of the entire ice sheet. The geomorphic signatures of the last SIS in the southern part of the Baltic Sea Basin are still poorly known and have not been analysed in detail so far. Until recently, the dynamics of the Baltic Ice Stream complex were mainly constrained by terrestrial observations. This research focuses on mapping submarine glacial landforms occurring on the southern Baltic seafloor. Our poster presents some relic glacial landforms delineated based on high-resolution multibeam swath bathymetry. We used grids of various resolution (from 0.5 to 5 m) interpolated from bathymetric data obtained from Hydrographic Office of the Polish Navy, RWE company and the Swedish Maritime Administration. Detailed mapping of submarine glacial geomorphology and GIS analyses of landform distribution enables us to decipher glacial processes associated with the Baltic Ice Stream complex and reconstruct the pattern of ice flow and margin positions in the southern Baltic Sea Basin.

Retreat of the Laurentide Ice Sheet margin in easternmost Québec-Labrador revealed by cosmogenic nuclide exposure dating

Dr. Pierre-Olivier Couette [1], ***Dr. Jean-François Ghienne*** [2], ***Dr. Patrick Lajeunesse*** [3], ***Dr. Jérôme van der Woerd*** [2]

1. *Département de géographie, Université Laval,* ***2.*** *Institut Terre Environnement de Strasbourg (ITES), UMR 7063, CNRS—Université de Strasbourg, France,* ***3.*** *Université Laval*

The Laurentide Ice Sheet was the largest ice sheet of the Northern Hemisphere during the last glacial cycle. The effects of its demise on global climate and sea level changes during the subsequent deglaciation are unequivocal. Understanding the interplay between ice sheets and long-term or shorter-term (e.g., abrupt) climatic events is therefore critical for assessing the contribution of melting ice masses to past and future sea level rise. Here, we present new cosmogenic nuclide surface exposure ages from easternmost Québec-Labrador that allow refining the regional deglaciation history. This chronological dataset reveal that the Laurentide Ice Sheet disconnected from the Newfoundland Ice Cap at ~14.1 ka. Additionally, samples collected from moraine boulders document the occurrence of five major stillstands and/or readvance stages of the Laurentide Ice Sheet margin at ~12.9 ka, ~11.5 ka, ~10.4 ka, ~9.3 ka and ~8.4-8.2 ka. Our results highlight a strong sensitivity of the LIS to temperature changes in the Northern Hemisphere, as the documented continental ice margin stabilizations coincide with abrupt cooling events recorded in Greenland ice cores. Furthermore, they support the idea of a negative feedback mechanism induced by meltwater forcings into the North Atlantic Ocean which, in turn, provoked repeated cold reversals during the Younger Dryas and early Holocene.

Reconstructing glacial retreat in southernmost Patagonia since the last glacial maximum

Ms. Carla Huynh [1]***, Dr. Andy Hein*** [1]***, Dr. Robert McCulloch*** [2]***, Dr. Juan L. García*** [3]***, Prof. Robert Bingham*** [1]***, Dr. Derek Fabel*** [4]

1. *University of Edinburgh,* ***2.*** *Centro de Investigación en Ecosistemas de la Patagonia (CIEP),* ***3.*** *Instituto de Geografía, Facultad de Historia, Geografía y Ciencia Política, Pontificia Universidad Católica de Chile, Av. Vicuña Mackenna 4860, Macul, Santiago, Chile,* ***4.*** *Scottish Universities Environmental Research Centre*

During the Last Glacial Maximum (LGM), a major outlet glacier of the Cordillera Darwin in southernmost Patagonia extended ~200 km through Canal Whiteside and into the large marine embayment Bahía Inútil. A suite of glacial landforms has previously been mapped and dated recording a series of re-advances shortly after the onset of deglaciation. Glacial retreat through Canal Whiteside is thought to have occurred between approximately 18-16 ka, but the exact timing and rate of retreat is poorly constrained. Marine geophysical data have suggested ice retreat occurred in stages, with the initial deglaciation of Bahía Inútil being slow, but accelerating as the ice retreated into deeper water in the northern part of Canal Whiteside. Stabilisation of the ice margin at a topographic constriction near Punta Yartou has been inferred based on the deposition of thick ice-proximal sediments in the strait, but the timing of this stabilisation was unknown. Here, we present new evidence from terrestrial cosmogenic nuclide dates from moraines on the eastern shore of Canal Whiteside near Punta Yartou. These moraines are nearly 70 km beyond modern ice limits in the Cordillera Darwin, and a similar distance from the LGM moraines in Bahía Inútil. The moraines mark the last known ice extent in Canal Whiteside before deglaciation in the fjords. We use these data along with published marine sediment cores and terrestrial radiocarbon dates from the fjords close to the current ice extent to constrain both the timing and rate of deglaciation in the region. We consider the role of climate, topography, and ice-loss through calving in driving this pattern of retreat. Our overall aim is to build an understanding of the rate of deglaciation and to understand how the ice sheet in this sector responded to Late Glacial and Holocene climate.

Early Pleistocene Glaciation records in cave sediments: insights from the French western Alps

Mr. Vivien Mai Yung Sen [1], _Dr. Yann Rolland_ [1], _Dr. Pierre Valla_ [2], _Dr. Stéphane Jaillet_ [1], _Dr. Xavier Robert_ [2], _Dr. Christian Crouzet_ [2], _Dr. Edwige Pons-Branchu_ [3], _Dr. Julien Carcaillet_ [4]

__1.__ Laboratoire EDYTEM UMR CNRS 5204 Université Savoie Mont Blanc, __2.__ ISTerre, Université Grenoble Alpes, CS 40700 38058 GRENOBLE Cedex 9, __3.__ LSCE-IPSL, Laboratoire des Sciences du Climat et de l'Environnement (CEA-CNRS-UVSQ), Paris-Saclay, __4.__ ISTerre, CNRS, Université Grenoble Alpes

In the French western Alps, pre-LGM glaciations are little known in terms of chronology, spatial extent and dynamics because their reconstruction is strongly limited by the poor preservation of sedimentary archives in a context of strong relief rejuvenation, especially in the internal reliefs. Thus, although the last glacial periods, as well as the post-LGM glacial retreat phases, have been extensively reconstructed based on surface geomorphological and sedimentological records, we are severely lacking on information about Early to Middle Pleistocene glaciations in the western Alps.

(Paleo-)glaciers have not only left morphologies and deposits in the landscape. Pre-existing endokarstic networks can be used by glacio-nival melt water flows. Thus, fluvio-glacial sediments may be preserved inside cave systems. While surface glacial records are mostly eroded over a glacial-interglacial cycle (100 ka) or by subsequent glacial advances, the potential for preservation is much better in endokarstic systems where sediments can be stored over long term. In addition, several glacial occurrences might be preserved in endokarstic networks, providing chronological archives over multiple glaciations.

For this study, we investigated two caves in the French western Alps: Vallier (1520m, Vercors massif) and Chevalier (1670m, Chartreuse massif). Due to their peripheral locations and high elevations, these endokarstic systems were not influenced by last glacial extensions (MIS2/MIS4, possibly MIS6) but present fluvio-glacial sediment deposits attributed to early-middle Pleistocene glaciations. We collected allochthonous sediments inside these caves, combined with speleothem sampling, and performed multi-method sedimentological and geochronological analysis (cosmogenic isotope burial and paleomagnetic dating on detrital sediments and U-series dating on calcite concretions). Our aim is to place chronological constraints, as well as provenance information, on these ancient fluvio-glacial deposits, with the objective of reconstructing the paleo-extent/thickness and ice fluxes of Early to Middle Pleistocene glaciations in the French western Alps.

The sensitivity of the mountain cryosphere

Prof. Jasper Knight [1]***, Prof. Stephan Harrison*** [2]

1. *University of the Witwatersrand,* ***2.*** *University of Exeter*

The presence of snow and ice is a distinctive characteristic of mid-latitude mountains worldwide. Under climate change, both through the late Quaternary and in the Anthropocene, the changing cryosphere exerts a strong influence on the dynamics of mountain systems. This includes their heat balance, regional climate and micro-climate, geomorphology, ecosystems and different types of human activity. However, the 'sensitivity' of the mountain cryosphere has been defined and interpreted in different ways in terms of key cryospheric properties such as mass balance and albedo. This means that the concept of cryospheric sensitivity is both ambiguous and multifaceted. In addition, mountain snow and ice have different distributions and dynamical controls and this suggests that any differential responses to climate forcing should result in changes to the snow/ice systems themselves as well as any downstream impacts on the land surface. This study examines the nature of the different sensitivities of the mountain cryosphere from both theoretical and field-based perspectives. Results show that snow and mountain glaciers have different sensitivities to radiative forcings that are linked to the surface properties of snow and ice bodies themselves. These sensitivities are strongly influenced by land surface feedbacks that are far more significant a control on cryospheric dynamics than equivalent feedbacks are for other elements of mountain systems. Thus, the cryosphere exerts a disproportionate control on the dynamics of mountain systems as a whole. Changes in snow and ice properties over time and space, across complex mountain topographies, give rise to temporal and spatial variations in sensitivity that show a nonlinear relationship to forcing. These feedbacks and outcomes of climate forcing are also not well parameterized through radiative models or regional-scale field observations. However, the sensitivity of the mountain cryosphere is critical in prediction of related slope hazards (in particular associated with deglacierization), meltwater yield into surrounding rivers, and sustainability of mountain landscapes, ecosystems and human activity.

Numerical modelling of subglacial ribs, drumlins, herringbones, and mega-scale glacial lineations reveals their developmental trajectories and transitions

Dr. Jeremy Ely [1], *Dr. David Stevens* [1], *Prof. chris clark* [1], *Dr. Frances E. G. Butcher* [2]
1. Department of Geography, University of Sheffield, 2. University of Sheffield

Initially a matter of intellectual curiosity, but now important for understanding ice sheet dynamics, the formation of subglacial bedforms has been a subject of scientific enquiry for over a century. Here, we use a numerical model of the coupled flow of ice, water, and subglacial sediment to explore the formation of subglacial ribs (i.e. ribbed moraine), drumlins and mega-scale glacial lineations (MSGL). The model produces instabilities at the ice-bed interface, which result in landforms resembling subglacial ribs and drumlins. We find that a behavioural trajectory is present. Initially subglacial ribs form, which can either develop into fields of organised drumlins, or herringbone-type structures misaligned with ice flow. We present potential examples of these misaligned bedforms in deglaciated landscapes, the presence of which means caution should be taken when interpreting cross-cutting bedforms. Under constant ice flow parameters, MSGL are absent from our experiments. However, drumlin fields can elongate into MSGL in our model if low ice-bed coupling conditions are imposed. The conditions under which drumlins elongate into MSGL are analogous to those found beneath contemporary ice streams, providing the first mechanism, rather than just an association, for linking MSGL with ice stream flow. Therefore, we suggest that the instability of subglacial bedforming explains the fundamental mechanics that lead to the initiation and growth of these landforms, solving the longstanding problem of subglacial bedform generation.

Evolution of sediment-landform assemblages at a recently deglaciated terrain: The case of the Grey glacier in southern Patagonia

Dr. Rodrigo Soteres [1], ***Dr. Lucia Guerra*** [2], ***Dr. Rosa M. Carrasco*** [3], ***Dr. Camilo Rada*** [1], ***Ms. Paulina Cifuentes*** [4], ***Ms. Alba Rubio*** [1], ***Mr. Fabian Riquelme*** [5], ***Dr. Mateo Martini*** [2], ***Dr. Esteban Sagredo*** [5], ***Mr. Rodrigo Hevia*** [5], ***Dr. Michael Kaplan*** [6], ***Dr. Javier Pedraza*** [7], ***Dr. Juan-Carlos Aravena*** [1], ***Dr. Patricia Sanchez-Baracaldo*** [4]

Patagonian glaciers have been retreating rapidly during the past decades leaving behind a suite of sediment-landform assemblages that reflect the response of the cryosphere to severe warming episodes in addition to non-climatic factors, such as topography and/or the existence of proglacial lakes. Combining remote sensing techniques, geomorphological mapping, sedimentary analysis and Schmidt hammer measurements, we assess glacier-landscape dynamics, including debris transport paths, deposition environments characteristics and weathering rates of the Grey glacier in southern Patagonia (~51° S). Our aim is to outline a detailed morphosedimentary model for a temperate glacier to further understand processes involved in glacier withdrawal and to provide a modern analog to improve paleoclimate reconstructions based on glacial geology. Our preliminary results indicate that the ice receded ~1.6 km from the innermost moraine to its present-day position since at least 1974. We identify a suite of sedimentary-landforms assemblages which indicate that the glacier terminus transitioned from terrestrial to lacustrine environments in past decades, such as subaerial and subaqueous moraines, shorelines and terraces. We hypothesized that dominant lithofacies varies from angular-to-subangular bouldery gravel tills in ice marginal features to angular gravels in supraglacial deposits and subrounded-to-rounded sandy gravel units in glaciolacustrine landforms. We expect that Schmidt hammer measurements on recently deglaciated bedrock outcrops will reveal a decreasing surface weathering transect from distal moraines to present-day ice front showing a potential correlation with external controlling factors. Our results will inform us about the coupled influence of climate variations and proglacial environments in glacier recession rates and, especially, how proglacial lakes might enhance climate-driven ice withdrawal, yielding key insights for better understanding the response of tidewater glaciers to the ongoing climate change and offering empirical constrains for past glacier behavior and paleoclimate modelling.

Post-Little Ice Age Glacial Geomorphology of Contrasting Topographic Settings at Skálafellsjökull, Southeast Iceland.

Ms. Sarah Walton **[1], *Dr. Robert Storrar*** **[2], *Dr. Naomi Holmes*** **[1], *Dr. Jonathan Bridge*** **[1], *Dr. Marek Ewertowski*** **[3], *Dr. Aleksandra Tomczyk*** **[3], *Mr. Andrew Jones*** **[1]**

Iceland's glaciers are known to be particularly sensitive to changes in climate and are heavily influenced by changes in atmospheric and ocean circulation in the North Atlantic, causing changes in glacier mass balance. Iceland lies at the boundary between major ocean currents, with changes in these currents impacting Icelandic climate throughout the Holocene. Glacier retreat is also influenced by several other factors including underlying topography, glacier hypsometry and geology, which impacts glacier response times to changes in climate. Understanding these changes in glacier response times is important for modelling changes such as future sea level rise and water availability.

Southeast Iceland has been the focus of numerous studies on glacier retreat since the Little Ice Age (LIA) (ca. 1250-1900 AD), however there has been less focus on glacier dynamics and topographic influence. Skálafellsjökull is an outlet glacier of the Vatnajökull ice cap in southeast Iceland that has been retreating since the LIA maximum (~1890). This glacier presents a topographically diverse mountainside, influenced by underlying geology, offering an opportunity to explore the relationship between glacier behaviour and underlying topography in an environment with the same climatic influence.

Here we present high resolution mapping of glacial landforms, using high resolution aerial orthophotos and digital elevation models, collected using an Uncrewed Aerial Vehicle (UAV). The landforms mapped are typical for southeast Icelandic temperate glaciers, comprising composite and recessional push moraines, sawtooth moraines, and associated fluting. The UAV-captured imagery shows three distinct topographic settings that each have a distinctive geomorphological signature. This new geomorphological mapping at Skálafellsjökull will be useful for understanding patterns and rates of retreat at Skálafellsjökull, and glacier response to varied underlying topography.

Exploring landform expressions of subglacial thermal regime in marine and terrestrial continental ice sheet settings

Dr. Anna L.C. Hughes [1], *Dr. Sarah L. Greenwood* [2], *Dr. Monica C. M. Winsborrow* [3]

1. Department of Geography, The University of Manchester, 2. Department of Geological Sciences, Stockholm University, 10691 Stockholm, Sweden, 3. Department of Geosciences, UiT The Arctic University of Norway, N-9037, Tromsø, Norway

Detailed geomorphological records of deglaciated continental margins are increasingly widespread, with their interpretation providing important insights into the flow and retreat behaviour of past and present ice sheets. This adds to the long tradition of glacial geomorphological scrutiny of deglaciated terrestrial areas. Based on such work, it has been possible to determine suites of landforms, and landform characteristics, that are indicative of particular formative glaciological environments and ice flow and/or retreat regimes. However, it has often been the case that such models for interpretative 'inversion' of the landform record have considered the marine and terrestrial domains in isolation and the fundamental applicability of interpretative models across the whole ice sheet bed is challenging to establish, and rarely tested.

Basal thermal regime - and, by extension, basal hydrology - is fundamental to how ice flows across its bed, and fundamental to landforming processes and landform preservation. Cold-based and warm-based basal conditions are known to vary beneath ice sheets, yet detailed knowledge of how such regimes interact and how they vary across space and time is limited, particularly so over the scales and life cycle of a continental ice sheet. Importantly, how a terrestrial- or marine-based setting influences thermal regime, and its manifestation in the landform record, is rarely considered. Using examples from the marine and terrestrial sectors of former Northern and Southern hemisphere ice sheets, we explore landform expressions of subglacial thermal regime. We ask to what degree differences in landforms associated with end-member subglacial thermal states of cold-based ice and channelised meltwater reflect contrasting glaciological processes governing ice flow and retreat in marine and terrestrial settings, and/or reflect sedimentological processes of landform construction in these different domains. With such insights, we hope to refine approaches to inverting the preserved glacial landform record for interpretation of subglacial thermal regime.

Channel geometries formed by meltwater turbidites across the last glaciation on the North Sea Fan

Ms. Aurora Garcia [1]***, Dr. Benjamin Bellwald*** [2]***, Prof. Ivar Midtkandal*** [1]***, Dr. Sverre Planke*** [3]***, Prof. Ingrid Anell*** [1]***, Prof. Pietro Sternai*** [4]***, Ms. Reidun Myklebust*** [5]

Meltwater discharge is an important process associated with retreating ice streams. We use the North Sea Fan to study the geometries of meltwater-turbidite channels formed during the last glacial highstand (23 – 19 ka). High-quality 3D seismic reflection data (vertical resolution of 2 m and bin size of 6.25 x 18.75 m) covering 14000 km^2 is used to map six surfaces, and subsequent seismo-geomorphological analysis allows for the delimitation of five units with different seismic facies. A roughness index is calculated using cross-sections along the mapped surfaces. Width and depth measurements are taken along twelve points in different channels at different stratigraphic levels.

Results show channel width varying from 100 m to >2 km, with channel depths reaching up to 105 meters. Channels exceed 100 km in length and have extremely low sinuosity, with maximum values of 1,05. Channel slope angles show small variations, ranging from 0.01º to 0.014º. Different roughness trends are recorded for units dominated by down-slope processes compared to those dominated by bottom currents and settling from suspension. Our interpretations suggest that units dominated by turbidity currents and debris flows have a distinguishably rougher surface. In contrast, results reveal poor correlation between depth, width and length measured, within a single horizon and across horizons.

The low-sinuosity meltwater-fed channels have dimensions varying from meter to kilometric scales, representing energy fluctuations of the flows that eroded into the paleo-seafloor. The high channel-property variability is compatible with a high-mobility system, where the channels are short-lived and easily affected by subsequent events during a 4000 years period. These new insights demonstrate the variability of predominant active processes, such as settling of the suspension load, turbidity and cohesive flows, during a period of extreme sedimentation on the North Sea Fan. These downslope processes significantly contribute to the formation of this glacial fan during the last glacial-interglacial cycle.

The deglaciation of Ésera Valley (Central Pyrenees, Spain): past evolution, current situation and future perspectives.

Mrs. Ixeia Vidaller [1]***, Dr. Ana Moreno*** [1]***, Dr. Penelope Gonzalez-Samperiz*** [2]***, Dr. Sergi Pla-Rabes*** [3]***, Dr. Jesús Revuelto*** [1]***, Mr. Eñaut Izagirre*** [4]***, Dr. Blas Valero-Garcés*** [5]***, Dr. Juan Ignacio López-Moreno*** [1]

University of the Basque Country (UPV/EHE), 5. Consejo Superior de Investigaciones Científicas, Instituto Pirenaico de Ecologia

The local Last Glacial Maximum in the central Pyrenees was reached 60,000 years ago, since then, deglaciation has included periods of stabilization and glacier re-advance. The scarcity of well-dated glacier landforms prevents assessing precisely the timing of the deglaciation stages and identify the response of past glaciers to known rapid climate changes. In this contribution we present Pllan d'Están lacustrine record in the Ésera Valley spanning the last 45,000 years of climate and environmental change. A combination of sedimentological, geochemical, pollen and diatom data from a 4.4 m long core, and age models based on radiocarbon in the lake sequence and cosmogenic dating from moraine deposits, allowed defining paleoenvironmental stages. The onset of the lake sequence is a carbonate-rich unit without organic matter, interpreted as a proglacial lake lasting from 45 to 34 ka. From 34 ka to 11.7 ka, the sediment is characterized by the alternation of dark and light laminae, suggesting more intense runoff processes. The first part of this period (34-14 ka) is dominated by steppe herbaceous pollen (mainly *Artemisia*) indicative of a cold scenario with the glacier nearby. After 14 ka the development of arboreal vegetation with the regional typical *Juniperus-Betula-Corylus* succession indicates a temperature increase, although with still arid conditions. Furthermore, changes in diatoms assemblages and the higher content of organic matter point to a limited glacier influence during this this second stage (14-11.7 ka). During the Holocene, the content of organic matter increased, and a peatbog was developed during the mid Holocene, as both diatoms and hydro-hygrophytes pollen assemblages indicate. Late Holocene sediments are badly-preserved, but glacier evolution was studied by combining geomorphological mapping and high spatial resolution satellite imagery. Since the end of the Little Ice Age, Pyrenean glaciers retreated to the cirques and their surface shrunk from 2,060 to 232 ha from years 1850-2020. In the Ésera Valley, the Aneto Glacier, the largest one in the Pyrenees, has decreased a 64.7% in surface and 30.5 m in thickness in the last 41 years. Considering the current remaining maximum ice thickness (11.8 m), we expect it to disappear in the following decades.

Reconstructing the evolution of a post-Little Ice Age deglaciated alpine valley through the DEM of Difference technique

Dr. Roberto Sergio Azzoni [1], *Prof. Manuela Pelfini* [1], *Prof. Andrea Zerboni* [1]

1. Department of Earth Sciences, University of Milan

Since the termination of the Little Ice Age (LIA, ca. 1830), the accelerated glaciers' shrinkage along mid-latitude high mountain areas promoted a quick readjustment of geomorphological processes. For that reason, proglacial areas are among the most sensitive Earth's landscapes to climate change. The latest deglaciation is still on-going and it is affecting large areas; one of the main result is the onset of fresh geomorphological processes (paraglacial dynamic) and the accelerated rate of evolution of freshly exposed surfaces. A potential useful remote-sensing method for investigating such dynamic areas is the DEM (Digital Elevation Model) of Difference techniques (DoD), which quantify volumetric changes of a territory between successive topographic surveys. We applied this method, coupled with a detailed geomorphological analysis and comparison with historical maps, for reconstructing post-LIA deglaciation dynamic and the onset of fresh paraglacial processes along the Martello Valley (Stelvio National Park, Central Italian Alps). The head of the Martello Valley is still glacierized with three main ice bodies resulting from the huge shrinkage of the single glacier active at the apogee of the LIA. Aftermath glaciers lost the 60% of the initial surface area and consequently largely modifying the landscape and expanding the surface of the proglacial areas. The DoD analysis of 2006-2015 timeframe highlights deep surface elevation changes ranging from +38m along the foot of rock walls, where gravitative processes are more active, and -47m where the melting of buried ice caused collapses of the proglacial surface. This approach permits estimating the volume of sediments mobilized and reworked by paraglacial processes. Here, in less than 10 years, ca. 23675 m^3 of sediment were removed along the proglacial area and transported down valley. This highlights the dynamicity of proglacial areas and the relevance of paraglacial processes today as much as during past phases of deglaciation.

Controls on late Holocene and 20th century ice shelf dynamics in northeast Greenland.

Ms. Holly Jenkins [1], ***Prof. David Roberts*** [1], ***Prof. Jeremy Lloyd*** [1], ***Dr. James Smith*** [2], ***Dr. Louise Callard*** [3], ***Prof. Mike Bentley*** [4]

1. Durham University, 2. British Antarctic Survey, 3. Newcastle University, 4. Department of Geography, Durham University, Durham DH1 3LE, UK.

Over the past three decades satellite observations over Greenland have revealed that marine terminating glaciers and ice shelves have been thinning at an accelerating rate in response to both increased air and ocean temperatures. Beginning in the early 2000s, the ice shelves that front the Northeast Greenland ice stream (NEGIS) (Zachariae Isstrom and 79N) have started to destabilise, causing great concern for the future stability of the Greenland ice sheet. This project will explore the Late Holocene and twentieth century evolution of the 79N ice shelf, which currently buttresses the NEGIS. The NEGIS drains the northeast sector of the Greenland ice Sheet (GrIS) and contains approximately 1.2 m sea-level equivalent. Its future stability is pivotal not only to future mass balance of the GrIS but also the freshwater flux to the northeast Atlantic and specifically, to the North Atlantic Deep Water overturning circulation. This project will focus on the late Holocene to 21st century sedimentary history of Blaso, an epishelf lake to the north of the 79N ice shelf. Lake sediment cores will be analysed using a multiproxy approach in order to establish an characterise the Late Holocene sedimentation processes and patterns. This characterisation will then be utilised to frame 20th to 21st century sedimentary changes in the lake, with an emphasis on changes over the last 20 years. This recent understanding will be key to determining the future of the 79N ice shelf and, critically, will aid in identifying recent ice shelf thinning and the first signs of contemporary breakup in response to both ocean warming (Atlantic Water ingress) and air temperature increase (increased freshwater flux). Gaining an understanding ice stream responses to climate from the little ice age to present, will enable scientists to better understand how 79N will respond to near future climate change.

Geomorphological record of a former ice stream to ice shelf lateral transition zone in Northeast Greenland

Understanding ice stream dynamics over decadal to millennial timescales is crucial for improving numerical model projections of ice sheet behaviour and future ice loss. In marine-terminating settings, ice shelves play a critical role in controlling ice-stream grounding line stability and ice flux to the ocean, but few studies have investigated the terrestrial geomorphological imprint of ice shelves during deglaciation. Here, we document the terrestrial deglacial landsystem of Nioghalvfjerdsfjorden Glacier (79N) in Northeast Greenland following the Last Glacial Maximum, and the lateral transition of that margin to a floating ice shelf. High-elevation areas are influenced by local ice caps and display autochthonous to allochthonous blockfields that mark the interaction of local ice caps with the ice stream below. A thermal transition from cold- to warm-based ice is denoted by the emplacement of erratics onto allochthonous blockfields. Below ~600 m a.s.l. glacially abraded bedrock surfaces and assemblages of lateral moraines, 'hummocky' moraine, fluted terrain, and ice-contact deltas record the former presence of warm-based ice and thinning of the grounded ice stream margin through time. In the outer fjord a range of landforms such as ice shelf moraines, dead-ice topography, and weakly developed ice marginal glaciofluvial outwash was produced by an ice shelf during deglaciation. Along the mid- and inner-fjord areas this ice shelf signal is absent, suggesting ice shelf disintegration prior to grounding line retreat under tidewater conditions. However, below the marine limit, the geomorphological record along the fjord indicates the expansion of the 79N ice shelf during the Neoglacial, which culminated in the Little Ice Age. This has been followed by 20th Century recession, with the development of a suite of compressional ice shelf moraines, ice-marginal fluvioglacial corridors, kame terraces, dead-ice terrain, and crevasse infill ridges. These mark rapid ice shelf thinning and typify the present-day ice shelf landsystem in a warming climate.

The transition from glacial to interstadial in the lithosedimentary and pollen records from Balbieriškis outcrop, Late Weichelian Glaciation in South Lithuania

Dr. Laura Gedminienė [1], *Dr. Violeta Pukelytė-Baltrūnienė* [1], *Dr. Valentinas Baltrūnas* [1]

1. Nature Research Centre, Akademijos Str. 2, LT-08412 Vilnius

Investigations of the Late Weichselian sequences in the Baltic region are of great importance for the determination of the extent of the Late Weichselian glaciation and for the evaluation of transition from glacial to interstadial. Lithosedimentary and paleobotanical studies of the deposits of the Late Weichselian glaciation in the midstream of the Nemunas River were performed. The paleogeographical and paleoclimatic conditions during the formation of intertill sediments in the Balbieriškis outcrop in Southern Lithuania were evaluated. The structure of these deposits analysed and studies of tills were carried out which allowed us to determine the paleogeographical conditions of their formation. Spores, pollen, and other microfauna (microflora) findings in intertill sediments were analysed and paleogeographical and paleoclimatic conditions of their sedimentation were evaluated.

The sequence of the Balbieriškis outcrop reflects the presence of nonglacial palaeoenvironments during the deglaciation of Late Weichselian ice. Two tills of the last glaciation, which differ significantly in their composition and glacier movement paths, and the relatively continuous sedimentation process indicating intertill sediments separating them, testify to global climate changes in the late ice age and to the restructuring of glacial lobes of deglaciation in the southeastern part of the ice sheet. These can be named as phenomena of the rank of a significant stage of deglaciation. Research of the intertill sediments testifies about the existence of climatic fluctuations which are reflected in both pollen and spores, and lithostratigraphic records. A discontinuous sedimentation and vegetation composition witness to an open landscape of steppe-tundra, scattered wooded areas vegetation, and the emergence of thermophilic vegetation afterward, which could point to increased annual temperature and higher humidity.

In Lithuania, the Late Weichselian Glaciation is referred to as the Late Nemunas Glaciation (Upper Nemunas Formation). The available material allows us to legitimize the Balbieriškis interstage period in the Late Nemunas Ice Age between the Grūda and Baltija stages (Grūda and Baltija sub-subformations) in the regional Quaternary stratigraphic scheme.

Acknowledgment: this project has received funding from the Research Council of Lithuania (LMTLT), agreement No [S-PD-22-77].

New Younger Dryas evidence of glaciers advances in the upper valleys of Făgăraș Massif (Romania) via 10Be exposure dating

Ms. Daniela Pascal [1], ***Prof. Alfred Vespremeanu Stroe*** [2], ***Mr. Regis Braucher*** [3], ***Dr. Razvan Popescu*** [4], ***Dr. Mihaela Enachescu*** [5], ***Mr. Alexandru Berbecariu*** [4]

Past glaciations extent and chronology in the Southern Carpathians have been the subject of a disputed debate during most of the 20th century. The Romanian Carpathians finally benefitted in the last two decades from several studies presenting numerical age datings of the glacial deposits and erosion surfaces that improved considerably the knowledge on the last glaciations chronology. Despite the fact that Făgăraș Massif is the highest massif from Southern Carpathians (and of the Romania) and the richest in terms of glacial features, with deep glacial valleys and large cirques, it has remained less studied and dated in relation with the Pleistocene glaciations.

New exposure ages based on in situ produced ^{10}Be, ranging from Bølling-Allerød to Younger Dryas and Early Holocene are in good agreement with the recent European records, displaying the complete ice melting during Bølling-Allerød warm phase, one possible glacial advance during the Older Dryas (around 13.6 ka), glacial reformation and advance during the Younger Dryas and possible Early Holocene advances related to Pre-Boreal Oscillation when cool and humid conditions have been present over Europe. Based on the morphology of the glacial cirques which hosted Younger Dryas glaciers (proven by numerical ages) we performed a morphometric analysis for all the glacial cirques and finally we model the presence of Younger Dryas glaciers in the whole massif.

Samples were chemically processed at LN2C at CEREGE, France and at RoAMS Laboratory - IFIN HH, Romania. Targets of purified BeO were prepared for AMS measurements and measured at *ASTER, the French National AMS Facility* (CEREGE, Aix en Provence).

Loess generation in western Ireland during the last glacial termination and implications for postglacial climate

Mr. Colin Bunce [1]**, *Dr. Gordon Bromley*** [2]**, *Dr. Thomas Stevens*** [3]**, *Dr. Martin Nauton-Fourteu*** [1]**, *Ms. Marta Cabello*** [1]**, *Dr. Shane Tyrrell*** [1]**, *Prof. David Chew*** [4]**, *Prof. Kathryn Fitzsimmons*** [5]

1. *University of Galway,* **2.** *Geography and Palaeoenvironmental Research Unit, University of Galway,* **3.** *Department of Earth Sciences, Uppsala University,* **4.** *Trinity College Dublin,* **5.** *Department of Geosciences, University of Tübingen*

We present the first quantitative analysis of loess to be recorded in Ireland. Located on Ireland's Atlantic coast, the Burren forms a classic upland glaciokarst characterised by extensive limestone pavement and ice-plucked escarpments. The origin and nature of a quartz-dominated sediment found here–and its relationship with climatic conditions in the broader North Atlantic–has remained obscure, although it is widely accepted that the Burren supported an extensive mineral soil cover until the Mid Holocene. Uncertainty around the timing of Late Quaternary deglaciation, and thus the window of opportunity for silt entrainment and deposition, has further compounded our understanding of this unusual sedimentary unit.

To address persistent questions surrounding the genesis of the Burren silts, and climatic implications of cold-climate aeolian sediments for Europe's Atlantic margin, we first established the timing of deglaciation (with beryllium-10) to Heinrich Stadial 1. We then applied a coupled sedimentologic-geochemical approach to deposits at 11 sites throughout the Burren, several of which reveal an intricate stratigraphic relationship with varved sediments and relict periglacial features. Grain-size analysis depicts a consistent modal size, with most samples classified as clayey-silt/silty-clay, while SEM imaging reveals predominantly angular grain morphologies and conchoidal fracturing. XRF indicates the silt chemistry is consistent regionally and with similar deposits in the UK and France previously identified as loess. Meanwhile, age profiling of zircons identifies the primary source as the Carboniferous Clare Basin (SW of the Burren), with secondary input from Devonian lithologies immediately to the east. Both sources suggest a highly localised origin for the Burren loess, rather than more distal transport of Eurasian loess.

At multiple locations, we observed a simple bi-fold stratigraphy, whereby the lower clay-rich unit is overlain by a coarser unit also containing ^{14}C-datable charcoal. By our working hypothesis, the lower unit represents the original *in situ* loess deposited immediately after deglaciation and under environmental conditions conducive to aeolian dust transport; the upper unit corresponds to subsequent remobilisation and redeposition during the mid-Holocene, potentially reflecting climatic and/or anthropogenic agents. Initial anisotropy of magnetic susceptibility data support this hypothesis, while ongoing OSL dating will afford direct dating of both loessic units.

Investigating the interactions between the Jura ice cap and the Rhone glacier using exogenetic cave sediments and glaciotectonized surface deposits

Mr. Neal Mathes [1], ***Dr. Marc Luetscher*** [2], ***Prof. Susan Ivy-Ochs*** [3], ***Dr. Catharina Dieleman*** [4], ***Dr. Naki Akçar*** [4]

1. Department of Earth Sciences, ETH Zurich, Sonneggstrasse 5, CH-8092 Zurich, 2. Swiss Institute for Speleology and Karst Studies (SISKA), Rue de la Serre 68, CH-2300 La Chaux-de-Fonds, 3. Laboratory of Ion Beam Physics, ETH Zurich, Otto-Stern-Weg 5, CH-8093 Zurich, 4. Institute of Geological Sciences, University of Bern, Baltzerstrasse 1+3, CH-3012 Bern

The Jura Mountains are home to many karstic features that can trap and retain sediments. These exogenetic deposits are an important archive for paleoenvironmental information due to their ability to preserve sediments that have otherwise been eroded or reworked on the surface. To better understand the spatiotemporal evolution of the Rhone glacier across the Alpine foreland and its interaction with the Jura ice cap, a sedimentological study and field investigation were made in the Orbe and Jougnena valleys and along the Petit Risoux in the central Jura. In this study, exogenetic cave sediments of Alpine origin from Grotte aux Fées were investigated using isochron-burial and simple burial dating techniques with cosmogenic ^{10}Be and ^{26}Al. While Alpine clasts were also found in other caves, the Grotte aux Fées was chosen for dating because it lies beyond the previously identified maximum extent of the Alpine ice sheet during the Last Glacial Maximum (LGM) as well as Middle Pleistocene glaciations. To better understand the context of the exogenetic sediments, a field investigation of surface features was conducted. Observations included variations in till composition, morphologic features, and proglacial deposits. Laminated glaciolacustrine sediments up to 50 meters thick are found in the Orbe and Jougnena Valleys and were deposited in glacially dammed lakes. When outcropping on the surface, these glaciolacustrine deposits often appear glaciotectonized. The glaciotectonism has recorded varying senses of shear, indicating advances from both the Jura ice cap and Rhone glacier and providing new information for understanding the dynamic interactions of glaciers competing for space on the southeastern valleys of the Jura.

Small drumlins melting out from underneath retreating glaciers – an under-used archive of recent glacier change?

Dr. Sven Lukas [1]***, Dr. Marie Busfield*** [2]***, Dr. Joshua R. Leigh*** [3]

1. *Department of Geology, Lund University,* ***2.*** *Aberystwyth University,* ***3.*** *Department of Geography, Durham University, Durham, DH1 3LE, UK.*

Most glaciers world-wide have been retreating for the last few years to decades. Due to atmospheric amplification effects, this change is most pronounced in high-mountain regions such as the European Alps and in the Arctic. One side-effect of this retreat is the observable de-icing of glacier forelands. We have witnessed and recorded the melting-out of new landforms that had hitherto been hidden from view underneath the ice in several locations. These landforms often include small and transient flutes, subglacial channels, small eskers, but also larger streamlined landforms, including drumlins, which are perhaps among the most enigmatic landforms produced by glaciers.
We here present detailed field observations and measurements from small drumlins in two very different glacier systems. Hornkees, Austria, is a small temperate valley glacier in the Eastern Alps that flows mostly over bedrock. Storglaciären on the other hand is a polythermal valley glacier of comparable size in Arctic Sweden that flows over a patchwork bed of bedrock and soft sediments. Using structural measurements of fractures and fissures, in-situ soil penetrometer measurements and laboratory data of water content, grain size and shear strength, we aim to shed some light on the influence of spatial and temporal variability on sediment properties. Equally, comparing these findings to former glacier dynamics enables us to establish clear genetic links between ice dynamics and landforms imprint. These links are extremely valuable for reconstructions of former ice dynamics displayed, for example, by the last ice sheets, including the Scandinavian Ice Sheet, during multiple glaciations during the Pleistocene.

A new ice sheet reconstruction method and its application to the land terminating sector of the Scandinavian Ice Sheet

Mr. Christiaan Diemont [1], ***Prof. chris clark*** [1], ***Dr. Stephen J. Livingstone*** [2], ***Dr. Anna L.C. Hughes*** [3], ***Dr. Frances E. G. Butcher*** [4]

1. Department of Geography, University of Sheffield, 2. Sheffield University, 3. Department of Geography, The University of Manchester, 4. University of Sheffield

The landform record provides a spatially-continuous and data rich opportunity for evaluating the evolution and dynamics of ice sheets. Developments in both chronological tools and the wide-spread availability of high-resolution Digital elevation models have called into question long-established ice margins of the Scandinavian Ice Sheet (SIS). Developing an ice sheet scale reconstruction is required to probe controls on dynamics, yet is difficult to do by synthesizing local studies. This is in part because assessing, comparing and evaluating evidence from regional studies can be difficult with differing regional observations and resulting in regional reconstructions often being irreconcilable. We have developed a landform-driven reconstruction method that can be applied at the ice sheet scale. We demonstrate the method with its application to the land terminating sectors of the SIS. Selective symbolic landform mapping off variable resolution DEMs of moraines, outwash fans, tunnel valleys, lineations forms the basis for reconstructing margin retreat patterns and geometries. Iterative retreat pattern reconstructions in sub regions are ultimately linked to from a broader regional pattern of ice dynamics. In domains where simple monotonic retreat patterns are unable to satisfy the symbolized landform record we show how numerous reoccupations of ice in the last glacial or previous glacial cycles can explain the preserved record. We further expand on ways transgressive ice marginal features such as meltwater channels and moraine belts can be assessed in a reconstruction. An ice margin reconstruction of the entire land terminating sector (~1.2million Km^2) of the SIS generated by our method is presented. We expect this reconstruction can serves as a useful empirical data set for the ice sheet modeling community as well as provide a contextualizing framework for crucial regional studies.

Chronology of patagonian deglaciation and Late Pleistocene Atlantic-to-Pacific drainage reversal of palaeolake

Dr. German Aguilar [1] ***, Dr. Joseph Martinod*** [2] ***, Mr. Matías Gallardo*** [3] ***, Dr. Christian Sue*** [2]

1. *Advanced Mining Technology Center, Facultad de Ciencias Físicas y Matemáticas, Universidad de Chile,* ***2.*** *ISTerre, University Grenoble Alpes, University Savoie Mont Blanc,* ***3.*** *Institute of Ecology and Biodiversity (IEB)*

We present a study on the glacial and paraglacial geomorphology of a Patagonian Cordillera Valley that is key to understanding evolution of the great lakes of Patagonia. 10Be cosmogenic nuclide exposure ages of ice-moulded surfaces from the Bayo River Valley confirm that the valley became ice-free before 13.4 - 14.2 ka. This valley constituted the first outlet of the Chelenko Lake, precursor of the General Carrera–Buenos Aires Lake (GCBAL), toward the Pacific Ocean. This age constrains the timing of the lake drainage reversal from the Atlantic Ocean to the Pacific Ocean. Alluvial fans and terrace levels recognized in the eastern segment of the valley at the same altitude as terrace levels observed in the GCBAL basin confirm that the Bayo Pass controlled the elevation of the lake once the drainage reversed to Pacific Ocean. 10Be cosmogenic nuclide exposure ages also confirm that the maximum advance of the Exploradores Glacier since its major retreat >13.4 - 14.2 ka ago occurred during the Little Ice Age, the last remnant of glacial drift in these valleys.

Chronology of glacial advances and deglaciation in the the southernmost Atacama Desert based on geomorphological mapping and cosmogenic 10Be exposure ages

***Dr. German Aguilar* [1], *Dr. Rodrigo Riquelme* [2], *Ms. Paulina Lohse* [2], *Dr. Albert Cabré* [3], *Dr. Juan L. García* [4]**

Vicuña Mackenna 4860, Macul, Santiago, Chile*

Glacier advances and deglaciation have left a geomorphic imprint that has recording sensible changes in moisture supply in the southernmost Atacama Desert. In this work, the glacial landforms of the Encierro River Valley (29.1°S-69.9°W, 5475 m asl) have been revisited and new detailed geomorphological mapping and 10Be exposure ages from moraine boulders and ice-molded bedrock surfaces is presented. We found that the former glaciers of El Encierro valley extended 16 km down valley (up to 3750 m asl) during the last local glacial maximums, when they built terminal moraine arcs in telescopic patterns (ENC 1a-d). These glaciers built five frontal moraine ridges, whose exposure ages in moraine boulders range between 26 and 33 Ka (ENC 1d) and 39 ka (ENC 1a). Exposure ages on lateral moraines and ice-molded bedrock surfaces were developed by recessional stages of the glacier during the retreat that occurred between 18-20 ka. Ten kilometers up valley from the ENC 1, the ENC2a-d moraine arcs correspond to small ice advance/still-stands by 17-18 ka. To explain the latter, the ice should have mostly disappeared fast in the main valley at 18 ka. Deglaciation may be related to the southward shift of the South-Westerly winds as reported in other paleoclimatic archives in Chile for this period.

Loamy mantle of East-European Plain: morphostratigraphy and facies architecture as a key to the Late Pleistocene regional correlations

Dr. Ekaterina Garankina [1], ***Dr. Ilya Shorkunov*** [1], ***Ms. Elena Sheremetskaya*** [1], ***Mr. Vasily Lobkov*** [1]

1. *Independent Researcher*

Periglacial areas of Weichselian ice sheets are long studied as a source of climatostratigraphic data correlatable with the global paleorecords and to understand the complex landscape response to changes in glacial dynamics. Pronounced loess-paleosol series majorly accumulated along the southern margins of the periglacial zone proved to be a reliable paleoarchive for such reconstructions. However, the closer periphery of past ice sheets still lacks a comparable paleorecord as the thickness of postglacial deposits declines northward against the growing intensity and dynamics of landscape transformations. A specific loamy mantle, which has remained a stumbling block for over a century-long scientific discussion, covers the interfluvial areas of central and northern parts of the East-European Plain. It can be regarded as a northern substitute of loess-paleosol series though of a rather more homogenous and less explicit structure that left its genetic and age interpretations quite inconsistent and controversial. Nevertheless, a detailed investigation of several uplands in the marginal zone of the Late Saalian glaciation allowed us to distinguish the facies architecture of cover loams. We elucidated the principal set and succession of characteristic lithostratigraphic units separated by a series of superimposed cryogenic and paleosol horizons, which eliminate the heterogenous origin and prolonged accumulation of the loamy mantle during the Late Pleistocene. Buried cryogenic deformations and paleosol features can be utilized both as stratigraphic markers and climate indicators when their position and replicability in paleolandscapes are considered. The lithological structure of each unit reflects a specific set of features indicating distinct changes in periglacial paleoenvironments that turn out to be either gradual or abrupt revealing several major erosion episodes during the Weichselian. That elaboration on the morphostratigraphy of cover loams was enabled due to a combined application of macro-, meso- and micromorphologic methods during both field and laboratory examination of 3D-organization of deposits supplemented by geomorphic analysis of modern and paleotopographies of interfluves. That provided a reliable basis for chronostratigraphic correlations throughout the entire Late Pleistocene periglacial zone showing a high potential of the hierarchical morphogenetic approach to unravel the depositional history of such clastic sedimentary covers often lacking a precise numerical age control.

Calderone glacieret, a unique archive for a possible paleoclimatic reconstruction of the Apennine region

Dr. Fabrizio de Blasi [1]***, Dr. Stefano Urbini*** [2]***, Prof. Jacopo Boaga*** [3]***, Mr. Mirko Pavoni*** [3]***, Dr. Alberto Carrera*** [3]***, Mr. Pino D'Aquila*** [4]***, Dr. Massimo Pecci*** [1]***, Prof. Carlo Barbante*** [1]***, Dr. Jacopo Gabrieli*** [5]

1. *Institute of Polar Sciences, National Research Council (ISP-CNR)),* ***2.*** *INGV, Bologna,* ***3.*** *University of Padova - Department of Geosciences,* ***4.*** *Engeoneering srl,* ***5.*** *Istituto di Scienze Polari, Consiglio Nazionale delle Ricerche, ISP-CNR*

The ongoing global warming has relevant effects on the worldwide cryosphere. During the last decades, the more negative consequences have been on the most delicate snow and ice environments. Calderone ice body, classified as glaciaret split in two separated portions since the summer of 2000, is one of the most significant examples of the transition from glacial to periglacial environment due to climate change. Calderone is the southernmost remained ice body in Europe and represents a unique archive for the paleoclimatic reconstruction of the Apennine region. Indeed, despite the high summer temperature that occurred in the last decades, the ice body is still conserved thanks to the presence of debris cover that protects the ice under layers from solar radiation. In the frame of Ice Memory project, last May one 27.2 m down to the bedrock ice core was extracted in order to identify the ice layeringand to achieve chemical and biological information that characterize the surrounding area. To better indagate the evolution of Calderone since 1999, a comparison among different Ground-penetrating radar (GPR) and topographic surveys were carried out. Considering the rapid temperature increase of the last years, since 2015 annual photogrammetric surveys have been conducted in order to calculate the geodetic mass balance. In addition, before the drilling operation of last May, in March 2022 a high-resolution GPR survey associated with Electromagnetic (EM) and GPS measurements were achieved to better indagate the bedrock morphology, the glacier thickness, and the ice stratigraphy.

Here we present the results of the 2022 geophysical surveys, the comparison with former measurements, and the first stratigraphic information from the ice core. The first preliminary results show that despite the rapid climate change of the last twenty years, since 2000 the thickness and the extension of the two portions of Calderone glaciaret have not undergone significant changes. This represents an amazing and unique example in the Apennine region of ice conservation under the massive temperature increase. For this reason, the Calderone ice core will be one of the best opportunity for paleoclimatic and paleoenvironmental reconstructions of the surrounding Mediterranean area.

Coastal dune timing, migration and formation on K'gari (Fraser Island) through the Quaternary

Prof. James Shulmeister [1]***, Dr. Nicholas Patton*** [2]***, Dr. Daniel Ellerton*** [3]***, Dr. Graziela Miot da Silva*** [4]***, Prof. Allen Gontz*** [5]***, Prof. Patrick Hesp*** [4]***, Prof. Tammy Rittenour*** [6]***, Dr. Kevin Welsh*** [7]

K'gari (Fraser Island) is the world's largest sand island and contains multiple sequences of parabolic and transgressive dunefields with aeolian sediments dating back to over 800 ka and surface dunes dating to at least 350 ka. This paper will discuss the role of antecedent topography, sediment supply and wind fields on dune morphology and extent. The earliest dunes date back to the Mid-Pleistocene Transition and all of the major dune units are associated with post-glacial marine transgressions. Over the southern two-thirds of the island, dunes relating to the MIS 7 high-stand dominate. For the Holocene, the largest and most extensive dunes are associated with the main post-glacial transgression and there are small dune sequences that relate to minor sea-level perturbations. This difference appears to be related to the relative scale of sediment supply associated with the events, with the main transgression driving significant sediment supply into the aeolian system. Dune formation varies along the K'gari coastline with steep ramparts in the southern part of the island limiting the inland migration of Holocene dunes. Where the rampart elevation is lower, more extensive Holocene dune fields, comprising both parabolic and transgressive dunes, have formed. The far northern part of the island is much lower elevation than the rest of K'gari and it is likely that this area was transgressed during a Late Quaternary high-stand, most likely MIS 5e. We conclude that terrestrial antecedent topography plays a key role in the modern form of the dune fields but that the limits of transgression are controlled by the magnitude and duration of the high sea-stands. Finally, we debunk a long-standing hypothesis that dunes on Kgari are related to aridity at the LGM.

Stratigraphy of the World’s Largest Coastal Sand System as Revealed by Ground Penetrating Radar, Great Sandy Coast, Queensland, Australia

Prof. Allen Gontz [1], *Prof. James Shulmeister* [2], *Dr. Daniel Ellerton* [3], *Prof. Adrian McCallum* [4], *Dr. Nicholas Patton* [5], *Dr. Kevin Welsh* [6], *Prof. Patrick Moss* [7], *Prof. Harald Hofmann* [7], *Dr. Justine Kemp* [8], *Dr. Jonathan Marshall* [9], *Mr. Cameron Schulz* [9], *Mr. Peter Negus* [9]

1. Clarkson University, 2. University of Canterbury, 3. Stockholm University, 4. Faculty of Engineering and Science, University of the Sunshine Coast, 5. Desert Research Institute, 6. The south east Queensland (SEQ) dune fields in Australia, contain K’Gari (Fraser Island), the Cooloola Sand Mass, Yarun (Bribie Island), Mulgumpin (Moreton Island) and Minjerribah (North Stradbroke Island). This system is home to three of the world’s largest sand islands and the world’s longest continually active coastal dune field. Their sands originate from a >1100 km longshore drift current that moves sediment from south central New South Wales northward until it is redirected off the continental shelf at K’gari’s Sandy Cape. This system has been the focus of several decades of research to determine the timing of large-scale aeolian activity, and to elucidate the relationships between abiotic and biotic drivers of coastal/dune field evolution (i.e., climate, sea level, human activity).

A series of ground penetrating radar (GPR) surveys were conducted along the SEQ coastline between 2012 and 2019. The aim was to assist in developing a stratigraphic framework to link surface expression of dune forms and other features (i.e., lakes, wetlands, coastlines) to subsurface architecture, as well as assist in reconstruction the physical aspects of the environment and support coring for temporal control. The research has been focused on K’Gari and Cooloola but supporting data has been collected on Minjerribah and other areas.

The GPR outputs were analyzed using a facies-based perspective to identify the characteristics of the bounding surfaces and internal reflections. The data provide an interpretation base for the original depositional processes, post-depositional modifications, and anthropogenic activities. Four (4) major classes of facies were identified (interference, primary deposition, modified and anthropogenically altered) along with subclasses that relate to the specifics of the environment of deposition or style of modification.

This paper will show examples of GPR collected in active/modern environments and link with GPR data from other locations where features do not possess a surficial expression. Ultimately, a database of GPR facies for the aeolian environments of the south east coast of Queensland will be developed for use in understanding the spatial and temporal changes to the environment and assist in extracting valuable information on how the landscape has responded to past variations in climate.

Stratigraphy, chronology, and provenance of paleodune sediments in the Aconcagua and Rapel basins during the Late Pleistocene: Towards a model of paleodune formation in coastal central Chile

The aeolian stratigraphic record on the coast of central Chile (32°-35°S) includes paleodune sequences separated by interstratified paleosols. Previous work has associated these sedimentary units with paleoclimatic changes linked to the oscillation and intensification of Southern Westerly Winds. Therefore, these eolian deposits are regarded as proxies of the paleoclimate of central Chile; nonetheless, detailed sedimentary analysis of these eolian records is lacking. The spatial distribution of the dune deposits (north of Andean river's mouth) suggests that the origin of the sands is related to former Andean to coastal glacial and/or fluvial processes. However, these processes have not been investigated in detail. Some unresolved questions are: When did coastal dunes in central Chile form? Which rocks provide the sediments that constitute the dunes? What role do Andean glaciations play in dune morphogenesis? What are the paleoenvironmental implications of the paleodune-paleosol sequences?

We present our methodological approach and results for the Aconcagua and Rapel basins, whose study sites include the paleodunes, dunes, fluvial terraces, and one moraine. At these sites, we collected detailed stratigraphic information, dated detrital zircons by LA-ICPMS (U-Pb in 100 grains per sample), and dated paleosols sands by ^{14}C and OSL. The latter is based on a pIRIR225 (post infrared, infrared stimulated luminescence @225°C) single aliquot regenerative (SAR) dose protocol for potassium-rich feldspar. This method has been successfully applied in previous studies and used to establish reliable chronologies for the aeolian sediment record of Central Chile. Our OSL results show that periods of dune accumulation and pedogenesis (interpreted to reflect wetter conditions) occur during MIS 4, 3, and 2. When comparing the U-Pb detrital zircon ages with the longitudinal geologic belts making up the Aconcagua and Rapel basins we identify different rock sources (e.g., Andean and Coastal). This is evidence of a restricted local basins provenance of sands that made up the paleodunes. The results suggest that main sources of sand change their relative importance through the last ice age (MIS 2 Andean-affinity; and MIS 4 Coastal-affinity). We discuss implication of our data towards a model of paleodune formation and their stratigraphic record in coastal central Chile.

The Southern westerly winds as recorded by the Chigualoco paleodune stratigraphic record in costal semiarid central Chile (31ºS) during the Late Pleistocene

Dr. Juan L. García [1]***, Ms. Estefanía Quilamán*** [1]***, Prof. Christopher Lüthgens*** [2]***, Dr. Marco Pfeiffer*** [3]***, Ms. Laura Gana*** [1]***, Dr. Paula Castillo*** [4]

1. *Instituto de Geografía, Facultad de Historia, Geografía y Ciencia Política, Pontificia Universidad Católica de Chile, Av. Vicuña Mackenna 4860, Macul, Santiago, Chile,* ***2.*** *University of Natural Resources and Life Sciences, Vienna, Department of Civil Engineering and Natural Hazards, Institute of Applied Geology,* ***3.*** *Departamento de Ingeniería y Suelos, Universidad de Chile, Santa Rosa 11315, La Pintana, Chile,* ***4.*** *Westfälische Wilhelms-Universität Münster, Institut für Geologie und Paläontologie, Münster, Germany*

The southern westerly winds (SWW) are probably the most important climate element of the southern middle latitudes. Their position and intensity governed by low and high latitudes temperature gradients affects ocean and atmosphere dynamics in the southern middle latitudes and beyond. Thus, determining the past SWW changes through proxy records have far-reaching implications for a better understanding of the climate system at different temporal and spatial scales. The paleodune sedimentary records in the coast of central semiarid Chile have been proposed as proxy for reconstructing the SWW variability through the last glacial cycle. This remark is based on the existence of stratigraphic sequences exposing alternating paleodune and paleosol sedimentary couplet units linked to SWW latitudinal variability (Dune= south shifted SWW, dry conditions in central Chile; Paleosol= north shifted SWW, humid conditions). Nonetheless, to present only few paleodune records have been investigated and their paleoclimate signal is still to be better understood. Moreover, the factors controlling paleodune formation in the region remain unclear. Here, we provide sedimentary, pedogenetic, geochronologic and provenance sand data of a new site "Chigualoco" in north central coastal Chile (31º S, 71ºS). The site is located few km south of the Estero Chigualoco and tens of km north of Estero Conchali, both coastal catchments and representing potential sources of the sands outcropping in the Chigualoco stratigraphic section. The site at 70 m a.s.l. and 0.5 km from the coastline includes a stratigraphic sequence with five paleosols and four paleodunes in a 15 m section. The chronology is based on luminescence ages determined using a pIRIR225 (post infrared, infrared stimulated luminescence @ 225°C) single aliquot regenerative (SAR) dose protocol for potassium-rich feldspar. This approach has been successfully applied in previous studies by the authors (e.g. García et al. 2019) and has been proven to provide reliable chronologies for the aeolian sediment record of central coastal Chile. We discuss the implications of this new record in terms of paleoclimate forcings and also factors controlling the formation of paleodunes. We use this occasion to contrast the role of Andean versus coastal catchments in forming paleodunes in the study area.

Variance of ostracod assemblages in a dynamic deltaic system during Late Holocene times: case study Danube Delta, Romania

Mr. Andrei Briceag [1], Mr. Sabin Rotaru [1], Mr. Radu Dimitriu [1], Mrs. Irina Stanciu [1], Mr. Bogdan Barbu [1], Dr. Bogdan Ispas [1], Mr. Ion Stanescu [1]

1. National Institute for Research and Development on Marine Geology and Geo-ecology – GeoEcoMar

Deltas are dynamic and unique natural systems impacted by many natural factors, such as wave and river influence, erosion and accumulation processes, along with subsiding and uplifting movements. The Danube River – Danube Delta – Black Sea is the most extensive river – sea system in Europe. The Danube Delta developed in the Quaternary when Danube started to flow into the Black Sea basin.

The present study is focused on the variations of the ostracod assemblages inflicted by the formation and evolution of Razelm-Sinoe lagoon system during late Holocene times. This lagoon complex is located in the southern part of the Danube Delta and consists of several lakes/lagoons that occupy about 85% of its surface. Multidisciplinary investigations were done on a 7-meter-deep core recovered from the western bank of the lagoon, currently located about 14 km from the Black Sea shoreline. During the Holocene, the development of this area was influenced by the local sea-level changes, shifting from brackish lagoon to a freshwater lake environment. The identified ostracod assemblages revealed salinity changes ranging from oligohaline to mesohaline conditions. The dominant mesohaline taxa are represented by *Cyprideis torosa*, *Heterocythereis amnicola*, *Amnicythere olivia*, *A. pediformis* and *Loxoconcha gibboides*. The mesohaline environment also contains benthic foraminifera represented almost entirely by abundant *Ammonia tepida*. The most representative oligohaline ostracod species are *Darwinula stevensoni*, *Candona neglecta*, *Pseudocandona compressa*, *P. albicans* and *Limnocythere inopinata*.

This study offers new insights into the Late Holocene paleoenvironmental and paleogeographic changes that took place in the Razelm-Sinoe lagoonal system. During the last 3000 years BP this area evolved from a freshwater wetland/reed marsh to a marine/brackish lagoon environment with episodes of opening and closuring, leading to salinity oscillations.

Holocene sea-level and storminess variations recorded at Kolga strandplain, northern Estonia

Estonian Marine Institute, University of Tartu

Holocene relative shoreline displacement and architecture of the Kolga coastal strandplain in the tideless southern Gulf of Finland are reconstructed using airborne LiDAR-based relief analysis, ground-penetrating radar (GPR) surveys, sedimentological and magnetic susceptibility (MS) analyses, and luminescence and AMS radiocarbon dating. The results show that this coastal system consists of at least 24 prominent swash-aligned ridges (some with aeolian aggradation) represented by mostly seaward-dipping (offlapping) sandy-gravelly coastal deposits. Its landward segment (~50% of strandplain width) consists of 12 traceable ridges formed during the regressive phase of the Ancylus Lake and Initial Littorina Sea between 11.1 and 9.6 ka. Following a ~5 m transgressive episode, which is visible in GPR records as a regional disconformity, the seaward ridge set a prograded at substantially slower rate during the subsequent Littorina and post Littorina Sea phases between 6.6 and 0.3 ka. This episode caused a rise in groundwater level that initiated peat formation in Ancylus-age paleo-swales, at progressively higher altitudes (onlap), between 8.4 and 7.1 ka BP at 22 and 25 m above mean sea level, respectively. GPR images show that at least 13 additional low-relief coastal ridges are buried by peat deposits in the older part of the strandplain alone. Subsurface truncations, variations in beachface gradients, and heavy-mineral anomalies in beach and dune sections likely reflect long-term storminess patterns. Our study demonstrates the potential of the Kolga complex as a geological archive of relative sea level (beach/dune contact and basal peat chronology) and storminess in the eastern Baltic Sea area.

Abrupt and extreme climate changes over the Late Glacial Stage

Dr. Federica Perazzotti [1], ***Prof. Vincenzo Pascucci*** [2], ***Prof. Stefano Andreucci*** [3], ***Dr. Daniele Sechi*** [2], ***Dr. Giulia Cossu*** [2], ***Mrs. Giulia Laura Faedda*** [2], ***Mrs. Nicole Ruberti*** [2], ***Mrs. Myriam Francesca Stelletti*** [2], ***Dr. Antonio Santonastaso*** [2], ***Mrs. Laura Pireddu*** [2], ***Dr. Mario De Luca*** [2], ***Prof. Pierluigi Pieruccini*** [4]

1. *University School for Advanced Studies - IUSS,* **2.** *University of Sassari,* **3.** *Università degli Studi di Cagliari,* **4.** *Dipartimento di Scienze della Terra, Università degli Studi di Torino, Italy*

Public awareness of extreme climatic events has risen sharply in recent years, partly because media attention emphasises the catastrophic nature of floods, droughts, storms, heat waves or cold spells. However, extreme events are also recorded in the geological record and their relationships to undetected millennial-scale climate cyclicity is crucial to assess any natural hazard evaluation. Coastal landscapes are among the most sensitive systems to abrupt climate changes and important archives of past and ongoing climatic changes. They can be used to reconstruct future scenarios potentially undergoing toward recurrent extreme climatic events. Four sites, located almost at the same latitude, were chosen to define how climate changes have modified the landscape and, in places, human adaptation during the last 125 ka, from the Last Interglacial (Marine Isotopic Stage-MIS 5e) to the Present (MIS1). The sites were selected because of detailed sedimentological, stratigraphical and geomorphological studies. They are located in North-West Sardinia (Porto Palmas), Tuscany (Baratti), Lazio (Circeo) and Apulia (Romanelli Cave). In all selected areas the Last Interglacial high-stand sea-level indicators are tidal notches or marine terraces buried by continental deposit attributed to the subsequent low-stand glacial phases (MIS 4-2). At Porto Palmas aeolian dunes cap valley fills and alternate with alluvial fans, dated between 70 ka and 8 ka. At Baratti, the alluvial record spans from about 108 ka to 15 ka. Circeo is characterised by alluvial fan and palaeosols deposits referred to MIS3. At Romanelli Cave the sedimentary record is made of sands, silts and clays deposited from MIS5 to MIS1 (10 ka) alternating with flowstones dated at 120 and 40 ka.
In order to improve and test the chronological settings of the cited Late Pleistocene successions we integrated the existing radiometric ages (U/Th, ^{14}C) with Luminescence dating. The preliminary results highlight how sedimentary systems evolve and behave under rapid climate fluctuation referable to Dansgaard-Oeschger and Henrich events, opening new scenarios for studying the potential cyclicity of extreme events.

Rise and decline of Holocene tufas across Europe: exploring east/west and north/south similarities and differences in the climatic and anthropogenic impacts on their development

Dr. Julie Dabkowski [1], ***Mrs. Léa Beaumont*** [2]

1. CNRS-Laboratoire de géographie physique: environnements quaternaires et actuels (UMR 8591 Université Paris 1 Panthéon-Sorbonne, UPEC), 2. Laboratoire de géographie physique: environnements quaternaires et actuels (UMR 8591 Université Paris 1 Panthéon-Sorbonne, UPEC)

Since the 1990s, the postulate that there would be a marked decline in the deposition of calcareous tufas in Europe since ca. 2500 BP (Goudie et al., 1993) has been widely discussed as a growing number of studies provided evidence of deposits developing until our present days. We recently demonstrated that the 'late-Holocene tufa decline' is actually a general view of a rather complex tendency: after a maximum during the Atlantic period, fluvial tufas are systematically affected by a decline from ca. 5 ka cal. BP but no general trend is shown in the development of proximal (spring-fed) or lacustrine tufas (Dabkowski, 2020-QSR). Using the same, updated, inventory of well-dated deposits, we here investigate similarities and differences across Europe in the timing of tufa onset and decline during the Holocene.

Eastern deposits start developing then reach a maximum slightly earlier than western tufas. Afterwards, they show a relative decline from ca. 6 ka cal. BP in the east and ca. 5 ka cal. in the west. Marked east/west differences in the timing and intensity of the climatic improvement during the first half of the Holocene explain the earlier development of eastern tufas compared to the west. After the Atlantic optimum, climatic variations become narrower and cannot explain on their own the decline observed both in the east and west, suggesting a strong influence of anthropogenic modifications in all Europe since the Bronze age.

Comparing southern deposits to other European tufas, significant differences in both their development and decline are observed, whether all or only fluvial deposits are considered, reflecting the important decoupling between Mediterranean and mid-latitude climatic records. However, the earlier and more intense tufa decline observed in the mid-/northern part of Europe is more likely to results from an earlier and faster development of farming and related deforestation at European mid-latitudes compared to southern Europe.

These data re-emphases the close relationship between tufa development and both climatic and anthropogenic changes but demonstrates spatial differences in the modalities of those impacts.

Quaternary travertine deposits derived from the recent activity of the Alhama de Murcia fault, Eastern Betic Cordillera, Spain.

Dr. Carolina Canora [1]***, Prof. Juan Miguel Insua Arévalo*** [2]***, Dr. Jose J. Martínez-Díaz*** [2]***, Dr. Jaime Cuevas*** [1]

1. *Universidad Autónoma de Madrid,* ***2.*** *Universidad Complutense de Madrid*

Continental carbonates, such as travertines and tufas, formed from CO_2-rich groundwater degassing as it emerges at the Earth's surface, are often associated with major crustal-scale faults. The Rosel site, in the Lorca-Totana section of the Alhama de Murcia Fault, Spain, presents a complex geomorphological landscape controlled by active tectonics. The Alhama de Murcia Fault is an 80 km long left-lateral strike-slip fault that is one of the main seismogenic structures in the Iberian Peninsula. In this work, we analyzed the carbonatic materials present in the Rosel site through the study of SEM images, thin sections and chemical analysis to determine the origin of these quaternary deposits. The aim is to explore the relation between quaternary travertine precipitation and the tectonic activity of the fault through morphological and geochemical studies. The $\delta^{13}C$ and $\delta^{18}O$ isotopic signals indicate that the origin of the carbonate deposits in the Rosel site are hydrothermal. In addition, the $^{87}Sr/^{86}Sr$ ratios in the samples suggest subsurface fluid interaction with the Miocene sediments and the Alpujárride basement, located below the alluvial deposits. The tectonic activity in the Alhama de Murcia Fault generates the opening of the deep water circulation in the crust every time a seismic event occurs, giving rise to the precipitation of hydrothermally derived carbonates. The deep waters rise and reach the surface interacting with the meteoric waters, resulting in the travertine formation. Therefore, the Rosel carbonate deposits study can inform us about the seismogenic cycle of the Alhama de Murcia fault in the Lorca-Totana section.

Uranium content in Italian Quaternary travertines and calcareous tufas: a review

Dr. Francesca Giustini [1], ***Dr. Mauro Brilli*** [1]

1. *Istituto di Geologia Ambientale e Geoingegneria, CNR, Roma*

A database consisting of 163 data of uranium content and $^{234}U/^{238}U$ initial activity ratio, from 15 Italian Quaternary travertine and calcareous tufa sites, has been compiled from the relevant literature. Applying a graphical method, data have been interpreted considering the uranium geochemistry in natural environments as well as the geological, hydrogeological and hydrochemical setting of each site. The U content and $^{234}U/^{238}U$ initial activity ratio in travertine and tufa appears to be due to interaction among different factors, such as the availability of U in the aquifer rocks, the redox state of the waters, and the water/rock interaction in the aquifer. Three groups of travertines/tufas, characterized by different U concentration and $^{234}U/^{238}U$ initial activity ratio, were identified; the groups include: i) carbonates precipitated from groundwater circulating, with short/fast flow path, in volcanic rocks with high radionuclide content; ii) carbonates precipitated from groundwater circulating, with long and/or the deep flow path, in carbonate/evaporite formations with relatively low radionuclide content; iii) carbonates precipitated from cold-waters associated to river systems, which are characterized by oxidized conditions and fed by high-discharge springs recharged by carbonate aquifers. Mixing between waters from different aquifers and different geochemical characteristics occurs frequently in the sites investigated. This interpretative model might be applied to other fossil travertine and calcareous tufa and contribute to reconstructing the paleo-environments of ancient depositing systems.

Investigation on the Quaternary interglacial deposits of the River Somme basin have allowed the discovery of an exceptionally well preserved calcareous tufa formation overlying an alluvial sequence at Caours on the lowest fluvial terrace of the Scardon River (tributary of the Somme). The basal periglacial gravels lies at + 6m above the modern valley bedrock and belongs to the lowest terrace within the Somme terrace system. The calcareous tufa is separated from the underlying periglacial alluvial gravels by fluvial calcareous silts overlain by a marshy soil and a thin peat layer. The whole sequence, has provided abundant malacological faunas allowing palaeoenvironmental and climatic reconstructions. The initial overbank fluvial silts yield assemblages of open ground including cold-loving species allowing the recognition of Lateglacial climatic conditions. In the upper part of the silts, land snails communities reveal a dramatic change to open forest environments indicating early Interglacial climate. Subsequent full temperate faunas in the tufa contain increasing amounts of forest snails, these are up to 70% in the last organic layer and correspond to the climatic optimum of the Interglacial. The upper part of the tufa shows a progressive decrease of the most thermophilous snails. Tufa geochemistry ($\delta^{18}O$ and $\delta^{13}C$) provides results consistent with this interpretation. The lower part of this sequence (»0.5 m) includes organic tufa horizons (micro marshy soils) that have yielded thousands of large mammal remains and Palaeolithic flint artefacts. Geochronological data obtained on U-series (TIMS) dates from stromatolith calcite crystals and TL dates from heated flints confirm the allocation of the archaeological layers to the Eemian optimum (MIS 5e: 123±3 ka /11 dates). Palaeontological, dating and archaeological approaches at Caours allow a very detailed reconstruction of the evolution of palaeoenvironments from the end of the Saalian and during the last interglacial. Moreover Caours appears now as one of the most complete and well preserved Palaeolithic site in Europe for the Eemian optimum demonstrating that Neanderthal was fully adapted to forested habitat and a temperate climate.

Ages and temperature of the Vértesszőlős Early Human site (Hungary)

During the Lower Palaeolithic, Central Europe is regarded as having a key position between the Near East, Central and Southern Asia, Mediterranean and Western Europe, being located on the “Out of Africa” route. At Vértesszőlős (Hungary), important archaeological settlements and remains of *Homo heidelbergensis* were preserved in loose sediments and tufa pools deposited at both glacials and interglacials from 557–223 thousand years ago (ka), corresponding to marine isotope stage (MIS) 14 to 7, with a peak at MIS 9. Tufa ages of 223 (±27) and 227 (±24) ka at the occipital bone confirm the overlap of *Homo neanderthalensis*–like and *H. heidelbergensis* fossils in Europe. Clumped isotope-based temperature of tufas range from 8 to 19 °C and 11 °C during the precipitation of the tufa containing the human occipital bone. The tufa–pools were thus slightly cool and their temperature have changed through time. The calculated $T(\Delta_{47})$ values do not follow the global MIS 9 to MIS 8 cooling trend, whereas the calculated $\delta^{18}O_{water}$ values range between –11.7‰ and –9.9‰, consistent with waters infiltrated during glacials. Due to relatively large analytical uncertainties, glacial and interglacial periods cannot be differentiated based on the present data set. Only a few MIS 9 paleoclimate records are available from Central Europe, and our clumped isotope-based temperature and $\delta^{18}O_{water}$ estimations are the first carbonate-based paleoclimatic evidence available from the Carpathian-basin for reconstructing the environment in which *H. heidelbergensis* lived.

Proxy records of Early-Middle Pleistocene Karahallı travertines for depositional environment and palaeoclimatic changes (Uşak, SW-Anatolia)

Prof. Ezher Tagliasacchi [1], ***Prof. Mine Sezgül Kayseri Özer*** [2], ***Dr. Tülay Altay*** [3]

1. Pamukkale University, 2. Dokuz Eylül University, 3. Afyonkarahisar University

The Karahallı travertines are situated in the north of the Baklan Graben in SW-Anatolia. This graben is formed as a NE-SW trending basin developed due to the extensional regime during the neotectonic period in the region. In this study, palynological, sedimentological, radiometric dating, and stable carbon-oxygen isotope of the Quaternary depositional system were firstly investigated. For this aim, 4 deep borehole logs (K-2, K-3, K-5, and K-6) included travertine levels were examined besides field observations. The results of this study contribute to a better understanding of the paleoenvironmental and palaeoclimatic changes of the investigated area as well as SW-Anatolia during the Quaternary period. Travertine precipitation was detected upper part of the Pliocene lacustrine deposits consisted of coal-bearing mudstone, clay, and clayey limestone. These travertine deposits, which have a thickness of about 40 meters, have interbedded with clastic inputs when travertine accumulation decreases or ceased. The Karahallı travertines were precipitated in a depression depositional system in the lacustrine environment characterized by micritic (laminated), reeds, pisoids, intra-clasts, extra-clasts, and algal levels. Travertine deposits are characterized chiefly by high depositional rates, horizontal bedding, low porosity, and permeability. Ostracod, gastropod fragments, and algal (Charophytes) forms are commonly observed. The ^{230}Th analysis on travertines selected from core samples were performed and according to dating results, these terrestrial carbonates continued to precipitate during the Middle Pleistocene (~288ka) In addition, $\delta^{13}C$ values of the Karahallı travertines are between -3.24 ‰ and 1.86‰ (V-PDB), while $\delta^{18}O$ values range from -9.67 ‰ to -8.36 ‰ (V-PDB). The oxygen isotope ($\delta^{18}O$) values recorded from lacustrine successions decreased significantly from the MIS 10 (cold-arid) to MIS 9 (temperate and rainy). 7 core carbonate samples were compiled for palynological analysis and due to pollen results, the Middle Pleistocene (MIS 10) microflora is characterized by dry herbs (NAP) and woody plants (AP). Moreover, the hydrothermal water influx played an important role in forming travertine precipitation and this might be strongly concerned with the active fault systems in the study area.

Asymmetric fissure-ridge travertine formation in active contractional zone: a structural inference (Yurtbaşı-Van/Türkiye)

Prof. Serkan Üner [1]***, Mr. Yılmaz Ağırtaş*** [1]***, Prof. Ezher Tagliasacchi*** [2]

1. *Van Yüzüncü Yıl University,* ***2.*** *Pamukkale University*

Eastern Anatolian Contractional Province (EACP) is characterized by a N-S compressional tectonic regime generated by the collision between Arabian and Eurasian plates. This tectonic regime is predominantly represented by E-W trending thrust faults, conjugate strike-slip faults, and rare normal faults. The region is also active in collision related volcanism. An asymmetric fissure-ridge travertine deposits are determined in the north of that collision zone, at the Yurtbaşı-Van (Türkiye). The Yurtbaşı Fissure Ridge Travertine having 700 m length and 70 m thickness. Travertine is mostly composed of bedded travertine deposits which formed as a result of flowing of surface waters. Banded travertine deposits are not observed due to lack of an active fracture. N-S aligned warm spring water (20-25 °C) pools are located on the top of the ridge. Disorganized water leakage zones determined on western wall of the ridge are interpreted as subvertical vein formations reached to the wall. Fissure ridge travertines are considered as ideal phenomena for identification of extensional deformation. Yurtbaşı Fissure Ridge Travertine formed as a N-S trending asymmetric ridge is one of the rare examples of extensional based syntectonic deposition at the Arabian and Eurasian collision zone.

Travertines between karsts and tectonics: a support for the analysis of fault activity and seismic hazard in Southeastern France?

Ms. Naïs SIRDEYS [1], *Prof. Olivier BELLIER* [1], *Dr. Vincent OLLIVIER* [2]

1. Aix Marseille University, CNRS, IRD, INRAE, College de France, CEREGE, Aix-en-Provence, France, 2. LAMPEA (UMR 7269; CNRS-Aix Marseille Université, Ministère de la Culture et de la Communication), MMSH 5 rue du Château de l'Horloge, 13094 Aix-en-Provence, France

Promising new results have been obtained on calcareous tufa/travertines sequences in the vicinity of faults in the south-east of France, an area considered to be of moderate seismicity (seismic zoning of France).
The first results were obtained on the following diachronic and regional formations: 1) the St Antonin sequence, close to the Sainte Victoire thrust; 2) the Thomassine formation (Manosque), close to the Middle Durance fault, and finally 3) in the ravine of Castillon (Ségriès), on a small local dexter strike-slip with verticalization and rupture of the deformation in close relation with the major thrust of the Castellane arch.
The approach uses pXRF analyzes to determine the elemental composition of the carbonate/calcareous tufa and travertines concretions in order to identify the origin of the waters: karstic or with a link between tectonic accidents and mineralization of springs?
Several studies have already displayed the capacity of travertine and tufa to trap a large proportion of metals and minerals in solution or in suspension in the water.
The first sites analyzed present elements absent from the surrounding lithologies and local environments (e.g., S, Zn, Pb, Cu, Nb, Mo). It highlights a (potential) deep origin of the waters (raised by faults or fracturing) and indicates a significant contribution of these systems in the genesis and development of regional calcareous tufa and travertine sequences.
This provides crucial information on the detection of new potentially active tectonic and fault ruptures through a simple and directly applicable fieldwork method.
The different approaches and methods developed within the DystraPaRnat program (CNRS INSU) combine the use of geomorphological/climatic markers (paleohydrology of travertine and detrital systems) with elemental geochemical analyses (of concretions fed by fluids transiting through faults and fracturing).
Applications in the Southeastern France provides a regional context clearly supported by the number and quality of the calcareous tufa and travertines of the Upper Quaternary.
This allows to associate long-term environmental information (since 100 ka) to the analysis of the notion of natural hazards in the studied area in an original and innovative way.

The buried travertine body of Prima Porta (Central Italy): a multidisciplinary approach to understand its genesis and subsurface setting

The results of recent studies carried out on a buried travertine deposit are presented. Travertine was identified in a drilling at Prima Porta, north-west of Rome (Italy), on the western boundary of the Tiber valley, a morpho-tectonic depression of extensional origin. This travertine was investigated using a multidisciplinary approach that included stable isotope geochemistry, mineralogy, petrography and radiometric dating, with the aims of understanding the depositional setting of the paleo-travertine system, the origin of travertine-depositing paleo-fluids, and the major processes controlling the formation and evolution of the travertine body. Geophysical and geochemical techniques (ERT, seismic refraction, ambient noise measurements, and CO_2 and ^{222}Rn concentrations in soil-gas surveys) were also applied to detect the subsurface setting of the fluvial incised-valley where the travertine body intercalates between alluvial deposits of the Tiber river.

Prima Porta travertine is associated with the rise of a deep-seated, hypothermal, saline, CO_2-rich fluid. According to macroscopic features of core (i.e., horizontal to sub-horizontal, irregular, wavy laminations) and microfacies associations (i.e., micrite crusts and rafts, both intercalated within and between the shrubs), travertine deposition was associated with a low to moderate energy environment, such as gently-dipping, shallow pools on low-angle, terraced slopes. U/Th dating suggested that activation of the travertine-depositing spring was probably coeval with the wettest climatic conditions occurring during MIS3, whereas the end of deposition coincided with the cold and arid phase of the last glacial maximum.

Applying non-invasive geophysical and geochemical methods, which complement each other, the geometry of the buried travertine body was defined and the subsoil structure of this sector of the Tiber valley was delineated. The upper surface of the travertine body appears to have a curved shape, gently dipping towards the E to the present-day Tiber river, forming a concave-upward section wedging out toward the S. Due to its hydrothermal origin, this travertine is hard and crystalline material, poorly porous, and consequently its specific electrical resistivity values were relatively high with respect to those measured in the embedding alluvial sediments (silt and silty sands).

Interbedded history of Holocene tufa and alkaline peat formations in the Somme valley (France)

During the Holocene, concomitant formations of peat and calcareous tufas are recorded on chalky basins of north-west Europe (Belgium, Netherlands, Germany, Poland). Since the 19th century, geologists have recorded tufa-peat formations on the valley floor of the Middle Somme valley. Two systems of calcareous tufa have been identified in the midst of the peat deposits: 1) in dome-shaped tufas that wind through the valley and overhang the actual peaty valley floor by about three metres and 2) in lateral banks below the chalky cliffs. The interstratification with the peat deposits shows both simultaneous growth and different hydraulic conditions. The relationship between these sediments is still poorly documented, but offers possibilities for complementary palaeoenvironmental reconstruction.

New fieldworks have provided a better understanding of these tufa-peat alternations. Stratigraphic surveys (tufa-peat sections and auger coring) of the Bourdon-Tirancourt sector and a GIS study of the valley floor were carried out, in order to characterise the geometry of the deposits and the environmental evolution during the Holocene. These surveys showed that the tufa domes developed in a paleochannel and at the bottom of dry valleys. Supplemented by a malacological study of a tufa dome in Bourdon and radiocarbon dating on peat, a first chronology of interstratification and environmental conditions is emerging to document the evolution of the water regime and aquifers of the valley floor during the Holocene.

The development of tufas begins in the Preboreal period, according to the dating and several archaeological artefacts embedded in tufas. From 2300 BP the deposits became more silty and their formation was interrupted during the Iron Age. The peat preserved alongside the tufa dates from the Subboreal (around 3500 BP). Thus, the altitude of the top of tufas would indicate a more important peaty filling which has undergone a strong degradation (erosion, mineralization) and heights of water tables much higher than those observed nowadays.

Organic Biomarkers in Modern Terrestrial Carbonate Deposits

Dr. Alex Brittingham [1]***, Dr. Ariel Malinsky-Buller*** [2]***, Dr. Alon Amrani*** [1]***, Dr. Yoanton Goldsmith*** [1]

1. *Hebrew University, Jerusalem,* ***2.*** *The Institute of Archaeology, The Hebrew University of Jerusalem, Jerusalem*

Terrestrial carbonate deposits, such as tufa and travertine, provide long term, continuous depositional sequences in many different environments. In trying to reconstruct vegetation and hydrological changes in the past, traditional stable isotope analyses ($\delta^{13}C$ and $\delta^{18}O$) of carbonate minerals within these deposits are often difficult to interpret due to fractionation during the deposition of carbonate minerals in these systems. However, given the co-deposition of carbonate minerals with organic remains from plant material and microbial life, these deposits can serve as archives of organic biomarkers. Analysis of these organic biomarkers within tufa and travertine deposits would allow for the potential reconstruction of hydrological (δD_{lipid}) and vegetation ($\delta^{13}C_{lipid}$) changes without the complications of fractionation during mineral deposition. Here we will present initial results from a pilot study on the preservation of lipid biomarkers in modern tufa and travertine forming in the Ararat Valley, Armenia and the Jordan Valley, Israel.

Tufa or travertine deposits in hyperarid basaltic regions: the singular case of the Khaybar oasis (NW Arabia)

Dr. Bruno Depreux [1]***, Mr. Sylvain Colin*** [2]***, Dr. Remy Crassard*** [1]***, Dr. Guillaume Charloux*** [3]***, Dr. Munirah Al Mushawah*** [4]

***1.** Archéorient, UMR 5133, University of Lyon 2-CNRS, 7 rue Raulin, 69007 Lyon, France, **2.** HADES Archéologie, **3.** Orient et Méditerranée, UMR 8167, CNRS, **4.** Royal Commission for Alula*

Carbonate deposits have just been discovered in the Khaybar oasis, in a desert area of the northwestern Arabian Peninsula. This oasis, located at the head of a catchment, is established in wadis that incise the Precambrian basement and the overlying Pliocene basaltic flows.

For the moment, six outcrops of these carbonate deposits have been identified within it and present several similar characteristics: they are currently inactive, highly indurated, and located on the basaltic slopes between 1 and 5 metres above the valley floor. Most of them are characterised by alluvial facies, and show a low sedimentary thickness (50 to 100 cm) and sometimes remains of continental molluscs or root systems. One outcrop is distinguished from the previous ones by a greater thickness (3 metres) and by a dam morphology across the wadi and by waterfall facies.

Such types of deposits remain largely unknown in this region, and more generally at these low latitudes. Indeed, the geological and climatic context makes this case study quite singular and already raises many questions about the presence and nature of these deposits. The first question we will try to answer concerns the origin of these deposits: are they thermogenic or meteogenic? The faulted Precambrian basement and the presence of aquifers in the basaltic flows keep the question open. Preliminary isotope tests should answer this question. Another unknown factor concerns the age of these deposits. Are the six identified outcrops synchronous or do they reflect different wet phases during the Pleistocene? Different dating methods will have to be used to determine their chronology: U/Th, OSL and possibly ^{14}C if the deposits allow it.

Depending on the answers to these questions, these deposits could constitute an unexpected palaeoenvironmental or even palaeoclimatic record in the Arabian Peninsula.

Analyses of Tsagaan Lake Sediment, Valley of The Gobi Lakes, Mongolia, to Understand the Past Environmental Changes and the Effect of Ongoing Global Warming

Mr. Shuukhaaz Ganbat [1], ***Prof. Noriko Hasebe*** [2], ***Dr. uyangaa udaanjargal*** [3], ***Dr. Davaadorj Davaasuren*** [3], ***Mr. Shinya Ochiai*** [4]

__1.__ Division of Natural System, Institute of Nature and Environmental Technology, Kanazawa University, __2.__ Institute of Nature and Environmental Technology, Kanazawa University, __3.__ School of Arts and Sciences, National University of Mongolia, __4.__ Low level Radioactivity Laboratory, Institute of Nature and Environmental Technology, Kanazawa University

The arid region of Mongolia is a sensitive region to climate change. Understanding global warming plays an important role to predict further climate changes. In this study, we aim to investigate the relationship between the climatic factor and sedimentation history on the centennial timescale (<100 years). We retrieved a core sample (136 cm depth) from the Tsagaan lake in the Valley of the Gobi lakes, Mongolia. The sediment core mainly consists of clay and silt sediments, occasionally interrupted by the sand-dominated layers. The sediment characteristics such as water, organic matter, carbonate, silica concentrations, and grain size were measured by 1 cm intervals. The major elemental composition was measured in 10-cm intervals using the XRF analysis. ^{210}Pb dating method was applied and three age models under the assumptions of Constant Rate of Supply (CRS), Constant Initial Concentration (CIC), and Constant Flux and Constant Sedimentation (CFCS), were investigated for the sediment chronology. In addition, a self-calibrating Palmer Drought Severity Index (scPDSI) was calculated for the study area using the Climate Research Unit (CRU) data (Harris et al., 2020). The CRS model revealed that the upper 26 cm sediment spans the sedimentation history of the last 87 years, which is more reliable than the CIC and CFCS models. The drought period (negative value of PDSI) is coinciding with the abundance of organic matter, carbonate, and silica with the coarser particles in the lake sediment. This result is also evidenced by the significant correlations of loading plots in Principal Component Analysis. The major elemental composition of sandy layers in the sediment core corresponds well with that of mobile sand in the catchment. The sandy layers are likely to indicate the aeolian activity in the past.

Dating early Quaternary aeolian deposits unravels coeval links between climate, tectonics, and erg generation

Dr. Shlomy Vainer [1]***, Prof. Ari Matmon*** [2]***, Dr. Yoav Ben Dor*** [3]***, Prof. Eric Verrecchia*** [4]***, Prof. Frank Eckardt*** [5]***, Dr. ASTER Team*** [6]

Evaluating the impact and implications of aeolian repositories that mark large-scale climatic transitions requires knowledge about the timing of their emplacement and the mechanisms responsible for their production, which remain highly uncertain. Here we apply numerical modelling of cosmogenic nuclide data measured in aeolian sand using two independent dating methods. Nineteen samples were collected in the largest continuous terrestrial body of sand on Earth, to determine settings under which the sand was generated, by constraining the timing of sand introduction into the interior of southern Africa. Our findings reveal that major events of sand formation and accumulation in the Kalahari Desert occurred between ~2.2 and 1 Myr ago. The establishment of the Kalahari sand field corresponds to regional, continental, and global scale climatic and morphotectonic changes that contributed to the mass production and widespread dispersion of sand. These changes substantially altered existing habitats, thus constituting a crucial milestone for flora, fauna, and hominins in southern Africa during the Pleistocene.

Timing of aeolian sediment deposition in eastern central Asia during the Late Quaternary

Dr. Georg Stauch [1]

1. RWTH Aachen University

Aeolian sediments are widespread in Central Asia and can provide important information on past climates. Accumulation phases are often interpreted as either strong aeolian activity or / and increased moisture, leading to the (final) sediment deposition. However, the interpretation is highly site specific and depends on several factors, e.g. sand availability in the source area and transport rate. For this study, optically stimulated luminescence (OSL) ages from aeolian sands and silts were analysed. The study area is covering heterogeneous landscapes like the Tibetan Plateau, the deserts of northern China, the basins of southern Mongolia and the mountains of central Mongolia. The timing of aeolian sediment deposition strongly varies between these regions. On the northern Tibetan Plateau, strong accumulation took place in the late Glacial and the early Holocene. This was followed by a second phase of aeolian reactivation in the late Holocene. In contrast, much older ages were obtained from the deserts of northern China, covering most of the Late Quaternary with clusters during the last glacial maximum (LGM) and the Holocene. In the large basins of southern Mongolia, aeolian sediments are mainly from the late Holocene, while aeolian sediments in the mountains of central Mongolia were continuously deposited since the LGM. Beside changes in moisture, e.g. due to variations in the Asian summer monsoon, the preservation potential of the sediments largely affects the regional aeolian stratigraphies. The preservation potential is particularly high in the deserts of northern China, due to the large amount of sand available. In contrast, aeolian sediments on the northern Tibetan Plateau and especially in the basins of southern Mongolia are frequently reworked, due to a lower amount of available material. Consequently, only few sediments dating back to the LGM exist. The generally finer sediments in the mountains of central Mongolia might have been preserved due to constantly wetter climate conditions and a therefore reduced remobilisation potential. Interpreting OLS chronologies from large areas with different environmental settings provide important information on climate changes, e.g. monsoonal variations. However, site specific information are extremely relevant and might complicate the supra-regional interpretation.

Interpreting aeolian dynamics by integrating cosmogenic nuclides and OSL (Cosmolian)

Dr. Yoav Ben Dor [1]***, Dr. Shlomy Vainer*** [2]

1. *4Geological Survey of Israel, 32 Yesha'ayahu Leibowitz, 9692100 Jerusalem, Israel,* ***2.*** *Department of Geography and Environment, Bar Ilan University, Ramat-Gan, Israel*

Dunes are a common landscape found across a wide range of climates and environmental conditions dominated by aeolian activity, and are often used for palaeoenvironmental reconstructions and landscape evolution studies. Recent developments in the dating of aeolian landforms in arid climates integrated cosmogenic nuclides and OSL dynamics to date aeolian landforms at the million-year time scale (*Cosmolian*). In this study, the vertical movement patterns of the one-dimensional *Cosmolian* model are investigated using multiple advanced time-series analysis approaches in order to determine whether model simulations that converge to a common cluster share similar dynamical properties related to dune mobility. By comparing the model simulations that cluster into coherent dating against background simulations, it is revealed that several dynamical properties are required in order to obtain the observed cosmogenic nuclides concentrations in dunes in some of the largest deserts on Earth. These findings may imply that aeolian processes are dictated by inherent dynamical features that control the pace of aeolian activity and dominate dune formation and mobilization across the world. This study presents a novel approach to the investigation of dune dynamics at the million-year timescale using time-series analyses, which sets the grounds for an improved understanding of aeolian dynamics over millions of years.

How old is a desert? New constraints on the Kalahari Desert age revealed by integrating cosmogenic nuclides and OSL (Cosmolian)

Dr. Yoav Ben Dor [1]***, Dr. Shlomy Vainer*** [2]

1. 4Geological Survey of Israel, 32 Yesha'ayahu Leibowitz, 9692100 Jerusalem, Israel, 2. Department of Geography and Environment, Bar Ilan University, Ramat-Gan, Israel

The wide extent of sand dunes in aeolian landscapes across continental interiors calls for improved dating and understanding of their morphodynamical properties for palaeoenvironmental reconstructions and for interpreting landscape evolution. However, the study of aeolian landscape evolution at the million-year timescale is difficult to achieve due to the interaction of different factors affecting dune migration and their self-destruction nature of chronostratigraphic information, which limits the applicability of traditional luminescence dating methods to ages younger than ~200 Ka. In this study, we present a new development for dating aeolian landscapes by simulating aeolian processes coupled with numerical modelling of cosmogenic nuclides accumulation based on luminescence-derived chronologies. This approach reveals ancient phases of sand introduction into the landscape, and provides an empirical process-oriented model that is packaged within a standalone program (Cosmolian), which facilitates the study of aeolian processes over multiple timescales. The new program was successfully applied for the Kalahari Desert in Africa and the Australian Simpson Desert, where it unfolds the timing of sand introduction into the landscape, corresponding with substantial changes in environmental settings. The correlation between the results of the Cosmolian model and the established paleoenvironmental framework exemplifies the applicability of process and data-based modelling in revealing key landscape evolution events in arid environments that may be identified by studying aeolian landforms.

Star dunes – A new combined research approach to deciphering their formation

Mr. Manuel Herzog [1], Dr. Katharina Anders [1], Prof. Bernhard Höfle [1], Prof. Olaf Bubenzer [1]
1. Institute of Geography, Heidelberg University

Complex star and mega dunes still remain, in contrast to small scale dunes like barchans, one of the most understudied aeolian bedform on Earth due to their unstable nature in time, overall size as well as morphometric and stratigraphic complexity. Due to these attributes our understanding of star dune morphometries is lacking sufficient detail and their influence on formation and evolution remains mostly theoretical. Capturing these complex features on surface and subsurface levels, in needed detail, represents significant technical challenges which have to be addressed and overcome to understand these dune forms.
We therefore applied a new approach combining high-resolution multitemporal surface changes reflecting actual aeolian dynamics with subsurface stratigraphical records describing older accumulation patterns. Our main research object for this approach is a complex star dune in Erg Chebbi, Morocco, which was analyzed over a timespan of four years (2018 – 2022) at two-year intervals using Terrestrial Laser Scanning (TLS), Real-Time Kinematic Global Navigation Satellite System (RTK-GNSS) and Ground Penetrating Radar (GPR). Multitemporal high-accuracy 3D surface models created form TLS point clouds were used for morphometric analysis and direct surface change analysis, which relates to sand transport summarizing the actual movement of a complete and complex star dune surface. The stratigraphical subsurface models created on all major dune branches via GPR, reveals relative depositional history and past movement of its major arms.
Our results showed the effects of a so far hardly observed shielding effect, pointing to a form of self-sustained dune growth, which has not yet been described in such spatial detail. This effect leads to the formation of isosceles dune arms with maximum inclinations which are found not only on star but also on other larger dune forms. Overall the methodic concept of combining surface and subsurface models on such large aeolian bedforms using highly resoluted data is promising and can be applied on all scales. Additionally, the suggested approach allows systematic drilling and sampling for luminescence dating to understand the chronological formation of these complex mega dunes in higher detail.

Terracettes in the hyperarid Atacama Desert – fog-driven landforms of Holocene age?

Dr. Simon Matthias May [1], Dr. Dirk Hoffmeister [1], Dr. Dominik Brill [1], Prof. Olaf Bubenzer [2]

***1.** Institute of Geography, University of Cologne, **2.** Institute of Geography, Heidelberg University*

Terracettes are quasi-contour parallel step-like microtopographic features consisting of repetitious platform-type benches and slope-type risers and are documented from hillslopes in a range of climates. While a number of studies emphasize their formation by trampling of livestock and grazing animals (cat steps or stock trails), it has been shown that terracette formation may also be explained by a number of natural processes, including solifluction or freeze-thaw processes, slumping, soil creep, or vegetation control. Despite this variability and the controversy about their origin, these micro-terraces may alter hillslope soil moisture and vegetation patterns, infiltration and surface hydrology, as well as downslope sediment flux, potentially disconnecting downslope conveyance processes of surface runoff. Given the process mechanisms discussed in these previous studies, the extremely hyperarid climate of the central Atacama Desert in northern Chile may be regarded as unfavourable for terracette formation; here, livestock and grazing animals are absent, moisture availability is extremely limited, and frost processes in elevations below ~1000 m asl are rare. Nevertheless, here we report on terracette-covered slopes in the central Atacama Desert located close to the Rio Loa canyon in the Coastal Cordillera, that represents an important inland pathway for coastal fog in the Atacama Desert. Based on sedimentological and geomorphological investigations, UAV-derived aerial photos and soil moisture monitoring, we present geomorphological, stratigraphical and soil hydrological characteristics of the terracettes and discuss potential drivers of terracette formation. Our observations suggest a combination of wind and fog-related moisture supply, particularly during several day-long periods of sustained high relative humidity and fog occurrence, as the key driver for terracette formation, adding to the various processes discussed in previous studies. Finally, OSL dating of terracette platform sediments suggests a Holocene formation of the terracettes, thereby illustrating the importance of fog-driven active hillslope dynamics for shaping the desert landscape in the Atacama under present hyperaridity.

Biogeomorphology of nebkhas in the Mu Us dune field, north-central China: Chronological and morphological results

Mr. Shihan Li [1], ***Dr. Zhiwei Xu*** [1]

1. *School of Geography and Ocean Science, Nanjing University*

Nebkhas, also known as nebkha dunes or coppice dunes, are a unique biogeomorphological aeolian landform that is common in arid and semi-arid regions. They are often regarded as a signal of regional desertification and could be potential dust sources due to their relatively large content of fine sediments, but they also serve as "fertile islands" that enhance biodiversity at a micro-habitat. How the interactions between plant growth and aeolian sand deposition affect the formation and development of nebkhas has not been well documented, though. In this study, the chronology and morphological features of nebkhas in the Mu Us dune field, north-central China were studied using radionuclide (137Cs) dating and unmanned aerial vehicle (UAV) photogrammetric survey. The results show that the nebkhas are mainly distributed around lake basins and dry river valleys with relatively flat topography. Most nebkhas have heights around 0.5–1.5 m, and according to a new integrated age-height model, they mostly formed in the last fifty years. Widespread nebkha growth over that time is interpreted as a response to both desiccation of lake beds and river valleys and a pronounced decline in strong wind frequency. The regular rounded shape of the nebkhas in the study area may reflect the growth form of prostrate, extensively branched *Nitraria tangutorum*, the dominant formative shrub, and response to the low-energy wind environment. A nebkha's height and horizontal length increase synchronously in the early stage of the development, while the increase in horizontal length and projected area accelerates when the dunes become larger. Feedbacks involving both aeolian sand transport and shrub growth can explain a decline in growth rate with increasing height and an apparent height limit of about 4 m. This study also implies that nebkhas are important biogeomorphological features demonstrating how biotic and abiotic interactions can shape landforms and influence ecological functioning in arid and semi-arid environments.

Sedimentology and geochemistry of aeolian sand in the Taklamakan Desert and Horqin Sandy Land, northern China: Implications for surface processes and provenance

Dr. Bo Chen [1]***, Dr. Xiaoping Yang*** [1]***, Dr. Sergio Ando*** [2]

1. *Zhejiang University,* ***2.*** *Università di Milano-Bicocca*

Dune fields of Quaternary age occupy large areas of the arid and semi-arid regions of northern China. However, limited research focused on understanding the provenances and Earth surface processes of aeolian sediment. This study examined the particle size distributions and geochemical composition (including major, trace, and rare earth elements: REEs) of 46 dune sand samples from the Taklamakan Desert and Horqin Sandy Land. The integrated data were used to explore the spatial variations in the characteristics of aeolian sediments and its drivers.

The mean Chemical Proxy of Alteration (CPA) and the Parker's Weathering (WIP) values both suggest the bulk samples from the Horqin Sandy Land experienced more intense chemical weathering, whereas physical weathering is a dominant process in the Taklamakan Desert. Furthermore, a combination of the index of compositional variability (ICV) and immobile trace element ratios shows that dune sand in the Horqin Sandy Land underwent more intense sedimentary recycling. These differences may be attributed to the fact that sediment supply was high in the Taklamakan Desert, which can shorten residence time exposure to chemical weathering and reduce the potential of the effective recycling for aeolian sand.

The Eu anomaly vs. $(La/Yb)_N$ diagrams suggest that the primary source-rocks contributing to the coarse (>75μm) and fine fractions (<75μm) in the Horqin Sandy Land are different but mainly derived from the Great Hinggan Mountains. In the Taklamakan desert, the Kunlun Mountains are the main source of the coarse fraction, whereas both the Kunlun and Tian Shan Mountains are the main sources of the fine fraction. Differences in the provenance of the fine- and coarse-grained fractions are primarily controlled by interactions between wind and fluvial systems. This study confirms that surface processes and sediment provenance in drylands of northern China have distinct spatial differences, implying that geochemical signatures in aeolian sand need to be interpreted in the specific climatic and tectonic contexts.

A Geoarchaeological investigation into the depositional and environmental context of southern Kalahari pan sediments in the Kgalagadi District, Botswana.

Ms. Inèz Faul [1], ***Dr. Stefan Dreibrodt*** [1], ***Mr. Phillip Segadika*** [2], ***Dr. Chris Green*** [1], ***Dr. Sarah Mothulatshipi*** [3], ***Dr. Michaela Ecker*** [1]

1. Christian Albrechts University Kiel, 2. Botswana National Museum, 3. University of Botswana

The Kalahari Desert is a semi-arid landmass that has savannah plant cover and encloses the majority of Botswana in southern Africa. The Kgalagadi district, which is the main focus area of this research, is located in the southern part of this sand plain roughly 518 km south of Gaborone. There is a general paucity of archaeological and palaeoenvironmental research in the southern Kalahari, apart from research conducted on the South African side of the border (for example, Wonderwerk Cave and Kathu Pan). However, a recent survey and excavation campaign carried out in July-August 2022 reported surface scatters of stone tools made of mostly quartzite that fit Middle and Late Pleistocene typologies, implying the presence of human populations in this 'thirstland'. These surface sites are mostly located on the ridges above pans.

Pans (ovate depressions) frequently contain water during the rainy season and are a regular occurrence in the Kalahari along with their lunette dunes. The palaeoenvironment can be examined by investigating the relationship between the pans and their dunes. The presence of these seasonal waterbodies in the past could also have affected the site choices of early humans. Despite this potential, pans have been under-researched for the purpose of palaeoenvironmental reconstruction in a geoarchaeological context. An array of techniques and methods are employed to establish a broad spectrum, depositional and environmental history of the pans and lunette dunes. These include particle size analysis, Loss-On-Ignition analysis, X-ray powder diffraction (XRD), X-ray fluorescence (XRF), Fourier-transform infrared spectroscopy (FTIR), and a microfossil analysis. This contribution aims to elaborate on the present understanding of the palaeoenvironmental conditions in the southern Kalahari basin. The preliminary results of this geoarchaeological analysis (consisting of sediments from four archaeological test pits, six exposed profiles, and three geotrenches) as well as a detailed discussion of the methodologies used are presented. These results provide more detailed information on the depositional context of the Kalahari sediments, which will assist in the investigation of more intricate theories concerning the link between pans and hominin site choices.

The influence of valley damming on Quaternary Vega sequences on the Eastern Canary Islands

Mr. Jakob Labahn [1]***, Dr. Christopher-Bastian Roettig*** [1]***, Dr. Thomas Kolb*** [2]***, Dr. Christina Günter*** [3]***, Dr. Anja Schleicher*** [4]***, Dr. Anna Pint*** [5]***, Mr. Carsten Marburg*** [1]***, Dr. Inmaculada Menéndez*** [6]***, Prof. Michael Zech*** [7]***, Prof. Dominik Faust*** [1]

1. *TU Dresden University,* ***2.*** *JLU Giessen University,* ***3.*** *University of Potsdam, Institute of Geosciences, Potsdam, Germany,* ***4.*** *GFZ - German Research Centre for Geosciences, Climate Dynamics and Landscape Evolution, Potsdam, Germany,* ***5.*** *University of Jena,* ***6.*** *Universidad de Las Palmas de Gran Canaria,* ***7.*** *Heisenberg Chair of Physical Geography with Focus on Paleoenvironmental Research, Institute of Geography, Technische Universität Dresden*

The Canary Islands are formed by several volcanic periods since the Cretaceous. Later volcanic phases were able to dam up former developed valleys. Those valleys were acting as sediment traps. The deposited sediments are so called “vega sediments”, which are mainly composed of three different types of material: sediments of volcanic origin (tephra and lapilli), sediments of the surrounding slopes and dust deposits originating from the northern African continent. Two different layer types characterize the vega sequences. On the one hand there are calcium depleted reddish sediments with high clay content (max. 90%) interveined by calcium enriched, fissure-like structures and on the other hand, there are layers dominated by extensive carbonate enrichment (up to 45% $CaCO_3$), also characterized by the highest quartz contents.
So far, the descriptions presume an intense slope-vega connectivity with erosion and deposition cascades of high frequency but low magnitude. Thus, the formation of the vega sequences seems to be primarily driven by continuous translocation processes from the slopes to the valley floor, rather than by direct dust deposition or abrupt erosion events. Soil forming processes seem to be restricted to the slope positions since the drainage conditions within the valley floors (>80% clay) seem not appropriate to vertical processes like de- and recalcification. Finally, it is unclear to what extent soil-forming processes took place on the slopes and in the valley floor and how and when sediment transport occurred. In that system, the damming effect plays a key role within the formation of vega sediments but is poorly understood yet.
A new site on Fuerteventura gives now the opportunity to evaluate the influence of the damming, since this site shows a comparable setting but without a damming situation. Even though those sequences do not show such a clear alternation of two distinct layer types, several carbonate enriched layers ($CaCO_3$ up to 45%) are separated by carbonate free, clayey fissure-like structures (clay content up to 83%). The comparison between the sites should contribute to the general understanding of the formation conditions, and could pave the way for integrating those geoarchives in the overall context of environmental paleoreconstruction.

Sub-)Recent Earth surface processes in the Kaukausib Catchment, southern Namib Desert

Dr. Felix Henselowsky [1] ***, Prof. Tobias Ullmann*** [2] ***, Dr. Max Engel*** [3] ***, Dr. Joel Mohren*** [4] ***, Prof. Erik Strub*** [5] ***, Ms. Marlene Trautmann*** [6] ***, Mr. Eric Möller*** [7] ***, Mr. Manuel Herzog*** [6] ***, Prof. Olaf Bubenzer*** [6]

1. Johannes Gutenberg University Mainz, Institute of Geography, Mainz, Germany, 2. Institute of Geography und Geology, Department of Remote Sensing, University of Wurzburg, 3. Universität Heidelberg, 4. Institute of Geology and Mineralogy, University of Cologne, 5. Division of Nuclear Chemistry, University of Cologne, 6. Institute of Geography, Heidelberg University, 7. Institute of Geography und Geology, Department of Remote Sensing, University of Wurzburg, Germany

Many current Earth surface processes in dryland environments remain poorly understood. One reasons for this is that representative locations are often located in remote regions without long-term observations. The Kaukausib catchment in the southern Namib Desert is a prime example, where even under long-term hyper-arid climate conditions rare, but significant individual short-term rainfall events can trigger strong landscape changes. Here, remote sensing is a very valuable tool to overcome the lack of (modern) long-term data on Earth surface processes. The analysis of archived satellite images integrating over the longest possible observation period, starting from the 1970s/80s, may govern landscape formation over (sub-)recent timescales.

We present results on vegetation changes mapped by using multispectral optical imagery and several frequently applied spectral vegetation indices, such as the Normalized Difference Vegetation Index (NDVI). Area-wide mapping of the NDVI from 1984 to 2022 is conducted using imagery of the Landsat archive. Within this time period, phases of increased “greening events” can be inferred, e.g. between 1999 and 2012, but a general decline in vegetation vitality is suggested. In addition, permanent vegetation within the study area was mapped using Corona satellite imagery (acquired in 1976) in comparison to present-day conditions. This initial analysis reveals a decline in permanent tree vegetation between 1976 and today.

These outcomes obtained from earth observation archives are complemented by field-based geomorphological mapping and sedimentological characterization of exemplary sediment profiles. For this purpose, the deposition history of a sediment profile consisting of alternating layers of still-water deposits and dune sands is investigated by quantifying fallout ^{137}Cs and ^{239,240}Pu activities at different depths. First results indicate that the accumulation of still-water sediments trapped by a barrier dune and subsequent fluvial incision into these sediments of about one meter are likely to have occurred during the last 70 years. This timescale is largely covered by our remote sensing records, allowing for a direct comparison of the different methods

We see this combination as an innovative new approach to characterizing decadal changes and use such modern analogues as an important basis for the interpretation of landscape changes in drylands also over longer time periods.

Fluvial Responses to Aeolian Encroachment – Aeolian-Fluvial Landform Evolution along Dunefield Margins

Mr. Lotem Robins [1], Prof. JOEL ROSKIN [2], Prof. Revital Bookman [3], Dr. Lupeng Yu [4], Prof. Noam Greenabum [3]

1. Department of Geography and Environment, Bar Ilan University, Ramat-Gan, Israel, 2. Bar-Ilan, 3. University of Haifa, 4. Luminescence Laboratory, School of Resources and Environmental Sciences, Linyi University, Linyi

Aeolian-Fluvial (A-F) processes, in particular damming of fluvial systems by dunes along dunefield margins have been shaping Quaternary landforms in arid zones. At the northwestern Negev dunefield (Israel) margins, high-resolution chrono-stratigraphic analysis of stratigraphic sections revealing remains of truncated vegetated linear dunes and fluvial fine-grained deposits associated with dune-dammed water-bodies documented A-F controlled environmental changes. Nineteen stratigraphic sections in two basins were studied using Portable Optically Stimulated Luminescence (POSL) and OSL dating.

The fine-grained dune-dammed waterbody deposits infilled former fluvial morphologies forming alluvial plains. Three distinct A-F sediment types were discerned in these deposits : (a) event-based couplets, (b) massive structureless loam and (c) fine-laminas. Each impoundment was generated by slightly or distinctly different dune-damming and sedimentary mechanisms depending on the location of the damming-dunes that were found to gradually propagate downstream into the dunefield. The size and depth of the waterbodies were confined by the accommodation space upstream of the dune-dam, while deposition and aggradation depended on the flow capacity and available upstream source sediments.

The three major sand incursions into the NW Negev during the LGM, Heinrich-1 and Younger-Dryas resulted in temporal waterbodies impounded by single to multiple dune-dams. Dune-damming persisted, but not necessarily continuously until the middle-Holocene. The early Holocene A-F sediments along the dunefield margins may reflect a climatic shift characterized by energetic fluvial systems, coeval to Sapropel-1 deposition in the Mediterranean basin. During this period, the upper and widespread portion of the alluvial plains was formed. When the dune-dams were breached during the middle Holocene the alluvial plain was eroded by rapid and reopening, rejuvenation and incision of the fluvial system.

We demonstrate that nature of the interaction between the aeolian mass and the fluvial system determine A-F landscape evolution. Vegetated linear dunes are prone to defined periods of wind-controlled activation, and stabilization that form the dune-dams while dune stability and maintenance accommodation space and sediment flux control the gradual and lagged shift from a dune-dammed fluvial system to an open fluvial-dominated system.

High-resolution analysis of late Quaternary aeolianites on the southeastern Mediterranean coast of Israel

Ms. Lucy Mokaya [1]***, Prof. Revital Bookman*** [2]***, Dr. Joel Roskin*** [3]

1. *University of Haifa, 199 Aba Khoushy Ave., Haifa, 3498838, Israel,* ***2.*** *University of Haifa,* ***3.*** *Department of Geography and Environment, Bar Ilan University, Ramat-Gan, Israel*

Aeolianite ridges are petrified dunes deposited at low to mid-latitude coasts. Their location, structure, and lithification reflect changes in sea level, strong wind power, fetch parameters, and sediment availability. The Israeli coast has a chain of submerged and inland ridges running parallel to the southeastern Mediterranean coastline. They consist of alternating loose sands, carbonated sandstones and red, sandy paleosoils representing periods of reduced wind power and stabilization. Previous studies present low-resolution dating methods, and their finds are poorly correlated with climatic and environmental events related to deposition or lithification.

This study describes the vertical and lateral evolution of an elongated aeolianite ridge. This dune accumulated and lithified along the paleo-Israeli Mediterranean coast during the last glacial period. The objective is to explore the dune development at single-bed to sand package stages in time and their relation to local environmental conditions, regional climatic trends, and possible changes.

The methodology included a detailed Portable OSL analysis, OSL dating and sedimentological characterization. Sedimentological analysis shows that aeolian accumulation occurred as discrete laminae that built-up cross-bedded sediment packages. The loose laminae consist of quartz grains, while the lithified laminae are by calcium carbonate cement. Since cementation is parallel to the aeolian accumulation, indicating it’s a surficial process that occurred while the dune was still active and accumulating. It may mean microbiotic crusts activated by moisture conditions. This can serve as biomarkers for wind power and wetness duration.

POSL measurements have bright blue OSL signals (12-17 million) and very similar depletion and IRSL-OSL ratios demonstrating sedimentological similarity suitable for reliable POSL profiling. POSL profiling revealed a high-resolution and in-order chronostratigraphy. Suggesting that the sand laminations represent specific wind events at a very high seasonal to even diurnal resolution. Lateral POSL results reveal a value range evidence that doesn’t indicate any significant change in depositional age. In contrast, the vertical profile indicates a linear upwards decrease in count values. The trends also show that the quartz grains do not possess a saturated OSL signal. Upcoming OSL dating and outcrop image analysis will better constrain the accumulation rates and their possible connection to environmental and climatic drivers.

Luminescence Dating of Dunes in the Western Thar Desert: New Data and Regional Synthesis

Dr. Sukumar Parida [1], ***Dr. Rahul Kaushal*** [2], ***Dr. Haresh Rajapara*** [3], ***Dr. Naveen Chauhan*** [4], ***Dr. Jitendra Pattanaik*** [5], ***Prof. Robert Wasson*** [6], ***Dr. R. P. Dhir*** [7], ***Prof. Ashok Singhvi*** [1]

1. *AMOPH Division, Physical Research Laboratory, Ahmedabad - 380009, India,* ***2.*** *AMOPH Division, Physical Research Laboratory Ahmedabad -380009, India,* ***3.*** *Department of Physics, Gujarat University, Ahmedabad - 380009, India,* ***4.*** *AMOPH Division, Physical Research Laboratory, Ahmedabad, Gujarat, India,* ***5.*** *Department of Geology, Central University of Punjab, Bathinda - 151401, India,* ***6.*** *College of Science and Engineering, James Cook University, Smithfield, Australia; Fenner School of Environment and Society, Australian National University, Canberra, ACT 2601, Australia,* ***7.*** *498, Defence Colony, Kamla Nehru Nagar, Jodhpur - 342009, India (deceased)*

Luminescence dating of desert dune sands began in the Thar Desert and has revolutionized studies of global deserts. The Thar has been shown to be older than 200 ka, confirming its geological rather than human origin. Dune accretion / preservation was driven by the SW monsoon winds and post-date glacial epochs. After the LGM, short duration episodes of dune accretion occurred around 13 ka, 11 – 9 ka, 8 – 7 ka, 6 – 4 ka, ~2 ka and <1 ka. New optical ages are presented for linear, transverse and parabolic dunes in the western Thar. TL sensitivity of quartz was used as a surrogate for the change in sediment sources of the dune sands. Synthesis of new and previously published luminescence ages suggests:

1. Increased sand accretion during the past 500 a due to both increased anthropogenic activities and preservation bias.
2. Different types of dunes accreted both synchronously and asynchronously, suggesting a varied control of wind regimes and sediment supply. The absence of transverse dune records at different sites between 6 and 3 ka may indicate the limitations of sampling, or a shift to a more multi-directional wind regime that impacted sediment supply/preservation.
3. The sensitivity of the 110°C TL peak of quartz from dunes of ages between 7 and 2 ka is nearly twice that of dunes with ages < 2 ka and > 7 ka. This suggests a change of sediment source. Comparable sensitivity of quartz from current interdune suggests that it could be the source of dune sands during 7 – 2 ka. Higher sensitivity of interdunal sediment of >29 ka age was possibly due to sediment transport over long distances from the exposed continental shelf during low sea level.
4. XRD studies also suggest intermixing and change in sediment sources in the last 8 ka.

Financial support under DST SERB-YOSCP grant and help by Dr. Amal Kar with the identification of sampling locations is gratefully acknowledged.

Aeolian-Fluvial Deposits in Large Fluvial System along Dunefield Margins The Northwestern Negev, Israel

Prof. Noam Greenabum [1]***, Mr. Lotem Robins*** [2]***, Dr. Lupeng Yu*** [3]***, Prof. JOEL ROSKIN*** [4]

1. *University of Haifa, Haifa 3498838, Israel,* ***2.*** *Bar Ilan University, Ramat-Gan, Israel,* ***3.*** *Luminescence Laboratory, School of Resources and Environmental Sciences, Linyi University, Linyi,* ***4.*** *Bar-Ilan University, Ramat Gan, Israel*

Aeolian-Fluvial (AF) processes and dune-damming along dunefield margins generate amplified sedimentation in water-bodies upstream of dune-dams, comprising regional drivers of late Quaternary landscape evolution. While relatively small basins (<10 km^2) often remain dune-dammed until today, large fluvial systems are often been breached and reconstructing their depositional environment is difficult. The role of the pre-existing fluvial relief and basin size upon these dynamics is still unclear. We analyze Wadi Besor, the largest fluvial system (680 km^2) that transects the northwestern Negev desert dunefield (Israel) and provide evidence, despite its size, that the system underwent dune-damming in the late-Pleistocene. Chronostratigraphic sections along the main channel and tributaries with basins of different magnitudes were analyzed and correlated.

The main Besor channel incised into a Plio-Pleistocene peneplain forming a series of 7 alluvial terraces up to 30 meters above the present channel, with a lateral extent of ~3 km. AF stratigraphic sequences in the Besor and its largest tributary, Wadi Revivim, show that catchments at magnitudes of (>10^2 km^2) are composed of fine-grained and sand deposits that reflect the Quaternary sedimentary cover in the drainage area, i.e., loess and sand-sheets. Such relatively high-order basins document both late-Quaternary loess activity-reduction cycles and AF processes following the dunefield encroachment, characterized by dune-damming. The terraced relief and consequent channel depth of large basins permits accommodation space for such depositions.

Smaller middle-sized tributaries (<10^2 km^2) are more sensitive to local AF processes, i.e., single dune encroachments and fluvial erosion of these damming dunes. Thus, smaller catchments provide high-resolution palaeoarchives of aeolian and fluvial processes in the dunefield margin zone.

Radar amplitude as a tool for valley floor monitoring in the Atacama Desert during flood events

Dr. Albert Cabré [1], ***Dr. Dominique Remy*** [1], ***Dr. Odin Marc*** [1], ***Dr. Germán Aguilar*** [2], ***Dr. Sebastien Carretier*** [1]

1. *Géosciences Environnement Toulouse (GET), Université de Toulouse, UPS, IRD, CNRS, 31400, Toulouse, France,* ***2.*** *advanced mining technology center*

Large volumes of sediment were transported downstream and disrupted the lives of the inhabitants of the Atacama valleys for several months (flooded urban areas, high death toll, etc.). The March 2015 pluvial event is the largest event to impact the study area (Cabré et al., 2020a,b; Aguilar et al., 2020; Garcés et al., 2022; Cabré et al., 2022).

We have tested the usefulness of the C-band Synthetic Aperture Radar (SAR) backscatter intensity (amplitude hereafter) (Sentinel-1) to track surface changes in the ephemeral valley floors of the Atacama Desert (27ºS) after flood events. SAR amplitude is an indirect measure of surface roughness and, therefore, grain size on un-vegetated surfaces is the parameter that plays an important role. Therefore, we have focused on an ephemeral channel to contrast SAR products with field measurements (grain size). To validate our results with several field campaigns for direct measurements of grain size distribution in the field and beyond preliminary results, we have also explored how topographic metrics (valley width, gradient, others) and the contribution of upstream area control the relative location of various sedimentary processes.

Characteristic dB values of SAR amplitude allowed us to identify surface types, which has aided the rapid mapping of a sedimentary process, but also to indirectly obtain regional grain-size maps. SAR backscatter intensity maps complemented with other remote sensing approaches can function as predictors of flow types within the ephemeral drainages of the Atacama Desert and will therefore aid mitigation strategies and understanding of arid landscapes to extreme precipitation events.

Fan-river interactions during extreme storm events: examples of El Huasco river, southern Atacama Desert

Dr. Albert Cabré [1], ***Mr. Álex Garcés*** [2]

1. Géosciences Environnement Toulouse (GET), Université de Toulouse, UPS, IRD, CNRS, 31400, Toulouse, France, 2. advanced mining technology center

High magnitude and low frequency extreme storm events have recently impacted the southernmost Atacama Desert. Considering that climate models at these latitudes suggest an increase in frequency of extreme storm events, coupling status monitoring of fan-river interactions represent an essential river management tool.

The efforts to simulate the spatial and temporal behavior of fans, under controlled boundary conditions, have been carried out with physical and numerical modellings. These studies aim to predict topographic effects of processes in fans under constant extrinsic variables by analyzing multi-temporal topographic data sets. The benefit of using experimental devices or numerical models instead of field examples is the rapid repeatability of the simulation of multiple debris flow surges to provide a long history of fan geomorphological changes. However, changes in connectivity between landforms ultimately determine the evolution of rivers under changing extrinsic variables. Unfortunately, due to the low-frequency nature of storms and the inaccessibility of arid landscapes there is a lack of detailed repeated-topography surveys that may assist in monitoring natural systems. The 24th March 2015 and 11st May 2017 storm events consequences in tributary-junction fans are outstanding field examples of how individual storms control fan geomorphology and sedimentology. High-resolution repeated topography, grain size analysis and detailed geomorphological mapping have been studied in the tributary-junction alluvial fans situated at El Huasco river valley (~29ºS). The results indicate that the deep incisions, due to entrenchment of the abandoned alluvial surfaces, resulted in the formation of new lobes on fan toes that, in many cases, blocked the main river or triggered river avulsion. The differences in sedimentology between the fans are a consequence of (i) different water to sediment ratios controlled by the amounts and intensity of rainfall during the events and, (ii) the characteristics of the catchments (e.g. net sediment storage, internal buffers, catchment gradient).
This approach could be used to monitor interactions between fans and the river in future storms that can help manage irrigation channel and water reservoirs. This information will be critical in a region where water resources are undergoing critical drought scenarios.

Geochemistry and microfacies study of travertine mounds from Slovakia

***Ms. Daniella Vieira* [1], Dr. Daniel Pivko [2], Dr. László Rinyu [3], Dr. Sandor Kele [4]**

1. Department of Earth Sciences, Eötvös Loránd University, 2. Department of Geology and Paleontology, Faculty of Natural Sciences, Comenius University, 3. Isotope Climatology and Environmental Research Centre, Institute for Nuclear Research, 4. Centre for Astronomy and Earth Sciences, Institute for Geological and Geochemical Research, Eötvös Loránd Research Network

Spring mound, a dome-shaped calcareous deposit surrounding a spring orifice, is a common travertine morphology in Slovakia. In this study, carbon, oxygen, and clumped isotope (Δ_{47}) composition of recently inactive travertine mounds from 9 locations (Santovka, Dudince, Čerin, Sliače, Liptovský Ján, Basenova, Vyšné Ružbachy, Gánovce, and Sivá brada) were measured to provide information about the origin of carbon, precipitation conditions, and paleotemperature. Petrographic analyses were used to identify microfacies types to reconstruct depositional environments.

Water discharge from the spring vent leads to the accretion of the mound ridges and formation of different travertine facies such as smooth slope, terraced slope, sub-horizontal layers of terrace pools and ponds, and subaerial deposits, where carbonate fabric is related to precipitation conditions of stagnant, fast or slow water flow. Based on petrographic descriptions, a variety of microfacies was identified, comprising several features such as crystalline crust, dendrites, coated grains, coated bubbles, reed molds, and rafts, formed by precipitation in situ, grains precipitated from thermal water or macrophytes coated by precipitated carbonates.

$\delta^{18}O$ and $\delta^{13}C$ values of travertine samples range from −12.2 to −5.8‰ (V-PDB) and 4.9 to 12.3‰ (V-PDB), respectively. $\delta^{13}C_{CO2}$ was calculated, providing values from −4.6 to 4.3‰. Carbon and oxygen data, as well as the calculated $\delta^{13}C_{CO2}$ values, imply isotopic signature typical for thermogene travertines, with thermal waters charged with isotopically heavy CO_2 of deep origin, possibly produced through thermometamorphic reactions. In Slovakia, mineral and thermal waters are mostly found in lowlands and in the Inner Carpathians depressions, which makes Triassic limestones and dolomites the most plausible carbon source.

Clumped isotope composition (Δ_{47}) of selected samples was measured, corresponding to temperature estimates ($T\Delta_{47}$) from 2°C to 32°C, using the calibration of Anderson *et al.* (2021). Comparing $T\Delta_{47}$ values with T°C measured in situ, Southern SK sites (Santovka, Dudince) are slightly higher than the present equivalents measured directly in thermal wells, while in Central SK (Čerin, Sliače, Liptovský Ján, Basenova) and Northern SK (Vyšné Ružbachy, Gánovce) paleotemperatures are slightly lower than temperatures measured in situ, except for one site (Sivá brada), that show higher values when compared to the temperatures measured nowadays.

Community engagement in safeguarding and salvaging the endangered rock art sites in Tanzania: a case from Ikungi District, Singida region (Central Tanzania)

Ms. Jasmine Kilela [1], ***Dr. Makarius Peter Itambu*** [2], ***Mr. Christian Gabriel*** [1], ***Prof. Marina Gallinaro*** [3]

1. *Deparment of Archaeology and Heritage Studies,* ***2.*** *Dept. of Archaeology & Heritage Studies, Univ. of Dar es Salaam, Tanzania Associate Researcher: - Department of Archaeology, Max Planck Institute for the Science of Human History, Germany,* ***3.*** *Department of Ancient World Studies, Sapienza University of Rome*

Located in the core of Tanzania, Singida region is characterized by an articulated landscape with plateaus, inselbergs, escarpments, and impressing rocky hills and Precambrian granite outcrops. These valuable features host a rich and variegated set of archaeological sites ranging from MSA-LSA and historic traditions, including a dense presence of rock art (paintings and engravings). Despite the ubiquitous presence of rock art and the characteristic landscape of Singida, only a few studies were carried out in the area. The research mainly focused in other areas, such as Manyara and Eyasi and Kondoa (declared a UNESCO World Heritage site in 2006 because of "its impressive collection of rock art"). Recent surveys, interviews and ethnographic inquiries revealed the potential of the area for the archaeological and geomorphological heritage. Lately, during our field surveys in 2022 on the eastern axis of the region (Ikungi District), we discovered more than 35 archaeological sites, typically with rock art (*Ngo'ngo a Bendera, Munini, Samamba, Gisamu, Makaho, Masaka* sites, between the others) with hunter-forager paintings such as naturalistic, stylized, schematic human and animal figures as well as geometric designs. The art stylistic motifs and subject matters painted by hunter-foragers recall the UNESCO heritage sites of Kondoa Irangi. However, the sites are facing major threats that need to be addressed, like "treasure hunting", looting and vandalism, or impact by stone quarries, as well as agricultural practices.

This paper presents some preliminary results of the actions adopted to mitigate these damages and eradicate the myth of treasure hunting on rock art painting sites through public archaeology and new management strategies. Furthermore, it calls for the salvage of the sites which are at risk of total disappearance due the encroachments by farmers and activities of the modern-day civilization.

Key Words: *Rock Art, Salvaging, Community Engagement, Conservation*

Glaciers of the Ladakh Range are depleting at an accelerated rate due to their relatively small size and are typically restricted to high altitudes. The recession of the glaciers has resulted in the formation of pro-glacial lakes which occupy the higher elevations and the ones below are seen as remnant/palaeolakes now scattered over the abandoned moraines. In order to understand the ecology and productivity in a nutrient-starved cold desert ecosystem, the analysis of diatoms, along with pollen/spores, was carried out in sediment-water interface of stream, ephemeral pools, and Tsoltak pro-glacial lake along the Chang La pass region. In aquatic environments, diatoms are highly sensitive indicator organisms and their microfossils, deposited in lake sediments, can be used to infer environmental changes while pollen assemblage determines the vegetation pattern.

Our results suggest that the stream/main channel has a very less population of algal remains indicating that the water quality is not suitable for their growth. Maximal growth of algae is observed in ephemeral pools and lake which possess a more diverse ecosystem. The pools and lake create an oligo-mesotrophic environment with high primary productivity (diatoms like *Didymosphenia, Cymbella, Ghomphonema, and Pinnularia*; desmids like *Cosmarium, Staurastrum dilalatum* and *S. punctulatum*. Pollen assemblage constitutes the *Artemisia-Tanecetum*-Apiaceae-*Ephedra;* an assemblage of steppe vegetation indicating the availability of soil-moisture and soil-nitrogen fixation influenced by moist summers. The $\delta^{13}C$ estimates indicate dominance of C3 vegetation and reduced $\delta^{15}N$ indicates atmospheric Nitrogen fixation in the sediments. The aims of the present study are twofold: to determine the productivity of the pro-glacial lakes using modern-day surface samples and to compare this data with the past and to develop predictive models for future climate change. Thus a palaeolake section near the Tsoltak pro-glacial lake was studied which reveals the palaeoecology and palaeo-productivity since the last ~ 6300 cal year BP. The results show a strong correlation with similar diatom forms and pollen assemblage as compared to the modern-day surface sediments pointing towards similar climatic conditions that may have existed in the past.

A new geoheritage map overview for the Netherlands

Dr. Harm Jan Pierik [1], *Ms. Dian Jansen* [1]
1. Cultural Heritage Agency of the Netherlands

Geoheritage sites are essential to show landscape history and human-landscape interactions in the past to the general public. Increased awareness of geoheritage will lead to more effective use of geological features in heritage policies, the energy transition and water safety.
Even in a relatively flat as the Netherlands, relief is present, which is very informative on landscape evolution and the landscape history. Awareness on these topics is essential for implementing climate adaptation strategies in a smart way and furthermore offers chances for enhancing regional identity. Not all these landscape elements can be easily recognized by a laymen's eye, so how to bring this knowledge to landscape planners, developers and citizens?
We here present a new and accessible national map viewer on Dutch geoheritage, which will be embedded in map datasets on cultural heritage. Using site level descriptions with a scientific base, the role of the site in the evolution of the country is outlined.

Poster - sessions 9, 36, 42, 43, 46, 69, 70, 71, 84, 88, 92, 99, 102, 112, 138, 163, 169

New chronological developments on the Migration Period in Greater Poland based on palaeoecological data – preliminary results

Paleoenvironmental reconstructions created in high chronological resolution can identify past anthropogenic impacts on the environment in detail. It is very helpful when archaeological recognition is inadequate, and thus, the reconstruction of chronology is severely limited. One such period in archaeology during the late Roman Period is the Migration Period (MP), dated in Poland to ca. 300-510 CE. The MP was characterized by climate deterioration and the mobility of people in Europe, initiated by the expansion of the steppe Huns tribe into Europe, which probably led to a massive displacement of the population.

A previous study from 36 published pollen data sets with robust chronologies from Polish Lowlands showed that after the MP forest expansion continued between 600-900 cal. CE, when the dawn of Slavic culture resulted in large-scale forest decline, especially in northwestern and north-central Poland.

However, in Greater Poland - where the first structures of Polish statehood were formed - little is known about settlements before 800 cal. CE. To fill this gap, we summarized preliminary results from four high temporal and chronological resolution pollen profiles (retrieved from peatlands and lakes) from areas where the first Slavic dynasty (Piast) created the State. This study aims to determine how the socioeconomic crisis during the MP before the appearance of Slavs in Greater Poland affected the local settlement (and whether was it continuous human activity or not) and how vegetation responded to this transition.

Preliminary results indicate the regeneration of oak-hornbeam forests shortly after the MP (ca. 360–510 CE). The hornbeam was gradually selectively logged from as early as 600 cal. CE, which proportion in forests decreased significantly until 900 cal. CE. In the Greater Poland region, it was the time of the first state structures establishment. In our data, this period corresponds to increased human impact indicated by an increase in the percentage of various pollen types of cereals and ruderals. This work constitutes the first step in exploring high-resolution paleoenvironmental changes (with a special focus on human impact) during the Migration Period in Greater Poland.

Project funded by National Science Centre, Poland (number: 2021/41/N/ST10/02044 and 2019/33/B/HS3/00193)

Treasuring the inevitable: soil loss as a tool for understanding archaeo-environmental palimpsests. A case study from Mahal Teglinos (Kassala, Eastern Sudan)

Dr. Stefano Costanzo [1]

1. Università degli Studi di Napoli "L'Orientale"

Damage caused by erosion on soils and landscapes is a foremost matter that is recurrently addressed by scholars belonging to different fields and working in diverse regions characterized by highly dynamic environments. All parts agree that sheet, linear, and gully erosion must be appointed as one of the most prominent manifestations of land degradation in all environments where intensive rainfall occurs. In arid lands, erosion-related loss of archaeological record - which is inherently embedded within the younger and most delicate geological strata and pedological bodies - represents a setback for researchers and local communities alike. Although mitigation techniques and conservation policies have been proposed, it is general consensus that, in the short and medium run, and where site remoteness represents an infrastructural limitation, soil loss cannot be avoided. Nevertheless, the dismantling processes not only represent an active manifestation of the morphogenetic and environmental history of sites and regions, but are also key to access buried extensive archaeological and environmental palimpsests that would be otherwise approachable only by means of test trenching and coring.
A noteworthy case-study is represented by the Sahelian site of Mahal Teglinos (Kassala, Eastern Sudan), a secluded small valley hosting rich Late Quaternary archaeological and pedosedimentary records. Therein, despite the hot semiarid regional climate (BSh), hydric erosion acting on delicate sediments is today the main driver of soil displacement and loss. Nonetheless, the erosional process unveiled buried and concealed features composing a thick natural palimpsest that testifies a highly dynamic succession of morphogenetic events, telling a story of Holocene climate changes and human adaptation. Stratigraphic correlation and archaeological evidence also suggest that the erosional surface processes started during the first millennium BCE, making the missing soil an effective feature of the archaeo-environmental palimpsest. Nonetheless, erosion is currently accelerating due to weather anomalies and climate change, threatening the remaining pristine contexts. This work represents a call for action in taking advantage of naturally exposed stratigraphy prior to its total loss, especially in remote and understudied areas where sites are hardly accessible and information yield may be ultimately favoured by undertaking regional-scale surveys rather than single-site deep excavation.

Lake record of black carbon from southern Sweden reveals increased flux in the early 18th century

Dr. Karl Ljung [1], *Mr. Edward Allison* [1], *Mr. Ethan Silvester* [1], *Ms. Hanna Hertzman* [1], *Prof. Dan Hammarlund* [1]

1. *Department of Geology, Lund University*

Black carbon (BC) is produced by incomplete combustion of organic matter and fossil fuels. The BC particles consist of highly condensed and aromatic carbon compounds with high resistance to degradation and are thus important for the long-term carbon storage in soils and sediments. BC particles are also part of the particulate pollution with severe health consequences.

Here we present BC concentrations and accumulation rates in the sediments of a small lake (Odensjön) in southern Sweden. The lake is situated at 60 m a.s.l. on a bedrock ridge, has a diameter of app. 150 m and a maximum water depth of 20 m. The lake is the southernmost site in Sweden with varved sediments. We have retrieved an 89 cm long freeze core and established a chronology based on ^{210}Pb, ^{14}C and varve counting. BC was quantified using the thermal chemical oxidation method (CTO375).

Our BC record has relatively high maximum concentrations (>0.92%) and shows an early increase in concentration and accumulation rate starting around CE1700. This early rise in BC accumulation rate took place around 150 years before the main phase of industrialisation in Sweden and was likely an effect of increasing population and small-scale industrialisation in the region. The BC accumulation rate continued to increase steadily until an accentuated rise in the mid-20th century. This further increase was likely a direct effect of the elevated fossil fuel consumption after CE1950. Intriguingly, the BC accumulation rate increased during the 1990s and has remained high. To further explore the history and sources of the BC pollution, we will measure the ^{14}C content of the BC fraction to differentiate between BC derived from burning of biomass and fossil fuels, respectively.

Palaeolithic Technosols as indicators of early inception of the Anthropocene at the Upper Palaeolithic sites Kostenki 14 and 17, East European Plain

Neolithic revolution is often considered an onset of significant anthropogenic impact on ecosystems, i.e., the onset of the Anthropocene. The substantial advancement in human-nature interaction on the verge of Neolithic revolution could have resulted in the appearance of new soil type, such as Technosols. Recent palaeobotanical studies provided evidence of niche construction during Upper Palaeolithic in Europe and Middle Palaeolithic in Eastern Africa, which triggered the discussion of earlier onset of the Anthropocene. Since “Soil is the mirror of landscapes” and Technosols are evidence of the significant local anthropogenic impact, they might serve as indicators of niche construction, thus, the inception of the Anthropocene.

New palaeopedogenic data obtained at the Upper Palaeolithic sites Kostenki 14 and 17 imply the existence of Palaeolithic Technosols. Cultural layers are often found within palaeosol horizons. Despite weak development of the studied palaeosols, their “soil memory” contains significant palaeoecological information, whose interpretation is yet unclear. Along with the versions of its natural genesis, the anthropogenic version has been suggested. The combination of magnetic and biogeochemical (FTIR, biomarkers) analyses indicates the pyrogenic effect on palaeosols and spatial variability of soil properties within the cultural layer. Combined with abundance of artefacts observed at macro and micro scales, this demonstrates the anthropogenic genesis of the discussed palaeosols.

The Antropocene signature in Mediterranean endorreic Iberian karstic lakes: Zoñar (Andalucia) and Estanya (Aragón)

Mr. Marcel-Saïd Galofré Penacho [1]***, Mr. Guillermo Pérez Villar*** [2]***, Ms. Inés de la Parra Muñoz*** [3]***, Dr. Jorge Pey*** [4]***, Ms. Alejandra Vicente de Vera*** [3]***, Dr. Antonio Delgado Huertas*** [1]***, Dr. Blas Valero-Garcés*** [3]

1. *Universidad de Granada, Instituto Andaluz de Ciencias de la Tierra (CSIC-UGR), 18071, Granada,* ***2.*** *Departamento de Geodinámica Externa, Ciencias de La Tierra, Universidad de Zaragoza, 50009 Zaragoza, Spain,* ***3.*** *Consejo Superior de Investigaciones Científicas, Instituto Pirenaico de Ecologia,* ***4.*** *ARAID - Instituto Pirenaico de Ecología (CSIC)*

The Anthropocene poses particular challenges in regions with Mediterranean climates as they are characterized by both a long history of human occupation, a strong seasonality of hydrological regimes and an annual water deficit. Predicting the impacts of future climate change in Mediterranean watersheds requires detailed knowledge of baseline watershed responses to past climate variability and assessing the magnitude of past human intervention in the landscape and the ecosystems. In this contribution we summarize the depositional evolution of two lake – watershed systems located in the Ebro and Guadalquivir Basins in region with a long history of human activities since the Neolithic. A multiproxy analysis of the sedimentary sequences of both lakes has been carried out, based on the study of facies, elemental geochemistry and the study of the isotopic signature of organic and inorganic components. In addition, we present the results of water and sediment monitoring until present date, which will help to better understand the mechanisms of these lakes in the past. The > 20 ka long Estanya sequence (Pyrenean Range, 42.027474, 0.530450>) show a rapid increased in sedimentation rate since Roman times and particularly since 10th century. Zoñar Lake (Guadalquivir Basin, 37.482889, -4.690522) illustrates large hydrological changes during the last 4000 years, and a strong impact in the watershed during Roman and Medieval times. In both cases, agricultural changes during the last century, and particularly since mid-20th have greatly altered the ecosystem with increased sedimentation rates, change in the depositional environment and oxygenation conditions. The past global change reconstructions will help to develop strategies for mitigation and adaptation to recent global changes in Mediterranean regions prone to long-term droughts and subjected to intense use of the resources.

Plutonium isotope records in marine sediments from the southern Gulf of Mexico

A suite of sediment cores collected from the continental shelf and upper slope region of the GoM consistently showed $^{240}Pu/^{239}Pu$ ratios consistent with global fallout Pu for this tropical region. In the continental shelf and upper slope regions, higher particle concentrations close to the margins favor significant scavenging and removal of Pu from the water column; in contrast with the deep-sea cores that show low $^{240}Pu/^{239}Pu$ ratios (0.07 – 0.13) and a much lower Pu inventory (< 7 Bq m^{-2}) implying a small fraction of the expected global fallout inventory has reached into the lower slopes and abyssal plain of the GoM. The low Pu ratios indicate that Nevada tests fallout was an important source of Pu to deep-sea sediments, and that this source was likely more efficiently removed from the water column than global fallout Pu. Analysis of Pu isotopes in two sediment traps from the upper slope regions show $^{240}Pu/^{239}Pu$ ratios comparable to the ones observed in the global fallout, indicating that global fallout Pu is currently the main source of Pu in the water column particles. These results imply that a significant fraction of global fallout Pu must still be present; either in a dissolved phase, or as biologically recycled material in the water column, or scavenged on the shelf and shelf break.

TerrACE: European Archaeology and Culture from Agricultural Terraces and Implications for Heritage and Agricultural Sustainability

Agricultural terracing is the greatest human alteration to the earths surface prior to the growth of cities and can be regarded as a hallmark of the Anthropocene. Despite this we have a very limited understanding of their chronology and archaeology and only some understanding of their geomorphological implications. This is now a serious problem as agricultural terraces (and lynchets) are under threat from mechanised agriculture and rural depopulation worldwide, yet it is believed that they are both sustainable and resilient if kept in continuous use and maintained. We present here the results from a Europe-wide study of terraces and lynchets from Norway in the north to Crete in the south. We brought to the question an integrated set of novel techniques (pOSL/pRSL, sedaDNA), along with established techniques for terrace mapping (UAV-SfM, TLS), dating (OSL, 14C) and palaeoenvironmental analysis (phytoliths, pollen, soil micromorphology, pXRF, FTIR). This data is nested into the digital elevation models (DEMs) derived from both UAV structure from motion (UAV-SfM) and terrestrial laser scanning (TLS). We have a chronology which spans from the mid-Holocene (Mid Bronze Age, c. 3500 BP) to the post-medieval period (<300 years BP). This has landscape heritage implications as well as showing how sustainable many ancient systems are. We also show how supplementing chronometric information with pOSL, pXRF and soil micromorphology can be used to indicate complex terrace history. Past crops are revealed by both pollen and phytoliths and we also show that sedaDNA is preserved in terraces from most of the regions, except the most arid. In some cases the crops revealed go beyond cereals (e.g. hops, vines, horticulture) and provide direct data on the nutritional and cultural contributions of terrace agriculture to these communities. This is the first use of sedaDNA for such ancient sites and, although there are significant problems of interpretation of taphonomy and bioturbation, extrinsic authentication suggests that they have high future potential. During the project innovations have been made in several areas including the fusion and modelling of soil volumes from UAV-SfM with TLS and the modelling of complex soil history and land use.

Mollic or anthromollic? – Phaeozems at the Bronze Age site of Toboliu (Romania)

Dr. Astrid Roepke [1] ***, Mrs. Mirijam Zickel*** [1] ***, Prof. Bruno Glaser*** [2] ***, Prof. Tony Reimann*** [3]

1. *Institute of Prehistory and Early History, University of Cologne,* ***2.*** *Institute of Agricultural and Nutritional Sciences, Martin Luther University Halle-Wittenberg, Halle (Saale),* ***3.*** *Institute of Geography, University of Cologne*

The Bronze Age tell of Toboliu (*Dâmbu Zănăcanului* Bihor County, Romania) and its outer settlement is located at the eastern margin of the Great Hungarian Plain, between the Crișul Repede floodplain in the north and the high plain of Miersig in the south. Today, the area is intensively used for agriculture. In the clayey loess Phaeoems have been developed, which are characterized by a mollic horizon enriched in organic matter and homogenized by bioturbation. Geomagnetic surveys, core drillings and excavations carried out by an interdisciplinary team indicate that the soils have been markedly modified by settlement activity, agriculture, gardening and animal husbandry. We assume that their signature is still stored in the soil. Geoarchaeological (micromorphological analyses, geochemical- und physical analyses, dating methods etc.) and biochemical methods (phenols, lipids, black carbon etc.) will be used to clarify the genesis of these dark brownish soils. In order to determine the degree of human influence - to differentiate Phaeozems from anthromollic Phaeozems and Anthrosols, soils from different parts of the Bronze Age settlement site and its surroundings will be analysed.

Recent environmental changes in the Yunnan–Guizhou Plateau inferred from organic geochemical records from the sediments of Fuxian Lake

Dr. Haibo He [1]

1. *State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences*

During the past century, many lacustrine environments have changed substantially at the ecosystem level as a result of anthropogenic activities. In this study, the distributions of n-alkane homologues, carbon isotopes ($\delta^{13}C_{org}$), organic carbon, and the C/N atomic ratio in two sediment cores from Fuxian Lake (Yunnan, southwest China) are used to elucidate the anthropogenic impacts on this deep, oligotrophic, freshwater lake. The carbon preference index (CPI) of long-chain components, average chain length (ACL), proportion of aquatic macrophytes (Paq), and terrigenous/aquatic ratios (TAR) show different temporal patterns that reflect variations in biological production. Notably the n-alkane homologues are shown to be more sensitive to environmental changes than $\delta^{13}C_{org}$ and the C/N ratio. Prior to the 1950s, minor variations in the sedimentary geochemical record were likely caused by climate changes and they represent a natural stage of lake evolution. The onset of cultural eutrophication in Fuxian Lake occurred in the 1950s, when the n-alkane proxies collectively exhibit high-amplitude fluctuations but overall decreasing trends that coincided with population growth and related increases in land-use pressure. In the 21st century, Fuxian Lake has become even more eutrophic in response to human activities, as indicated by sharp increases in C/N ratio, Paq, $\delta^{13}C_{org}$, ACL, CPI, and TAR. Our findings provide robust molecular sedimentary evidence confirming that the environmental evolution of lakes in the Yunnan–Guizhou Plateau over the past century was closely associated with enhanced anthropogenic activities.

The rise of pyrometallurgy and 7000 years of continuous anthropogenic metal pollution in southeastern Europe

Archaeological data document early cultural traits in southeastern Europe linked to ancient metalworking by 5500 years BCE, but lack of data precluded a precise understanding of their long-term environmental impact. Here we report geochemical and isotopic data from several Carpathian peat profiles showing evidence of lead (Pb) excess denoting anthropogenic metal pollution already by ca. 5200-4300 BCE. Our find directly corroborates the archaeological evidence, as the dazzling array of early metal artifacts considerably exceeds evidence from elsewhere making this a phenomenon largely exclusive to southeastern Europe. Using also Pb isotopic constraints we conclude that the rise in Pb by ca. 5200-4300 BCE represents a direct record of environmental pollution during this era of primitive but widespread smelting and proto-metallurgical experimentation in southeastern Europe. We also observe another period of anthropogenic Pb pollution during the Late Copper/Early Bronze Age □3,600 years BCE, to date one of the earliest such evidence documented in European environmental records. By 1000 BCE the environmental signal of excess Pb became ubiquitous in southeastern Europe, peaking during the Iron Age and the Roman period. A steady, almost linear increase in Pb concentration after 600 BCE, until ca. 700 CE is observed, documenting the development in both sophistication and extent of southeastern European metallurgical activity throughout Antiquity and the Roman period. A sustained medieval Pb pollution spanning 10th to 16th centuries AD reached pollution levels and a Pb flux comparable to the modern period.
Our reconstruction of environmental pollution contrasts and complements evidence from western Europe. We advocate this reflects regional variability in metal pollution output linked to developments attained by the different European societies for last millennia. Our results add crucial evidence to the long-range and long-lasting legacy cast upon the environment by past metal processing in Europe already from the Late Neolithic, c. 7000 years ago.

Some geomorphological perspective on the (paleo-)Anthropocene: early human overprint on landforms

Prof. Andrea Zerboni [1], ***Prof. Kathleen Nicoll*** [2]

1. Department of Earth Sciences, University of Milan, 2. University of Utah, Salt Lake City, Utah

The current debate on the concept of Anthropocene is mostly dedicated to the definition of the formal chronostratigraphic position of the onset of this phase of the history of planet Earth. More recently, alternative hypotheses have been postulated to overcome this issue, and several authors proposed to define the Anthropocene as an event rather then a formal geological epoch. Beside the debate on the formal definition of the Anthropocene epoch along the geological time scale, emerging evidence suggests a pristine and long-lasting human overprint on natural ecosystems and surface processes. Since at least the Holocene, humans have intensely interfered with geomorphological processes; they accelerated and/or decelerated the rate and efficiency of certain natural geomorphological processes and contributed to activate and/or deactivate other processes. At the meantime, such interference on natural surface processes resulted in increased vulnerability of the human environment to paroxysmal events. From a different perspective, humans contributed to the destruction of natural landforms directly, for instance with building and quarrying activities, or indirectly, enhancing erosion. But when did humans start altering pristine landforms and influencing permanently geomorphic processes? The geoarchaeological record offers new evidence reporting on permanent human agency on geomorphological processes, thus further sparking debate about the onset of the Anthropocene. In this contribution, we will discuss the meaning of the term “Anthropocene” and its relevance for the possible early onset of human agency on geoarchaeological and geomorphological processes.

Human Traces: a PAGES working group synthesizing sedimentary records of human 'footprints'

The Human Traces working group is developing tools and knowledge to gain a better global perspective of human impacts over the (paleo-) Anthropocene using sedimentary archives. Sediments from lakes, ponds, wetlands and coasts are reliable stratigraphic archives of natural variability and human-induced changes in the environment. The principal aim of this PAGES working group is to elaborate tools and reviews to help synthesize information based on data gathered from aquatic sedimentary archives, that will lead us to a better understanding of the timing, nature and magnitude of human impacts on the environment at various spatial and temporal scales. Indeed, the human footprint on the natural environment can vary in origin and proportion in various regions of the world through time. This is due to a multitude of factors, including the timing and direction of human migrations and the state of technological development. There is still a paucity of long-term environmental regional data and a global synthesis of human impacts on aquatic ecosystems is lacking. We are therefore working on creating a global database of sedimentary records of human traces on the environment. In this presentation, we will describe the scientific activities and projected outcomes of the working group, which has been running since 2021 and will likely continue for the next 3 years.

Written in Stones: Man and environment relationship in Indian archaeological records

Dr. Garima Khansili [1]

1. *North-Eastern Hill University*

Homonin species have been utilising natural resources before they even became fully developed into anatomically Homo-sapien-sapiens. In India, we begin to see the earliest evidence of Homonin around 1.5 Ma in the form of stone tools. Initially, exploiting rocks as raw materials for producing tools to now altering the eco-system altogether. In this paper, I aim to discuss 5 independent archaeological records from different time periods and from different regions of India that provide evidence of Man and environment relationship. The bullet points of evidence are as follows-

1. Inscription that mention about construction and repair of dam
2. Inscription that mention about a royal kitchen and food (particularly meat)
3. Baolis (stepwells) for storing water in western India
4. *Navle* for storing water in central Himalayas
5. Inscription that mention about multiple floods in river Narmada

The aim of the paper is to discuss various archaeological and ethnographic records that may help us in reconstructing man and environment relationship in the past and present.

The geo-environmental characterization of contaminated coastal sites as tool for the analysis of human footprint on marine and coastal environments.

Dr. Angela Rizzo [1]***, Mr. Francesco De Giosa*** [2]***, Mrs. Antonella Di Leo*** [3]***, Mrs. Antonella Marsico*** [4]***, Dr. Giovanni Scardino*** [1]***, Prof. Giovanni Scicchitano*** [1]

(ENSU),* ***3.*** *Istituto di Ricerca sulle Acque (IRSA) Consiglio Nazionale delle Ricerche,* ***4.*** *Department of Earth and GeoEnvironmental Sciences, University of Bari Aldo Moro,*

In Italy, several coastal sites are affected by intense modifications and diffuse environmental pollution due to the strong industrialisation and urbanisation processes that have taken place since the second half of the XIX century. Despite its remarkable geomorphological, ecological, and touristic value, the coastal sector of the Apulia region (Southern Italy) hosts three of the main contaminated Italian sites (Sites of National Interest), for which urgent environmental remediation and reclamation actions are required. In this study, the assessment of direct and indirect impacts of past and present anthropogenic activities in the Apulian coastal sites is carried out by coupling geophysical, sedimentological, and chemical analysis performed in the framework of several characterization activities founded in the last years. The study is aimed at highlighting the main criticalities affecting the investigated coastal sectors (e.g., chemical pollution, anthropogenic traces on the sea floor, litter distribution) and how the multidisciplinary investigation can support the identification of tailored management actions for the environmental reclamation as well as for the evaluation of the best characterization procedures.

An interdisciplinary approach to understanding resilient woodlands in an Anthropocene landscape

Ms. Hannah Sellers [1], ***Ms. Rachael Holmes*** [1], ***Dr. Juan-Carlos Berrio*** [1], ***Dr. Richard Jones*** [1], ***Dr. Shola Olabode*** [1], ***Dr. Stephen Himson*** [1], ***Dr. Stefano De Sabbata*** [1], ***Dr. Moya Burns*** [1], ***Prof. Mark Williams*** [1]
1. *University of Leicester*

In the heavily human-modified landscape of the English Midlands, UK, Ancient Semi-Natural Woodland sites have undergone extensive human disturbance for millennia, including severe modification such as clear-felling in the 20th century. Here we use an interdisciplinary approach to examine the long history of disturbance and identify patterns of ecosystem resilience to change, taking the area of East Leicestershire and Rutland as our case study area.
Through the integration of information from the fossil pollen record (early Holocene to present), place-name evidence of past vegetation cover (extending back to medieval times), LiDAR data, and recent botanical surveys, our methodology aims to identify regions that have maintained long-term, stable woodland cover and to elucidate how ecosystems have recovered after natural environmental or anthropogenic disturbances. We aim to develop an integrated spatiotemporal framework that quantifies the resilience of woodland ecosystems to change, and to use this as a dataset to inform the stewardship of Anthropocene landscapes into the future. Though we apply this in a UK-setting, such interdisciplinary approaches have likely utility in a range of woodland/forest contexts.

The biogeographical history of Carpinus betulus in the Iberian Peninsula

***Dr. José Antonio López Sáez* [1], *Dr. Juan Ochando Tomás* [2], *Prof. Donatella Magri* [2], *Prof. José Carrión* [3]**

***1.** CSIC, Madrid, **2.** university of Rome Sapienza, **3.** University of Murcia*

The Iberian Peninsula is part of the Mediterranean hotspot and displays a high rate of endemism involving Mediterranean, Eurosiberian, Alpine, Boreal, Macaronesian and North African plant species. Arctotertiary and Lauroid floras reach Mediterranean mountains of the peninsula where appear to have refuged during the late Quaternary. In some cases, the remnants of past distributions are limited in number and range. This is the case of *Carpinus betulus* (hornbeam), a boreal species widely extended nowadays in Northern Europe but showing only three small populations in Iberia. Here we deal with this apparent anomaly and question (i) whether the distribution of hornbeam in the Iberian Peninsula was always so restricted, (ii) where was this species present during various phases of the Quaternary, (iii) why was it more widespread in the past within the study region, and (iv) which were the climatic and/or anthropic pressures exerted to provoke populational depletion upto the current situation. To this goal, we review pollen records of *Carpinus betulus* in the Iberian Peninsula during the Pleistocene and Holocene, and report of study of the species´pollen rain, and its significance in terms of population size and dispersive capacity.

New records of terrestrial and freshwater mollusc species for the Quaternary of Uruguay

Dr. Fernanda Cabrera [1]***, Mr. Felipe Montenegro*** [2]***, Mrs. Ana Clara Badin*** [3]***, Dr. Martín Ubilla*** [4]***, Dr. Sergio Martínez*** [1]

***1.** Paleontology Department, Facultad de Ciencias (UdelaR), Montevideo., **2.** Facultad de Ciencias, Montevideo, Museo de Historia Natural, **3.** Paleontology Department, Facultad de Ciencias (UdelaR), Montevideo, Uruguay., **4.** Facultad de Ciencias Montevideo*

Few studies about the Quaternary continental molluscs of Uruguay had been published over the last decades, despite the high occurrence of this group in many of the Pleistocene outcrops of the country, all of them better known for their classic Ice Age mammal assemblages. In order to overcome this situation, new studies had been conducted, collecting new samples in 23 localities belonging to two lithostratigraphic units, the Sopas Formation (~45,000 – ~13,000 AMS ^{14}C calBP) from northern Uruguay (12 localities), and the Dolores Formation (~27,000 -~11,000 AMS ^{14}C calBP) from the West and South-West (11 localities). The species of continental molluscs recorded in the Quaternary of Uruguay are included in the families Sphaeriidae, Cyrenidae, Mycetopodidae, Hyriidae (freshwater bivalves); Ampullariidae, Cochliopidae, Tateidae, Chilinidae, Physidae, Planorbidae (freshwater gastropods); Scolodontidae, Succineidae, Charopidae and Bulimulidae (terrestrial gastropods). As a result of these new samplings, the Sopas Formation molluscs species account raised from 20 to 29 species and the Dolores Formation from six to 29 species. Seventeen of those species are new records for the Quaternary of Uruguay: the freshwater bivalves *Afropisidium sterkianum* and *Pisidium vile*; the freshwater gastropods *Pomacea lineata*, *Asolene platae, A. spixii, Stenophysa marmorata, Drepanotrema heloicum, D. kermatoides, Heleobia robusta, Potamolithus catharinae, Hebetancylus* cf. *H. moricandi* and *Uncancylus* cf. *U. concentricus*; and the terrestrial gastropods *Miradiscops brasiliensis, Zylchogira costellata, Omalonyx convexus, Succinea meridionalis* and *Plagiodontes dentatus.* Regarding all the species records (new and old ones), for the Sopas Formation two bivalves, five freshwater gastropods and a new terrestrial gastropod were added; while for the Dolores Formation four new bivalves, 14 new freshwater gastropods and five new terrestrial gastropods were added. The Dolores Formation clearly was the most understudied unit until now, increasing its biodiversity in 23 species. These new records of freshwater and terrestrial gastropods, not only increase the biodiversity of the continental molluscs of the Late Pleistocene of Uruguay, it also increases the knowledge and biogeographical range for Quaternary continental molluscs of the region.

Anthropogenic alteration of the marine fossil record

Dr. Rafal Nawrot [1]***, Prof. Martin Zuschin*** [1]***, Dr. Adam Tomasovych*** [2]***, Dr. Michał Kowalewski*** [3]***, Dr. Daniele Scarponi*** [4]

__1.__ Department of Palaeontology, University of Vienna, __2.__ Earth Science Institute, Slovak Academy of Sciences, __3.__ Florida Museum of Natural History, University of Florida, __4.__ Dipartimento di Scienze Biologiche, Geologiche e Ambientali, University of Bologna

The youngest fossil record is an indispensable source of data on long-term human impact on marine ecosystems. However, human actions alter not only marine communities and their habitats but also sedimentary and biotic processes controlling the formation of the stratigraphic archives recording those changes. Anthropogenic drivers can modify sedimentation rates, depth and intensity of sediment mixing, and preservation potential of skeletal remains. These drivers are diverse and include, among others, changes sediment fluxes due to reshaping of alluvial and coastal landscapes, seabed disturbance by bottom trawling and ship traffic, ocean acidification and anoxia, removal of native species, and introduction of invasive ecosystem engineers. These physical, geochemical and biological disturbances can affect the temporal resolution of the youngest fossil record and shape the stratigraphic expression of human-driven ecosystem shifts. The resulting taphonomic and stratigraphic signatures can pinpoint historical changes in ecosystem functioning, as many key ecosystem processes also control the burial and preservation of skeletal remains. At the same time, however, systematic changes in the quality of the record induced by human actions are a challenge for environmental, paleoecological and paleoclimatic reconstructions based on the data from sediment cores and surface death assemblages. Understanding complex feedbacks between human impacts on the ecosystem processes and their preservation in the marine stratigraphic record is thus crucial for correct interpretation of geohistorical archives that document the ongoing anthropogenic transformation of the oceans.

Radiocarbon dates shed light on the extinction chronology of endemic rodents from the Tiburon Peninsula, Haiti

Dr. Brooke Crowley [1] ***, Dr. Siobhán Cooke*** [2]

1. *University of Cincinnati,* ***2.*** *Johns Hopkins University*

The island of Hispaniola has been considered the center of Caribbean rodent biodiversity. Until recently, it was home to 10-12 endemic species, but today, just one endemic species is present (*Plagiodontia aedium*, Cuvier's hutia). The timing of rodent species loss across the Caribbean, and on Hispaniola specifically, is poorly constrained, which makes the identification of extinction triggers challenging. Both human activities and climate have been implicated. We radiocarbon dated eight rodent specimens from Trouing Jérémie #5, a paleontologically-rich sinkhole on the Tiburon Peninsula, in southwestern Haiti and combined these with two recently published dates for the site. This combined sample included seven endemic extinct taxa (*Plagiodontia ipnaeum*, *Brotomys voratus*, *Isolobodon montanus, I. portoricensis*, *Hexolobodon phenax*, and *Rhizoplagiodontia lemkei*) and introduced murid *Rattus*. Radiocarbon dates for these rodents demonstrate that bone accumulations at Trouing Jérémie #5 span the Holocene. The single specimen for the largest species, *P. ipnaeum* (5.3-5.9 kg), dates to the very early Holocene (median calibrated age=11,091 calendar years before present; Cal BP). *Hexolobodon phenax* (3.2-3.3 kg), *I. montanus* (1.5-3.1 kg) and *R. lemkei* (1.3-2.0 kg) date to the mid-Holocene (6297-7050 Cal BP), *B. voratus* (ca. 0.4 kg) dates to the late-Holocene (3122 Cal BP), and the two dates for *I. portoricencis* (1.0-1.4 kg) span the mid- to late-Holocene (5164 and 1659 Call BP). These dates confirm that the sampled extinct taxa were all present into the Holocene, and several coexisted with humans, who arrived on the island ca. 6000 years ago (*I. portoricensis and B. voratus* appear to have overlapped with humans for several thousand years). However, we do not know if any endemic rodents were still present when Europeans arrived in the late 15th and early 16th centuries. Both murid *Rattus* specimens date to the last few centuries (307 and 502 Cal BP), suggesting that rats likely spread rapidly on Hispaniola after introduction. Additional radiocarbon dates from Trouing Jérémie #5 and other sites in the Tiburon peninsula will help clarify regional extirpation patterns and provide a chronological framework for examining ecological change.

This research was supported by USA NSF EAR-2047817 and EAR-2047818.

Birds and Quaternary climate changes: avifaunal shifts on the Eastern Adriatic coast, Croatia

Dr. Ankica Oros Sršen [1], ***Dr. Jelena Kralj*** [2]

1. *Institute for Quaternary Paleontology and Geology, Croatian Academy of Sciences and Arts,* ***2.*** *Institute of Ornithology , Croatian Academy of Science and Arts*

The Mediterranean region is very rich in avifauna, with Croatia being one of the richest countries in Europe in terms of biodiversity. This is the result of its specific geographic position in-between Mediterranean, Alpine and Continental biogeographic regions, and its geomorphology, especially its karstic region. Here we present Eastern Adriatic Late Pleistocene and Holocene bird assemblages (without small passerines) found at sites with abundant bird remains. A total of 60 species were identified in the avifaunal assemblages from the sites of Marlera I, Šandalja II, Ljubićeva pećina and Vela spila, while the recent list includes 168 species. The relative frequency of different faunal types was temporally (MIS 3 vs. MIS 2 vs. MIS 1) and spatially (NW vs. SE Adriatic) compared. The general composition of the Late Pleistocene and Early Holocene avifaunal assemblages is broadly similar to that found today. Species of Palearctic faunal types dominate, followed by Holarctic species. A few of the species identified in Late Pleistocene assemblages are of Arctic and Siberian faunal elements that today live on the mountains or in Northern Europe. Species that belong to the Arctic faunal type were present at both parts of the Adriatic, while those of the Siberian faunal type were present only on the northwestern Adriatic. Arctic and Siberian species recorded along the coast today are passage migrants or winter visitors, in contrast to the Late Pleistocene assemblages when species of those faunal types were residents. The Early Holocene avifauna consisted of extant bird taxa of the eastern Adriatic coast, whether present as seasonal migrants or year-round residents. Recent avifauna is enriched with Indo-African, Ethiopian, Mongolian-Tibetan and North Atlantic species compared to the Late Pleistocene and Early Holocene assemblages where representatives of those faunal types were not recorded. There is thus a slight temporal trend in taxonomic composition from species adapted to temperate-boreal climates during the Pleistocene to those adapted to temperate-Mediterranean climates during the Holocene. Late Pleistocene avifauna was enriched by northern species without a significant loss of species adapted to more temperate conditions, which further confirms the eastern Adriatic coast as one of glacial refugia.

A Conservation Paleobiology approach over an endangered freshwater bivalve genus from South America

Dr. Fernanda Cabrera [1], ***Dr. Sergio Martínez*** [2]

1. *1Paleontology Department, Facultad de Ciencias (UdelaR), Montevideo.,* ***2.*** *Paleontology Department, Facultad de Ciencias (UdelaR), Montevideo.*

The extant South American genus of freshwater bivalve *Cyanocyclas* is recorded for the Quaternary of Uruguay mainly in the Sopas Formation (Late Pleistocene – MIS3) and in only one locality of the Dolores Formation (Late Pleistocene – Early Holocene). When present, it occurs in a large number of specimens. It is mainly recorded in coarse to sandy strata that usually are located over coarser strata with records of large bivalves, such as representatives of the genus *Diplodon.* The historical record *Cyanocyclas* indicates that it was present in rivers and streams throughout the territory. The geopaleontological analysis and the historical record indicate that the species normally inhabited coarse to sandy, firm substrates, and occasionally soft substrates. Since the 1990s and to the present, the alien species *Corbicula fluminea* has gradually invaded the freshwater systems of South America, including Uruguay. The Asiatic species belong to the same family as the autochthonous genus, Cyrenidae, and has successfully displaced the *Cyanocyclas* species from their habitats. Now, *Cyanocyclas* can hardly be found in most of the localities where they originally were recorded. Mainly, it can now be found in soft, fine sand to pelitic bottoms, rather than the consolidated sandy substrates where historically it inhabited the most. Some authors indicate that the substrate change can be explained as an adaptation to colonize habitats that are harder to colonize by the invader species, since siphons in *Cyanocyclas* are larger than in *Corbicula,* allowing them to better adapt to soft, fine substrates. The paleontological and historical data corroborate that *Cyanocyclas* tend to inhabit mostly firm substrates (as *Corbicula*), but it was capable of inhabiting soft bottoms as well. Therefore, although this is only the first approach in the Conservation studies for this genus, it is clear that the inferences of other authors about the causes of the decline in *Cyanocyclas* populations would be correct. The environment in which the autochthonous species inhabited, both in the historical record and in the fossil record, indicates that the species prefer firm substrate environments, where today we find the invasive species, being the autochthonous species displaced to softer substrates.

The Raigón Formation (Plio-Pleistocene of Uruguay), a disruption in space and time?

Dr. Daniel Perea [1]

1. Dpto. de Paleontología, Instituto de Ciencias Geológicas, Facultad de Ciencias/UdelaR, Iguá 4225, 11400 Montevideo, perea@fcien.edu.uy

The Raigón Formation, deposited in the Santa Lucía Basin, southern Uruguay, was defined by Goso and Bossi in 1966. Previously Francis and Mones defined the San José Formation, unit which is nowadays considered the basal member of the Raigón Formation. It is characterized by gray-greenish sandstones and conglomerates of fluvial origin at the base, changing to fine clayish sandstones with carbonate septi intercalated with loess at the top. Sterile when first defined, the San José "Formation" yield it first fossil right away, a fossil rodent, *Cardiatherium talicei* Francis and Mones 1965. Prior to the aforementioned formal stratigraphic definitions Kraglievich and Castellanos, among others, described fossils that today can be assigned to the Raigón Formation. As this unit continued to be studied, a very particular fauna was unveiled. Posteriorly to the description of *C. talicei* new taxa integrated to a particular faunal association where mammals abound were discovered. This association is characterized by endemic species, others representatives of the South American Cenozoic and others of North American origin. Endemic taxa include the large rodent *Josephopartigasia* (Francis & Mones 1966) Mones 2007, the proterotherid *Uruguayodon alius* Corona, Perea & Ubilla, 2019, and the toxodont *Charruatoxodon uruguayensis* Ferrero, Schmidt, Pérez-García, Perea and Ribeiro, 2022, among others. *Trigodon* Ameghinio, 1882, and *Devincenzia* Kraglievich, 1932, among others, are present in the Raigón Formation and the Neogene of Argentina. Finally, the striking presence of cf. *Xenosmilus* Martin, Babiarz, Naples & B Hearst, 2000, together with other clearly Quaternary taxa such as *Catonyx tarijensis* (Ameghino), 1891, and *Plaxhaplous* Ameghino , 1884 in this unit reveals a very particular faunal composition that can be interpreted in different ways. This work will present a synthesis of the biostratigraphy of the Raigón Formation, including new paleontological data, and OSL datings from the top of that unit. Through it, a Late Pliocene-Chibanian lapse is proposed for its deposition, with a particular fauna that could be the result of recurrent episodes of geographic isolation, climatic fluctuations, and exclusive fossil record during the origins of the La Plata River Basin. Partial support by project C108-347 CSIC/UdelaR, PEDECIBA, and ANII, Uruguay.

When rhodolith beds are heterogeneous, who can help? Studying the associated mollusk thanatocoenoses to unravel (paleo)environment

Dr. Valentina Bracchi [1], ***Dr. Agostino N. Meroni*** [2], ***Mrs. Vivien Epis*** [2], ***Prof. Daniela Basso*** [1]

1. *milano Bicocca University,* **2.** *Dipartimento di Scienze dell' Ambiente e della Terra, University of Milano-Bicocca*

Rhodoliths are marine biogenic carbonate nodules that often form extensive beds on the shelf. They increase the complexity of the seafloor that translates in supporting high biodiversity, which led them to be included in several international programs for sustainable management and conservation. Although several studies focused on rhodoliths, it is still not clear how the combination of biotic and abiotic factors controls the different rhodolith morphostructures that frequently form heterogeneous beds. Moreover, they have a consistent fossil record at least for the whole Cenozoic that is often hard to be interpreted because of the scarce knowledge of rhodolith bed dynamic and its taphonomic bias.

But how much (paleo)biological and (paleo)environmental information is preserved within rhodolith beds?

Quaternary studies offers the possibility to study rhodolith beds as they are now, and then use these observations to better interpret their fossil analogues, and trace changes through time. Therefore, to answer this question, we focus on the study of present day rhodolith beds *plus* associated mollusks, together with data on grain-size and environment (temperature, current). Mollusks represent a tool for tracing hidden diversities among heterogeneous rhodolith beds, because: 1) their ecological and environmental requirements are well known and 2) they show a strict fidelity to specific environmental conditions. This work reports the results of the study of three heterogeneous rhodolith beds from the Tyrrhenian Sea (Italy), where rhodoliths show different shape and morphotype, but often combine in having heterogeneous beds. Mollusk thanatocoenoses combined with rhodolith morphometry, grain-size and environmental data, reveal that such beds are characterized by limited differences in associated edaphic factors which however determine the occurrence of "sentinel" mollusk species that characterize exclusively different rhodolith beds (*Alvania cimicoides*, *Goodallia triangularis*, *Dosinia exoleta*, *Tetrarca tetragona*, *Limatula subauriculata*, *Clausinella fasciata*).

Vegetation changes in the Osumi Peninsula, southern Japan before and after the Kikai Akahoya eruption, inferred from phytolith records

Dr. Naoki Hayashi [1], *Prof. Jun Inoue* [1]

1. *Osaka Metropolitan University*

The Kikai Akahoya eruption occurred at 7.3 ka in the Kikai caldera, located approximately 50 km southwest of Kyushu Island, Japan. Southern Kyushu Island's ecosystems were devastated by the Kikai Akahoya tephra, particularly the pyroclastic flows (Koya pyroclastic flow). We examined phytolith assemblages in paleosols in the plateau and mountain areas in the Osumi Peninsula in the southernmost part of Kyushu Island to assess the influence of the pyroclastic flows on vegetation. The appearance of broad-leaved arboreal phytoliths characterized the phytolith assemblages in the paleosols under Kikai Akahoya tephra, suggesting that the evergreen broad-leaved forests were distributed in the study region before the eruption. In the plateau area, where the pyroclastic flows were more thickly distributed, the phytolith assemblages in the paleosol between the Kikai Akahoya tephra and Ikedako tephra (6.4 ka) were characterized by the predominance of Andropogoneae (*Miscanthus*)-type phytoliths and the absence of arboreal phytoliths. In the mountain areas, evergreen broad-leaved arboreal phytoliths were observed in the paleosol under the Ikedako tephra, despite Andropogoneae (*Miscanthus*)-type phytoliths being more common in the paleosol above the Kikai Akahoya tephra. These results suggest that the vegetation transition after the eruption in the plateau and mountain areas differed in the study region. The evergreen broad-leaved forests were destroyed, establishing Andropogoneae (*Miscanthus*) grasslands in the study region after the eruption. The evergreen broad-leaved forests hardly recovered even 900 years after the eruption in the plateau area. In contrast, the evergreen broad-leaved forests recovered within 900 years in the mountain area. The little pyroclastic flow reaching the areas would have left some untouched forest sites as refugia, and the forest would have recovered from the refugia.

Refuge areas and postglacial dynamics of Arbutus in Western Eurasia

Mr. Simone De Santis [1], ***Prof. Francesco Spada*** [2], ***Prof. Donatella Magri*** [1]

1. *Dipartimento di Biologia Ambientale, Sapienza Università di Roma, Roma (Italy),* ***2.*** *Department of Ecology and Genetics, Uppsala University*

Arbutus is a genus belonging to the Ericaceae family with four species currently recorded in the Old World, according to outputs of phylogeny and taxonomy. They are centered in the Mediterranean Basin, scatter along the Atlantic coast, and reach Macaronesia, being one of the most important representatives of the Mediterranean broadleaved evergreen element. We investigate the present and past distribution of *Arbutus* to reach a better understanding of the drivers and constraints of its biological requirements and its postglacial dynamics.

We collected, compared, and screened a body of information based on the floristic and geobotanical historical literature, the available online databases, and personal observations, to edit a high-resolution geographic grid-based map of the species occurrences and ranges, useful to match the palaeobotanical georeferenced data of *Arbutus* from late Quaternary fossil records. Range maps of past distribution have been produced for the last 30 ka at 1000-year intervals, based on pollen and macro-remains, including a total of over 1300 fossil sites. Pollen grains of the genus *Arbutus* are clearly distinct from other Ericaceae, although not identifiable at the species level.

In the Iberian Peninsula, the geographic range of *Arbutus* shows a surprising abundance even during the Last Glacial Maximum. An increasing density of occurrences during the postglacial period suggests a pervasive local persistence with an increase in population density rather than expansion. In the Italian peninsula, *Arbutus* is only detected starting from the Early Holocene. In the Eastern Mediterranean region, it is recorded since the Middle Holocene. It appears that a longitudinal pattern occurs in the population dynamics of *Arbutus* across the Mediterranean Basin in the last 30 ka BP. The local persistence of *Arbutus* along the Atlantic coast of France is difficult to assess, as even its recent scattered populations are not detected by pollen analysis. These marginal populations, as well as the sparse stands living along the coasts of the Black Sea, should be considered for conservation actions.

Ecoclimatic sensitivity in the tropics to Last Glacial Termination: climate change through data mobilization in the Neotoma Paleoecology Database

Mx. Adrian George [1], ***Dr. Suzette Flantua*** [2], ***Dr. Annika Herbert*** [3], ***Prof. Simon Haberle*** [3], ***Dr. Sarah Ivory*** [4], ***Dr. Ondrej Mottl*** [2], ***Prof. Jessica Blois*** [5], ***Dr. Jack Williams*** [1]

1. *University of Wisconsin–Madison,* ***2.*** *University of Bergen,* ***3.*** *Australian National University,* ***4.*** *Pennsylvania State University,* ***5.*** *University of California–Merced*

Given the prospect of widespread ecosystem transformations caused by current anthropogenic climate change, a key research priority is to better assess the sensitivity of ecosystems to past, present, and future climate change. Better quantification of the ecoclimate sensitivity in the tropics is particularly critical, because of their high biodiversity, high carbon storage in rainforests, and positive feedbacks in carbon and water cycling. Global networks of fossil pollen records retrieved from lakes and mires are the primary data source for understanding climate-driven vegetation dynamics at local, regional, and global scales. Pollen data of the Neotoma Paleoecology Database, a community-curated paleoecology resource, historically were weighted towards temperate and high-latitude ecosystems in North America and Europe. However, recent data mobilization campaigns across the tropics now enable macro-scale analysis of tropical ecosystem ecoclimate sensitivity to climate changes since the Last Glacial Maximum (LGM).
Using Neotoma API services, we downloaded all pollen records from 23 thousand years BP (ka) to present between 25˚N and 25˚S. We selected data and temporal quality criteria, harmonized taxa lists using the new RFossilpol package (Mottl, Flantua et al., in review) and recalibrated all age-depth models using the *bchron* R package. We obtained reconstructions of global surface air temperature (SAT) data at 1.9°×2.5° resolution from Tierney et al (2020) and bilinearly interpolated all SAT temperatures to site locations. We estimated ecoclimate sensitivity by calculating community turnover from the LGM to present, then regressed turnover against LGM-to-present temperature anomalies. We analyzed the spatiotemporal patterns in ecoclimate sensitivity through mixed effects models with elevation and temperature predictor variables. The initial data retrieval from Neotoma yielded over 300 tropical records. We recalibrated age-depth models for 270 records and identified 73 records with at least one sample in the periods 5-2ka and 23-15ka. Initial results suggest a high community sensitivity of tropical ecosystems, particularly in montane regions. Variations among tropical regions in apparent climate sensitivity can be attributed to site factors such as elevational position and continentality. These results suggest that 21st-century climate scenarios will have substantial effects upon tropical plant distributions and community composition.

Benthic foraminifera and environmental changes in northern Sardinia: the case of the La Maddalena Harbour

Dr. Roberta Dessi* [1]*, Dr. Riccardo Racis* [2]*, Prof. Sandro Demuro* [3]*, Prof. Daniela Basso* [4]*,
***Dr. Valentina Bracchi* [4]*, Dr. Carla Buosi* [2]**

***1.** University Milano-Bicocca, **2.** University of Cagliari, **3.** Università di Cagliari, **4.** milano Bicocca University*

Benthic foraminifera are reliable tools to paleo-environmental reconstructions because they are wide spatial-temporal spread, and they are sensitive to short-time environmental changes induced by both natural and anthropogenic events. Their community structure provides useful information on the general characteristics of the environment quality and some species are sensitive to specific environmental parameters. Changes in benthic foraminifera abundance, species composition and variation in test morphology provide evidence of fluctuation in several environmental factors and can therefore be used as an efficient method for determining the ecosystems conditions.
This study presents the first micropaleontological data obtained through the analysis of a sediment core drilled from the shallow seabed (maximum depth 15 m) in the Ex-military arsenal of the La Maddalena harbour located on the southern-eastern coast of La Maddalena island (Sardinia, Italy). This area underwent different scenarios and environmental stresses over its history, in particular the investigated harbour worked as naval arsenal for nearly one century with heavy impact on the coastal zone. This study has been carried out to have information on the main environmental changes and to propose the most likely factors that caused these changes. The results showed that in the examined core, benthic foraminiferal assemblages were composed by over 90 species. The most frequent species were *Elphidium crispum, Ammonia tepida, Planorbulina mediterranensis, Spiroloculina ornata,* and *Quinqueloculina* spp.. Several biotic indices (species diversity, foraminiferal density, Shannon, Dominance, etc.) were also calculated. In general, the diversity indices show a decreasing from the first 50 cm of the core to the bottom. This slight decline is accompanied by changes in the foraminiferal assemblages. The results concerning changes in foraminiferal species composition, their abundance and biodiversity, supported by statistical analyses (cluster analysis), allowed identification of three major foraminiferal associations corresponding to different coastal-marine environmental settings.

Rescuing the red dog: using the Pleistocene fossil record of the dhole (Cuon alpinus, Pallas 1811) to inform modern conservation initiatives

Ms. Mollie Mills [1] ***, Prof. Simon Blockley*** [2] ***, Dr. David Redding*** [3] ***, Prof. Danielle Schreve*** [1]

1. *Royal Holloway, University of London,* ***2.*** *Department of Geography, Royal Holloway University of London, London, United Kingdom,* ***3.*** *Institute of Zoology, Zoological Society London*

The dhole (*Cuon alpinus, Pallas 1811*) is a medium-sized evolutionarily distinct canid, currently distributed only in Southeast Asia after experiencing drastic range contraction and eventual extirpation from North America and Europe after the Late Pleistocene. Despite being threatened by prey depletion, habitat destruction and competition, little is known about the dhole's distribution and ecology. Dhole-specific conservation strategies are minimal, if not entirely absent in most range countries. Populations reside mainly in areas designated as protected for other charismatic species, such as tigers and elephants, but their adequacy for dhole conservation is undetermined. Species distribution models (SDMs) that relate georeferenced occurrence records to environmental variables could be used to identify suitable dhole conservation strategies. However, modern dhole distribution data is sparse and heavily influenced by human interactions, which could introduce bias into model projections and misinform conservation actions. Incorporating the dhole's Pleistocene fossil record into models could potentially reduce the effects of limited contemporary ecological data, by including palaeoclimate, palaeoenvironmental and competitive forcing factors over a longer time period. Fossil records can offer deep time insights into the responses to past environmental change of both individual species and ecological communities, as well as broadening understanding of species' full environment relationships prior to extensive human activity.

Population resilience of a wetland species near the limits of its range (the root vole Alexandromys oeconomus in Poland) vs. the geological history and connectivity of hydrogenic habitats – implications for species conservation

Prof. Elżbieta Jancewicz [1] ***, Prof. Ewa Falkowska*** [2]

1. Warsaw University of Life Sciences - SGGW, Institute of Forest Sciences, Department of Forest Zoology and Wildlife Management, 2. University of Warsaw, Faculty of Geology, Żwirki and Wigury 93, 02-089 Warsaw, Poland

Small, environmentally specialized species with a short migratory capacity are very sensitive to the loss of connectivity between habitat patches. This makes them very good for testing environmental changes. Habitat fragmentation, leading to the isolation of populations and consequently to gene pool depletion, may result from anthropogenic factors and/or natural processes of landform evolution. Differences can therefore be expected in how such habitats evolve in areas with different geological history, which in turn may give rise to different species responses to habitat change across such areas. The aim of the study was to examine how the geological history of the landscape close to the southern range limit of the root vole *Alexandromys* (*Microtus*) *oeconomus* in Poland affects the species' genetic variation and thus population resilience. The study was carried out at 9 locations, situated in two areas of Poland with differing geological surface structure characteristics: the Sandomierz Basin and western Polesie. The research included DNA analysis of root voles and geomorphological investigations. The analysis of DMT, satellite images, geological maps and cartographic field work showed that the habitats optimal for the root vole are configured differently in the two areas considered, occurring mainly in river valleys and in isolated wetlands of lake-land plains, respectively. Based on an analyses of 12 microsatellite loci (N=118) and the 908 bp of cytochrome b sequences (N=107), higher genetic variability was found in individuals from Polesie than from the Sandomierz Basin. Within the Sandomierz Basin itself, differences between results for populations from the Tanew and San valleys within the same catchment were further demonstrated. Simultaneous analysis of both the spatial configuration and connectivity of habitats, and the voles' evolutionary directions and genetic parameters, supports the conclusion that the linear character of highly fragmented riverine habitats, additionally inundated during episodic flooding, is less favorable for the gene dispersal of small mammals than extensive wetlands, even despite locally occurring barriers. We conclude that the geological history of the landscape needs to be taken into account in conservation management of hydrogenic habitat areas, especially those close to the range limit of a species with demanding habitat requirements.

Conservation efforts and paleobiology meet in the Coralligenous algal reefs

Prof. Daniela Basso [1], ***Dr. Valentina Bracchi*** [1], ***Dr. Pietro Bazzicalupo*** [2], ***Prof. Marco Bertolino*** [3], ***Dr. Mara Cipriani*** [4], ***Dr. Francesco D'Alpa*** [5], ***Dr. Gemma Donato*** [5], ***Prof. Adriano Guido*** [4], ***Dr. Mauro Negri*** [2], ***Prof. Rossana Sanfilippo*** [5], ***Prof. FRANCESCO SCIUTO*** [6], ***Prof. Antonietta Rosso*** [5]

1. *milano Bicocca University,* **2.** *Dipartimento di Scienze dell' Ambiente e della Terra, University of Milano-Bicocca,* **3.** *Department of Earth, Environment and Life Sciences (DISTAV), University of Genova,* **4.** *Dipartimento di Biologia, Ecologia e Scienze della Terra, Università della Calabria, Rende (CS),* **5.** *Department of Biological Geological and Environmental Science, Catania University,* **6.** *C/O DIPARTIMENTO SCIENZE GEOLOGICHE*

The algal reef Coralligenous is one of the most important biogenic frameworks of the present-day Mediterranean continental shelf. As observed in its Quaternary records, it mainly consists of calcareous red algae and, to a lesser extent, of skeletonized invertebrates, such as bryozoans and serpulids. This complex and very heterogeneous habitat hosts a rich and diverse macro- and microfauna composed of several invertebrate taxa, among which mollusks, sponges and foraminifera are the most common elements.

The Italian FISR project "*CRESCIBLUREEF - Grown in the blue: new technologies for knowledge and conservation of Mediterranean reefs*" was aimed at the multidisciplinary exploration of the components, growth rate and accretion style of the Marzamemi (SE Sicily) coralligenous bioconstructions, and at the development of non-invasive techniques for the study and conservation of this priority habitat. The data collected range from remote sensing maps to the monitoring of environmental parameters, to the analysis of the components identity, their association, and radiocarbon age, that enable a reconstruction of the temporal and spatial dynamic of Coralligenous, and its role as archive of environmental changes trough the Holocene. This wide data set, including both the physical habitat engineers (calcareous algae, bryozoans, serpulids, mollusks) and the macro- and micro-dwellers, suggests that Coralligenous is a geo-historical structure and major in situ recorder of the coastal dynamics trough time and space, providing new hints about the response of the Mediterranean shelf environment to the Holocene climatic fluctuations and historical human impacts.

The formation and time averaging of shell beds of Lake Tanganyika, Africa: Implications for conservation of a unique lacustrine habitat

Dr. Michael Soreghan [1], ***Dr. Andrew Cohen*** [2], ***Dr. Michael McGlue*** [3], ***Dr. Jordon Bright*** [4], ***Dr. Darrell Kaufman*** [4], ***Dr. Ishmael Kimirei*** [5]

Lake Tanganyika, Africa, hosts an extraordinary level of faunal diversity, much of which occupies the nearshore (littoral) environments of the lake. Threats to the lake's biodiversity stem from both lakewide impacts (e.g. climate change), but also local impacts (e.g. sediment pollution and overfishing) that also vary spatially and temporally. Up to 30% of the lake's littoral area consists of shell beds, in water depths of 5-40 m, dominated by a single gastropod species (*Neothauma tanganyicense*); these shell beds form habitats for cichlids, ostracodes, sponges and other mollusks. Our observations over the past decade are that these shell-bed substrates are variably impacted by surface sedimentation, creating patchy or completely buried shell beds in some areas. Further, living *Neothauma* are rare to absent within these shelly substrates at some locations, implying either a negative feedback, where accumulation of dead shells limits the presence of modern populations, or the presence of acute anthropogenic impacts that are reducing populations of the snail at least locally. Radiocarbon dating of surficial shells, corrected for a carbon reservoir effect in the lake, suggest shell production varied with changes in climate and lake level. Shells as old as 3100 yrs before present (BP) exist, but production peaked between 1600-1200 yrs BP, when the lake was lower and climate more arid. A second mode of shell ages corresponds to the Little Ice Age, when lake level again was slightly lower. There is an age gap in shell production between these time periods, which is marked by a lake transgression (wetter climate). In regions of the lake where nearby land disturbance is high, the shell age distributions reflect limited shell production in the last 100 years, suggesting that anthropogenic sediment input may be inhibiting shell production. This is also consistent with changes in ostracod diversity and sponge abundance data. A breakdown of the shell-bed habitat will likely have a cascading effect on other organisms and is a threat to overall biodiversity of the lake. Conservation methods, however, will need to differ relative to those employed along rocky shorelines of the lake because of differences in population pressure and land use.

Changes in small mammal community composition over the last 25,000 years across multiple western North American cave localities

Ms. Julia Schap [1]***, Dr. Jenny McGuire*** [1]***, Dr. Julie Meachen*** [2]
1. *Georgia Institute of Technology,* ***2.*** *Des Moines University*

Natural Trap Cave (NTC) is an 80-foot deep karst sinkhole located at the base of the Bighorn Mountain range in Wyoming, USA. An exceptional fossil record of microfaunal remains are found from well-stratified layers in the cave stretching back 30,000 years ago, before the end-Pleistocene megafauna extinction, up until a few hundred years ago. While many studies have examined how communities respond to environmental changes in a single location through time, few have observed how community responses vary across different habitats. We compared standardized richness, evenness, and relative abundances, using NISP, of the small mammal communities from NTC, Samwell Cave, Two Ledges Chamber, and Homestead Cave to observe how small mammal communities shifted through time across diverse landscapes. Then, a closer look was taken at the shifts in functional traits of the small mammal community of NTC. Results from a PCoA found that NTC and Samwell Cave were more similar to each other than to Homestead Cave and Two Ledges Chamber. Despite differences in local environments, open and arid at NTC and closed and forested at Samwell Cave, small mammal accumulation at both these caves are the result of packrat midden collection. Richness and evenness were then compared between NTC and Samwell Cave. We found that evenness decreased at both caves from the Late Pleistocene to the Late Holocene. Richness also decreased through time at Samwell Cave but increased through time at NTC, though this may be influenced by small sample sizes in the Late Pleistocene. The Pleistocene community at NTC had the highest percentage of taxa with low tooth crown heights (42%) with that percentage reducing by half into the Holocene. Dietary generalists were also more common in the Pleistocene community (61%) with communities dominated by taxa eating exclusively plants in the Middle Holocene (62%) and Late Holocene (57%). It may be that as temperatures warmed into the Holocene, plants around NTC diversified allowing more herbivorous taxa to increase in abundance whereas those focusing on invertebrates, fruits, or seeds were more limited.

The late occurrence of hunter-gatherer occupation of tropical rainforest in northwestern Thailand

Dr. Kantapon Suraprasit [1] ***, Prof. Rasmi Shoocongdej*** [2] ***, Dr. Kanoknart Chintakanon*** [3] ***, Dr. Athiwat Wattanapituksakul*** [3] ***, Prof. Hervé Bocherens*** [4]

1. *Department of Geology, Faculty of Science, Chulalongkorn University, Bangkok, 10330, Thailand,* ***2.*** *Department of Archaeology, Faculty of Archaeology, Silpakorn University, Bangkok, 10200, Thailand,* ***3.*** *The Prehistoric Population and Cultural Dynamics in Highland Pang Mapha Project, Princess Maha Chakri Sirindhorn Anthropology Centre, Bangkok, 10170, Thailand,* ***4.*** *Department of Geosciences, Biogeology, University of Tübingen, Hölderlinstraße 12, 72074, Tübingen, Germany*

Archaeological sites in highland Pang Mapha, Mae Hong Son Province in northwestern Thailand have yielded several Late Pleistocene to Holocene human and animal remains associated with the Hoabinhian techno-complex. Savannah-like grasslands have been suggested to be a hunter-gatherer related habitat during the late Pleistocene based on the stable isotopic evidence, while other archaeological data have implied rainforest specialization for Holocene hunter-gatherers. However, human reliance on rainforest resources in the region has not been demonstrated comprehensively. To refine the timing of dietary changes and ecological adaptations of hunter-gatherers, we measured stable carbon isotope compositions of tooth enamel of humans and their associated mammals from several archaeological sites in highland Pang Mapha, dated between 9,800 and 1,100 yr BP, and compared the isotopic results with previously analyzed data from the late Pleistocene archaeological site of Tham Lod Rockshelter. The stable carbon isotope data have revealed that the significant dietary shift of hunter-gatherers to more exclusive C_3 food items occurred around the early Holocene or probably during the Pleistocene-Holocene transition, and their succeeding reliance on rainforest resources possibly remained consistent in the region throughout the Holocene. Subsistence strategies with more emphasized rainforest foraging illustrate an ecological adaptation of Hoabinhian populations in response to more homogeneous and closed environments and wetter climate in northwest Thailand after the end of the Pleistocene. Compared to other neighboring regions, our isotopic results document the late occurrence of mainland Southeast Asian rainforest hunter-gatherers.

Microblade Runner: Changing environments and the emergence of microblades in the northern Japanese archipelago

Ms. Cindy Hsin-yee Huang [1]

1. *Arizona State University*

The appearance of microliths and their rapid spread throughout Eurasia is one of the major developments in the evolution of Paleolithic technologies, since microliths and microblades, as part of complex modular tool packages, became the dominant technology in the late Pleistocene and persisted into the Holocene. The pressure flaking techniques associated with microblade technologies in East Asia are argued to have emerged in northern Asia, with some discussion of northern Japan as a possible region of initial emergence. As such, much research has been done on the function, variability, and timing of microblade industries in the region. Qualitative assessments of the archaeological record and the Paleoenvironmetal reconstructions suggest the emergence of some microblade industries as a response to the changing environments. These arguments can be strengthened through additional quantitative analyses. This project constructs a diffusion model of microblades in northern Japan and conducts a spatial analysis between the emergence of microblades and the Paleoenvironments in order to explore how hunter-gatherers in northern Japan adapted their technological toolkits to the rapidly changing environments of the late Pleistocene.

Rethinking the diversity of lithic technology and human behaviour in the terminal Pleistocene of Hokkaido, Northern Japan: a view from bifacial point traditions

Dr. Jun Takakura [1]

1. *l Archaeological Research Center, Hokkaido University*

In understanding the behaviours and adaptive strategies of the terminal Pleistocene (19-11.5 cal ka) human populations in Hokkaido, Northern Japan, much attention has long been focused on the evolution of microblade technology. There is a large body of research on the issue of human behaviours in lithic assemblages where microblade technology is recognised. However, recent findings from several archaeological sites in Hokkaido have confirmed the development of bifacial point traditions during the terminal Pleistocene. Understanding of the behaviours and adaptations of these bifacial point producing populations in Hokkaido is an important question in discussing the dynamics of human populations from Northeast Asia to North America during the terminal Pleistocene. How to interpret the relationship between people who produced microblades and those who produced bifacial points is also an issue that researchers need to address. In addressing these issues, the uncertain dating of lithic assemblages with bifacial points in Hokkaido has so far been a major barrier to progress the debate. In this paper, I explore the bifacial point traditions of the terminal Pleistocene Hokkaido in terms of its chronology, distribution, and lithic technology. In addition, I discuss how the occurrence and development of bifacial point traditions in Hokkaido can be assessed in the light of the characteristics of bifacial point lithic assemblages in the Japanese archipelago.

Using calibrated surface roughness dating to estimate coastal dune ages at K’gari (Fraser Island) and the Cooloola Sand Mass, Australia

Dr. Nicholas Patton [1], ***Prof. James Shulmeister*** [1], ***Prof. Tammy Rittenour*** [2], ***Prof. Peter Almond*** [3], ***Dr. Daniel Ellerton*** [4], ***Prof. Talitha Santini*** [5]

1. University of Canterbury, 2. Utah State University, 3. Lincoln University, 4. Stockholm University, 5. The University of Western Australia

Here we present a novel application of landscape smoothing with time to generate a detailed chronology of a large and complex dune field. K’gari (Fraser Island) and the Cooloola Sand Mass (CSM) dune fields host thousands of emplaced (relict) and active onlapping parabolic dunes that span 800,000 years in age. While the dune fields have a dating framework, their sheer size (~1930 km^2) makes high resolution dating of the entire system infeasible. Leveraging newly acquired (n=8) and previously published (n=20) optically stimulated luminescence (OSL) ages from K’gari and the CSM, we estimate the age of Holocene dunes by building a surface roughness-age relationship model. In this study, we define surface roughness as the standard deviation of topographic curvature for a dune area and we demonstrate an exponential relationship (r^2 = 0.942, RMSE = 0.892 ka) between surface roughness and timing of dune emplacement on the CSM. This relationship is validated using ages from K’gari. We calculate surface roughness utilizing a 5 m digital elevation model (DEM) and apply our model to predict the ages of 726 individually delineated Holocene dunes. The timing of dune emplacement events are assessed by plotting cumulative probability density functions (PDFs) derived from both measured and predicted dune ages. We demonstrate that both dune fields had four major phases of dune emplacement peaking at <0.5, ~1.5, ~4, and ~8.5 ka. We observe that our predicted dune ages did not create or remove major events when compared to the OSL-dated sequence, but instead reinforced these patterns. Our study highlights that surface roughness-age modelling can be an easily applied relative or absolute dating tool to dune fields globally. This systematic approach can fill in chronological gaps using only high-resolution elevation data (3-20 m resolution) and a limited set of dune ages.

Points to keep in mind when predicting the impact of sea-level rise on coastal ecosystems: Focusing on mangrove ecosystems

Dr. Kiyoshi Fujimoto [1]***, Dr. Keita Furukawa*** [2]***, Dr. Kenji Ono*** [3]***, Dr. Shin Watanabe*** [4]***, Dr. Kodai Hasada*** [5]

1. Nanzan University, 2. Association for Shore Environment Creation, 3. Forestry and Forest Products Research Institute, 4. University of the Ryukyus, 5. Nara University

Early studies to predict the effects of sea-level rise induced by global warming on mangrove ecosystems were often conducted using geomorphological and geological methods, which were estimated the threshold rate of past sea-level rise that mangrove forest floor deposits, especially mangrove peat, could catch up from their spatial distribution and sedimentary age. These studies clarified that mangrove forests, which had maintained their habitat by accumulating mangrove peat with a small amount of sediment inflow, were submerged under sea-level rise exceeding 5 mm/year. However, our subsequent studies on Pohnpei Island in Micronesia, where a sea-level rise exceeding 8 mm/year has been observed in recent years, clarified that the ground level in the communities of *Rhizophora* spp. has been rising due to the deposition of mangrove peat, though the *Sonneratia alba* community located at the seaward forest edge and the *Bruguiera gymnorrhiza* community where the tree density of *Rhizophora* trees has been decreased due to vegetation succession have already been undergoing significant surface erosion. Namely, the mangrove peat sedimentation rate estimated by the geomorphological and geological methods was the average value in the order of hundreds to thousands of years, and the decline in mangrove peat accumulation rate due to vegetation succession was not considered. In recent studies, the vulnerability of mangrove forests was often evaluated from changes in the distribution area of mangrove forests using satellite images, but phenomena such as surface erosion occurring in forests were not captured. In addition, mangrove forests were treated collectively in many cases, and evaluations were not made at the community level. Ground elevation changes in mangrove habitats are controlled by root system dynamics including dead roots, especially fine roots which are the main parent material of mangrove peat, in addition to allochthonous sediment budget. Fine root productivity and dynamics differed depending on species and site environments. To predict the impact of sea-level rise more accurately, it is necessary to evaluate not only geomorphological processes such as sediment budget but also biological processes such as root system dynamics at the community level.

Computing of uncertainty subsidence-associated along a 2D geological model in the Po Delta Area (northern Italy)

Dr. Eleonora Vitagliano [1], Dr. Ilaria Spassiani [1], Dr. Chiara D'Ambrogi [2], Prof. Rosa Di Maio [3]

__1.__ Istituto Nazionale di Geofisica e Vulcanologia, Rome (Italy), __2.__ Geological Survey of Italy - ISPRA, Rome, __3.__ Dipartimento di Scienze della Terra, dell'Ambiente e delle Risorse, Università di Napoli "Federico II"

Quantifying uncertainty in geological problems is not an easy task, although it plays a fundamental role in ensuring robust and accurate results. In fact, uncertainty affects a wide range of fields, including the natural variability of a system, the sampling rate of key parameters used for describing a system, measurement errors, modeler's experience, etc. Some of the approaches that deal with uncertainty treat the error sources in a single and non-integrated manner, while more advanced procedures consider the impact of uncertainty based on geostatistical methods, or by combining geostatistics and stochastic simulations arising from multiple sources of error. In the present study, we propose a workflow to account for the "multiple-source uncertainty" associated with a 2D geological model aimed at assessing natural subsidence rates in deltas. The geological section that we modeled crosses the Po Delta (northern Italy) and involves the late Pleistocene-Holocene sequences. We first focused on the factors that control uncertainty in the geological modeling finalized to subsidence computation (e.g., instrumental error in the horizon picking or different depth interpretation for the same horizon). Then, we isolated the effect of the single source of error on each calculation step of the backstripping procedure, which has been used for the quantitative subsidence assessment (e.g., sediment compaction or isostatic loading steps). Afterward, we evaluated the effects of concatenated errors on the final result, performed a sensitivity analysis and identified the source with the highest influence on the uncertainty. In addition, we focused on the empirical relationships among the analyzed uncertainty factors.

Finally, we compared uncertainty estimates related to subsidence computation from different commercial softwares and research scripts available in the literature, and automated the best procedure in a Matlab code.

The geomorphology and significance of perched coastal lakes in Ireland

Prof. Jasper Knight [1] ***, Prof. Helene Burningham*** [2]

1. University of the Witwatersrand, 2. University College London

Perched coastal lakes, located within the elevation range between present sea level and the position of the mid-Holocene maximum recorded along any one coast, have the potential to record late Holocene coastal sediment dynamics, especially along coastlines that have subdued glacioisostatic influence but where they may be exposed to storms or other drivers of large waves (such as tsunamis). Although many individual coastal lakes globally have been examined with respect to their overwash chronologies, there have been few studies that have (1) considered the typologies of different coastal lakes in a single region, (2) compared the geomorphology and sedimentology of these lakes in order to better understand their different evolutionary patterns and controls, and (3) compared the overwash records of adjacent lakes to understand the spatial and temporal patterns of storm events across a region, rather than from just a single lake whose record may be incomplete or unrepresentative. This study takes the first step towards resolving these three issues by considering the different perched coastal lakes that are present around the coasts of Ireland. This study maps and then classifies these lakes (approximately 50) in terms of their elevation, size, substrate type and seaward bar. Broadly, four lake types are identified according to their seaward bar (bedrock lip, gravel ridge, sand dune, beach/barrier). These are located along different coastline types (bedrock controlled, sediment dominated) and with respect to the trajectory of local relative sea-level change (by glacioisostatic-driven emergence/submergence). These types are characterized by different patterns of geomorphic development, related to coastline sediment supply, the likelihood of wave washover, and landward sediment transport. This has implications for sediment infilling of the lake basin, infill stratigraphy, and the likelihood of storm overwash sediment signatures being preserved. (Palaeoecological and water salinity proxies of overwashing are not considered in this study.) A subsample of test sites and their results of geomorphic and sedimentary mapping are presented in this study, and this provides a baseline for a systematic survey of coastal lakes across the Irish coast.

The tectonic rock uplift history of northern Guam (Mariana Islands) deduced from marine terraces

Dr. Blaž Miklavič [1]***, Prof. Cengiz Yildirim*** [2]

1. *University of Guam, Water and Environmental Research Institute of the Western Pacific,* ***2.*** *Eurasia Institute of Earth Sciences, Istanbul Technical University, Turkiye*

Guam is the southernmost island of the Izu-Bonin-Mariana island arc system associated with the subduction of the Pacific under the Philippine Plate. The island is part of a unique tectonic setting that led to the formation of the deepest subduction trench and the only modern active submarine serpentine volcanoes on Earth. It is a seismically very active zone with more than thirty earthquakes of magnitude higher than three per year and coseismic events that can cause vertical displacements of ca. 10 cm.

The northern part of the island is capped with uplifted limestone with a series of marine terraces that allow studying of long-term tectonic uplift history. Our research focuses on the highest set of terraces. Geomorphic mapping and morphometric analysis based on high-resolution DEM were used for terrace identification and modelling of the uplift rate. For age model control points, U-Th dates obtained from datable corals found on the lowest terrace, and speleothems from flank margin caves were used.

Our preliminary results indicate that the northern part of the island episodically uplifted (at least three times); however, it was also strongly denudated during the Pleistocene, which was taken into account when quantifying the rock uplift rate. The results also show the complexity of the tectonic history of the island and its surroundings. They will not only help to understand the formation of some of the unique features of the planet, but also help to better comprehend Guam's aquifer that developed in such conditions, which provides fresh water to the growing population of the already densely populated island.

Geomorphological map of the Tyrrhenian coastal sector of the northern Calabria-Basilicata (southern Italy)

Dr. Ciro Cerrone [1]***, Dr. Francesca Filocamo*** [2]***, Prof. Gaetano Robustelli*** [3]***, Prof. Alessandra Ascione*** [1]

1. *Dipartimento di Scienze della Terra, dell'Ambiente e delle Risorse, Università degli Studi di Napoli Federico II,* ***2.*** *Dipartimento di Scienze e Tecnologie, Università degli studi di Napoli Parthenope,* ***3.*** *University of Calabria*

In this work, we present the 1:20,000 scale geomorphological map of the Basilicata-northern Calabria coastal stretch of the Tyrrhenian coastal sector of the southern Apennines (Italy). The study area spans for c. 20 km from Maratea in the North to Scalea in the South, and is particularly interesting for the presence of a well-preserved staircase sequence of marine terraces located from a few m up to ~ 170 m a.s.l. They consist of both erosional and depositional paleo-shorelines in several instances covered by alluvial fans. In addition, evidence of cross-cut relationships between the paleoshorelines, deposits (e.g., slope/alluvial fan deposits and speleothems) and landforms (karst caves and conduits) of terrestrial environment occurs.

The geomorphological map synthesizes the results of a detail-scale study carried out in the last years that was based on the combination of field surveys with the geomorphological analysis of detailed topographic data (1:5,000 scale topographic map, LiDAR data with 1 and 2 m resolution and a 5 m resolution DEM) and integrated by geochronological dating of several marine and continental environment deposits. The new chronological data provide constraints to the formation of the marine terraces in the elevation range of 2 - 60 m a.s.l. and, therefore, allow us to extend the sequential reconstruction to the marine terraces located above 60 m a.s.l. In addition, marine terrace dating allows us to reconstruct the main stages of both coastal and continental landform sculpturing and, therefore, constrain and distinguish several stages of alluvial fan growth and progradation.

All such information has been reported in the geomorphological map. In fact, besides careful and detailed mapping of the coastal and alluvial/slope landforms that occur in the study coastal stretch, information in the map synthesizes the stages of the geomorphological evolution of the study area during a time frame that spans from the Middle Pleistocene to the latest peaks of the Last Interglacial (LIG).

Holocene coastal response to sea level rise of high coasts in quite stable areas: the case of Punta Licosa promontory(Campania Region)

Dr. Maria Francesca Tursi [1]***, Dr. Gaia Mattei*** [1]***, Dr. Claudia Caporizzo*** [1]***, Prof. Silvio Del Pizzo*** [1]***, Dr. Francesco G. Figliomeni*** [1]***, Dr. Antonio Minervino Amodio*** [2]***, Prof. Claudio Parente*** [1]***, Prof. Carmen M. Rosskopf*** [3]***, Prof. Pietro P.C. Aucelli*** [1]

1. *Dipartimento di Scienze e Tecnologie, Università degli studi di Napoli Parthenope,* ***2.*** *ISPC- CNR, Potenza,* ***3.*** *Università degli Studi del Molise, Pesche, Isernia*

Punta Licosa promontory is located in the northern part of Cilento coast in the southern Tyrrhenian basin. This promontory is bordered by cliffed coast connected to a wide shore platform sloping slightly towards the sea. This area is considered stable at least since Late Pleistocene, as testified by a series of evidence, well-known in literature.

The aim of this research is to reconstruct the main coastal changes occurred in this area since the late Holocene by means of literature data, aerial photo interpretation, satellite images, GPS measurements, direct underwater surveys, GIS elaborations of high-resolution DTMs, bathymetric data and high-resolution orthophotos taken by UAV.

Particular attention was paid to the wide platform positioned between -6.0 ± 2.0m MSL and the present MSL, being these coastal landforms interpreted as the main consequence of seacliff retreat. The spatial analysis of this landform was compared with the GIA models calculated for the southern Tyrrhenian area, allowing establishing that it was shaped during the last 6.0 ± 2.2 ky BP. The interpretation of archaeological and geomorphological markers allowed defining the shoreline evolution of this coastal sector since 6.0 ky BP which can be well depicted by two morpho-evolutive scenarios.

The first scenario is related to 6.0 ± 2.2 ky BP, and it is relative to the time when the decreasing rate of sea-level rise favoured the seacliff retreat in the whole coastal sector and the starting point of the platform formation, testified by the outer margin of the present-day platform.

The second scenario is related to 1.0 ky BP, as testified by the remains of the roman harbour located at S. Marco di Castellabate, in the northern part of the study area, being harbour structures excellent sea-level indicators, as they were built in direct functional relation with the ancient sea level. The Related RSL at this time can be located at -1± 0.3 m MSL.

This research provides new data useful for climatic studies aimed at evaluating the high coast vulnerability to the effects of the ongoing accelerated RSL along the Cilento coast representing a perfect example of Holocene coastal evolution in quite stable areas.

New insights into the palaeolandscape of the Scheur, a hotspot for Late Pleistocene fossils off the Belgian coast

Dr. Thomas Mestdagh [1], ***Dr. Ruth Plets*** [2], ***Dr. Maikel De Clercq*** [3], ***Dr. Tine Missiaen*** [2]

__1.__ Flanders Marine Institute (VLIZ), InnovOcean Campus, Jacobsenstraat 1, 8400 Oostende, Belgium, __2.__ Flanders Marine Institute (VLIZ), InnovOcean Campus, Jacobsenstraat 1, 8400 Oostende, België, __3.__ Jan De Nul, Tragel 60, 9308 Hofstade (Aalst), Belgium

Over the past decades, bottom trawling and dredging in the vicinity of the 'Scheur' navigation channel (~5 km NE of the harbour of Zeebrugge, Belgium) has yielded vast amounts of unique Late Pleistocene palaeontological material. Besides finds related to prehistoric land mammals (including mammoth, woolly rhinoceros, aurochs and straight-tusked elephant), an exceptional quantity of walrus (*Odobenus rosmarus*) bones has been discovered. The walrus assemblage contains remains of 50 to 100 animals (both males, females and juveniles), which are most likely preserved *in situ* because they show no or little signs of abrasion. It can therefore be concluded that at some point(s) in the Late Pleistocene, one or multiple walrus colonies must have lived in the Scheur area. However, several questions remain to be addressed: (i) From which stratigraphic level(s) are the walrus fossils sourced? (ii) What is their age (given that radiocarbon dating indicates an age beyond the detection limit, > 45000 yr BP)? (iii) Why do we find such a large abundance of fossils in this specific area, so unusually far south? Key to answering these questions is a better understanding of the geological context and evolution of the Late Pleistocene coastal/nearshore landscape off Zeebrugge. This study contributes to this need by presenting new geophysical (ultra-high-resolution sub-bottom and multibeam) data and information from sediment cores. The results have led to the identification of a potential source layer for the walrus fossils, shed new light on the diversity in and stratigraphic superposition of sedimentary environments in the study area, and reveal the influence of human activities (specifically, dredging of the navigation channel) on the denudation of the fossil-rich strata. With this new information, more targeted sediment sampling, geophysical data acquisition and visual seabed inspections can be planned, to further elucidate the relationship between the abundant presence of (walrus) fossils and the Late Pleistocene landscape evolution around the Scheur.

Geoarchaeological analysis to unravel the ancient settlement dynamics: examples from the Ionian coastal landscape of Basilicata, southern Italy

Dr. Giuseppe Corrado [1], ***Dr. Dario Gioia*** [2], ***Dr. Ester Annunziata*** [1], ***Dr. Paola Di Leo*** [3], ***Prof. Marcello Schiattarella*** [1]

1. *University of Basilicata,* ***2.*** *CNR ISPC,* ***3.*** *CNR-IMAA*

In the ancient territory of the Greek settlements of Heracleia and Metapontum (Ionian sector of Basilicata, southern Italy) geomorphological mapping, GIS-supported statistics, and landform topographic features were investigated and combined to extract settlement rules and site dynamics. Analyses of environmental dynamics as well as of spatial and temporal settlement evolution were carried through an integrated approach that, starting from a detailed geomorphological analysis, tried to extract the spatial relationships between archaeological site locations and landform/landscape features. Spatial analysis was used to investigate the relationships between environmental parameters and archaeological sites (i.e., between humans and the evolving environment). The analysis was carried out in two distinct areas, each about 50 km-large, including the main settlements and other sites of that territory. A model describing interactions between sites and parameters such as elevation, slope, aspect, landforms, land use, and distances from rivers was constructed. In the present work, emphasis has been put to analyze the sensibility maps deriving from the selected parameters and their changes through time from Prehistorical and Protohistoric Ages to Roman period for five archaeological categories, i.e. Settlement, Productive area, Farmhouse, Necropolis and Sacred area, contextualized within the most likely paleoclimate scenario. Sensitivity maps are able to unravel the settlement dynamics in the study area, relating them to both social-political transformations and landscape evolution mainly linked to the sea-level changes.

Present-day bathymetry and paleocoastline modelling – perhaps not such a good idea? A case study from the Gulf of Trieste, northern Adriatic Sea

Dr. Ana Novak [1]

1. Geological Survey of Slovenia; Dimičeva 14, 1000 Ljubljana, Slovenia

Paleoreconstructions are becoming increasingly important as we try to understand and predict future changes of our environments. This also applies to paleo-landscape modelling of present-day coastal areas in an effort to better understand future challenges related to sea-level changes. One aspect of coastal paleoreconstruction deals with geographical modelling of paleocoastlines. Here, the two main factors controlling the results are the used sea-level curve and paleotopographical model. While significant efforts are usually dedicated to produce and/or use the most representative sea-level curve, more often than not, present-day bathymetry is used as the topographical model input. While this can be an acceptable approximation where not much variation is expected in the topography, it can potentially induce significant errors in settings where the present-day bathymetry considerably differs from the pre-transgressional topography. This study considers one such example - the Gulf of Trieste (northern Adriatic Sea), a low‐gradient area with fairly well-resolved bathymetry and pre‐Holocene (i.e. pre‐trangressional) paleotopography. Both topographical models are used for paleocoastline modelling in order to determine the variability of the modelled coastline locations. The results demonstrate that coastlines determined from the two different input topographies can differ by as much as a few kilometers resulting in significantly different landscape reconstructions. Present-day bathymetry in paleocoastline modeling should be used very cautiously and only in settings where not much topographical variability is expected since the sea-level rise/fall. The findings of this study are especially important for low-gradient continental shelf areas where even small sea-level variation can affect vast expanses of the shelf.

Unveiling the Brazilian equatorial margin: the Potiguar Basin shelf-edge.

Dr. Helenice Vital [1], ***Mr. Victor Lopes*** [2], ***Dr. Narelle Almeida*** [3], ***Mr. Luan Pantoja*** [1]

1. *Universidade Federal do Rio Grande do Norte,* ***2.*** *Serviço Geológico do Brasil - CPRM,* ***3.*** *Universidade Federal do Ceará*

The study area is located between 100 m and 2000 m deep, along the coast of Rio Grande do Norte State, Northeast Brazil. It is in the transition between the continental shelf, site of future offshore wind installations, and deep waters, new oil exploratory frontier in the so-called Equatorial Margin. The main objective of the research was to generate knowledge to support the sustainable management of natural resources and energy in sensitive marine areas, associated with the training of human resources, as well as contributing to the Decade of the Oceans. The data were collected aboard the Hydro-oceanographic vessel Cruzeiro do Sul, in a partnership between Brazilian educational institutions, the Brazilian Navy and the Brazilian Geological Service. Data from multibeam bathymetry (MBES), high-resolution seismic (CHIRP), measurements of speed of sound along the water column (XBT) were acquired, among others. The results indicated the presence of different marine features and potential areas to Geohazards on the slope. In particular with emphasis on submarine canyons, which have the potential to lift and transport cold water masses (upwelling) over the shelf and edge of the continental shelf. These results confirm, in unprecedented detail, recent studies that showed that submarine canyons generate the ideal flow-topography environment, inducing the process of seasonal uplift (greater intensity in summer) of colder and saline water masses from the deepest to the shallowest areas, resulting in the formation of vortices, ecological differentiations, as well as the seasonal fertilization of the waters of the Northeast coast of Brazil, breaking the paradigm of an exclusively oligotrophic zone.

Using archaeological and geological data to reconstruct human-environment interaction on and around the former (pen)insula of Testerep (Belgium)

Ms. Zoë Vanbiervliet [1]

1. Multidisciplinary Archaeological Research Institute (MARI), Vrije Universiteit Brussel, Belgium

The Middle Belgian coastal area has been subject to many changes over the past 5000 years. Currently dominated by a linear dike platform, the area previously consisted of a dynamic system of tidal gullies, mud flats, and marches. The emergence, reclamation, and eventual partial demise of the (pen)insula of Testerep in this area is a great example of sea level rise impact on coastal landscapes and communities. The Testerep project focusses on reconstructing the evolution of this former (pen)insula. This will include the integration of new and existing on- and offshore data in a GIS-database. This GIS-database, which will include data obtained through a.o. LiDAR, geophysical surveys, coring and excavations, will be a basis for reconstructions and modelling of the physical landscape.

The setting up of this database also allows for insights into human-environment interaction on a local scale. Over 200 archaeological observations were made in the Testerep-area. In some cases, studying the evolution of specific sites allows us to learn about the way specific coastal communities adapted, or failed to adapt, to their coastal environment. Roman and Medieval settlements developed in the coastal plain, taking advantage of the opportunities provided by proximity to the sea. Despite a strong and maintained Roman presence on a nearby sandy outcrop overlooking the coastal plain, and apparent investments in localised coastal defence, Roman sites nearer the coastline appear to have been overtaken by the sea in relatively short timespans. Early and High medieval habitation in the coastal plain appears to be limited to areas further away from the coastline, on natural outcrops and elevations. High and Late Medieval coastal communities settle in the coastal plain, taking advantage of natural defensive opportunities and creating them when not available. The apparent longer lasting success of these settlements is due in part to historically attested investments in coastal defense. Many excavation reports include underutilised geological information. Integrating this information with larger geological datasets can add to reconstructions of the physical landscape. Studying the impact of settlements on the environment and vice versa can provide useful factors to include in later modelling phases of the project.

Estuarine coastline evolution of the northern Tagus margin combining geological, archaeological and cartographic data

Dr. Ana Maria Costa [1], *Dr. Jacinta Bugalhão* [2], *Prof. Maria da Conceição Freitas* [1]
1. IDL – Instituto Dom Luíz, Faculdade de Ciências da Universidade de Lisboa, 2. Direção-Geral do Património Cultural

In this work we present the results of a cross-disciplinary study aimed to reconstruct the evolution of the northern Tagus estuarine coastline in the Lisbon old city centre. Based on sedimentological analyses, archaeological findings, and old cartography, we propose different and consecutive steps for the anthropic *conquer* of the estuarine margin since the Iron age/Roman period.

The first occupation of the marginal area took place during the Iron age, with the construction of several housing buildings on the berm of beaches forming the downstream margins of a Tagus estuary tributary (Esteiro da Baixa; EB). In the Roman period, the EB and the proximal Tagus margin were densely occupied by several public housing, production structures, and harbour facilities, certainly constraining the EB margins. Based on archaeological findings and its typology, urban morphology, altimetry and sedimentological analyses performed in sediments collected in marginal archaeological sites, an estuarine coastline was proposed for the Roman period. According to these data, the coastline located ca. 400 m inland from the present-day coastline.

During the Medieval period the margin continued progressively to be conquered essentially by the deposition of waste deposits, that later are occupied and used mostly for the development of anthropic maritime-related activities. During the Late Medieval ages, the successive advances of the estuarine coastline are materialized by the construction of the defensive city walls during the reigns of D. Diniz and D. Fernando respectively that, in the Lisbon downtown, mark the land-estuary limit. Later, during the 15th/16th centuries, D. Manuel I promotes a reorganization of the area, renewing the importance of Lisbon downtown by the construction of a new and important landfill that moved southwards the estuarine coastline by ca. 200 m.

The 1755 seismic/tsunami event severally damaged Lisbon and the estuarine frontline, and during the following years an effort was done to rebuild the city. Finally, during the 19th century a vast new landfill was constructed, the Aterro da Boavista, linearizing and artificializing the margin in an extension that covers the entire municipality.

Stratigraphic architecture of the Rhone delta in the Holocene: Relationship between sedimentary flows in the delta and Climatic & Anthropogenic impact in the Rhone basin

Mr. Théo Martinez [1], ***Dr. Rémy Deschamps*** [1], ***Dr. Gabriel Ducret*** [1], ***Mr. Claude Vella*** [2], ***Dr. Gwenael Jouet*** [3], ***Dr. Adam Hammoumi*** [1], ***Dr. Maxime Moreaud*** [4], ***Prof. Alessandro Amorosi*** [5], ***Dr. Hervé Piegay*** [6], ***Dr. Jean-François Berger*** [7]

1. *IFP Energies Nouvelles, Rueil-Malmaison, France,* **2.** *CEREGE,* **3.** *Univ Brest, CNRS, Ifremer, Geo-Ocean,* **4.** *IFP Energies Nouvelles, Solaize,* **5.** *Department of Biological, Geological and Environmental Sciences, University of Bologna,* **6.** *ENS Lyon, UMR 5600 CNRS, Univ. de Lyon 2,* **7.** *Environnement, Ville et Société-IRG, UMR 5600 CNRS, Univ. de Lyon 2,*

Deltas are vulnerable ecosystems, sensitive to variations in sedimentary input and sea level. Projections indicate that by 2035, 75% of the population will live within 100 km of the coast. The study of the morphological response of deltas to climate change is therefore essential.
The Rhone delta is located at the outlet of a watershed of 97 800km2 and currently covers 1740Km2. It began its construction about 7000 years ago thanks to a slowing down of the rise of the sea level and to strong sedimentary contributions. The successive functioning of several sedimentary lobes: Saint-Ferréol, Ulmet, Peccaïs, Bras de Fer, Roustan, ... allowed the delta to prograde on the sea.
The sedimentary data in the delta have been made available through the collaboration of several academic teams (IFP Energies Nouvelles, EVS-University Lyon 2, IFREMER, University of Bologna, Cerege). This study proposes an update of the stratigraphic architecture of the Rhone delta during the Holocene through the analysis of about fifteen cores located in the emerged delta and the Rhone prodelta.
The identification of depositional environments and the contribution of new dates have allowed the realization of correlation transects on the Rhone delta as well as the updating of paleo-maps of the delta. The calculation of sediment flux and the analysis of the chemical composition of the cores have allowed the identification of sediment sources and flux variations during the Holocene.
All these data are related to previous work in the Rhone basin. The aim is to identify the climatic and anthropic contributions of the watershed on the Rhone delta from the millennial to the centennial scales.
The contribution of these new data constraining the stratigraphy of the Rhone delta during the Holocene and the link with the functioning of the watershed make possible the modeling of the Rhone delta building. This stratigraphic modeling allows to test the coupling between the physical processes of the watershed and the resulting geological objects in the delta. This modeling (with Dionisos software) covers the entire Holocene until the anthropocene forcing period, and will allow the realization of several predictive scenarios for the year 2100.

Morfo-evolutive study of Gaeta Bay (central-southern Tyrrhenian sector) during the Late Holocene from geoarchaeological and geomorphological data

Dr. Andrea Gionta [1], ***Dr. Claudia Caporizzo*** [1], ***Dr. Gaia Mattei*** [2], ***Dr. Ettore Valente*** [3], ***Prof. Pietro P.C. Aucelli*** [1]

***1.** Dipartimento di Scienze e Tecnologie, Università degli studi di Napoli Parthenope,* ***2.** Dipartimento di Scienze e Tecnologie, Università degli Studi Parthenope di Napoli,* ***3.** Università degli Studi di Napoli, Federico II*

This research aims to present the first geoarchaeological data from a multidisciplinary study carried out along the coasts of the Gulf of Gaeta in order to identify possible evidence of recent tectonic activity. The study area has never been extensively studied from a late Quaternary geological/geomorphological evolution point of view and its morphology is the result of the interaction between significant structural features and the action of slope and littoral morphogenetic processes.

Since the end of the 2nd century BC, the Gulf of Gaeta experienced a large urban development associated with the construction of numerous maritime villas and quays. In this key, this research presents results related to several geoarchaeological direct and indirect surveys performed along the coastal sector between Formia and Gaeta municipalities.

The direct investigations concerned numerous ancient Roman structures characterized by the presence of structural elements (i.e., fish tanks, pilae, and breakwaters), directly related to the former sea level and considered among the most accurate sea-level markers, together with extensive geological and geomorphological surveys. Where possible, direct underwater measurements were coupled with extensive indirect morpho-acoustic and optical analysis.

The GIS-aided analysis of the collected data combined with a high-resolution digital terrain model (DTM) from Lidar and iconographic research allowed for the reconstruction of the high-resolution geomorphological map showing the precise position of archaeological structures identified and to propose its detailed interpretation of the Late Holocene evolution of this coastal sector.

In particular, our results suggest that the local sea level during the Roman period (I century BC) was no higher than - 0.55 ± 0.29 m MSL. These results largely agree with the GIA models (ice sheet chronologies ICE-5 G, ICE-6 G and the coupled ice sheet-sea level ANICE-SELEN model) specifically calculated and published for this coastal sector, highlighting the tectonic stability of this sector during the last 2.0 ka.

Characterization of alongshore variation in coastal erosion by a wave energy model

Ms. Camila Arróspide [1]***, Dr. Hugo Carrillo*** [2]***, Dr. German Aguilar*** [3]

1. *Departamento de Ciencias Geológicas, Universidad Católica del Norte,* ***2.*** *Inria Chile Research Center, Av. Apoquindo 2827, Piso 12, Las Condes, Chile.,* ***3.*** *Advanced Mining Technology Center, Facultad de Ciencias Físicas y Matemáticas, Universidad de Chile*

Determining the rates and modes of rocky coast erosion remains a fundamental challenge for coastal scientists and engineers. The analysis of rocky coastal evolution is difficult due to the imperceptible change at the human scale, the complex relationship and feedback between a wide range of formed processes, and the lack of field data and a deep understanding of some processes, such as nearshore hydrodynamics. Numerical models have long been used to better understand coastal evolution and to calculate rates and modes of erosion at different time and spatial scales, especially on hard-rock coasts. However, models usually simplify estimates of coastal erosion by ignoring nearshore hydrodynamics such as wave energy dissipation during breaking. We aim to understand how the distribution of the breaking point locations, given a certain bathymetry with local variations, affects the wave energy transfer from deep water to the shoreline and so the spatial variability of rates of coastal erosion. We developed a numerical model that allows us to calculate: (1) the location of the breaking point and the surf zone width, and (2) the surf energy of those waves reaching the shoreline. Then, we characterize the alongshore variation of coastal erosion rates. We find that the distribution of breaking point locations is heavily influenced by nearshore bathymetry and deep-water wave regime (height and period). Given certain bathymetry, the possibility of breaking near the shoreline and producing erosion is achieved only by small waves (H_0 = 1 m) with short periods (T = 6 s).

In those places where waves break near the shoreline, they have enough mechanical energy to erode the coastal rocks. In addition, the possibility that waves break closer to the shoreline is increased by local bathymetric variations that become the seabed steeper. In those places where the breaking point is almost at the shoreline, we observed maximum erosion rates. Thus, by knowing the wave regime, bathymetry, and some rock parameters such as lithology, we may expect certain ranges of coastal erosion rates according to this wave energy transformation model.

Late-Holocene relative sea-level changes and palaeoenvironment of the Pre-Viking Age ship burials in Saaremaa Island, eastern Baltic Sea

***Dr. Triine Nirgi* [1], *Dr. Ieva Grudzinska* [2], *Prof. Edyta Kalińska* [3], *Dr. Marge Konsa* [4], *Prof. Helena Alexanderson* [5], *Prof. Argo Jõeleht* [1], *Prof. Alar Rosentau* [6], *Prof. Tiit Hang* [1]**

***1.** Institute of Ecology and Earth Sciences, University of Tartu, **2.** Institute of Biology, University of Latvia, **3.** Faculty of Earth Sciences and Spatial Management, Nicolaus Copernicus University in Toruń, Poland, **4.** Institute of History and Archaeology, University of Tartu, **5.** Department of Geology, Lund University, **6.** Institute of Ecology and Earth Sciences, University of Tartu, Estonia*

Two unique Pre-Viking Age ship burials were found from Salme village, Saaremaa Island, Estonia, containing remains of seven men in the smaller and 34 men in the larger ship. According to the archaeological interpretations, these ships belonged to a viking crew who possibly came from the Stockholm-Mälaren region, eastern Sweden.

Geoarchaeological research was conducted in the area to reconstruct Late-Holocene relative sea-level (RSL) changes and to provide environmental context to these burials. A new Late-Holocene shore displacement curve shows an almost linear RSL fall from 5.5 to 0.8 m a.s.l. between 1000 BC and 1300 AD with an average rate of 2 mm/year. A slowdown in regression may be attributed to accelerated sea-level rise after the Little Ice Age and during the industrial period, being consistent with the tide-gauge measurements from the 20th century.

Salme ships were buried sometime between 650–770 AD into the sandy-gravelly coastal deposits which had accumulated in the open coastal zone about 710–450 years earlier. GIS-based palaeogeographic reconstructions indicate the existence of a narrow strait in the Salme area at this period. The wind-protected shores of the strait were probably the most suitable places in the area for landing the viking ships. A sedimentological study with palaeoreconstructions show that the ships were not buried on the beach but were located about 2–2.5 m above coeval sea level and more than 100 m from the coastline. The orientation of the ships suggests that they were probably moved from the shore of the Salme strait to the higher ground for burial. The sedimentological evidence and diatom data show the narrowing of Salme palaeostrait between 1270 and 1300 AD, resulting in the strait becoming a river.

Understanding the activity of rocky coastal cliffs: an exploration from numerical models

Ms. Camila Arróspide **[1]** ***, Dr. German Aguilar*** **[2]** ***, Dr. Joseph Martinod*** **[3]** ***, Dr. María Pía Rodríguez*** **[4]** ***, Dr. Vincent Regard*** **[5]**

1. *Departamento de Ciencias Geológicas, Universidad Católica del Norte,* ***2.*** *Advanced Mining Technology Center, Facultad de Ciencias Físicas y Matemáticas, Universidad de Chile,* ***3.*** *ISTerre, University Grenoble Alpes, University Savoie Mont Blanc,* ***4.*** *Universidad de Atacama, Departamento de Geología, Copiapó, Chile,* ***5.*** *Géosciences Environnement Toulouse (GET), Université de Toulouse, UPS, IRD, CNRS, 31400, Toulouse, France*

Cliff activity in shoreline systems is modulated by several processes, such as landmass uplift, marine erosion, previous topographical conditions, and changes in global sea level. We present here an exploratory numerical model to study the influence of these processes on the activity of coastal original cliffs. These original cliffs are formed at the beginning of the modelling; that is, the upper, older cliffs in model profiles. This model purposely considers values of uplift (rates and onset), marine erosion factor, and initial topography according to the Great Coastal Cliff in the Atacama Desert in Northern Chile. This cliff is the tallest and most uninterrupted coastal cliff on Earth. The results of the model show that a faster uplift rate (> 0.3 mm/yr) or an older onset of uplift (3 Myrs) favors the formation of inactive cliffs, whereas active cliffs form under conditions of a slow uplift rate (0.2 mm/yr) or a younger uplift onset (1 Myr). Given certain rate and onset of uplift with no considerable spatial variations, low erosion (< 1 m^2/yr), allows the preservation of sequences of staircase marine terraces, leaving behind an inactive coastal cliff. On the contrary, high erosion (>1 m^2/yr) totally erases any marine terrace in formation, keeping the cliff activity. The effect of erosion on the cliff activity is enhanced or reduced by the initial topographic slopes. Steep coasts (> 5-10°) may hamper cliffs to reach an inactive state. Thus, our model is capable enough to gives information about the relative importance of these variables on the development of active and inactive cliffs. We show that the morphology of the coastal zone does not simply reflect the rate of tectonic uplift. It depends on several parameters that interact and that must be taken into account to decipher the tectonic signal highlighted by the presence of perched inactive cliffs.

Plant wax biomarker record from the Plio-Pleistocene site Guefaït-4.2 (Eastern Morocco)

National Institute of Sciences of Archeology and Heritage RABAT

The earliest archaeological evidence from North Africa dates to ca. 2.4 Ma. Nevertheless, the palaeoenvironmental setting of hominins living in this part of the continent during the Early Pleistocene remains poorly-document, particularly in comparison to eastern and southern Africa.

The Guefaït 4.2 palaeontological site in the Aïn Beni Mathar-Guefaït (Jerada) basin of Eastern Morocco fills a crucial gap in the palaeoecology of North Africa, being correlated to the Plio-Pleistocene boundary based on biostratigraphy of large and small mammals and on preliminary magnetostratigraphic studies.

Here we present a new record of past vegetation and precipitation obtained from plant wax biomarker *n*-alkanes and their compound specific isotope analyses extracted directly from GFT paleontological site sediments. We provide a record of past hydroclimate and local vegetation dynamics, through the analysis of C_{25}-C_{31} *n*-alkane molecular indices (ACL - average chain length, CPI - carbon preference index, P_{aq} - aquatic plant ratio, and STR - submerged terrestrial ratio) and *n*-alkane δD and $\delta^{13}C$ values from the Guefaït 4.2 sedimentary sequence.

The plant wax biomarker distributions are dominated by odd-numbered, high- and mid-chain lengths, suggesting that both emergent and terrestrial plants contributed to the Guefaït 4.2 sediments, and that the mid-chain (C_{22}-C_{25}) and long-chain (C_{27}-C_{31}) biomarkers came from multiple biosynthetic sources. Additionally, changes in ACL, STR, and Paq show that the basin alternated between terrestrial and wetland habitats. The $\delta^{13}C$ data from C_{25}-C_{31} *n*-alkanes are fairly consistent throughout the stratigraphic column, ranging between -31.5 ‰ and -28.0 ‰ (-29.4 ± 1.0 ‰, n = 36) and revealing a C_3-dominant ecosystem. Hydrogen isotope measurements for the C_{29}-C_{33} *n*-alkanes range between -164.4 ‰ and -60.3 ‰ (-107.6 ± 20.3 ‰, n = 34), with isotope variability being associated with fractionation due to differences between plant ecological lifeforms and changes in local hydroclimate conditions.

The paleoecological data from GFT reveals diverse habitat types in the basin, ranging from grasslands, to woodlands, to wetlands. Meanwhile, increased water availability in the past seems to have allowed for diverse mammal communities to flourish in an area that today is dry and dominated by limited floral biodiversity.

Estimated paleotemperature through oxygen isotope analysis of Equus sp. teeth during Middle to Upper Paleolithic transition in central Italian site

Dr. Marco Romboni [1]***, Prof. Giovanni Boschian*** [1]***, Prof. Damiano Marchi*** [1]***, Prof. Sergio Tofanelli*** [1]

1. *University of Pisa*

Rapid climate changes during the Middle-to-Upper Paleolithic (MP-UP) transition are considered one the most critical factors of the Neanderthal-Anatomically Modern Humans (AMHs) transition. These phenomena impacted population dynamics, fragmentation of optimal habitats, the deterioration of environmental conditions, and weakened local communities after the severe cold and dry stages. If compared to colder and less hospitable climate in northern and central Europe, the southern European peninsulas have long been considered refugia during periods of rapid climatic change in the Pleistocene. The Italian Peninsula mainly played a key role due to its geographical position (at the center of the Mediterranean) and broad environmental diversity. An accurate determination of the environmental conditions in the MP-UP transition is needed to understand the influential role of climatic change in the extinction of the Neanderthals in this area. In this perspective, evaluations of the high-resolution archives in tooth enamel from anthropogenically accumulated faunal assemblages are a welcome complement to the paleoclimatic proxies from oceanic and ice-core records. Oxygen isotope analyses of skeletal remains ($^{18}O/^{16}O$, $\delta^{18}O$) are a powerful tool for exploring past human-environment interactions and reconstructing paleoclimate and paleoseasonality. Here, we present phosphate-oxygen isotope ($\delta^{18}O_{PO4}$) data from horse (*Equus sp.*) tooth enamel (bioapatite) from the late Musterian, Uluzzian, and early Aurignacian find levels at the archaeological site of La Fabbrica Cave, Italy. Based on the relationship between obtained $\delta^{18}O_{PO4}$ of bioapatite, body water, local precipitation, and air temperature, these data have been used to estimate paleoclimatic conditions in different cultural phases during the neanderthal/sapiens transition. Sequential oxygen isotope measurements of enamel bioapatite phosphate ($\delta^{18}O_{Phos}$) formed complete or partial sinusoidal curves with summer (high temperature) peaks and winter (low temperature) troughs for teeth being studied. $\delta^{18}O_{PO4}$ values were then used to calculate $\delta^{18}O$ of local environmental water and mean annual air temperature (MATs) during the aforementioned phases of MIS3. This approach overcomes the problem of the scarcity of climatic information on short time scales in archaeological sites due to uncertainties in the chronometric dates, by providing direct estimation of mean air temperature at the precise time of their occupation.

Quantifying Heterogeneity in Hominin Environments In and Out of Africa.

Ms. Tegan Foister [1] ***, Prof. Mikael Fortelius*** [2] ***, Dr. Indrė Žliobaitė*** [3] ***, Dr. Miikka Tallavaara*** [1]

1. *Department of Geosciences and Geography, University of Helsinki,* ***2.*** *Finnish Museum of Natural History, LUOMUS and Department of Geosciences and Geography, University of Helsinki,* ***3.*** *Department of Computer Science, University of Helsinki, Department of Geosciences and Geography, University of Helsinki & Finnish Museum of Natural History, LUOMUS*

To understand Homo sapiens expansion we need to investigate the plasticity which has enabled our species' rapid dispersal. By investigating the environments which hominins adapted to throughout time we can better understand the origins of plasticity. By conducting a systematic review of published environmental reconstruction of Hominin sites in the early Pleistocene, we have found that during this period Homo was occupying heterogeneous environments. However, this heterogeneity appears to be distributed variably. At sites within the African continent the heterogeneity is within localities; outside of Africa the heterogeneity is between localities. To understand how plastic the niche Homo occupied in this period was we need to further investigate this heterogeneity and validate these findings.

To validate our finding of between locality heterogeneity out of Africa we have utilised mean ordinated hypsodonty of large plant eating mammals to investigate the environmental variability of the regions occupied by Homo during the early Pleistocene. Hypsodonty is a measure of tooth height and is an evolutionary response to increased dental wear. The increased wear associated with hypsodonty arises from several interrelated factors such as the proportion of grass in the food ingested, the occlusal pressure required to break the plant tissues and the dust load on the vegetation. The higher the mean hypsodonty of a herbivore community, the more open, grass dominated, and seasonal the environment tends to be. Our preliminary results show that the variance of mean hypsodonty across sites occupied by Homo in the early Pleistocene increased out of Africa, with the highest variance displayed in Asia. This supports the burgeoning hypothesis that Homo in this period was not constrained to the environmental limits of its African niche, but was increasingly able to exploit a wider range of environments.

A new record of a climate change in southeastern Spain during the cycle MIS 31–MIS 30, a key time for early human dispersal in Europe

Dr. Pedro Piñero [1], ***Prof. Jordi Agustí*** [1], ***Dr. Hugues-Alexandre Blain*** [1], ***Dr. Marc Furió*** [2]

1. IPHES-CERCA, Institut Catala de Paleoecologia Humana i Evolucio Social, 2. Departament de Geologia, Universitat Autònoma de Barcelona

The Early Pleistocene Quibas-Sima sequence (southern Spain) represents the longest and most complete pre-Jaramillo to Jaramillo continental vertebrate succession in Europe. The age of Quibas-Sima was estimated to roughly 1.1–0.9 Ma for the whole sequence, immediately post-dating the oldest hominin record in Europe, as represented at the sites of Barranco León, Fuente Nueva-3 and Sima del Elefante. Quibas-Sima records a polarity change from a reverse interval (QS-1) to a normal one (QS-2, QS-3, QS-4) plus a second reverse one (QS-6 and QS-7). The normal polarity interval was identified as the Jaramillo subchron (1.07–0.99 Ma). Quibas-Sima is one of the very few palaeontological localities in Europe where the Jaramillo subchron has been certainly identified. This paleomagnetic interval characterizes the early phase of the Early-Middle Pleistocene transition, a time span that presents major changes in the Earth's climatic cyclicity. Moreover, this episode is particularly relevant concerning the earliest hominin occurrence in Western Europe. A significant change in the small vertebrate composition has been observed from the pre-Jaramillo QS-1 to the Jaramillo QS-4. Among the small mammals, this change involved the extirpation of species associated to woodland habitats and water bodies such as the flying squirrel *Hylopetes* and the water shrew *Neomys*. Among reptiles, it involved a shift towards species with a preference for dry and open areas, such as the snakes *Vipera latastei* and *Malpolon monspessulanus*. A paleoecological reconstruction using the Habitat Weightings Method based on herpetofauna suggests a progressive increase of open dry areas from QS-1 to QS-4. A bioclimatic model based on rodents points to a relative decrease in temperature and precipitations. Therefore, these methods point towards a progressive environmental change involving an increase in aridity, reduction of tree cover and spreading of shrublands in the onset of the Jaramillo subchron. This change is coincident with the transition from the warm MIS-31 interglacial (1.081–1.062 Ma) to the cold MIS-30 glacial. With this, Quibas-Sima becomes a reference locality to improve knowledge on the climatic events that occurred around 1 Ma at the Iberian Peninsula, as well as to increase our understanding of the paleoenvironmental context of early humans in Europe.

Early Pleistocene Environmental Conditions in the Levantine Corridor as Interpreted from a Multi-Proxy Study of a Sediment Core at ‘Ubeidiya: A Cornerstone for Understanding Early Hominin Migration

Dr. Silas Dean [1]***, Prof. Nicolas Waldmann*** [1]***, Mr. John Greenlee*** [2]***, Dr. Yadav Ankit*** [3]***, Dr. Omry Barzilai*** [4]***, Prof. Miriam Belmaker*** [5]

__1.__ University of Haifa, __2.__ Syracuse University, Department Of Earth Sciences, USA, __3.__ University of Goettingen, __4.__ Israel Antiquities Authority, __5.__ University of Tulsa

‘Ubeidiya, central Jordan Valley in Israel (1.4 ±0.2 Ma), is a key site for studying Early Pleistocene hominin dispersal through the Levantine Corridor and is characterized by a rich faunal and lithic assemblage including hominin skeletal remains. The site was recently subjected to a renewed excavation aiming at producing a high-resolution chronology and reconstructing the environmental conditions that prevailed in the region. In 2021 we drilled a ~16 m core through ’Ubeidiya’s lowermost (and earliest) lacustrine cycle and subjected the pristine sediments to a set of sedimentological and geochemical analyses. The record includes a wide range of lithologies including carbonates, silts, massive clayey-silts, and well-preserved mm-scale clay laminae. Analyses included high-resolution magnetic susceptibility measurements coupled with elemental geochemistry and grain-size distribution. The results suggest that during the drilled time span, the lake experienced significant fluctuations in the associated depositional environments and lake-levels, ranging from prolonged low-stand episodes with massive carbonate deposits to a deep-lake setting characterized by oxic and sub-oxic conditions in the hypolimnion and deposition of finely laminated clays. Occasionally, the lake was affected by events inducing high-energy deposits (perhaps seismites or floods). Moreover, the measurements point to possible oscillations between a closed (endorheic) system to an open (exorheic) lake. This in turn might have left a great imprint on the mixing conditions and ventilation of the lake waters. Our contribution provides a solid basis for better understanding the different environmental settings and hydrological conditions that might have allowed early hominin migration in the Levantine Corridor.

Reconstructing the paleoenvironment of Southern Levant during Early Pleistocene using oxygen and carbon isotopic compositions in vole teeth

The site 'Ubeidiya (Jordan Valley, Israel, 1.4 ± 0.2 Ma) is located on the major route of hominin dispersal from Africa to Eurasia during the early Pleistocene, and is one of the earliest sites to document these dispersal events outside of Africa. The role of arid vs. humid habitats in the dispersal of early *Homo* into the Levant has been debated. Therefore, quantitative, regional- to local-scale paleoenvironmental records in Southern Levant during Calabrian stage (1.8 – 0.77 Ma) may allow an examination of human-environment interactions during the time of their dispersal between the two continents.
To develop a modern model for the relationship between vole teeth and environmental variables in the Levant. We measured the stable carbon and oxygen isotopic ratios of modern Levant Vole (*Microtus guentheri)* teeth collected across Israel, and correlated these values to GIS derived temperature and precipitation data.
To reconstruct the past climate and vegetation compositions of Calabrian Levant we sampled teeth of the extinct vole *Lagurodon arnakae* from multiple strata across 'Ubeidiya. These were analysed for oxygen ($\delta^{18}O$) and carbon ($\delta^{13}C$) isotopic compositions.
In comparison to modern Israeli voles, the Calabrian samples exhibit more negative $\delta^{18}O$ values (Mean = -2.4 ‰ ± 1.5SD) and more positive $\delta^{13}C$ values (Mean = -6.8 ‰ ± 3.8SD) than modern ones ($\delta^{18}O$ Mean = -1.4 ‰ ± 1.1SD; $\delta^{13}C$ Mean = -15.5‰ ± 1.3SD). A negative relationship was found between local rainfall amount and the $\delta^{18}O$ values of modern samples. Therefore, the isotopic signals of the Calarbian samples suggest a likely more humid environment in the past.
The results provide further insights into the climatic conditions which the hominin experienced when dispersing out of Africa and assessment of their adaptability to novel habitats. It lends support to the hypotheses that humid environments were significant in the dispersal of early *Homo* into the Southern Levant.

Vole mesowear and microwear as a novel proxy of vegetation structure: application in the early Pleistocene site of ‘Ubeidiya, Israel

The Levant was a key corridor for hominin dispersals from Africa to Eurasia during the early Pleistocene. However, there is debate over the extent to which climatic fluctuations may have influenced these dispersals, and whether early Pleistocene *Homo* showed behavioural plasticity by adapting to different landscapes and environments, or simply took advantage of an expansion of grassland environments at this time. Whilst global and regional palaeoclimatic trends are well established, there is a paucity of local-scale palaeoenvironmental reconstructions associated with early Pleistocene *Homo* dispersals. The site of Ubeidiya, Israel contains some of the earliest evidence for hominin dispersals outside of Africa (1.4 ± 0.2 Ma) and a rich faunal assemblage including abundant *Melanopsis* spp. freshwater gastropod shells which enable local palaeoenvironmental reconstructions via multi-proxy analyses.

In this study we characterise the local environment and hydroclimate from Ubeidiya using geochemical and sclerochronological analyses of *Melanopsis* spp. shells sampled from the 1960-1999 Ubeidiya excavations. We analysed bulk and high-resolution sequential oxygen (δ^{18}O) and carbon (δ^{13}C) stable isotopes using both conventional isotope ratio mass spectrometry and sensitive high-resolution ion microprobe (SHRIMP), and clumped isotopes on bulk shells. The bulk analyses revealed that hydrological conditions fluctuated between wetter and drier conditions several times throughout both the older limnic inferior (LI) and the younger fluviatile inferior (FI) deposits, with clumped isotopes also indicating fluctuating temperatures throughout the sequence. *Melanopsis* shells grow continuously throughout the year, capturing the full range of seasonal variability. The sequential analyses revealed high amplitude δ^{18}O variability during the FI cycle at around 1.58 Ma, possibly indicating a more seasonal distribution of rainfall at this time. In agreement with other proxies emerging from this site, this evidence suggests that early Pleistocene *Homo* were not reliant on grasslands but were adaptable to new habitats and were resilient to significant palaeoenvironmental fluctuations. By providing local, high-resolution palaeoenvironmental context for the early Pleistocene Levant, this study facilitates a more nuanced understanding of early *Homo* dispersal patterns out of Africa.

Macrofaunal stable isotopes from 'Ubeidiya, Israel, shed light on environmental setting of an early presence of Homo in the Levant

Dr. Sarah Pederzani [1], ***Mr. Zuorui Liu*** [2], ***Dr. Amy Prendergast*** [3], ***Prof. Russell Drysdale*** [4], ***Prof. Miriam Belmaker*** [5]

The spread of *Homo* out of Africa into new habitats represents a key process in our evolutionary history. Climatic fluctuations are thought to have played an important role in shaping such dispersals, but the niche and climatic tolerance of Early Pleistocene *Homo* remains poorly understood.
Here present we new evidence on the climatic conditions *Homo* experienced during the expansion out of Africa during the Calabrian (1.8-0.781 Ma) using stable isotope analysis of fauna from 'Ubeidiya, Israel (1960 – 1974 and 1988 – 1999 excavations). Due to its intermediate environmental character and geographical position between Africa and higher latitude Eurasia, the eastern Mediterranean could be considered a 'stepping stone' for dispersals of *Homo* in broader Eurasia. The site of 'Ubeidiya preserves one of the most important records of the Calabrian in this region (1.4 ± 0.2 Ma), encompassing a large palaeontological collection as well as *Homo* fossils. Bulk Oxygen (δ^{18}O) and carbon (δ^{13}C) stable isotope analysis from hippopotamus (*Hippopotamus behemoth*) and deer (*Pseudodama* sp.) teeth are used to generate semi quantitative data on relative aridity and vegetation structure. The comparison of a taxon tracking baseline hydroclimatic impacts on δ^{18}O (hippopotamus) with a taxon that tracks evapotranspiration in plant water (deer) means that aridity can be reconstructed while confounding baseline changes are controlled for. Using this approach, we document varying levels of water availability, including data on strata that have yielded fossil and/or implement evidence of the presence of *Homo*. The results exhibit a tentative trend of increasing relative humidity from the older limnic inferior (LI) cycle to the younger fluviatile inferior (FI) deposits. Overall, the data indicate a relatively humid environment with mixed C3/C4 vegetation with high proportion of C3 plants, indicating an absence of dry, open environments. This lends support to an increasing amount of data indicating that *Homo* was not necessarily dependent on open grasslands to expand into new habitats and underlines the importance of generating numerical climatic data directly from archaeological sites. Questions remain, however, about the seasonal distribution of rainfall and and additional work using sequentially sampled tooth enamel is needed to explore this further.

Geomorphology and lithology of Dakhla yardangs

Dr. Driss Chahid [1], ***Prof. Aicha Oujaa*** [2], ***Prof. Larbi Boudad*** [3], ***Dr. Arnaud Lenoble*** [4]

In many localities on earth and other solid planets, yardangs as the most spectacular aeolian landscapes. In the region of Dakhla (Morocco), yardangs are hills with a « teardrop » shape and a typical orientation NNE as it the orientation expressing prevailing winds. The conjunction of deflation and abrasion in a desert zone with sparse vegetation such as our study area, may be up the formation and evolving reliefs into these regular morphologies.

This study presents the first identification of the yardangs sculpted into Quaternary and Plio-quaternary formations during the Holocene in the Moroccan Sahara. In addition, this primary work focus on their geomorphological and lithological characteristics. The statistical results made on morphometric parameters provide valuable information for further investigations. Several data (lithology, topography, climate, etc.) and the comparison with other localities in the world have allowed discussing the factors and phases of the evolution of this wind erosion landscape.

Chronostratigraphic framework of a Middle Stone Age occupation at Oued Charef (NE Morocco)

Within the framework of a long-standing multidisciplinary and collaborative investigation involving Moroccan and Spanish institutions, whose aim is to identify and contextualize evidence of Palaeolithic occupations in the Aïn Beni Mathar – Guefaït (ABM-GFT) region (NE Morocco), a Middle Stone Age site was found in 2006 in the outcropping sediment of the riverbanks of the Oued Charef (NE Morocco), a tributary of the Moulouya River. Archaeological excavations carried out in 2007 produced > 350 remains, largely dominated by lithic artefacts (97%), with a few additional burnt bones and charcoals. Interestingly, the lithic assemblage is dominated by flakes and cores, and numerous artefacts refits have been identified.

The sedimentary sequence is made of an about 5 m-thick succession of fluvial deposits associated to the Oued Charef. The archaeological horizon is located in a silty layer of the lower part of the sequence. While some previous studies suggested an Holocene age for the upper part of the sequence, the lowermost deposits have usually been assumed to be Pleistocene, although the absence of numerical age results did not allow any further chronological constraints.

In order to fill this gap, we used a combination of palaeomagnetism, Electron Spin Resonance (ESR) dating of quartz, Optically Stimulating Luminescence (OSL) dating of quartz, infrared stimulating luminescence (IRSL) dating of feldspars and U-series of bones. This multi-technique dating approach suggests that the archaeological horizon was deposited sometime during the MIS 5 interglacial complex, while this conservative interpretation of the existing data set might enable to refine this estimation to the late MIS5. These results convert Oued Charef into one of the very few, if not the only one, open-air MSA site in Morocco with robust age control.

Changes in the water level of Jili Lake in northern Xinjiang during the past 5200 years and its impact on the ancient Silk Road

Dr. Ruijin Chen [1], *Prof. Jianhui Chen* [1], *Prof. Aifeng Zhou* [1], *Dr. Haipeng Wang* [2]

1. Lanzhou University, 2. Northwest Institute of Eco-Environment and Resources, Chinese Academy of Sciences

The rise and fall of the ancient Silk Road has always been the focus of both scholarly and public attention. This route, which facilitated cultural exchange and commercial trade between eastern and western civilization, crossed through one of the most inhospitable deserts in the world. And water resources were a crucial natural element that directly influenced human activity along the ancient Silk Road. However, there is still lack of research on the water resources variations along the ancient Silk Road, especially those available to humans. This study, we recovered the lake level changes of Jili Lake in northern Xinjiang during the past 5200 years, by analyzing the relative abundances of Hydroxylated glycerol dialkyl glycerol tetraethers (%OH-GDGTs) from sediment core. Our result show a gradual expansion of Jili Lake since 5200 BP, superimposed by significant centennial-scale water level fluctuations. By synthesizing records from other regions of Xinjiang, we recovered the relative changes in water levels in oasis lakes along the ancient Silk Road. The results reveal a general increasing trend of water levels in the oasis lakes since late mid-Holocene. During the past 2000 years, the water levels of oasis lakes reached record highs. The flourishing periods of the ancient Silk Road all coincide with periods of high water levels, while the interruptions and eventual decline of the ancient Silk Road correspond to periods of low water levels in the oasis lakes. Our research reveals that the water resources of oasis lakes in the desert played an important role in facilitating communication along the ancient Silk Road. It is worth noting that an inverse relationship between oasis lake levels and regional humidity on centennial-scale. During the warm period, the regional environment turns arid, while the water level of the oasis lakes rises, and vise versa. We argue that temperature-controlled snow and ice melt water played crucial role in driving oasis lake levels on centennial-scale. This suggests that we need to be careful to consider the distinction between regional humidity and the water available to humans, when exploring the role of water resources changes in the ancient Silk Road.

Human adaptation at the monsoonal threshold: Palaeolithic archaeology and Quaternary environments in western South Asia

Dr. James Blinkhorn [1]***, Prof. Hema Achyuthan*** [2]***, Prof. Ajithprasad Pottentavida*** [3]***, Mr. Praveen Kumar*** [4]***, Mr. Avinandan Mukherjee*** [3]***, Mr. Anil Devara*** [3]

1. *Max Planck Institute for Geoanthropology,* ***2.*** *Institute for Ocean Management, Anna University, Chennai 600025,* ***3.*** *Department of Archaeology and Ancient History, The Maharaja Sayajirao University of Baroda, Vadodara, Gujarat, India,* ***4.*** *Archaeological Survey of india*

Western South Asia sits at the margin of the Indian Summer Monsoon system and is regularly hypothesised to have been placed on major routes of Pleistocene hominin expansion across Asia. This region coincides with numerous major thresholds that could influence human adaptation and expansion across western South Asia, including changes in geology, topography, climate and biogeography, and impact broader patterns of eastward dispersal. Examining Quaternary sediment archives presents an important means by which to examine how global patterns of climate change were manifest at this critical threshold, and thus the extent to which this landscape may have facilitated or prohibited human expansions, as well as presented a region that is favourable for long term inhabitation. Whilst western South Asia has a long history of Palaeolithic research, new fieldwork over the past decade has been transforming our understanding of the human occupations of this region and its significance for broader debates surrounding technological innovation, ecological adaptation, and hominin expansions and interactions. Here, we synthesise the results of recent studies of fluvial, aeolian and lacustrine archives of Quaternary environmental change with current examinations of the Palaeolithic record, focusing on Late Acheulean and Middle Palaeolithic sites.

Tales of Molar: Lingual-Labial Axis of Cercopithecidae molars as a proxy of Ecology and Diet in Late Pleistocene to Early Holocene Tropical Rainforests of Sri Lanka

Ms. Kalangi Rodrigo [1], ***Dr. Wijerathne Bohingamuwa*** [2]

1. *Department of Prehistoric and Anthropological Sciences Faculty of Humanities, University of Ferrara C.so Ercole I d'Este 32, 44 100 Ferrara, Italy,* ***2.*** *Department of History and Archaeology, University of Ruhuna, Matara -81 000, Sri Lanka*

Sri Lanka's lowland rainforest caves, which have undeniable zooarchaeological materials consumed and discarded by prehistoric humans for over 48,000 years, hold some of the oldest fossils in South Asia. Among many taxa, Cercopithecids comprised about 20-25% of this fossil record, which can contribute to major themes of the island's prehistory, including hunting strategies and environmental change. This study aims to seek molar morphological differences among temporally synchronous but ecologically distinct groups by identifying morphologically disadvantaged species. Further, it attempts to underpin interpretive studies that aid contemporary biological and ecological studies and those concerned with adaptive changes through time due to environmental fluctuations. Molars can be a great indicator of diet variation, reflecting ecological adaptations.
The purpose of this study is to understand the difference between molars from two distinct groups of *Cercopithecidae* preserved in different geological epochs using morphometric analysis and statistical methods. The morphometric data was explored using Principal Component Analysis, Permutational Multivariate Analysis of Variance and Discriminant Analyses to evaluate inter- and intraspecific shape differences. The methods and theories proposed here provide ample information for understanding ecological selection and dietary preferences in the past. The results suggest a distinct pattern in the occlusal surfaces of the two clusters in the Cercopithecidae. The cusps of *Semnopithecus* were more denied, whereas the cusps of *Macaca* were enlarged in the lingual-labial axis. Therefore, taxonomic recognition established on molars, certainly on monkeys, is functional, especially with archaeological materials. Furthermore, geometric morphometric analysis has the potential to correlate changes in molar attributes in paleoenvironmental perspectives, phylogenetic variations, and morphological growth. The study is an effort to resolve the ongoing debate over the presence of the dry species *Semnopithecus priam* in Sri Lanka's Pleistocene Rainforests.
Keywords: *Cercopithecidae*, Geometric morphometrics, Osteology, Primate archaeology, Zooarchaeology

Looking for specific biomarkers of animal species to describe the development of the livestock

Ms. Ane Gorostizu-Orkaiztegi [1], ***Ms. Paula Saez-Aduna*** [1], ***Ms. Ainhoa Elejaga-Jimeno*** [1], ***Ms. Amaia Alday-Izaguirre*** [1], ***Dr. Josep María Vergès*** [2], ***Dr. María Carmen Sampedro*** [1], ***Dr. Alicia Sánchez-Ortega*** [1], ***Dr. Asier Vallejo*** [1]

1. *Universidad del País Vasco UPV/EHU,* ***2.*** *IPHES-CERCA, Institut Catala de Paleoecologia Humana i Evolucio Social*

Along the development of the domestication, rock-shelters and mountain caves have been used as stables for animals. During Neolithic and Chalcolithic ages the dung was piled it up and burned to eliminate the accumulated parasites and clean the space. This continuous behavior forms structures called *fumiers*. These remains are preserved under favorable conditions over time, being able to identify lipidic compounds in them.

The analysis of the biomarkers accumulated in those *fumiers* allows to know what species were stabled in those sites in order to obtain more information about the evolution of grazing. Nowadays, the analyses of lipids, such as sterols, phytosterols, and bile acids, are able to identify the origin of these organic remains using proxies obtained from contemporary samples. Nevertheless, these proxies supposes that the elimination or degradation ratios of these biomarker is similar for all of them, but really, there are not any research that corroborates this hypothesis.

Therefore, it is necessary to search for new biomarkers that make possible to distinguish these species clearly (pig, wild-pig, goat, sheep, cow, horse) without proxies or using more realistic ones and obtain clear information about the development of the livestock.

Consequently, in this research work, a high resolution mass spectrometry technique, such as liquid chromatography quadrupole Time of Flight, has been used for lipidomic analysis from animal faeces to find a specific biomarker for each animal species. Samples from goat, sheep, cow, horse, wild-pig and pig from different locations and diets were analysed. The results obtained were applied to facies collected from El Mirador cave in Sierra de Atapuerca, Burgos, Spain.

Lanoline residues on lithic blades to identify the beginning of sheep shearing: an experimental approach

Dr. Asier Vallejo [1], ***Dr. Josep María Vergès*** [2], ***Ms. Ane Gorostizu-Orkaiztegi*** [1], ***Ms. Amaia Alday-Izaguirre*** [1], ***Ms. Ainhoa Elejaga-Jimeno*** [1], ***Dr. María Carmen Sampedro*** [1], ***Dr. Alicia Sánchez-Ortega*** [1]

1. *Universidad del País Vasco UPV/EHU,* ***2.*** *IPHES-CERCA, Institut Catala de Paleoecologia Humana i Evolucio Social*

Sheep shearing represents the easiest way to remove the wool from the sheep to keep them cool in the warmer months and reduce the presence of parasites. This activity could have been started with the domestication of the sheep at the Neolithic ages and being the lithic blades the most likely shearing tool. Lanoline is a natural wax produce by the sheep and is accumulated in shearing tools during the cut. The remain of this wax in lithic blades could be a good biomarker of prehistoric sheep shearing. Therefore, the aim of this work was to determine if lanoline is a good biomarker of prehistoric sheep shearing in lithic blades.

For this purpose, four sheep of two different breeds, Latxa and Churra, from two different herds (Miñano, Araba/Álava, Basque Country, and Arlanzón, Burgos, Spain) were shorn using lithic blades (eight in total) for the characterization of lanoline residues remained in the blades. This remain was characterized extracting the total amount of lipids by ultrasound energy and analyzing them using analytical techniques such as gas-chromatography mass-spectrometry. In addition, optical instruments such as optical microscopy and environmental scanning electron microscope (ESEM) were used for determining the distribution of lanoline along the lithic blades and collect the sample more precisely.

In the future, these results will be used to identify shearing activity in Neolithic sites such as El Mirador cave in Sierra de Atapuerca, Burgos, Spain.

Lipid biomarkers at the Late Pleistocene open-air loess site Ollersdorf-Heidenberg (Austria)

***Dr. Marjolein Bosch* [1], *Dr. Margarita Jambrina-Enríquez* [2], *Dr. Stéphane Pirson* [3], *Dr. Freddy Damblon* [4], *Mr. William Murphree* [5], *Dr. Carolina Mallol* [6], *Dr. Walpurga Antl-Weiser* [7], *Prof. Philip Nigst* [8]**

The period from 36,000 years ago towards the Last Glacial Maximum sees changes in environmental conditions with a general slow shift to a colder and more arid climate. The open-air loess site of Ollersdorf-Heidenberg (Austria) comprises a Gravettian archaeological horizon dated to around 29,000 years ago and two additional Upper Palaeolithic archaeological horizons. Rescue excavations in the 1990s and 2000s yielded rich lithic and faunal assemblages as well as evidence of charred plant matter. During new fieldwork at the site in 2017, 2018 and 2022 we used lipid biomarkers from sediments to assess anthropogenic activity and their environmental context throughout the sequence.

Our results show that (1) organic matter is well-preserved throughout the sequence, (2) the sequence preserves several stabilisation horizons in an open-grassland environment, which are sometimes accompanied with archaeological remains, and (3) brown lenses observed in the field comprise uncharred organic matter. No evidence of combustion activity could be detected through the lipid biomarker approach. We hypothesise that observed brown lenses are caused by an increase of organic matter input - potentially through anthropogenic activity - rather than the result of climatic improvement. These results are congruent with those from our soil-micromorphological and macroscopic geological analyses. The preservation of organic matter confirms the potential of Ollersdorf-Heidenberg for investigating human responses to environmental conditions.

Residue analysis as a tool for reconstructing funerary and agricultural practices and vessel use history at the dawn of Egyptian history

Dr. Amber Hood [1]***, Dr. Julie Dunne*** [2]***, Prof. E. Christiana Köhler*** [3]***, Dr. Friederike Junge*** [3]

1. *Department of Geology, Lund University,* ***2.*** *Organic Geochemistry Unit, School of Chemistry, University of Bristol,* ***3.*** *Institute for Egyptology, University of Vienna*

This paper will present results from organic residue analysis of an assemblage of funerary ceramics from ancient Egypt's Early Dynastic Period/early Old Kingdom (~3000–2600 BCE) from both royal and non-elite contexts. Owing to the restrictions in place on the exportation of archaeological samples from Egypt, this research has been carried out on material housed in international museum collections.

Absorbed and bulk organic residue analysis using both GC-MS (gas chromatography-mass spectrometry) and GC-C-IRMS (gas chromatography-combustion-isotope ratio mass spectrometry) has successfully extracted lipids from both sherd and intact vessel material. The results enable discussion not just of vessel use in funerary contexts but also of initial considerations of diet, subsistence, and animal husbandry during this period and through the lens of residue analysis, which has, to date, been severely under-utilised in Egyptian archaeology. Analyses will be presented alongside contemporary archaeological evidence from more recent excavations and in consideration of chronometric dating carried out on the material using a combination of radiocarbon and luminescence dating.

Dietary lipid residues and insights for land use and vegetation change

Dr. Emma Loftus [1], **Prof. Simon Hammann** [2]

1. Institute for Prehistoric Archaeology, Ludwig Maximilian University of Munich, 2. Department of Chemistry and Pharmacy, Friedrich-Alexander-Universität Erlangen-Nürnberg

A Late Holocene shift from forest to grassy vegetation on the eastern coastal plain, South Africa, has long been attributed to the agricultural activities of early farming groups. First millennium AD pioneers are suggested to have rapidly destroyed widespread coastal forests upon their arrival through slash-and-burn activities and the grazing of cattle. However, the ephemerality of early farming sites here, alongside generally poor organic preservation, means that we lack detailed information about the subsistence of these communities. This includes whether, and to what extent, cattle and other livestock were a part of early subsistence economies. Using lipid residue analysis, we investigate the molecular traces of foods preserved in the matrix of ancient cooking pots from Early Iron Age sites in KwaZulu-Natal, South Africa, from deposits that together span the first millennium AD. We assess evidence for the utilisation of dairy and other resources through time, and the implications for landuse and late Holocene vegetation change.

Lipid biomarkers and micromorphology of a Middle Paleolithic combustion structure from Axlor cave (northern Spain)

Dr. Margarita Jambrina-Enríquez [1]***, Dr. Antonio V. Herrera-Herrera*** [2]***, Dr. Carolina Mallol*** [2]***, Dr. Jesús González-Urquijo*** [3]***, Dr. Talía Lazuen*** [3]

Archaeological combustion features have been an important focus of research in the past decades. Stratigraphically, they may comprise a black layer representing charred soil matter beneath the fire, overlain by white or grey ashy layers associated with combustion activity. Microstratigraphic and biomolecular (lipid biomarkers) and isotopic analyses of these layers allows identification of combustion residues and substrate components to infer past fire-related activities and their environments. Here, we present the results of a biomarker, compound-specific and micromorphological study of a combustion feature from Stratigraphic Unit N at Axlor cave, a Middle Paleolithic site in northern Iberia. This Unit dates *circa* 100 ka. and contains abundant burned and unburned bones, charcoal, and lithic artefacts. Our molecular (n-alkane, aromatics, ketones, alcohols, and fatty acids) and isotopic ($\delta^{13}C_{16:0}$ and $\delta^{13}C_{18:0}$) analysis reveals good preservation of the organic matter and low temperature combustion. Micromorphological features point to an in situ human occupation surface with combustion residues postdepositionally stretched and deformed by mass movement. These data provide valuable clues about Neanderthal behavior and indicate high potential for organic geochemical analysis at Axlor.

Neolithic Human Diet Based on Studies of Coprolites from the Swifterbant Culture Sites, the Netherlands

Coprolites are often referred to as the missing links in our knowledge of prehistoric diet and health. They offer direct evidence for dietary diversity and the consumption of food. They also mirror the health of ancient societies. A multidisciplinary approach was applied to study the Neolithic human diet. This research resulted in an extensive dataset including faecal steroid lipid biomarkers, micro-CT scans, SEM images, animal bone remains, phytoliths, pollen, intestinal parasites and starch granules. The results of this multidisciplinary project formed an extensive source of data for prehistoric dietary diversity and health. It also provided new insights into the Early Neolithic Swifterbant tradition and food culture.

Degradation patterns by thermoalteration of lipid biomarkers: an experimental case for tracking Neanderthal behaviour.

The identification of anthropogenic signatures in archaeological contexts through preserved molecular markers requires an exhaustive previous experimental work to characterise the specific biomarkers involved in different activities from the anthropic occupation of natural spaces. The site of the Cueva Des-Cubierta Cave (Pinilla del Valle, Madrid), which has a symbolic interpretation, consists of an archaeological record characterised by an important collection of Mousterian lithic industry and abundant faunal remains - including an unusual number of horned skulls -, and is an ideal location to carry out this research.

The circulation of water and the complex sedimentary nature of the cavity makes it difficult to have a preserved archaeological record. However, the a priori recurrence inside the cavity of various activities related to the use of fire and the processing of skulls of large ungulates may have left a specific lipidic imprint in the sediment of the Late Pleistocene stratigraphic sequence.

The biomolecular characteristics resulting from this probable Neanderthal behaviour attempt to be defined in this work by analysing the patterns of abundance and distribution of the compounds found in the different lipid fractions (alkanes, aromatics, ketones and fatty acids) obtained in the exhaustive sampling of four replicative experimental hearths involving different variables and materials related to these activities (lithics, bones, speleothems and sediments).

Analytical techniques in biomolecular archaeology allow us to obtain quantifiable data on the preserved lipid compounds. The degradation and preservation of the different compounds detected in the lipid fractions involved in combustion provide us with reference data on a microscopic and molecular scale that will allow us to compare it with the profiles preserved in the archaeological samples in order to trace these Neanderthal activities inside the cavity documented on a macroscopic scale. Obtaining data relating to the stable isotopes preserved in both the experimental and archaeological samples will allow us to study in depth the environmental implications of this unusual archaeological context.

Domestication, diet and defecation: an integrated biomolecular and micro-contextual approach to archaeological faecal matter in sedentarising societies

Dr. Aroa Garcia-Suarez [1]***, Dr. Marta Portillo*** [1]

1. Spanish National Research Council

In this contribution, we present a multi-proxy study of settlement contexts from Near Eastern Neolithic sites aimed at securely identifying and analysing faecal matter from humans and animals, a material particularly prone to degradation. Out research integrates biomarkers (sterols and bile acids) with thin-section micromorphology and plant and faecal microfossil analysis to shed new light into herding practices, domestic uses of animal dung, foddering strategies, discard patterns, and human health.

Data from our earliest sites reveals the presence of herbivore faeces in combustion features, suggesting the use of dung as fuel might pre-date the development of cultural strategies of animal control. Results from later sites suggest shifts in the penning locations and grazing grounds of herds over time, likely a response to environmental changes. The identification of human faecal matter in open contexts points to the emergence of early sanitation practices at the dawn of sedentism.

Sensitive identification and quantification of food biomarkers in roman age ceramic pottery

***Ms. Ane Gorostizu-Orkaiztegi** [1], **Ms. Paula Saez-Aduna** [1], **Ms. Amaia Alday-Izaguirre** [1], **Ms. Ainhoa Elejaga-Jimeno** [1], **Dr. María Carmen Sampedro** [1], **Dr. Alicia Sánchez-Ortega** [1], **Dr. Mattin Aiestaran** [2], **Dr. Jose Antonio Múgica** [3], **Dr. Asier Vallejo** [1]*

The use of the ceramic as storage or cooking recipient was a breakthrough for the daily life of human beings since Neolithic age and its study provides information about human behavior and evolution.
A useful tool for understanding better the consumed, stored, or transported food is the analysis of organic biomarkers from pottery. The porous structure of the ceramics provides the capability of accumulating persistent organic biomarkers for years. Thus, these biomarkers, such as fatty acids, sterols, phytosterols, *n*-alkanes,,,, can help to understand better the habits of the humanity due to the possibility to distinguish, for instance, between animal or vegetal fats.
This work presents the results obtained from the study of Roman age ceramic pottery from four different archaeological sites such as, Irulegi castle (Navarra, Spain) and Aiatzio, Esnaurreta and Argabi in Sierra de Aralar (Gipuzkoa, Spain). Wine, milk, fats (vegetal and animal fats), wax, resin, boiling ceramics and opium biomarkers were studied using a gas chromatography-mass spectrometry technique, after a one-step ultrasound extraction and hydrolysis.
Through this technique, SCAN mode was used for detection and identification of all the analytes. For qualification, an own library was built with the mass spectrum of each compound of interest. The identification of the compounds was carried out by the deconvolution of the chromatogram for each sample. However, the sensitivity of SCAN mode is limited, and more sensitive working mode must be carried out to detect some biomarkers. Therefore, the use of Single Ion Monitoring working mode can help us to detect those biomarkers not detected by SCAN mode.
In this study, a comparison between these working modes has been carried out. Thus, we observed that SIM mode is able to detect and quantify the analytes in a lower concentration which are not able to detect by SCAN mode.

Recent environmental changes around the cross-border channel of ‘’Gbaga”

Prof. Ibouraïma Yabi [1], ***Mr. Bernard Gbadessi*** [1], ***Dr. Innocent Akpaka*** [1]

1. *University of Abomey Calavi*

The “Gbaga” cross-border channel, a singular space because of its ecological importance and its geostrategic importance, is not on the sidelines of global changes that affect all regions of the world. In addition to the loss of natural resources, the consequences of its degradation have diplomatic aspects between the Republics of Benin and Togo. This research analyzes the recent global environmental changes in this space.
Climatic, hydro-morphological and land cover data are used. The diagnostic (statistics) and prospective (modeling) approaches made it possible to process the climatic and hydrological data. The diachronic analysis of satellite images and observational data is used to understand morphological mutations. Changes in land cover are examined using the mapping tool. Modeling according to several scenarios made it possible to predict possible future changes in the main environmental components.
The environment is characterized by rainfall instability and thermal warming with a high occurrence of floods and coastal erosion. The plant cover is degrading at an accelerated rate and the channel is gradually filling up. The changes affect more the coastline, freshwater ponds and marshes, mangrove ecosystems and the Beninese part is more affected. Anticipatory measures will have to be taken by Benin, which risks losing nearly 50% of its part of the territory by 2050.
Keywords: transboundary channel (Gbaga), climate change, coastal erosion, degradation of vegetation cover, sustainable management

Socio-economic and environmental impacts of the spatial evolution of temperature and dissolved oxygen in the fisheries of Lake Nokoue (southern Benin).

Dr. florentin totin [1]***, Prof. Ernest AMOUSSOU*** [2]***, Prof. Henri Sourou TOTIN VODOUNON*** [2]

1. *Laboratoire Pierre PAGNEY. Climat, Eau, Écosystème et Développement (LACEEDE),,* ***2.*** *Department of Geography, University of Parakou*

Lake Nokoue, located in the South East of Benin, is shared by five municipalities belonging to three different departments. It includes hydro-ecoregions whose ecological characteristics favor significant colonization by fishery resources. The objective of this study is to contribute to a better knowledge of the socio-economic and environmental impacts of the spatial distribution of physico-chemical parameters (temperature and dissolved oxygen) in its various stations or hydro-ecoregions that constitute it.

Methodology and results: Data on physico-chemical characteristics were collected monthly from February 2017 to January 2018 in 20 fisheries integrated into Lake Nokoue. These main parameters such as dissolved oxygen (mg/l), temperature (°C), were measured by various appropriate devices. The spatialization of these physico-chemical parameters in the 20 surface and deep water sampling stations confirms the great variability of the factors depending on the weather and the hydrological area of the lake. Some variations are close to accepted tolerance thresholds for the survival of most freshwater and freshwater fish species.

The main results show that the different concentrations obtained are very close to the physico-chemical tolerance thresholds of certain species of fish or of the fishery resources living in the environment, specifically in areas with low human density. However, these same results also provide some insight into potential threats to the survival of aquatic species in areas of high human density. Lake Nokoue is experiencing serious environmental issues that threaten its existence and pose harmful risks to the populations benefiting from its goods and services. Threats related to this instability constitutes hazards that hinder the socio-economic development of the populations dependent on this lake and the retraining of the actors.

Keywords: Lake Nokoue, dynamics, spatialization- physicochemical parameters, impacts.

Drivers of the evolution and amplitude of African Humid Periods

Dr. Laurie Menviel [1], ***Dr. Aline Govin*** [2], ***Mr. Arthur Avenas*** [3], ***Prof. Katrin Meissner*** [4], ***Dr. Katharine Grant*** [5], ***Prof. Chronis Tzedakis*** [6]

__1.__ Climate Change Research Centre/ESSRC, The University of New South Wales, __2.__ LSCE-IPSL, Laboratoire des Sciences du Climat et de l'Environnement (CEA-CNRS-UVSQ), Paris-Saclay, __3.__ IFREMER, __4.__ University of New South Wales, __5.__ Research School of Earth Science, Australian National University, Canberra, Australia, __6.__ University College London

During orbital precession minima, the Sahara was humid and more vegetated. Uncertainties remain over the climatic processes controlling the initiation, demise and amplitude of these African Humid Periods (AHPs). Here we study these processes using a series of transient simulations of the penultimate deglaciation and Last Interglacial period performed with an Earth system model of intermediate complexity (LOVECLIM). These results are compared to a transient simulation of the last deglaciation and Holocene. We find that the strengthening of the Atlantic Meridional Overturning Circulation (AMOC) at the end of deglacial millennial-scale events exerts a dominant control on the abrupt initiation of AHPs, as the AMOC modulates the position of the Intertropical Convergence Zone. In addition, residual Northern Hemispheric ice-sheets can delay the peak of the AHPs. Through its impact on Northern Hemispheric ice-sheets disintegration and thus AMOC, the larger rate of insolation increase during the penultimate compared to the last deglaciation can explain the earlier and more abrupt onset of the AHP during the Last Interglacial period. Finally, we show that the mean climate state modulates precipitation variability, with higher variability under wetter background conditions.

Finding Suitable Grounds: Early crop cultivation in the lagoonal-deltaic landscapes of the Netherlands

Ms. Elena Familetto [1], ***Prof. Hans Huisman*** [2], ***Dr. Kim M. Cohen*** [1], ***Dr. Wim Hoek*** [1], ***Prof. Esther Stouthamer*** [1]

1. *Dept. of Physical Geography, Faculty of Geosciences, Utrecht University,* ***2.*** *Groningen Instituite of Archaeology*

During the Mesolithic-Neolithic transition, the adoption of crop cultivation by the inhabitants of what is now the Netherlands faced a dynamic wetland environment. Meandering fluvial channels, rising sea levels, and repeated flooding in lowland areas produced a landscape with variable suitability for farming. Under such conditions, in both lagoonal lowlands served by small rivers and the deltaic setting served by branches of the river Rhine, it appears incipient farming was restricted to specific landscape niches.

Early and Middle Neolithic Swifterbant culture sites (6000-4000 BCE), including settlements, burials, and tilled fields have been found on contemporary levee features. These riparian zone land surfaces with short-lived fluvisols were locally cleared to establish fields and have been buried and submerged by subsequent deposition, resulting in excellent preservation of the sites and off-site soils. This offers a great opportunity to study human subsistence and the transition to agriculture in the back-barrier coastal plains along the North Sea. In the “Finding Suitable Grounds” project, we sample these strata in the Rhine delta and the Netherlands’ central lagoon and investigate them geoarchaeologically and archaeobotanically to place the actual agricultural activities within the landscape surrounding known settlement sites.

Repositories of previously collected regional palaeolandscape information (which includes decades of coring, mapping, and palaeoenvironmental characterization of the Dutch subsurface), in addition to newly available geophysical data, enable us to target and sample a swath of river channels active during the Early to Middle Neolithic. Micromorphological samples from these cores are used to identify soil formation, flooding frequency, and potential anthropogenic disturbances of the natural levee sedimentation sequence, including indications of clearing, burning, and tilling. Parallel research uses the same cores for botanical proxies, ^{14}C dating, and geochemistry. By applying this detailed multi-faceted analysis to a regional-level landscape study, we aim to understand if, where, and for how long suitable soil conditions for early cultivation were present in the Dutch wetland environments during this transitional period. And if so, whether thin-section micromorphological analysis reveals evidence for human subsistence activities that would not be otherwise visible.

The micromorphology of iceberg-keel scoured diamictons from the Bellingshausen and Amundsen Seas: An approach to improving reconstructions of West Antarctic Ice Sheet extent

Dr. Lorna Linch [1], ***Dr. Claus-Dieter Hillenbrand*** [2], ***Dr. James Smith*** [2], ***Prof. Jaap van der Meer*** [3], ***Dr. Rob Larter*** [2], ***Dr. Alastair Graham*** [4], ***Dr. Benedict Reinardy*** [5]

1. University of Brighton, 2. British Antarctic Survey, 3. Queen Mary University of London, 4. University of South Florida, 5. Stockholm University

In the past the West Antarctic Ice Sheet (WAIS) extended beyond its present-day limits, sometimes as far as the continental shelf edge during e.g. the Last Glacial Maximum (LGM, ~19-23 ka). Sediment deposited at the base of grounded ice is known as subglacial diamicton (or 'till'). In addition, diamictons can be formed in a range of other glacimarine depositional environments including sub-ice shelf or seasonally open marine settings, as iceberg rafted and scoured diamictons, or glacigenic debris flows. Whilst there has been some progress in characterising subglacial and iceberg scoured diamictons at both macro- and micro-scales, historically it has been difficult to distinguish between different types of diamictons formed in very different settings. This is particularly true for areas where several glacial and glacimarine processes operate, and thus, overprint each other. However, distinguishing between the different types of diamictons is crucial if we are to reliably reconstruct the maximum extent of the WAIS in the past and the timing of its retreat. This information is urgently needed for ice sheet and climate models that are used to predict future WAIS changes and resulting global sea-level rise. The aim of this study is to macro- and microscopically examine, and determine the origin of, diamictons from the outer shelves of the Bellingshausen (core GC371) and Amundsen Seas (cores VC430, VC436), in West Antarctica. Although the three cores examined in this study were retrieved from sea floor areas affected by iceberg scouring, their diamictons may also represent any or all of the other aforementioned diamicton-forming processes. Micromorphological analyses show that diamictons in all three cores have undergone stress resulting in pervasive deformation subsequent to deposition. Cores GC371 and VC430 contain diamictons with more abundant and better developed microstructures than core VC436, indicating more intense deformation than in core VC436. Micromorphological structures in all three cores demonstrate complicated and/or inverse downcore deformation patterns, which often do not complement a traditional strain profile. This indicates potential overprinting of structures at several horizons after multiple deformation events. Future research should focus on attempting to identify and unravel separate deformation events in Antarctic diamictons.

Sand, hearths, lithics, and a bit of bioturbation: Micromorphological investigations at Umhlatuzana rockshelter, South Africa

Ms. Irini Sifogeorgaki [1]***, Mr. Hans Huisman*** [2]***, Dr. Panagiotis Karkanas*** [3]***, Ms. Viola Schmid*** [4]***, Mr. Gerrit Dusseldorp*** [1]

1. *Faculty of Archaeology, Leiden University, Einsteinweg 2, 2333, CC, the Netherlands,* ***2.*** *Groningen Institiute of Archaeology,* ***3.*** *M.H. Wiener Laboratory for Archaeological Science, American School of Classical Studies at Athens, Athens, Greece,* ***4.*** *Austrian Archaeological Institute, Austrian Academy of Sciences, Hollandstrasse 11-13, 1020 Vienna,*

Umhlatuzana rockshelter is located in KwaZulu-Natal, South Africa and demonstrates a virtually continuous archaeological record throughout the Middle Stone Age, Later Stone Age, and Iron Age (~70,000 years BP to present). We conducted multi-proxy geoarchaeological analyses (micromorphology, XRD, SEM-EDS) to reconstruct the depositional and post-depositional history of the site. The Pleistocene deposits appear macroscopically homogenous but micromorphological analysis revealed depositional, unaltered micro-layering throughout the sequence. Sediments related to combustion activities are observed throughout the sequence although the preservation conditions appear much better in the Holocene. Post-depositional geochemical alterations resulted in the formation of phosphatic minerals that affect the site's taphonomy. One of those phosphates is vashegyite, a rare magnesium-phosphate mineral associated with acidic and moist sedimentary environments. Although bioturbation features are evident, sediment mixing does not seem to affect the vertical distribution of the artefacts meaning that the lithics can be analysed as coherent assemblages.

Compositional, micromorphological and stratigraphic characterization of Holocene Tiber floodplain deposits (Rome, Italy)

Dr. Daniel Tentori [1]***, Dr. Marco Mancini*** [1]***, Prof. Salvatore Milli*** [2]***, Dr. Francesco Stigliano*** [1]***, Dr. Massimiliano Moscatelli*** [1]

1. *Istituto di Geologia Ambientale e Geoingegneria (IGAG), Consiglio Nazionale delle Ricerche, Via Salaria km 29,300, Monterotondo Stazione, 00015 Rome, Italy,* ***2.*** *Department of Earth Sciences, Sapienza University of Rome*

The sequestration of sediment deposited on alluvial floodplains may release an identifiable fingerprint on sediment composition and texture. In this regard, soil micromorphology, can be used to better discriminate the role of autocyclic and long-term factors in controlling the environmental condition of soil formation when framed into Quaternary stratigraphic record. In this study, we report a high-resolution micromorphological characterization of the Holocene Tiber River floodplain soils for a better understanding of the soil processes related to changes in water table, biological activity, weathering, and accommodation space and integrate soil micromorphology with sequence stratigraphy. Petrographic and micromorphological features from a borehole advanced 60 m into the Tiber channel belt and floodplain, document incipient pedogenetic modifications across stratigraphic markers evidenced by faunal and plant activity, accumulation of peat, and typified by precipitation of heavy metals, iron oxides and secondary carbonates. All these features developed in correspondence of surfaces of stratigraphic significance and reveal depositional features and post-depositional modifications associated with different environmental changes. These observations tell us about a specific history case of incipient soils formation in the Late Pleistocene to Holocene Tiber Depositional Sequence but may serve as a model to reconstruct the stratigraphic evolution of ancient relict soils in similar alluvial settings. This work demonstrates that a combination between sedimentological and stratigraphic observations and soil micromorphology can be critical to supplement field observations and determine the relative effect of pedogenic and depositional processes on the organization, composition and texture, and geotechnical properties of floodplain in urban areas.

Investigating duricrust diagenesis through high-resolution petrographic and geochemical methods

Dr. Shlomy Vainer [1]***, Prof. Eric Verrecchia*** [2]

1. *Department of Geography and Environment, Bar Ilan University, Ramat-Gan, Israel,* ***2.*** *Institute of Earth Surface Dynamics, University of Lausanne, 1015 Lausanne, Switzerland*

Duricrusts are surficial biogeochemical deposits that are recognized as a significant repository of information to study paleoclimate and paleoenvironments. Multiple mechanisms at different diagenetic stages are involved in duricrust formation, resulting in various types of fabrics and shapes. While diagenesis in duricrusts is commonly apparent, diagenetic processes in continental settings and their products are challenging to differentiate, leaving their variability and signature on geochemical and geochronological proxies far from being fully understood.

We use optical and cathodoluminescence petrography coupled with high-resolution elemental analyses to study the diagenetic history of duricrust deposits from the Kalahari Basin in southern Africa. We construct a relative chronological framework of duricrust formation, which is based on a visual investigation of various shapes, textures, and relationships of the cements with the host material. By disassembling the various mechanisms involved in the diagenesis of the cements through investigating their geochemical proxies, we link various diagenetic processes occurring during duricrust development with the different environmental settings that trigger these processes. This framework is tested against what is known for the paleoenvironmental conditions that prevailed across the Kalahari during the Quaternary.

Morphological analysis of mineral grains from different sedimentary environments using automated static image analysis

Ms. Fruzsina Gresina [1]***, Ms. Beáta Farkas*** [2]***, Dr. Szabolcs Ákos Fábián*** [2]***, Dr. Zoltán Szalai*** [1]***, Dr. György Varga*** [3]

1. *Geographical Institute, Research Centre for Astronomy and Earth Sciences, Budapest, Hungary; Institute of Geography and Earth Sciences, Eötvös Loránd University, Budapest, Hungary,* ***2.*** *Department of Physical and Environmental Geography,Institute of Geography and Earth Sciences, University of Pécs, Pécs, Hungary,* ***3.*** *Geographical Institute, Research Centre for Astronomy and Earth Sciences, Budapest, Hungary; Department of Meteorology, Eötvös Loránd University, Budapest, Hungary*

The transport mechanisms of different geomorphological and sedimentary environments are reflected by the grain shape properties of the sediments. The spread of new, high-resolution analytical methods has made it possible to examine grain shape properties quickly and by large number of observed individual mineral grains. We investigated mineral particles of three sediment types from different depositional environments (wind-blown sand, floodplain and channel deposits, infilling material of sand wedges, [n=20]) from the Carpathian Basin (Central Europe) by using automated image analysis (Malvern Morphologi G3-ID). Our vital aim was to determine the key variables that can help us to distinguish certain geomorphological environments. During the analysis and data processing (e.g. hierarchical cluster analysis, Wilks' λ, Kruskal-Wallis, MANOVA, PCA) we examined four variables related to grain shape which were the following HS circularity (form), convexity (surface texture), solidity (roundness) and elongation (form).

The objective and quantitative study revealed that distinguishing between geomorphological environments can be made based on HS circularity, convexity and solidity parameters of the sediment grains. According to univariate and multivariate statistics, HS circularity is the most effective attribute and the elongation variable proved to be the least influential parameter on differentiating sedimentary environments. The transport distance can be inferred from the HS circularity parameter. The transport energy can be obtained from the solidity parameter. The convexity parameter can be used as the indicator of transport distance, energy and post-depositional processes.

Some sand wedge materials underwent at least two transport processes in a high energy aqueous, wind transport mechanism and a post-depositional alteration process (frost weathering), while others originated from sand-sheet covered areas (active during Pleistocene glacials).

Solidity parameter proved to be an effective variable on separating sediments that had similarly high convexity values (smooth surface) which were in our case from aeolian and fluvial environments. Our research support that aeolian transport is more effective in rounding the grains than aqueous environment.

Support of the National Research, Development and Innovation Office (Hungary) under contract NKFIH FK138692, ÚNKP-22-3 and RRF-2.3.1-21-2022-00014 are gratefully acknowledged.

Micromorphological insights within the Middle Pleistocene-Holocene cave sediment record of Grotta Romanelli, Italy

Dr. Guido Stefano Mariani [1]***, Prof. Pierluigi Pieruccini*** [1]***, Dr. Luca Forti*** [2]***, Dr. Ilaria Mazzini*** [3]***, Dr. Beniamino Mecozzi*** [4]***, Prof. Raffaele Sardella*** [4]

Approaching the sedimentary and anthropogenic input within fine-grained or very fine-grained sediments in caves can be improved by micromorphological investigations. In fact, weakly developed sedimentary structures or apparently massive structures often characterize human settled cave environments and the microscale information is of paramount importance for the determination of the sedimentary and geomorphological context.
Grotta Romanelli offers a unique chance to correlate the Middle Pleistocene (ca. 350 ka BP) to the Early Holocene (ca 11 ka BP) human frequentation with the sedimentary processes and the origin of the sediments that filled progressively the cave. The micromorphological investigations were carried out on the fire-related Middle Pleistocene levels on top of coarse-grained marine in-cave deposits and on the silty-clayey and sandy clayey Late Pleistocene-Holocene layers.
Micromorphology revealed several microfacies associated with the finer-grained sediments. The in-cave sediments are of external origin, as indicated by the abundance of aeolian quartz and pedorelicts of leached soils that were eroded and transported within the cave. The microfacies analysis indicates run-off and standing water processes and redistribution within the cave of the external sedimentary input, including phases of biological activity and related relative surface stability and anthropogenic inputs. The anthropogenic input is not linked to specific areas and locations within the cave, mostly due to the dimensions of the cave itself and the volume of already excavated sediments in historical archaeological digs in the mid-frontal sector of the cave. Therefore, anthropogenic materials are sparse within the different microfacies and consists of evidence of use of fire and food activities (burnt bones, charcoals, charred plant tissues etc.).

Soil Micromorphology of Agricultural Terraces in Europe

Dr. Daniel Fallu [1]***, Prof. Antony Brown*** [2]

1. *The Arctic University Museum of Norway, UiT, The Arctic University of Norway,* ***2.*** *Arctic University of Tromso*

Agricultural terraces are an important factor in the development of agriculture, allowing for expansion, intensification, diversification and even specialization. To date, the archaeological study of these fossil agricultural landscapes has been slow, hampered largely by difficulties in disentangling the complex chronologies generated by the construction, use, management, and abandonment of agricultural terraces. Despite this, the understanding of soil development on terraces remains an integral part of reconstructing past subsistence and understanding the impact of the terraces themselves on the soils, the crops, and ultimately the socioeconomic systems they helped to support.

This poster presents the preliminary results of soil micromorphological analysis of agricultural terraces from 10 sites across continental Europe, ranging from sub arctic conditions to dry Mediterranean conditions. Samples were taken from terraced soils representing agricultural activity ranging from roughly 1600 BCE to 1900 CE, and encompassing such common crops as potato, grains (wheat and barley), and vines (winemaking). Photomicrographs of fabric and features generated through the agricultural reworking of the soil are presented here, alongside evidence from elemental and molecular analysis via pXRF and FTIR. The depositional and pedological features presented are also assessed via pOSL, to understand the relative chronologies of the accumulation and in situ development of terrace soil features. This research is hoped to provide a new geographically extensive record of soil microfeatures related to agriculture and agricultural terraces in particular.

Floodplain dynamics, natural resources and human settlement change from the Archaic to the Postclassic in the Basin of Mexico.

Dr. Kurt Heinrich Wogau Chong [1]***, Dr. Guillermo Acosta Ochoa*** [1]***, Dr. Carlos Cordova*** [2]***, Dr. Luis Morett*** [3]***, Dr. Tamara Cruz y Cruz*** [4]***, Dr. Philipp Hoelzmann*** [5]

1. National University of Mexico, Institute of Anthropology Investigations, 2. Oklahoma State University, 3. Universidad Autónoma Chapingo, 4. Escuela Nacional de Antropologia e Historia, 5. Freie Universität Berlin

The endorheic Basin of Mexico (BM) is characterized by a heterogenous landscape that comprises volcanic and tectonic structures, and a diversity of depositional systems that include glacial, alluvial, fluvial, eolian and lacustrine sediments. The alluvial plains around Lake Texcoco are complex features formed by medium to low order fluvial drainages. Additionally, the structure of these plains is complicated by the influence of springs and wetlands, many of which are associated with archaeological sites of various periods. The proposed work aims at studying landscape evolution of floodplain areas in tandem with human occupations spanning the pre-ceramic, agricultural, and the Aztec periods on the eastern side of Lake Texcoco. In addition, we will study how humans transformed the environment to implement diverse subsistence strategies. A paleolandscape reconstruction will be performed using the floodplain sediments of San Bernardino and Chapingo fluvial systems as natural archives and the archeological record from the pre-ceramic burial site of the Texcoco Man. A GIS model was constructed to analyze the landscape attributes that influenced the fluvial dynamics. Based on this model and field surveys, we selected six different locations between the San Bernardino and Chapingo fluvial systems, to perform a series of test pits. The preliminary results reveal that the lower section of the sedimentary sequences comprises a series of muddy facies with a high content of calcium carbonate according to the p-ED-XRF and XRD results, with a minimum age of 3373-3221^{14}C cal yr BP. The upper facies are formed by intercalation of silty and sandy facies partly interrupted by the formation of soil horizons and with a maximum age around 2258-2156 ^{14}C cal yr BP. Thus, our preliminary results suggest a regression phase Lake Texcoco during the beginning Meghalayan stage of the Holocene, accompanied by a sequential progradation in the fluvial system towards the lake. We hypothesized that sequential lake regressions and transgressions in conjunction with fluvial activity and spring activity produced a rich environment full of natural resources. In consequence, this landscape was attractive to the establishment of diverse human groups and settlements.

Human-environment interactions in the Gete catchment (Belgium). An interdisciplinary approach.

Ms. Marleen van Zon [1], ***Ms. Renske Hoevers*** [2], ***Dr. Ward Swinnen*** [2], ***Prof. Bart Vanmontfort*** [3], ***Prof. Gert Verstraeten*** [2]

1. KU Leuven, Department of Archaeology, Centre for Archaeological Research of Landscapes & KU Leuven, Department of Earth and Environmental Sciences, Division of Geography and Tourism, 2. KU Leuven, Department of Earth and Environmental Sciences, Division of Geography and Tourism, 3. KU Leuven, Department of Archaeology, Centre for Archaeological Research of Landscapes

Floodplains are highly dynamic environments that have attracted humans throughout history. They have been shaped by the interplay of geomorphological, ecological and hydrological processes, as well as directly and indirectly by human activity. It is in these parts of the landscape that we find ideal research areas to study and reconstruct human-environment interactions from a long-term perspective. For this paper we will focus on one such area: the Gete catchment.

Geomorphological and palynological research shows that floodplain geo-ecology underwent a gradual transformation from a marshy wetland environment to a stereotypical alluvial floodplain. A change that was initiated already around 5000 to 4000 BP, roughly 2000 years earlier than other studied floodplains in the Belgian loess belt. This difference in timing can be explained through the long agricultural history of this specific catchment, which starts with the arrival of the first farmers in the Early Neolithic and runs like a thread through its evolution. Archaeological and historical sources are studied and integrated at a catchment scale to increase insight in key aspects of this history: changes in population size and density along with changes in subsistence- and land-use strategies.

This approach provides us with a high-resolution reconstruction of the effects of increasing and decreasing human impact on floodplain geo-ecology. Not only in relation to the start of the aforementioned transformation, but also the speed at which it took place, when it was completed and signs of within-catchment variability. As such the data is not only illustrative of the effect humans had on their environment, but also of environmental resilience: changes in floodplain geo-ecology only occurred when changes in human impact were large enough and reached a certain threshold. This can have important implications for future floodplain management. By taking into account the past, it will not only enable us to understand how the present-day landscape came about, but it can also learn us lessons to adapt and employ towards a more sustainable future.

Palaeoecological Evidence for the Domestication of the Wetlands of the Bolivian Amazon.

Ms. Loretta-Ann Jilks [1]***, Dr. Neil Duncan*** [2]***, Dr. John Walker*** [2]***, Dr. Emma Hocking*** [1]***, Dr. Emma Pearson*** [3]***, Dr. Maarten van Hardenbroek*** [4]***, Prof. Bronwen Whitney*** [1]***, Dr. Michael Jeffries*** [1]

1. *Geography and Environmental Sciences, Northumbria University, Newcastle, UK,* ***2.*** *University of Central Florida,* ***3.*** *Newcastle University,* ***4.*** *Geography, Politics & Sociology, Newcastle University*

Recent palaeoenvironmental reconstructions of Amazonia have shifted our understanding of past human manipulation, or 'domestication', of the landscape. Evidence includes extensive earthworks, ancient field systems and alteration of forests for economically useful taxa. Most studies have focused on terrestrial landscapes, with few investigating the impact on aquatic ecosystems.

The Llanos de Mojos is a 135,000 km^2 sub-basin of the Bolivian Amazon characterised by a strong annual flood cycle and a forest/savannah/wetland mosaic. Pre-Columbian earthworks have been identified throughout the Mojos which are hypothesised to have controlled the annual flood cycle. Examples include raised fields, forest islands, fish weirs, and causeways. Construction of earthworks are integral to socio-environmental interactions of Pre-Columbian societies, which then impacted components of ecosystems within the Mojos.

The Quinato Wetland (13°38'45.7"S, 65°35'03.8"W) is a permanent wetland situated within a ca. 320km long palaeoriver channel surrounded by raised fields, forest islands and fish weirs. Previous palaeoecological investigations of two sediment cores (QM, ME) extracted from areas adjacent to forest islands demonstrated landscape domestication began at least 3500 yrs ago with evidence for local hydrological management and fire use, implying terrestrial and aquatic resources were managed concurrently. Evidence for establishment of permanent wetlands at both sites suggests fish weirs were the mechanism which managed the floodwaters.

This study aims to characterise domestication of the wetland and associated ecological impacts through new palaeoecological analysis of existing (QM, ME) and new (LA, MI) sediment records using a multiproxy approach (charcoal, diatoms, pollen, invertebrate remains and organic geochemistry). Basal ages of the cores range from 7460–1230 yrs BP. Through diatom and aquatic pollen analysis on MI (located adjacent to a fish weir) we test whether its construction was the mechanism which controlled local wetland floodwaters. Wetland domestication is hypothesised to have enabled better management of aquatic food resources (e.g. fish). Through aquatic ecology indicators (invertebrate remains, aquatic pollen, diatoms) and organic geochemistry analyses, newly applied to this region, we will investigate the impact of wetland manipulation on ecology and biodiversity. The results will highlight the legacy impact of past domestication on wetlands today; increasing our understanding of water-human-environment interactions in tropical regions.

Geoarchaeological study at the “Kakoryca-4” archaeological site (Southern Belarus)

Mr. Dmitry Tsvirko [1], *Dr. Tatyana Yakubovskaya* [2], *Prof. Piotr Kittel* [3], *Dr. Mikola Kryvaltsevich* [4]

1. University of Lodz, Doctoral School of Exact and Natural Sciences, 2. Independent Researcher, 3. University of Lodz, Faculty of Geographical Sciences, Department of Geology and Geomorphology, 4. The National Academy of Sciences of Belarus, Institute of History

The archaeological site “Kakoryca-4” is located on the territory of Belarusian Polesie, in the basin of the Yaselda River and Lake Sporovskoye, beyond the border of the last glaciation. Vast area around the studied site is occupied by meadows and wetlands. Most of the archaeological finds from the “Kakoryca-4” is dated to the Neolithic and Bronze Age (V–II millennium BC), and attributed to the following cultures: Pripyat-Neman and Neman Neolithic cultures (V-III millennium BC); the Corded Ware culture circle and Epi-Corded Ware culture horizon (middle of the IIIrd - beginning of IInd millennium BC); Trzciniec cultural circle (II millennium BC).
The presented in this paper sediment cores were collected in the surrounding of the archaeological site. They were studied using spore-pollen, carpological, radiocarbon, sedimentological, geochemical analyses, as well as archaeological research methods. The collected sediment cores were of Late Glacial and Holocene age. The Late Glacial deposits were predominantly mineral and consisted of sands, as well as calcareous and non-calcareous gyttja. In turn, the Holocene deposits were predominantly organic and consisted of gyttja and peat.
The obtained results allow for the palaeoecological reconstructions for the studied area, mostly: regional and local vegetation reconstruction, fluctuations in the size of Lake Sporovskoye, the stage of increased fluvial activity of the Yaselda River, sedimentation changes in the Late Glacial and Holocene. The study of the archaeological data revealed the history of functioning of human communities and their survival strategies. The correlation of palaeoecological and archaeological data allow for deeper study on human-environment relationships since the Stone Age in the Belarusian Polesie.

Multiple approach in palynological analyses to characterize human / environment dialectic in lakeshore environments: new data from the emerged sector of the early Neolithic site of La Draga (Banyoles, Spain).

Ms. Liz Charton [1], *Dr. Jordi Revelles* [2], *Dr. Isabel Expósito* [3]

1. *Muséum National d'Histoire Naturelle,* ***2.*** *IPHES Catalan Institute for Human Palaeoecology and Social Evolution. Tarragona, Spain.*

The spread of farming lifestyle is considered a key point in the debate on early human impact on environment and climate in the past, and the beginning of the Anthropocene. The Early Neolithic lakeshore settlement of La Draga, dated between 7270 and 6750 cal. years before present (BP), represents the oldest known archaeological evidence of farming societies settling in a lacustrine environment in the Iberian Peninsula. Previous pollen analyses in both the lacustrine record of Lake Banyoles and the archaeological waterlogged sequence evidenced for the first-time human modification of the landscape through broadleaf deciduous trees deforestation at a local and regional scale in north-eastern Spain. New palynological data from the emerged sector (Sector A) of the settlement brings new interesting results to the debate. Our increasing knowledge of the vegetal landscape of the Neolithic community points toward a stronger impact of human activities locally, resulting in a clear dominance of non-arboreal vegetation, in particular ruderal herbaceous taxa and crops around the settlement: in the emerged sector, the maximal human imprint on the landscape was recorded corresponding to the second phase of occupation (between 7100 and 6700 cal. years BP). Spatial analyses applied to palynological data in Sector A has proved useful in determining patterns of social use of space linked to plant management activities, and patterns of taphonomical alteration of the record. Most of the horizontal variability of the record is explained by human activities such as crop storage and processing, and taphonomical processes linked to subaerial clay sedimentation that altered the preservation of pollen and the development of fungal organisms. Still, results support the critical importance of non-pollen palynomorphs identification and interpretation to understand taphonomical and anthropic processes that impacted the pollen assemblage. This multiple approach, integrating the traditional palynological methodology as well as intra-site spatial analyses, multivariant statistics, and non-pollen palynomorphs, allows to draw a complete interpretation of the palynological assemblage in an archaeological site at a paleoenvironmental, taphonomical and cultural level. Integrated palynological analyses in wet environments thus represent a valuable approach to understand the dialectical relationship between past human societies and natural environment.

Late-Holocene climate change and the cultural landscape of Weipa, Australia

Ms. Victoria Miller [1], ***Dr. Janelle Stevenson*** [1], ***Dr. Ulrike Proske*** [1]

1. ARC Centre of Excellence for Australian Biodiversity and Heritage; School of Culture, History and Language, The Australian National University

Weipa, on the western Cape York Peninsula of Queensland, Australia, has long been a hot spot of archaeological research due to its rich cultural history that stretches back over many thousands of years. Sites of archaeological interest include shell mounds, earth mounds, scarred trees and stone artefacts. Recent studies on the shell and earth mounds at Wathayn, south of Weipa, have shown that shell mound activity was concentrated between 2500-2000 cal. years BP, while earth mound building commenced after 2200 cal. BP but was most prevalent over the last 500 years. Palaeoecological data can potentially provide the environmental context surrounding these changes currently missing from archaeological theories and narratives.

This study reconstructs the environmental history of Bellevue Creek Swamp and the surrounding landscape south-east of Weipa, over the last 6400 years based on the analysis of pollen and charcoal extracted from sediment cores. This late-Holocene record shows that swamp initiation began after 5000 cal. BP and that permanent running water existed from approximately 2200 cal. BP until after 150 cal. BP when anthropogenically forced changes on the landscape transformed the swamp surface to a sedgeland. The surrounding eucalypt woodland remained essentially stable for the period from 6400-150 cal. BP. While a regional fire signal is present throughout the record, only one pronounced period of localised burning is recorded, occurring over the last 150 years. The hydrological change to a wetter environment and permanently running water that occurred after 2200 cal. BP overlaps with the end of intensive shell mound building and the beginning of earth mound building at nearby Wathayn.

It is suggested that suboptimal conditions for shell beds arose with the increase of freshwater into the system after 2200 cal. BP. Parallel to this, a wetter environment likely expanded available resources located further inland at Weipa, and around the creek lines themselves leading to the building of earth mounds. This study highlights the importance of palaeoecological studies to build an environmental context for archaeological interpretations.

The impact of Early to Middle Bronze Age settlements and farming on vegetation, ecology, nutrient flux and sedimentation at Lake Lucone, northern Italy

Dr. Giulia Furlanetto [1], ***Dr. Federica Badino*** [2], ***Dr. Renata Perego*** [3], ***Dr. Davide Abu El Khair*** [4], ***Dr. Marco Baioni*** [5], ***Prof. Roberto Comolli*** [4], ***Dr. Francesco Saliu*** [4], ***Dr. Cesare Ravazzi*** [3]

We produced an integrated history of terrestrial and lake ecosystems from a high-resolution stratigraphy from Lake Lucone, a small, closed lake, in the Prealps of northern Italy, which is characterized by predominantly endogenic, biologically controlled sedimentation covering the last 5500 years.
Our analytic approach combines ordination techniques with time series analysis to detect correlated changes among microbotanical variables (upland and aquatic pollen, algae, cyanobacteria, dung spores, microcharcoal particles), sedimentary proxies (LOI steps, calcimetry, FTIR spectrometry) and main nutrients, which are stable under waterlogged conditions (P_{inorg}, P_{org}, K).
The impact of the Bronze Age pile dwelling is recorded by massive effects on terrestrial ecosystems, lake sedimentation, and nutrient influx. Forest conditions and lake sedimentation returned to semi-natural baseline at the end of the 700-year long phase of Early to Middle Bronze Age settlement, but lake-side forests did not fully recover, and further changes on landscape composition occurred from the Iron Age onwards. Time series correlation of micro-botanical proxies and P forms have enabled to detect different patterns of human impact, and the contrast of internal and external P sourcing. During the dwelling phase intensive P mineralization, produced by fireplaces triggered P_{inorg} sinking. P_{inorg} was promptly immobilized by calcite absorption, thus preventing blooms of green algae and cyanobacteria. Analyzing waste disposals, we could also distinguish domestic hearth production from a contribution by animal husbandry, the latter marked by P_{org} increase. External sourcing was prompted by farming and cropping in the lake catchment. The observed changes, in littoral sedimentation and biological proxies in the 5500-years long sequence, are primarily affected by human impact. Lake Lucone represents a key site, since it documents interactions between bronze Age settlements and related ecological impacts on both terrestrial environment and lacustrine sedimentation, as recorded in a continuous sequence, as well as the end of Bronze Age pile dwelling culture.

Mountainous vegetation succession in the Peloponnese (Greece) during the last two millennia

Dr. Katerina Kouli [1], Ms. Grammatiki Vasiliadi [1], Dr. Georgios C. Liakopoulos [2], Dr. Alexandros Emmanouilidis [3], Mr. Ioannis Prevedouros [3], Prof. Pavlos Avramidis [3], Dr. Cristiano Vignola [4], Dr. Alessia Masi [5], Dr. Adam Izdebski [2]

1. Department of Geology and Geoenvironment, National and Kapodistrian University of Athens, 2. Max Planck Institute for Geoanthropology, 3. Dept of Geology, University of Patras, 4. Dipartimento di Biologia Ambientale, Sapienza Università di Roma, Roma (Italy), 5. University La Sapienza

The significant regional topographic and climatic variability, along with human activity are the main shaping factors of the vegetation development in the Mediterranean. In particular, the mountain ecosystems and their valuable natural resources have long been attractive to human societies. The Peloponnese (southern Greece) has been the scenery for development of numerous human communities. So far, the existing paleovegetation records from the Peloponnese derive from lowland sites, while the vegetation succession of the mountains is not clearly understood.

Located on Panachaiko Mountain, the Rakita wetland preserves an exceptional archive of the vegetation succession. A detailed palynological analysis of the deposits was conducted at a mean 20-year temporal resolution and the age-depth model is based on 9 AMS radiocarbon dates. Whereas the Rakita area has been inhabited since the Mycenaean times, robust demographic data are available only after the mid-15th century CE. Ottoman and Venetian population surveys show that a number of small and medium-sized settlements existed in the area.

The well-preserved pollen assemblages accompanied by NPPs highlight significant shifts in the vegetation during the last 2000 years. Our record provides the first insights to the plant landscape evolution from the upland Peloponnese. The base of the sequence is characterized by open vegetation, while the deciduous *Quercus* woodland and the coniferous forest components, such as *Abies* or *Pinus* appear restricted. The concurrent high abundance of Cerealia-type and the presence of weed species, feature an interval of significant anthropogenic activity in the area, corresponding to the Late Antiquity. Following, the increase of deciduous *Quercus* and the drop in all human pollen indicators mark the expansion of the deciduous oak forest and the retreat of human pressure on the mountainous environment during the Early/Middle Byzantine. At the beginning of the Late Byzantine Period a sharp opening of the deciduous forest is evidenced, while the expansion of Cichorieae and other ruderal taxa underlines pastoralism as the main human activity. During the Ottoman period, the moderate expansion of the deciduous forest and the amplification of evergreen maquis showcased the introduction of sustainable land use practices during an interval of increased population in the area.

Vegetation and land-use history of the 'Kromme Rijn' area near Utrecht (Netherlands) during Roman and medieval times

Dr. Emmy Lammertsma [1]***, Mrs. Hendrike Geessink*** [2]***, Dr. Wim Hoek*** [3]

1. BIAX Consult Biological Archaeology & Environmental Reconstruction, ***2.*** *Stichting Het Utrechts Landschap,* ***3.*** *Dept. of Physical Geography, Faculty of Earth Sciences, Utrecht University*

The river 'Kromme Rijn', part of the Rhine in the centre of the Netherlands, has witnessed important historical events over the past millennia. In Roman times, the river served as border of the *Lower Germanic Limes*, the northern border of the Roman Empire. After the Dark Ages, the settlements Utrecht and Dorestad thrived along this part of the Rhine. To prevent the risk of flooding and to gain new lands, Bishop Godebald of Utrecht ordered the damming of the Kromme Rijn in 1122 AD, after which the river reduced in size but remained an important transportation route. How did these historical events affect landscape and land-use in the Kromme Rijn area? To reconstruct past vegetation and land-use of the Kromme Rijn area near Utrecht the infill of a residual channel has been studied. This residual channel was a meander, cut-off from the active river system in the Roman period. The c. 3m thick undisturbed channel fill encompasses Roman to late medieval times and includes the moment of embankment. High-resolution Loss on Ignition and palynological analyses have been performed to reconstruct depositional processes and changes in local and regional vegetation. In addition, other palynomorphs have been studied as indicators of water quality and human activities. The records reveal increasing openness of the landscape, interrupted by a phase of apparent reforestation. Opening of the forest cover is an indication for periods of human activity. The presence of cultural indicators such as pollen of cereals, and later buckwheat and cornflower, indicate agricultural activity in the near surroundings.

The Bisenzio Project: transdisciplinary investigation strategies to reconstruct human and palaeoenvironmental history of the Bolsena Lake (Central Italy)

Dr. Andrea Babbi [1], ***Dr. Alessandra Celant*** [2], ***Dr. Paolo Maria Guarino*** [3], ***Dr. Mauro Lucarini*** [3], ***Dr. Fabrizio Michelangeli*** [2], ***Dr. Giorgio Vizzini*** [4], ***Dr. Matteo Maggi*** [4], ***Dr. Sergio Bravi*** [5]

1. Institute of Heritage Science of the National Research Council of Italy ISPC-CNR, Montelibretti Rome, 2. Dipartimento di Biologia Ambientale, Sapienza Università di Roma, Roma (Italy), 3. Dipartimento per il Servizio Geologico d'Italia - ISPRA, 4. Centro Nazionale per la rete nazionale dei laboratori - ISPRA, 5. Di.S.T.A.R., Università di Napoli Federico II.

The Bisenzio Project focuses on reconstructing human-environment relationships at the Bisenzio archaeological site. The ongoing research combines scientific methodologies, archaeological procedures, and field techniques, aiming at integrating past socio-economic dynamics into a broader perspective of long-term environmental changes.

Three continuous sediment cores were collected up to 20 meters deep in the alluvial plain bordering the archaeological area. Lithostratigraphic analyses were carried out to characterize depositional facies and outline the evolution of the depositional system in relation to lake level oscillations. The sediment fractions were further examined for the recognition of microfauna and archaeological artifacts. Preliminary results suggest the presence of high-energy streams with archaeological evidence found up to a maximum depth of about 6 meters. At the same time, high-resolution bathymetric surveys were carried out on the submerged sector of the archaeological sites, providing a detailed isobath contours that revealed a complex morphology of the lakebed. Two sediment cores about 5 m in depth were extracted from the lakebed offshore at 27 m water depth. Sedimentological analysis of lacustrine sediment revealed recurrent organic layers characterized by vegetal remains, consistent with the occurrence of remarkable lake level variations. Exploratory palynological analysis suggested a depositional hiatus in the uppermost portion of the cores. A suite of radiocarbon dates have been designed to define the chronological frame of the sedimentary sequences and to identify changes in timing and rate of sediment accumulation, both in the alluvial plain and the submerged lacustrine depositional environments.

Archaeological surveys and limited soundings have been carried out both in the fields around Mount Bisenzio and in the nowadays underwater region. The former provided evidence for a backdating of the earliest human presence in the area, the pace of the settlement evolution, as well as the extension of the residential area. The latter yielded contexts and stratigraphic sequences hinting at the lake level during the end of the archaic phase. Palynological and palaeobotanical investigations of in-situ archaeological samples and plant macroremains from domestic contexts allow to reconstruct the surrounding vegetational landscape, outlining some aspects of human activities related to the exploitation of natural resources at the site.

The Lower Havel River and Greater Donaumoos Regions: 'Failed' or 'successful' reclamation of floodplains and peatlands? – A comparative analysis

The historical reconstruction of reclamation, colonisation and hydro-engineering in floodplains and peatlands is a key objective for improving our knowledge about human forcing on natural fluvial landscapes and environments (Werther et al. 2021).

The major aim of the new interdisciplinary project is a comparative assessment of these human interventions and corresponding ecological transitions towards two Fluvial Anthropospheres located in Central Europe. These are the Lower Havel River Region and the Greater Donaumoos Region. For the first time, we will reconstruct socio-ecological processes with a multi-methods approach from historical archaeology, geoscience and plant ecology. In addition, we will create through further data categorisations, transferable models and joint interpretations at intra- and interregional scales. We want to i) reconstruct human interventions on floodplains and peatlands during the medieval and pre-industrial modern periods, ii) reconstruct potential 'great transitions' and iii) validate the vulnerability of human intervention towards multidecadal climatic variability.

The presentation shows a first compilation of hydrological changes based on historical map records within both study regions and indicates fundamental changes of both natural river landscapes towards the development of Fluvial Anthropospheres.

Werther, L.; Mehler, N.; Schenk, G. J.; Zielhofer, C. (2021): On the Way to the Fluvial Anthroposphere - Current Limitations and Perspectives of Multidisciplinary Research. Water 13 (16), 2188, doi:10.3390/w13162188.

Interpreting the Holocene Deposits of the Niger River between Kotonkarfe and Idah in Northcentral Nigeria.

Dr. Tope Alege [1]***, Prof. Cornelius Nwajide*** [2]

1. *Department of Geology, Federal University Lokoja. Nigeria,* ***2.*** *Geoscan Nigeria Limited*

Present-day deposits (sand bars and overbank muds) of the Niger River (Nigeria), to the north and south of Lokoja (confluence of the River Niger and River Benue), between Kotonkarfe in the north and Idah in the south were sampled and studied for their petrographic and palynological attributes to deduce the provenance and tectonic setting of the source area. Quartz, commonly rounded, is expectedly the dominant framework accounting for more than 70% of the mineral constituents with no felsic minerals in all sample points. The virtually complete absence of feldspar is attributable to the climatically-induced (warm and humid) intense chemical weathering in the crystalline basement parent rocks, mechanical breakdown as well as multiple sediment reworking during the long transport from the derivation localities. The heavy mineral suite contains some opaques, but the non-opaques are mainly the ultrastable trio – zircon, tourmaline and rutile (ZTR) species – exhibiting rounding and overgrowths. Palynological analysis of the overbank muds yielded fern spores, *Laevigatosporites* sp., *Retitricolporites irregularis* and *Zonocostites ramonae,* as well as fungal spores *Proxapertites cursu*s and the freshwater algae *Botryococcus braunii,* all of which indicate a transitional paleoclimatic phase of humid (alternating wet and dry) tropical climate. Thus, the mineral components of the fluvial channel sand bars, and the palynological faunal aspects extracted from the floodplain deposits, exhibit properties traceable to the long-distance transport along the Niger River drainage line heading from the Fouta Djallon in the Guinea Highlands under the prevalence of humid tropical climatic setting in the Holocene Epoch of the Quaternary.

What do megadunes look like and how were they formed? A story from the glacial lake-outburst floods in NE Poland at the end of the Weichselian glaciation

***Prof. Piotr Weckwerth* [1], *Prof. Wojciech Wysota* [1], *Prof. Jan Piotrowski* [2], *Prof. Arkadiusz Krawiec* [1], *Mr. Marek Chabowski* [1], *Prof. Edyta Kalińska* [1], *Mr. Aleksander Adamczyk* [3]**

***1.** Faculty of Earth Sciences and Spatial Management, Nicolaus Copernicus University in Toruń, Lwowska 1, 87-100 Toruń, Poland, **2.** Department of Geoscience, Aarhus University, **3.** State Water Holding, PolishWaters RegionalWater Management Authority in Bydgoszcz, Al. A. Mickiewicza 15, 85-071 Bydgoszcz, Poland*

Glacial lake-outburst floods are one of the geological processes that have contributed significantly to the evolution of the glacial landscape at the decline of the last glaciation. On the basis of geomorphological studies carried out in the proximal part of the Augustów outwash plain (Augustów sandur) and in the Rospuda outwash track (NE Poland), landforms typical for the glacial lake-outburst floods were identified and investigated. These landforms include mega-scale dunes (megadunes), classified here as two- and three-dimensional features according to their crest shapes. Two-dimensional (2-D) megadunes, occurring in the Augustów sandur, form three clusters. The first cluster is located south of Suwałki (sites Ateny 1-4 and Płociczno 1-4), the second lies south of Lake Wigry (sites Bryzgiel 1 and 2) and the third is located east of Augustów (Płaska 1 nad 2 sites). The 2-D megadunes on the Rospuda outwash track were identified in its central part and at the contact with the Augustów sandur (Topiłówka 2 and Augustów 1-2 sites, respectively), while 3-D megadunes were recognized in the distal part of the Rospuda outwash (Topiłówka site 1). Most of the analysed 2-D magadunes are characterized by the presence of crestal depressions. The main objective of the research was to identify the morphology and the architecture of sedimentary facies forming megadunes in north-eastern Poland in order to interpret their depositional environments. The observed sedimentary successions represent both immature and mature stages of megadunes development and indicate a multiphase evolution of these bedforms. The first phase corresponds to transitional conditions from sub- to supercritical flow regime, which was associated with the development of successive occurrences of humpback dunes, upper plane bed and bedforms of hydraulic jumps. During the second phase, the migration and overlapping of medium and large-scale sandy and sandy gravel bedforms occurred mainly under the condition of subcritical flow regime. In the third phase, as a result of the development of meta- and post-depositional normal, crestal depressions were formed.
This study was carried out as part of the scientific project financed by the National Science Centre, Poland, project no. 2018/31/B/ST10/00976 and Danish Council for Independent Research (FNU) grant DFF-7014-00156.

Reconstruct the paleoenvironmental changes in the arid area: Imprints in the sediment from Olgoy lake, Mongolia

Dr. uyangaa udaanjargal [1]***, Prof. Noriko Hasebe*** [2]***, Prof. Davaadorj Davaasuren*** [1]***, Dr. Hitoshi Hasegawa*** [3]***, Dr. Katsuta Nagayoshi*** [4]***, Mr. Shuukhaaz Ganbat*** [5]***, Dr. Baasansuren Gankhurel*** [2]***, Prof. Fukushi Keisuke*** [2]

1. *School of Arts and Sciences, National University of Mongolia,* **2.** *Institute of Nature and Environmental Technology, Kanazawa University,* **3.** *Faculty of Science and Technology, Kochi University,* **4.** *Faculty of Education, Gifu University,* **5.** *Division of Natural System, Institute of Nature and Environmental Technology, Kanazawa University*

To assess the regional paleoenvironment, this study analyzed a 10.5 m sediment core retrieved from Olgoy lake (Olgoi Nuur) in the west central part of Mongolia. The sedimentary features are investigated as environmental proxies, including whole and mineral grain size, water, organic matter, carbonate, amorphous silica contents, and variations in elements analyzed by scanning X-ray fluorescence. The core was divided into six units based on lithology and analytical results: unit 1 with clayey sediments and brown silt, unit 2 is thoroughly dominated by silty layers, unit 3 depicted an abundance of sandy layers with brownish silt and gravel layers, unit 4 is dominated by sand and grey silt and intercalated gravel layers, unit 5 with brownish silt layers and unit 6 has alternations of mainly sand and gravel layers. The age model is given by OSL, IRSL, and Carbon-14 dating. Multivariate statistical analysis is applied to interpret long-term records. Factor 1 indicates in-lake activity and authigenic productivity. Factor 2 reveals detrital input /weathering/ terrigenous input, and Factor 3 implies the melting input from glacial and permafrost. MIS 2 and 3 stages were wet conditions in the Khangai mountains. At the same time, the Olgoy lake basin was humid. However, abrupt changes occurred via temperature increases accompanied by a dry climate during the Younger Dryas.

Three decades (1986-2015) of thermokarst lakes/ponds shrinkage on the northeastern Qinghai-Tibet Plateau

Dr. Serban Raul-David [1] ***, Prof. Huijun Jin*** [2]***, Dr. Mihaela Serban*** [3]***, Dr. Giacomo Bertoldi*** [1]

1. *Institute for Alpine Environment, Eurac Research, Bolzano,* ***2.*** *Institute of Cold-Regions Science and Engineering, School of Civil Engineering, Northeast Forestry University, Harbin; School of Resources and Environment, University of Chinese Academy of Sciences, Beijing,* ***3.*** *Applied Geomorphology and Interdisciplinary Research Centre, Department of Geography, West University of Timișoara,*

Identifying changes in thermokarst lake dynamics has a significant impact on landscape-scale hydrology and carbon budgets in permafrost regions. Thermokarst lakes and ponds are abundant in the Headwater Area of the Yellow River (HAYR) on the northeastern Qinghai-Tibet Plateau (QTP). This study aims to quantify changes in thermokarst lakes and ponds for a 150 km^2 permafrost area in south-central HAYR as a representative area for the discontinuous permafrost zone on the QTP. Water bodies inventories were generated based on Landsat satellite images for the periods 1986, 2000, and 2015 using the supervised Maximum Likelihood Classification (MLC). MLC performed better than other supervised and unsupervised classifiers (k-means, Density Slicing) and machine learning algorithms (e.g., Random Forest, Support Vector Machines). Although the overall accuracy ranged from 96% to 97% and the Kappa coefficient from 0.87 to 0.91, manual editing of misclassifications was still required. The number of water bodies larger than 0.36 ha decreased from 1986 to 2015 by 40% (461 to 277), while the total surface area decreased by 25% (542 to 406 ha). The ponds category (smaller than 1 ha) recorded the most substantial change, as their number decreased by 44% and their water surface extent by 41%. Additionally, the surface extent of lakes larger than 10 ha declined by 20%. Most of the ponds did not disappear but shrank to sizes smaller than 0.36 ha. Moreover, many large lakes were partially drained, forming several remnant ponds too small to be mapped on this data. This shrinking pattern of lakes and ponds is consistent with the warming permafrost in the HAYR, which suggests intense permafrost degradation. Future work will focus on a better understanding of water-heat dynamics of thermokarst lakes and ponds in association with permafrost degradation at higher spatial resolution.

Insights on the events surrounding the final drainage of Lake Agassiz-Ojibway based on high-resolution analyses of the Lake Matagami varve series (Québec, Canada)

Ms. Méliane Carrier-Favreau [1], ***Prof. Martin Roy*** [1], ***Dr. Patrick Lajeunesse*** [2], ***Dr. Pierre-Marc Godbout*** [3]

1. Geotop-Université du Québec à Montréal, Montréal, Canada, 2. Université Laval, 3. Geological Survey of Canada

The drainage of glacial Lake Agassiz-Ojibway in the North Atlantic at the end of the last deglaciation has long been held responsible for the 8.2 ka cooling event through a perturbation of the Atlantic Meridional Overturning Circulation. The impact of this freshwater forcing is still debated as the number and chronology of drainage events are poorly constrained in geological archives. Varve records provide an annual resolution on the lake's history, which spans over 2,000 years according to a composite sequence developed from varve sections across the Ojibway basin. However, part of the uncertainties about the succession and timing of late-stage events are due to the lack of resolution of a key varve sequence spanning the final stages of the lake history – the so-called Lake Matagami series. We sampled varve sequences from stratigraphic sections exposed along Lake Matagami (northwestern Québec, Canada), in addition to over 20 km of sub-bottom acoustic profiles to provide a high-resolution revision of the Matagami varve sequence and visualize the basin geometry. Varve sequences were analyzed using a CT scanner to document density variations and sediment structure. Varve couplets and thicknesses were counted and measured on these high-resolution images to correlate the sequence with the main Ojibway varve chronology template. Preliminary results show marked thickness variations indicating the influence of the fluctuating ice margin in sediment deposition. Upcoming grain size and X-ray fluorescence chemical analyses as well as the counts and measures should help correlate these sedimentological changes with nearby sections where drainage beds occur. Sub-bottom acoustic profiles show accumulations of more than 20 m of glaciolacustrine sediments, with occurrences of mass transport facies and erosional features consistent with active ice-margin dynamics prior to the final drainage of Lake Ojibway. Results from this study should improve the Ojibway varve series covering the final segment of the lake history and thereby contribute to refining the sequence of events preceding the final drainage of Lake Agassiz-Ojibway. Ultimately, refining the final deglaciation stages should help understand the role of the attendant meltwater discharges in the events that affected the North Atlantic climate in the early Holocene.

Constraining the contribution of Ungava-Labrador glacial lakes to early Holocene freshwater discharges: the case of Lake Cambrian in north-central Quebec (Canada)

Ms. Arianne Vallée [1], ***Prof. Martin Roy*** [1], ***Dr. Hugo Dubé-Loubert*** [2], ***Dr. Etienne Brouard*** [3], ***Dr. Joerg M. Schaefer*** [4]

1. Geotop-Université du Québec à Montréal, Montréal, Canada, 2. Ministry of Energy and Natural Resources of Quebec, Val-d'Or, Quebec, 3. Geological Survey of Canada, Natural Resources Canada, 4. Lamont-Doherty Earth Observatory, Columbia University

The retreat of the Laurentide ice sheet in northern Quebec and Labrador (Canada) led to the formation of several large ice-dammed lakes. These glacial lakes drained into the Labrador Sea where repeated meltwater discharges could have destabilized the North Atlantic Ocean conditions. However, assessing the impact of these freshwater inputs on the ocean circulation and climate is limited by the of lack constraints on the configuration, volume, and chronology of these lakes, as well as the position of the ice margin that controlled meltwater drainage pathways.

Here we studied the extensive sediment and landform records associated with glacial Lake Cambrian that occupied the Caniapiscau and Koksoak River valleys south of Ungava Bay in north-central-Quebec. Lake Cambrian was reconstructed through remote mapping of raised shorelines and deltas using high-resolution satellite images. Observations were validated through fieldwork, which allowed high-precision DGPS (± 1 m) elevation measurements of shorelines and deltas (45 sites) along a 170 km-long north-south transect. Preliminary results indicate that the lake experienced three well-defined levels at 180 m, 130 m, and 110 m. The occurrence of glaciolacustrine rhythmites suggests a relative long-lived stability of the lake basin. The extent of the lake will be reconstructed using a GIS model that corrects for the effects of post-glacial rebound and allows the calculation of realistic estimates of meltwater volumes. The chronology of the lake development will be constrained by the application of Terrestrial Cosmogenic Nuclide (10Be) dating to boulders of well-developed shorelines and deltas.

Together these results will constrain the development and evolution of Lake Cambrian and nearby glacial lakes during the last deglaciation and thereby reinforce paleogeographic reconstructions. Upcoming Be-10 ages will further place the meltwater discharges from the Ungava Bay region within the global deglaciation framework, which should lead to a better evaluation of the role of meltwater discharges in the early Holocene climate variations – an important contribution considering the recent increase in freshwater inputs coming from the melting of Greenland and other Arctic glaciers around the North Atlantic.

Keywords: deglaciation, glacial lake, quaternary mapping, cosmogenic dating

“Finis Ætatis Glacialis” – the drainage of the Central Jämtland Ice Lake and its connection to the Swedish Varve Chronology

Dr. Carl Regnéll [1], ***Dr. Sarah L. Greenwood*** [2], ***Dr. Richard Gyllencreutz*** [1], ***Dr. Gustaf Peterson Becher*** [3]

1. *Department of Geological Sciences, Stockholm University, Sweden,* ***2.*** *Department of Geological Sciences, Stockholm University, 10691 Stockholm, Sweden,* ***3.*** *Geological Survey of Sweden*

At the end of the 19th century, it was concluded that in the late stages of the deglaciation an extensive system of ice-dammed lakes, the Central Jämtland Ice Lake Complex, formed between the Scandinavian mountains in the west and the eastward retreating ice-sheet margin. Some years later, in the early 20th century, in his efforts to establish the varve-based “Swedish time scale” of the last deglaciation, Gerhard De Geer chose an exceptionally thick and coarse-grained varve in eastern Jämtland as the zero-year varve of his time scale, “Finis Ætatis Glacialis”; marking the end of the Ice Age and the boundary between the Finiglacial and the Postglacial subdivisions of the late Quaternary. De Geer believed this varve to stem from the opening of an eastern outlet and a catastrophic drainage of the Central Jämtland Ice Lake into the Baltic basin and, therefore, this zero-varve should represent the first definitive bipartition of the receding Scandinavian Ice Sheet.

However, the correlation between the zero-varve and a drainage of the Central Jämtland Ice Lake was only assumed and, at the time, no erosional features from the supposed enormous drainage had been found. In fact, since the middle of the 20th century, the very existence of the Central Jämtland Ice Lake has been challenged, and its palaeo-shorelines instead explained as formed in numerous marginal lakes within and around stagnant ice. Consequently, the draining of these lakes was believed to have been a more gradual process through a disintegrating dead ice-sheet.

About a century and a half after its first discovery, we now present geomorphological evidence in agreement with the original reconstruction of the Central Jämtland Ice Lake being a c. 3500 km^2 large and open lake, dammed by a coherent and actively retreating ice-margin. Most notably, we have found the “missing” extensive erosive features along with large sediment deposits relating to the catastrophic glacial lake outburst flood that followed when the damming ice margin broke in two. When this dam broke, the drainage was effectively reversed, from its western outlet across the present-day water divide to an eastern outlet and into the Baltic basin.

Microscale Approaches to Studying Glaciolacustrine Sediments – lessons from Palaeolake Riada, Central Ireland

Dr. Cathy Delaney [1], Mr. Matthew Carney [1], Dr. Kathryn Adamson [1], Prof. PHILIP HUGHES [2]

1. Manchester Metropolitan University, 2. The University of Manchester

Proglacial, ice-contact lakes act as sediment sinks, providing a continuous record of meltwater and sediment output from ice sheets and glaciers. The resulting deposits are commonly rhythmically laminated and sometimes annually laminated (varves) useful for constructing high-resolution chronologies of glacier and meltwater inputs. These rhythmites are composed of multiple sub-millimetre laminations, that reflect variation in sediment and meltwater input paths and processes and can be used to reconstruct environmental change during the existence of the lake. Careful examination of these sedimentary structures, along with the temporal context provided by the seasonality of varves, allows detailed insight into sediment transport mechanisms and pathways. However, in order to describe and contextualise these laminations in full detail microscopy is needed.

Using cores retrieved from Palaeolake Riada, central Ireland, we explore three ways of examining sub-millimetre sedimentary structures - examination of cleaned sediment surfaces using low-resolution binocular microscopes, thin section analysis and scanning electron microscopy (SEM) of intact sample. We consider how useful each method is for identifying a range of features, some of which are useful for distinguishing varved sequences from other laminated sediments. These characteristics include textural characteristics, including grain shape and size and sediment fabric, the nature of contacts between laminations and internal grading of laminations, identification of intraclasts and dropstones, and a range of deformation structures including micro faults with millimetre-scale displacement, soft sediment deformation structures and possible bioturbation. Our results indicate that all three methods can provide useful information on primary and secondary sedimentary structures within these sediments and can assist palae-environmental reconstruction. We consider the implications of our results for sedimentation processes and environmental reconstruction for Palaeolake Riada. The lake sediments contain both varved and non-varved sediments that record the pattern of ice retreat, readvance, lake level lowering and final drainage of the palaeolake.

Reconstructing ice retreat of the south-eastern margin of the Laurentide Ice Sheet using proglacial lake sediments

Ms. April Howden [1], ***Dr. Timothy Lane*** [1], ***Dr. Kathryn Adamson*** [2], ***Dr. Matthew Finkenbinder*** [3], ***Ms. Erika Wintersteen*** [3], ***Mr. Robert Hawkins*** [3]

1. *School of Biological and Environmental Sciences, Liverpool John Moores University,* **2.** *Manchester Metropolitan University,* **3.** *Wilkes University*

Establishing the behaviour and retreat of palaeo ice sheets is vital to better understand future global atmospheric and oceanic processes. The retreat of the Laurentide Ice Sheet (LIS) after the Last Glacial Maximum (LGM) led to a significant contribution of approximately 80 m to global sea-level rise, but the timing and impacts of this retreat are still not fully understood. Prior work has used moraines and till extents in the north-eastern US to spatially constrain the southern LIS LGM and post-LGM ice margins, but age discrepancies between cosmogenic nuclide ages (from moraine boulders) and ^{14}C ages (from lake sediments) have led to disagreements on the initial timing of deglaciation. This issue is further compounded by the inclusion of imprecise bulk ^{14}C ages.

To address this, the project aims to reconstruct ice lobe behaviour in north-east Pennsylvania (NEPA) using collated local ^{14}C ages and new high-resolution multi-proxy analysis of lake sediments. Previous works have focused solely on mapping NEPA glacial deposits, but very little research has been dedicated to constraining the timing of ice retreat within the region. This new data will therefore provide an important contribution to the overall LIS deglacial chronology.

Recent work at two NEPA lakes (Cranberry Pond and Nuangola Lake) show clear, gradual transitions from ice-proximal minerogenic to organic post-glacial sediments. New macrofossil AMS ^{14}C from the post-glacial clays constrain deglaciation to as early as 19.2 cal. ka BP; 3000 years older than the currently accepted AMS macrofossil ages obtained throughout the north-eastern US.

In this study, new sediment cores have been obtained from three NEPA lakes, transverse to ice margin retreat, to establish LIS retreat pattern and palaeoenvironmental change post-LGM. High-resolution physical (e.g. Grain Size Analysis, Dry Bulk Density, Magnetic Susceptibility), geochemical (e.g. X-Ray Florescence) and organic (e.g. Loss-on-Ignition) analyses have been used to trace changes in lake sediment characteristics. Chronological control is provided by ^{14}C dating of macrofossils at key stratigraphic boundaries. Importantly, these will be tied to the glacial geomorphological record using new cosmogenic nuclide ages from nearby moraine boulders to address potential environmental lag times.

Geomorphological and palaeogeographical significance of infilled lake basins: insights from the Cordillera Blanca, Peru

Dr. Adam Emmer [1]

***1.** University of Graz*

The infilled lake basins represent common form in the complex high mountain landscape of the Cordillera Blanca, Peru. While recent case studies indicate that those areas influence sediment cascades and can help to buffer decreased discharge from shrinking glaciers during the dry season, a systematic inventory is lacking. In this work, I present an inventory of infilled lake basins of the Cordillera Blanca, analyze their morphometrical characteristics, types and occurrence patterns in relation to selected physical geographical variables. This inventory is further exploited to: (i) reconstruct past glacier extents considering large infilled lakes as indicators of LGM glacier limits; (ii) estimate the volume of trapped material and formulate the implications for sediment yield and mobility.

2000 years of small glacier activity recorded by a proglacial lake in South-East Tibet

Mountain glacier ice cores provide detailed records of glacial evolution over the Tibetan Plateau. However, they reflect massive glacial systems, while small glaciers accounting for 50% of high-mountain Asia glaciers may have different dynamics, especially in the context of climate change. While the interpretation of stable isotope data in the monsoon domain is not straightforward, proglacial lake sediments may provide direct records of glacial activity in various settings through glacial induced erosion.

Here, we present a lacustrine archive recording 2000 years of glacial activity in SE Tibet. Lake Yun Zhu is a small (0.01 km²) proglacial lake in the Daxue range, eastern Hengduan mountains. Five cores ranging from 47 to 123 cm-long, were retrieved in 2021 with a gravity corer. The cores were dated using short-lived radionuclides, radiocarbon ages, and palaeomagnetic secular variations. Multiproxy analyses applied on these cores included XRF (continuous core scanning and discrete analyses), magnetic parameters, SEM observations of the sedimentary microfacies, grain size measurements, and hyperspectral data. Because the sediment is relatively homogeneous and poor in organic material, we used geochemical ratios and pigment analyses to reconstruct the evolution of detrital inputs and lake primary productivity. We show that clastic sediment derived from glacial erosion increases at the expense of organic production during cold periods. The observed peaks of enhanced erosion coincide with regional phases of glacier advances at 1320 ± 30 to 1410 ± 40 CE, 1490 ± 40 to 1590 ± 50 CE, and 1630 ± 50 to 1800 ± 40 CE, i.e., corresponding to the Little Ice Age period. We also indentified two older stages of enhanced erosion between 350 ± 30 and 510 ±20 CE, and between 1120 ± 30 and 1220 ± 30 CE.

Tracing Stone Tool Technology as Markers of Late Pleistocene Human Migrations in NE Asia and North America

Dr. Karisa Terry [1]***, Prof. Masami Izuho*** [2]

1. Central Washington Univeristy, 2. Tokyo Metropolitan University

Recent review of human genetic markers and archaeological materials indicate the earliest occupations of North America have their roots in NE Asia during the late Pleistocene roughly 21,000-14,000 BP, however the details of localities and process of human movements are unclear. Some researchers (i.e. Buvit et al. 2021) suggest that late Pleistocene Paleo-Sakhalin-Hokkaido-Kuril (Paleo-SHK) peninsula and Honshu Japan may be the origin of founding populations into North America based on stone tool assemblage similarities coupled with periods of population out-movements from this region and timing of population in-movements into North America. To more clearly test whether stone tool technology can facilitate our understanding of these patterns, this paper is concerned with using stone tool technological markers as they are distributed over time and space during the late Pleistocene of NE Asia and North America. Utilizing cladistic analysis, key technological features of stone tool assemblages from several sites in NE Asia, including Japan and Siberia, occupied between roughly 21,000 to 14,000 ^{14}C BP are compared to those of early sites in North America occupied between roughly 16,500 and 12,000 ^{14}C BP. Comparisons focus on stone tool assemblage composition as well as specific technological markers and processes within each assemblage. These data are then set against geographical distribution of these attributes within sites and the radiocarbon record, thus providing geographic and chronological distribution of similarities and divergence in stone tool assemblages and technology over time and space. These data are then used to infer whether late Pleistocene Paleo-SHK and Honshu Japan contain foundational technological attributes of NE Asian lithic assemblages and subsequent population movements across NE Asia and North America.

New insights into subglacial processes in overdeepened settings revealed by swath bathymetry of young proglacial lakes

Mr. Siro Hosmann [1]***, Dr. Marius W. Buechi*** [2]***, Dr. Stefano Fabbri*** [3]***, Dr. Andreas Bauder*** [4]***,***
Prof. Flavio Anselmetti [3]

***1.** Institute of Geological Sciences and Oeschger Centre for Climate Change Research University of Bern,* ***2.** Institute of Geological Sciences & Oeschger Centre for Climate Change Research, University of Bern, Bern, Switzerland,* ***3.** Institute of Geological Sciences and Oeschger Centre of Climate Change Research, University of Bern, Switzerland,* ***4.** VAW ETH Zürich*

The formation of subglacial overdeepenings is widely debated and essential for understanding glacial systems and their geomorphic processes. Knowledge of how landscapes were formed by glaciations is in particular important as receding glaciers currently uncover subglacial landscapes that are prone to a series of natural hazards. We present high-resolution bathymetric data of a proglacial lake in front of the Rhone Glacier (Swiss Alps) that started to form ~20 years ago and is not yet completely ice-free. These data were collected in two years (2015 and 2021) using a multibeam echosounder yielding a 1x1 m digital bathymetric grid allowing an unprecedented look into a freshly uncovered glacier bed in an overdeepened setting.

The bathymetry is characterized by a series of subaquatic moraines that exhibit various sedimentary features such as delta fans and subaquatic delta channels. The new data allow to accurately correlate the succession of these moraines with the glacier's retreat history as seen on aerial photos, providing critical understanding of when, where and how such subaquatic moraines form. Sub- and englacial conduits control the location of active and inactive lake-inflow channels. These conduits carry large amounts of sediments that rapidly infill the inherited subglacial landscape produced by the deglaciation. Moreover, comparing the two surveys from 2015 and 2021 enables us to quantify the accumulation and erosion processes in the central basin of the lake. The lake bed is further characterized by the backscatter-intensity map, which differentiates between fine- and coarse-grained sediment and bedrock, and by series of short gravity cores, allowing to identify channel activity evolution. Towards the glacier front, which still extends subaquatically into the lake, our high-resolution data visualizes how the submerged ice front is interacting with its proglacial lake. This highly dynamic frontal glacier setting is characterized by iceberg calving, as observed in September 2021, by fluctuating outflow conduits and by rapid sedimentation as particle-laden meltwaters and dumped glacial debris supply efficiently material continuously shaping and filling the lacustrine basin.

Mapping submerged beachrocks using low-altitude aerial photogrammetry-UAV on the northern coast of the Sea of Marmara, NW Turkey

Mr. Mustafa Geyik [1], ***Dr. Ufuk Tari*** [1], ***Prof. Orkan Özcan*** [2], ***Prof. Gursel Sunal*** [1], ***Prof. Cenk Yaltirak*** [1]

1. *Department of Geological Engineering, Faculty of Mines, Istanbul Technical University, 34469, Istanbul, Turkey,* **2.** *Istanbul Technical University, Eurasia Institute of Earth Sciences, 34469 Maslak, Istanbul*

Low-altitude high-resolution aerial photographs allow for the reconstruction of geomorphological properties of shallow submerged beachrocks and the quantification of their topographic complexity. Beachrocks as a coastal deposits are largely used to estimate past sea-level positions and deformation rates in studies focusing on climate and tectonic processes at different temporal and spatial scales. In this study, we present submerged beachrocks relative paleo sea-level indicators found on the nearshore coastal area of Tekirdag city (Altinova), the northern Sea of Marmara. However, our knowledge of the submerged beachrocks in the Sea of Marmara coasts is limited and scarce. The Tekirdag-Altinova coastal area is also located in the tectonically active western Marmara Region. This tectonic activity is controlled by the North Anatolian Fault Zone which played a crucial role in the coastline evolution at different periods of the region.

Recent studies of submerged beachrocks using UAV data have demonstrated that these deposits can be readily isolated from other coastal deposits in the coastal area. Thus, the submerged beachrocks were identified at a depth 2 m below the present sea level with a ~5 km coastal extend, by using a combination of high-resolution aerial photos and morphological analysis techniques in this region. It was used specifically to generate a dense point cloud and then a high-resolution bathymetry of these beachrocks by correcting the effect of water on light refraction. Hereby, the Structure-from-Motion photogrammetry technique was exploited for low-cost and effective UAV-derived imagery to achieve the monitoring of these beachrocks.

Then, to accomplish the objectives a high-resolution bathymetry (5 cm) was analyzed using Geographic Information Systems and Terrace M application. This application allows estimating the shoreline angle and its associated error using high-resolution bathymetry. Then, shoreline angles, a geomorphic feature correlated with the high-stand position of past sea levels, were mapped by analyzing swath profiles perpendicular to the isobaths. In summary, most of the submerged beachrocks with their shoreline angles between approximately -0.3m and -1.1m. The preliminary results gave us novel routines to map the elevation and spatial distribution of beachrocks and to estimate reliable uplift rates in the nearshore area of the study region.

First pollen record from the Late Holocene forest environment in the Lesser Caucasus

Pollen-based vegetation change has been inferred from sediments in Kalavan Red Lake. This small lake is placed in the beech-oak-hornbeam forest, about three kilometres away from archaeological remains. It has the potential to document the Holocene forest history and climate and human impacts on the Lesser Caucasus, West of the Caspian Sea. However, this lake happens to be formed by a large landslide.

Pollen and XRF analysis are provided over the last 3800 years. The basal age of the Kalavan sediment approximates the landslide age. This created a not vegetated slope including the lake catchment. Erosion and sedimentation processes brought coarse and heavy minerogenic elements, declining with the catchment revegetation by tall-grassland. This shift in the sedimentation continues, suggesting less erosion in the catchment when an admixture of *Quercus* and grasslands settled. Starting from 2000 cal. BP, arboreal pollen increases successively thanks to the step afforestation of *Quercus*, *Carpinus orientalis* and *Fagus*.

The comparison with available pollen reconstruction illustrates the uniqueness of the vegetation dynamic recorded at Kalavan. However, the duration of this succession is also questionable. An intermediate hypothesis is proposed: the Kalavan's dynamic is first initiated by the landslide with the tall-grass development, then paced by the regional vegetation dynamic.

Linking vegetation history and erosion with regional climate and archaeological data helps to evidence short-term climate change and human impact on this branch of the Silk Road. Antique arid phase (2000-1600 cal. BP), the Medieval Warm Period and Little Ice Age affect the vegetation, while demography variations during the Medieval period and Modern Age are shown by habitation and pastoral activity.

Evidence for an Illinoian (MIS 6) aged 3,500 km2 proglacial lake in the Midwestern United States

Ms. Sadie Richter [1], *Mr. Phillip Kerr* [2]

1. University of Iowa, 2. Iowa Geological Survey

New surficial geology mapping efforts have revealed the presence of Glacial Lake Prior, a proglacial lake which was formed by an Illinoian Episode (MIS 6) ice lobe. The flow path of the ice was southwest then westward out of the Great Lakes region and dammed the Wapsipinicon, Cedar, Iowa, and Skunk rivers in Iowa. Water well records in the area contain fine-grained sediment, interpreted to be lacustrine in origin, and coarse-grained outwash buried by Illinoian (MIS 6) till. There is also a distinctive upland morphology caused by a repeated "fill-and-spill" process. As ice dammed rivers, valleys at higher elevations filled with water until they would overflow into adjacent basins via the lowest path, i.e., pre-existing tributaries. The modern upland surface contains forms of these overflow channels, and they have a similar slope dipping to the south.

Glacial Lake Prior offers a unique perspective into the processes and interactions between continental ice lobes and pre-existing drainage networks. Specifically, ice flowing against the established drainage pattern. In addition, the valleys buried by the ice advance do not match the geometry of the modern Mississippi River Valley. This, combined with the fill-and-spill geometry, support the idea that major river diversions are primarily controlled by ice proximity rather than long-term isostatic processes. Future work will constrain the timing of Lake Prior's development and its interaction with the Illinois Lobe and older glacial advances.

Human-animal interaction in the Harappan Civilisation: regional distribution of domesticated animals and an evaluation of current research practices

Mr. Siddharth Kutty [1], ***Dr. Kalyan Sekhar Chakraborty*** [1]
1. *Ashoka University*

Archaeozoological studies of Harappan sites have become increasingly common in the last few decades, and a general top-down understanding of animal utilization within this civilization now exists. However, our knowledge about the variation in regional human-animal interactions is extremely limited, particularly if regional geographical, climatic and socio-political differences impacted how domesticated animals were exploited. Furthermore, most Harappan faunal analyses are site-specific and not uniform across the pan-Indus region. Not only are the site-specific data sparsely distributed across the civilization, but the collection of samples, analysis and data presentation methodologies employed by researchers need to be standardized. This lack of standardizations adds additional obstacles in translating site-specific faunal information to larger geographical contexts. Using already published data, this paper aims to reconstruct the region-specific distribution of domesticated animals within the Harappan Civilisation and, in this process, evaluates issues related to method, data standardization and publication within the field of Harappan archaeozoology. Using an array of statistical measures, this paper will discuss legacy data to estimate if the exploitation of domesticated animals varied across regions or if they were standardized, and what the extent of this standardization was within the civilisation. By factoring in differences in methodologies applied to interpret zoo-archaeological results from different sites, this paper will also discuss the sources of bias and the possible existence of inter-analyst variation. Recognition of these analytical conundrums has broader implications for developing a bottom-up understanding of human-animal-environment interaction within the Harappan civilisation. Furthermore, the geographic distribution of domestication practices within the Harappan Civilisation will help reconstruct the regional cultural response to geographical and climatic variation and how animal herding and exploitation practices may have varied spatially and temporally. As the first great civilization in South Asia, knowledge of Harappan adaptations to the environment is a step towards understanding the larger sociocultural evolution of humans in this part of the world.

Sclerochronology of pectinids from the warm Mediterranean Pliocene: what can we learn about species response to future climate change?

Dr. Silvia Danise [1], ***Ms. Giada Giachetti*** [1], ***Dr. Ilaria Baneschi*** [2], ***Dr. Martina Casalini*** [1], ***Dr. Francesco Miniati*** [1], ***Dr. Stefano Dominici*** [3], ***Dr. Chiara Boschi*** [2]

1. *Dipartimento di Scienze della Terra, Università degli Studi di Firenze, Via La Pira 4, I-50121 Firenze, Italy,* ***2.*** *Istituto di Geoscienze e Georisorse, Consiglio Nazionale delle Ricerche, (IGG-CNR), Via G. Moruzzi 1, 56124, Pisa, Italy,* ***3.*** *Museo di Storia Naturale, Università degli Studi di Firenze, Via La Pira 4, I-50121 Firenze, Italy*

Sclerochronology investigates the geochemical composition of bivalve shells and gives insights on climate conditions archived during the lifetime of an organism and its adaptation to them. Growth increments represent interval of times in which the organism produces its shell, and can inform on environmental conditions during growth, and growth lines identify periods of growth cessation, which can be caused either by physiological processes (e.g., spawning) or abiotic factors, typically temperature.

Here we analyse the relationship between micro-growth increments and stable-isotopes ($\delta^{13}C$, $\delta^{18}O$) of two stenohaline Pectinidae, *Gigantopecten latissimus* and *Pecten jacobaeus*, from Zanclean (Early Pliocene) deposits (Tuscany, central Italy). *G. latissimus*, with large (length > 20 cm) and heavy shells, got extinct around 3.0 Ma ago, when Mediterranean Sea surface temperatures shifted from subtropical to temperate at the intensification of the Northern Hemisphere glaciation. *P. jacobaeus*, survived to Plio-Pleistocene climate cooling and is the largest scallop inhabiting the Mediterranean Sea today (length up to 15 cm). Aim of the study was to characterize the growth patterns of the two species and to investigate whether different life strategies might have controlled species extinction or survival.

In *G. latissimus*, strong correlation between growth patterns and $\delta^{18}O$ values ($p < 0.001$) clearly indicates high growth rates during the colder months (higher $\delta^{18}O$) and slower rates during warm periods, with summer cessation. This behaviour resembles that of large modern subtropical scallops, like *Nodopecten subnodosus*, in which spawning occurs only once per year, at the end of the warm season. Given this specialized physiological adaptation, we hypothesize that a drastic decrease in summer temperature after 3.0 Ma, hampered the reproduction potential of *G. latissimus* contributing to its extinction.

In *P. jacobaeus,* although we observe a tendency of precipitating the shells during colder intervals, the correlation between growth patterns and $\delta^{18}O$ values is not significant, suggesting a more variable life strategy for this species. Studies on modern specimens confirm this interpretation, showing that *P. jacobaeus* displays growth summer cessation but also has multiple spawning seasons through the year, making it more adaptable to a changing climate.

The stratigraphy and sedimentology of the Roman-Byzantine El-Araj archaeological site at the northern coast of the Sea of Galilee, NE Israel

***Prof. Noam Greenabum* [1], *Dr. Nathaniel Bergman* [2], *Prof. Mordechai Aviam* [3], *Prof. Steven Notley* [4]**

***1.** University of Haifa, Haifa, 3498838, Israel, **2.** University of Haifa, Haifa 3498838, Israel, **3.** Kinneret Institute for Galilean Archaeology, Land of Israel Studies, Kinneret College on the Sea of Galilee, Israel, **4.** Alliance University New York, NY 10004*

The archeological site of El Araj (Bet Habek) is located on a large delta deposited by the Jordan River and three other central Golan Heights streams. It is situated on the edge of a pronounced shoreline break, where modern lake level reaches a maximum height of 208.8 m below sea level at the contact with the delta front. The Roman-Byzantine archeological excavation of El-Araj is 3.5 m deep located over natural fluvial basalt gravel and coarse sand layers with the absence of the molluscs typical for the lacustrine deposits of the Sea of Galilee, indicating that the site was settled over a dry natural alluvial fan, while the lake shoreline was further to the south. This suggests that the lake level was lower than 211.5 m b.s.l. However, natural fluvial layers up to 0.4 m thick were found covering the Roman archaeological layer at 211m b.s.l. under the overlying Byzantine layer at 210.5 m b.s.l.

The general stratigraphy and sedimentology of the site suggest alternating lake sediments with coarse fluvial sediments transported during large floods. The coarse texture of the natural layers resembles the texture of some of the layers exposed at the nearby bank of the Meshushim stream supporting the fluvial origin of the sediments rather than the finer lake layers. The trace of the nearby N-S Jordan fault – a segment of the Dead Sea Transform (DST), located about 600 meters east of the site, does not show any local evidence of surface rupture neither sedimentological evidence for liquefaction at the site. Nevertheless, some subsidence along the fault may have formed an accommodation space for the fluvial deposition.

Our conclusion is that the Roman archaeological layer was buried by fluvial sediments from floods probably originated from the Meshushim stream.

Poster - sessions 10, 38, 56, 78, 95, 107, 108, 109, 115, 121, 180, 182, 184, 187

The 3D Pollen Project: super-resolution scanning a representative sample of the world's pollen diversity in two and three dimensions

Dr. Oliver Wilson [1]***, Prof. Robert Marchant*** [1]

1. *University of York*

Pollen is fundamental to the functioning of the natural world, and to the sciences which research it. This extends far beyond palaeoecology. The flow of beautifully patterned pollen grains underpins plant reproduction and evolution, ecosystem function and productivity – and ultimately human health. Pollen grains, preserved in rocks and sediments by immensely tough outer shells, reveal the development, adaptation and decline of species and ecosystems from geological to human timescales. And for hundreds of millions of people worldwide, pollen simply gets up their nose (perhaps 30% of the global population is allergic).

Engaging non-specialists with pollen-related research can be challenging, though – not least because pollen is microscopic. 3D scanning and printing can produce morphologically accurate, larger-than-life, tactile models of pollen grains, and has allowed audiences to interact with pollen in new ways – to hold these microscopic marvels in their hands and bring close the worlds of pollen and related research. However, to date, only a small and biased subset of the world's pollen diversity has been made available for these purposes.

The 3D Pollen Project aims to scan and share 2D and 3D data on a representative sample of the world's pollen types, for use in outreach, education and research. New technological approaches, combined with superresolution scanning and traditional microscopy, allow for the high-throughput digitisation of existing pollen reference collections, producing data with SEM/TEM-like resolution without requiring additional processing. This poster sets out how we are applying these methods to a large and (ecologically, geographically, morphologically and phylogenetically) representative sample of the world's pollen diversity – and explains how you can help.

PalaeoScope: an augmented reality app for visually telling stories about the past

Dr. Georgios Lyras [1], Mr. Emmanuel Galanopoulos [2], Mr. Nikolaos Karydas [2], Mr. Alexandros Iakovidis [2], Mr. Konstantinos Paraskevopoulos [2], Mr. Konstantinos Gelegenis [2], Dr. Georgia Kotzamani [1], Dr. George Kontakiotis [1], Ms. Evangelia Besiou [1], Mrs. MYRSINI VOULGARI [1], Ms. Alexia Grambas [1], Ms. Vasiliki Alexoudi [1], Mr. George Sofianopoulos [3], Prof. Assimina Antonarakou [1]

***1.** National and Kapodistrian University of Athens, **2.** InDigital, **3.** Foundation of the Hellenic World*

The Acropolis of Athens is one of the most visited landmarks of Greece. Located on the top of a hill, at the center of Attica basin, it offers an excellent view of Athens. Since most visitors spend a significant amount of time taking pictures of the city with their phones, it makes only sense to create an app for telling stories about the city and its environment. We therefore developed an augmented reality app that turns phones into a tool for visually describing the landforms, vegetation, and animals of the past. The phones will use their video-see-through systems to overlay visuals onto the live environment. The early Pleistocene, early Holocene and the historical periods play key roles in our reconstructions. The recreation of the past has required our scientific team to push beyond typical questions and data. For example, the team had to make decisions about the spatial distribution of flora during the Pleistocene and early Holocene. Such data are few for Attica basin, thus our team had to additionally rely on palaeobotanical data from other localities with compatible geomorphological and climatological attributes. Literary sources and landscape depictions were also used for the reconstruction of vegetation in historical periods. The early Pleistocene faunas are well represented in Attica. Two fossil localities, Tourkovounia and Psychiko, have yield fossil vertebrates ranging from MN16 till MNQ19. Nevertheless, they consist mostly of small vertebrates. We therefore used data from other Greek localities for recreating a realistic Pleistocene megafauna. Palaeozoological data for the early Holocene were taken from Vraona (East Attica), which yield a significant number of large-mammal fossils. Our app aims to help the public engage with the past. For example, by contrasting the present human-shaped landscape with that of the early Holocene, the visitors can realize that the rivers of Attica are forced to flow in sewers bellow major avenues, that the present vegetation in Attika is depleted and that the megafauna is absent. This research was co-financed by the European Regional Development Fund of EU and Greek national funds through the Operational Program Competitiveness, Entrepreneurship and Innovation, call Research-Create-Innovate (Project: PalaeoScope T2EDK-03781).

Climate change – the boardgame: a free educational resource to discuss paleoclimate, evolution and conservation

Dr. Michela Leonardi [1], ***Prof. Andrea Manica*** [1]

1. *Department of Zoology, University of Cambridge*

Climatic variations through time are one of the key drivers of evolutionary dynamics in animal species, leading to changes in distribution, migration, adaptation, or extinction. While specialists are aware of how the different factors involved interact in complex and variable ways, most often the general public fails to grasp the overall complexity of the picture.

We decided to increase awareness about this topic by creating “Climate Change – the board game” (https://michelaleonardi.netsons.org/climate-change-board-game/) inspired on our research on how climatic changes affect animal species over long timescales.

In the game, each player is a species, living in a world where the climate may change without warning. Each species has a given genome with associated traits that, through mutations, allow it to adapt to different environments. Whenever the climate changes, the environment follows and the species must react by migrating or adapting, or it goes extinct.

This board game explores in a rigorous but simple way complex scientific concepts such as adaptation, evolution, and extinction. There is also the opportunity to explore the effects of the current human-induced climate changes with respect to natural ones.

The game is available in four different languages (English, Italian, Portuguese and Turkish) and can be played for free either in person by downloading the materials or online through the dedicated website.

Challenges and opportunities in communicating interdisciplinary paleoscience

Ms. Giorgia Camperio [1], Dr. Maria Elena Castiello [2], Dr. Ignacio Jara [3], Prof. Thijs van Kolfschoten [4], Dr. Katarzyna Marcisz [5], Ms. Daniela Moraga Lopez [6]

1. *Geological Institute, ETH Zürich,* ***2.*** *Institute of Archaeological Sciences (IAW) University of Bern,* ***3.*** *Centro de Estudios Avanzados en Zonas Áridas (CEAZA),* ***4.*** *Faculty of Archaeology, Leiden University, Einsteinweg 2, 2333, CC, the Netherlands,* ***5.*** *Climate Change Ecology Research Unit, Faculty of Geographical and Geological Sciences, Adam Mickiewicz University, Poznań, Poland,* ***6.*** *Pontificia Universidad Católica de Chile*

In current times of environmental crisis it is crucial to effectively communicate scientific results. Scientists are often confronted with the question of how to communicating their research outcomes to different audiences and in different contexts. In November 2022, during the Past Socio- Environmental system workshop in La Serena, Chile, 26 Early Career Researchers (ECRs) from different paleoscientific backgrounds gathered to discuss the overarching themes of past climate-environment-cultural changes. During focus sessions participants worked on three main questions that summarized 150 questions posed by the ECR community, which revolved around types of proxies and archives, semantic barriers, and analytical frameworks in past socio-environmental systems. Challenges and opportunities of communicating interdisciplinary emerged as a transversal theme encompassing the summary questions and was further developed as a pivotal point of discussion. Challenges and opportunities were divided in three main topics 1) Research, 2) Funding 3) Outreach. For each topic the main actors were identified and challenges and opportunities further outlined. An *Octopus* was used as a graphical visualization where tentacles represented all the different aspects an ECR has to consider when it comes to communicating science. The message being that ECRs do not have to act as an octopus trying to juggle between different ways of conveying information but rather focus on preferred aspects as an opportunity, among others, to increase their visibility, develop further skills, and increase networking opportunities.

Communicating Quaternary science to community collaborators in Timor-Leste

Dr. Simon Connor [1]***, Dr. Frederico Santos*** [2]***, Dr. Sarita Camacho*** [3]***, Dr. Larissa Schneider*** [1]***, Dr. Susan Rule*** [4]***, Ms. Zoë Taylor*** [5]***, Mr. André Aleixo Araújo*** [6]***, Prof. Simon Haberle*** [1]

1. *ARC Centre of Excellence for Australian Biodiversity and Heritage; School of Culture, History and Language, The Australian National University,* ***2.*** *Instituto do Petróleo e Geologia, Dili,* ***3.*** *Escola Superior de Educação e Comunicação, Universidade do Algarve, Faro,* ***4.*** *ARC Centre of Excellence for Australian Biodiversity and Heritage, School of Culture, History and Language, The Australian National University,* ***5.*** *ARC Centre of Excellence for Biodiversity and Heritage, School of Earth, Atmospheric and Life Sciences, University of Wollongong,* ***6.*** *School of Culture, History and Language, Australian National University, Canberra, ACT*

Quaternary science is a unique form of storytelling that emphasises past changes as a means of understanding the world. This emphasis on the past means that Quaternary science could have much to share with Indigenous cultures with long oral histories and deep storytelling traditions. But there are significant barriers to this kind of dialogue, in part due to the lack of a common language and the mistrust engendered by colonisation. How can we explain Quaternary science in ways that resonate with local communities? How can we create possibilities for telling stories together about the past that are inclusive, scientific and culturally relevant? In this presentation, we describe a children's book developed by our joint Australian-Timorese team: "How to Understand Past Climate Changes?" Through the medium of watercolour illustrations, we communicate Quaternary research questions, methods and outcomes in ways that diverse audiences can quickly and easily grasp. The book is written in three languages as a teaching resource for Timorese schools and it will be made available through Creative Commons licensing so communities can make it their own. Communicating science in this way is time-consuming and overlooked in current research metrics, but can open pathways to stronger connections with communities and places, as well as facilitate a deeper understanding of the Quaternary through the sharing of different knowledge systems.

A timeline for the history of Quaternary studies in Italy from Arduino to the nineteen-seventies

***Prof. Giuseppe Orombelli* [1], *Prof. Maria Rita Palombo* [2], *Dr. Renata Perego* [3], *Dr. Cesare Ravazzi* [3]**

***1.** University of Milano Bicocca, Department of Environmental and Geological Sciences, **2.** CNR IGAG, **3.** CNR-IGAG, Laboratory of Palynology and Palaeoecology*

We present a timeline stepping the development of Quaternary sciences in Italy, starting by the origin of the Quaternary concept, which was given by Giovanni Arduino. We focus on historical milestones achieved until the onset of contemporaneity.

The marine sediments of Southern Italy stimulated stratigraphic research since Lyell introduced the "Newer Pliocene" (1831), then renamed Pleistocene. Several marine stages were defined in Italy - Sicilian, Calabrian, Tyrrhenian, Milazzian and other later on. The 18th IGC in London started the debate on the Plio-Pleistocene boundary, to be placed "at the horizon of the first indication of climatic deterioration in the Italian Neogene succession" on the base of changes in marine faunas.

The post-Tertiary continental deposits were mapped as "alluvial" and "diluvial terraines" until 1870. Glacigenic deposits were recognized at the foot of the Western Alps (1850), and Central-Eastern Alps (1861). Around 1890, researchers started to distinguish more than one glaciation and first recognized glaciers in the Apennines. Since 1909, the four-glaciation scheme was generally adopted.

Yet in the Renaissance, Quaternary mammals remains were collected from the Upper Valdarno. Around 1900, the knowledge of the Pleistocene mammal fossil record in continental Italy greatly improved and new endemic species were discovered in Sicily and Sardinia. In 1865 the Villafranchian Stage was proposed for the fluvial and lacustrine sequence of Villafranca d'Asti (Piedmont). The mammalian faunal assemblage of Villafranca led successively to the definition of the "Villafranchian European Land Mammal Age".

The Quaternary paleobotanical identity was pointed (1833), as "characterized by animal and plant species similar to modern living ones at the same site". Plant macrofossils species were then classified by the Linnean system. In 1896 the aliquot of extinct and eradicated plant relicts in N-Italy was stepped through the Pliocene, interglacial and the postglacial periods. Evidence from excavating peats stimulated a stratigraphic organization of the macrofossil record. In 1931-32, the introduction of palynology in Italy promoted the application of micro-botanical stratigraphy to vegetation history and to plant-climate-human interactions.

Lastly, we outline the beginnings of paleoanthropology and the noteworthy Paleolithic human remains discovered in Italy.

If lakes could tell stories...: an illustrated children's book about Palaeolimnology

Dr. Celia Martin-Puertas [1]

1. Royal Holloway, University of London

Written by Celia Martin-Puertas
Illustrated by Samuel Torres
Scientific learning in early childhood is important for future scientific understanding but also to build important skills and attitude for thinking. Literacy has a transformative power and may be an engaging learning resource at home but also for classrooms. The number of scientific books for children is increasing in the last years and they cover a wide range of disciplines, although Quaternary Sciences is still underrepresented.

"If lakes could tell stories" is an illustrated children's book about palaeolimnology, which takes children on a journey into lake sediments and time travel. The book describes the basic steps to study the evolution of a lake, from lake coring to sampling, environmental interpretation of proxies and developing of a chronology. The book offers children the opportunity to explore their world and promotes palaeo and Quaternary literacy as to support early years teaching and learning.

PollenScape: a tactile teaching and engagement tool for visualising landscapes of the past.

Dr. Janelle Stevenson [1], ***Dr. Kelsie Long*** [1], ***Dr. Elle Grono*** [2], ***Dr. Simon Connor*** [1], ***Dr. Rebecca Hamilton*** [3]

1. *ARC Centre of Excellence for Australian Biodiversity and Heritage; School of Culture, History and Language, The Australian National University,* ***2.*** *School of Archaeology and Maritime Cultures, University of Haifa,* ***3.*** *Max Planck Institute for Geoanthropology*

When palaeoecologists (palynologists) extract pollen from their sediment cores and peer down the microscope, they reconstruct what was growing in the landscape back through time. At least this is what the specialists sees. It is much harder for the public, school students and even our undergraduates to make this cognitive leap. The PollenScape project is an educational tool that enables students and the broader community to overcome this challenge and connect more meaningfully with our research.

Studies have shown that hand-held 3D models reduce many of the obstacles associated with the study of complex structures and data, providing students with a more enjoyable learning experience while, at the same time, developing a learning environment that encourages deeper engagement. To do this effectively we need to bridge differences in knowledge, experience, and backgrounds, to communicate not just our findings but the research process itself.

PollenScape is all about linking what we see under the microscope with a 3D hands-on reconstruction of landscape and builds on our existing contributions to public and research good with the creation of a unique communication tool, making accessible a complex discipline that many people find beautiful and fascinating.

Science communication for community engagement in Australian Quaternary Science.

Ms. Kelsey Boyd [1], *Dr. Haidee Cadd* [1], *Dr. Emma Rehn* [2], *Mr. Alexander Wall* [3], *Ms. Jacqueline Wales* [1]

1. *ARC Centre of Excellence for Biodiversity and Heritage, School of Earth, Atmospheric and Life Sciences, University of Wollongong,* ***2.*** *College of Science and Engineering, James Cook University, QLD, Australia & ARC Centre of Excellence for Australian Natural and Cultural Heritage CABAH,* ***3.*** *Australian National University*

Engaging with local communities, schools, and other stakeholders is an increasingly crucial aspect of Quaternary Science research globally. Engagement comes in many forms, including ongoing discussions with all stakeholder groups surrounding permission and consent, as well as the active participation of communities in the processes of knowledge production. For successful engagement and a high level of participation, long-term partnerships, knowledge sharing, and informed consent need to be established for all groups involved. This includes effective communication of the goals, techniques, and outcomes of the research. However, this is often complex, such as when working in remote regions where communication with groups is limited, or in communities where different primary languages may reduce understanding. Science communication tools provide an opportunity to effectively communicate this information. Tools such as brochures, infographics, flyers, and websites can be used to visualise knowledge and methods with diagrams, maps, and photographs for local communities.

In Australia this is of particular importance where all research is occurring on unceded Indigenous lands and informed consent to undertake research is important, especially for important cultural and spiritual sites. The ARC Centre of Excellence for Australian Biodiversity and Heritage (CABAH) is working to develop a series of resources for science communication and engagement, including brochures, infographics, website links, and videos. CABAHs mission statement is to conduct culturally inclusive research and collaborate with local Indigenous communities. These resources aim to explain what, why, and how scientists perform work on Country, targeted at local communities and other stakeholders. This will help reduce the confusion and miscommunications that often surround this work to build informed consent, as well as encourage the participation of communities in research. Visual content explaining different aspects of the research undertaken by CABAH is essential to explain techniques and build informed consent for all groups. Many of these projects also aim to build knowledge and skillsets for communities by guiding groups through these activities via guides and videos on websites. Ultimately, both series aim to visualise science to create informed consent, build long-term partnerships, and encourage active participation of local Indigenous communities in Quaternary Science research in Australia.

Painted Stories of Norway Spruce Migratiion in Scandinavia

Dr. Laura Parducci **[1]**, ***Dr. Kevin Nota*** **[2]**, ***Dr. Jill Pelto*** **[3]**

1. *Department of Environmental Biology, Sapienza University of Rome,* ***2.*** *Department of Evolutionary Genetics, Max Planck Institute for Evolutionary Anthropology, Deutscher Platz 6, 04103 Leipzig, Germany,* ***3.*** *University of Maine*

How we as scientists communicate paleo-genetic-research can be complicated. Yet many people would be fascinated to learn more about ancient DNA studies: how DNA is carefully extracted and transformed to piece together Earth's relatively recent biological past. As this technique evolves, so does its capability to answer important questions about evolution, phylogeography and origin of species. Collaboration amongst natural science disciplines is a necessity to addressing the myriad of questions about Earth's history. Additionally, collaborating across other disciplines outside of the sciences can help to expose this research to broader audiences. Paleo-genetic-research has the power to capture human imagination by painting a picture of our past as a species. Therefore, utilizing that potential is a keyway to gain interest in and support of this type of research and art can be used to help illustrate graphical results, depict laboratory processes, or highlight the stories about the past we are uncovering. One method to doing so is to create artwork with effective visual narratives of Quaternary studies. In this presentation I will show results from our recent collaboration with artist and climate change scientist Jill Pelto who created five paintings depicting research and laboratory processes of a recent work done in Scandinavia using ancient DNA extracted from lake sediments.

InSAR surface deformation, geological structure and fault model of the 2019 Mirpur earthquake.

Mr. Divya Sekhar Vaka [1], *Dr. Tejpal Singh* [2], *Dr. Y. S. Rao* [1]

1. Centre of Studies in Resources Engineering, Indian Institute of Technology Bombay, Mumbai, 2. CSIR-Central Scientific Instrument Organisation, Chandigarh

The Himalayan Mountain belt is seismically very active due to the continued convergence between the Indian and Eurasian plates. The current active deformation is largely concentrated around the Main Front Thrust (MFT), where several moderate to high-magnitude earthquakes occur. In this work, we map the coseismic surface displacement of the 24 September 2019 Mirpur earthquake (M_W ~ 5.4) using ascending and descending pass LiCSAR data. The coseismic displacement maps indicate clear deformation lobes corresponding to uplift (+) and subsidence (-). The coseismic displacement ranges from +9.2 cm to -5.6 cm and +6.3 cm to -7.0 cm in ascending and descending passes, respectively. Visual inspection of the displacement maps did not reveal any evidence of a surface rupture. The two-lobe displacement pattern and the absence of surface rupture suggest the blind nature of the causative thrust fault. Spatially the uplift and subsidence areas correspond to the Mangla Samwal Anticline (MSA). The deformation extents in ascending and descending passes are marginally shifted relative to each other indicating minor horizontal motion due to the earthquake in addition to the predominant vertical motion.

The inversion of coseismic deformation was carried out using Steepest Descent Method (SDM). We also considered a structure model developed from regional geological information, remotely sensed imagery and published literature while inverting. It considered one, three, four, and six fault panels with varying dips. The length of the MSA is maintained at 7 km. The width, depth, and dip of the six panels are assumed according to the structure model. The six-segment model performed better than the other models indicating a data-model correlation of 0.82 and 0.94 with mean residual of 1.8 cm and 0.7 cm in ascending and descending passes, respectively. The inversion results suggest that the earthquake occurred at a depth of 6.1 km on a fault striking ~ 290°. The resultant maximum slip is 0.85 m, and the derived moment magnitude is Mw 5.8. In conclusion, it is inferred that geological considerations significantly improved the assessment of surface deformation and allowed a more consistent fault model.

Reassessing the oldest archaeological evidence of Colombia

Dr. Brunella Muttillo [1], ***Dr. Ettore Rufo*** [2], ***Prof. Roberto Lleras Pérez*** [3], ***Dr. Giuseppe Lembo*** [2]

1. *Dipartimento di Scienze Fisiche, della Terra e dell'Ambiente, Università degli Studi di Siena,* ***2.*** *Ministero dell'Istruzione e del Merito,* ***3.*** *Academia Colombiana de Historia, Bogotá*

Colombia is the gateway to South America, the first territory to be settled by the early humans moving from Central to South America. Despite its crucial role in the international debate on the first peopling of South America, the prehistory of Colombia is an under-researched field and the earliest human evidence remains controversial.

The scarcity and fragmentary nature of the earliest archaeological record, together with the presence of critical elements related to several sites, prevent a full and detailed comprehension of chronology, routes of dispersion and technology of the earliest hunter-gatherers of Colombia. Considering the almost absolute absence of anthropological remains for the most ancient period in Colombia, the study of lithic technology is an issue of primary importance because it is a clue to ancient dispersals, subsistence and adaptation strategies.

The early human settlement of Colombia is characterised by a widespread interregional technological and typological diversity in lithic assemblages, distinctive contemporaneous regional features and patterns, whose origins and interactions are still unclear. According to the available evidence, the early peopling of Colombia occurred during the final Late Pleistocene/Early Holocene (ca. 12,500 – 9,000 BP). More precisely, the oldest sites of Colombia (final Late Pleistocene) are located on the Andean highlands, precisely in the Sabana de Bogotá (Eastern Cordillera, ca. 2,600 m.a.s.l).

In this area the most important sites of the territory were discovered by the end of the 1960s/beginning of the 1980s: El Abra and Tibitó represent the reference sites not only for the prehistory of Colombia but also abroad, traditionally mentioned in any synthesis on the early human peopling of South America. Here we present a critical overview of the oldest archaeological evidence recovered in this area, the result of a multi-year revision work. Our results reveal several discrepancies and critical elements contained in previous studies, with repercussions, not only on the interpretation of the lithic industries but also on the chronology of the sites.

Techno-economic approach to early lithic industries of Fuego-Patagonia: dynamic interactions among culture, society and the environment at Finis Terrae (50º-56º South Latitude)

Dr. Flavia Morello [1], ***Dr. Consuelo Huidobro*** [2], ***Dr. Fabiana María Martin*** [3], ***Dr. Luis Alberto Borrero*** [4], ***Dr. Marianne Christensen*** [5], ***Dr. Marta Alfonso Durruty*** [6], ***Dr. Mauricio Massone*** [7], ***Dr. Ismael Martínez*** [7], ***Dr. Robert McCulloch*** [8], ***Dr. Claudia Mansilla*** [9], ***Dr. Jimena Torres*** [1], ***Dr. Victor Sierpe*** [1], ***Dr. Manuel san román*** [1]

1. *Centro de Estudios de Historia y Arqueología (CEHA), Instituto de la Patagonia, Universidad de Magallanes; Cape Horn International Center (CHIC),* ***2.*** *Departamento de Antropología, Facultad de Ciencias Sociales, Universidad Alberto HUrtado,* ***3.*** *Centro de Estudios de Historia y Arqueología, Instituto de la Patagonia, Universidad de Magallanes,* ***4.*** *Universidad de Buenos Aires e Instituto Multidisciplinario de Historia y Ciencias Humanas (IMHICIHU-CONICET), Buenos Aires,* ***5.*** *UMR 8068 TEMPS, Université Paris 1 Panthéon-Sorbonne,* ***6.*** *SASW Department, Kansas State University,* ***7.*** *Centro de Estudios de Historia y Arqueología (CEHA), Instituto de la Patagonia, Universidad de Magallanes,* ***8.*** *Centro de Investigación en Ecosistemas de la Patagonia (CIEP),* ***9.*** *Centro de Investigación GAIA Antártica, Universidad de Magallanes, Punta Arenas, Chile.*

The techno-economic approach used to study the early lithic materials from Fell cave and Cueva del Medio (c. 13.000 cal BP), in comparison with Holocene industries from Punta Santa Ana 1, Marazzi 1, Cabo Monmouth 20, Pizzulic 2 and others representing the oldest peopling of the western channels and archipelagos of Fuego-Patagonia are discussed. Three main axes are assessed: transport and interactions related to non-local raw materials; second, elaborated core reduction methods and débitage with predetermination (for example Levallois, bifacial shapping, blade and blade tendency reductions) as the action modes that can be related to complex processes of knowledge sharing and transmission; and functional analysis related to *chaine operatoires* and tool kit behaviour managements.

The comparison of spatial and chronological information related to these main axes of discussion allow us to move from general trends of macro-regional scale that display the existence of shared conceptions, as in an integrated, transmitted and generalized knowledge corpus for Fuego-Patagonia, to very specific understanding of tool kit strategies deployed at particular archaeological sites. Still a large range of techno-economic strategies are observed and better understood within multiple scales and degrees of interaction among human groups and paleoenvironments.

The results have direct rapport with the key role of the early marine nomads since c. 7000 cal BP and dynamics related to biogeographic barrier notions relative to the Strait of Magellan, for example. Thus, the existence of a common cultural background that transcends the terrestrial-maritime dichotomy and in-between group division (cfr. ethnic) is worthy of remark and discussion, as other sources of information as genetic, diet, bioanthropological, etc. The geographic and time distributions of lithic industries can be approached as measurable data changes regarding interaction intensity and adaptation, and general dynamic co-evolution among cultures, societies, and the environment.

This presentation is funded by grants: ANID/BASAL FB210018, FONDECYT 1190984, 1180272 & 11200857, and ECOS190041.

Early maritime peopling of the Pacific tundra and the first archaeological records from Brecknock Peninsula, Tierra del Fuego (54ºS/72ºW)

The maritime peopling of Fuego-Patagonia is framed by scenarios of significant change related to global eustatic processes that shaped the landscapes/seascapes and combined with regional dynamics of isostatic rebound, and tectonics, transformed this space into fully maritime environments c. 9,500 cal BP. This suggests that the available chronology for early marine human settlement may be biased by the effects of marine incursion, associated with the loss of emerged surfaces and potential archaeological evidence due to the erosive action of the sea and/or submerged landscapes, key issue for the discussion of initial peopling of South America. On the other hand, we propose that there are other types of biases associated with conceptual frameworks and interpretations that have ignored data that precedes the archaeological assemblages defined as the early expression of marine adaptations in this region. We consider two relevant axes of research: the first is anchored in the expansion of the geographical scale of survey, incorporating a broad insular area. Second, we propose the exploration of sectors that are now submerged, based on paleoenvironmental and geomorphological reconstructions that nourish and guide archaeological survey.

The first results of this research for early evidence of maritime peopling at the archaeological site Brecknock 1 are presented. Surveys at the southwestern extreme of the Fuegian archipelago, an area associated with hyperhumid Magellanic tundra environment, have rendered conditions of low to null archaeological visibility and the record of the earliest human occupations with c. 7,000 cal BP. The evidence is consistent with the idea of a wide range of geographic dispersion for marine hunter-gatherer populations with navigation media. The findings suggest circuits of long-distance human mobility, supported by elements such as obsidian lithics. Also, results show that preservation conditions of organic elements, except for periostracum and charcoal, have obliterated most of the archaeological record. In other words, it is a search for evidence with little or no preservation of shells, bones and hard animal materials.This presentation is funded by grants: ANID/BASAL FB210018, FONDECYT 1211976.

Can we use geochemical signals to link tsunami deposits and seismo-turbidites in a coastal lake system? First results from Lakes Cucao and Huillinco (northern Chilean Patagonia)

A main challenge in subduction zone paleoseismology is the evaluation of event synchronicity across sites. This is due to age uncertainties of paleo-tsunami, paleo-rupture and paleo-shaking events which are typically in the order of decades/centuries. Therefore, it is difficult to robustly reconstruct the along-strike rupture length and downdip location of megathrust ruptures.

Here we study a coastal lake system on Chiloé Island (northern Chilean Patagonia) and test whether we can stratigraphically link (published) tsunami deposits in coastal Lake Cucao with a new seismo-turbidite record from the connected lake Huillinco. Lake Cucao is separated by a ~1.1 km wide barrier from the ocean and holds a 4.2 kyr record of past tsunamis in the form of sandy clastic deposits within organic-rich mud. Tsunami inundation is facilitated by a river channel connection, which at present is an active tidal channel due to coseismic subsidence of the giant 1960 earthquake (M_W 9.5). However, its past role is unclear. Lake Huillinco is located 2 km farther inland of and is deeper (47 m vs 25 m) than Cucao, which makes it ideal for recording turbidites induced by seismic shaking. The lakes share their lake level and are connected by a narrow and over-deepened river channel.

For correlating the sedimentary records, we trace geochemical signals in the organic-rich background sediments by using high-resolution XRF scanning, TOC, C/N and C/S. XRF scanning data is processed by PCA and cluster analysis in the center-log ratio space. Some of the inferred geochemical signals are interpreted as the result of marine inundations by tsunamis and/or following coseismic subsidence, leading to a trapped saline water body in Huillinco. This leads to a strong water column stratification and anoxic bottom water conditions, allowing varve formation for a few decades following the events. To better understand the geochemical signature in the sediments, we also studied the transient nature of the post-1960 saline water body by comparing water-column data of a study in 1997 and our survey in 2022. Our approach bears the potential of directly linking past evidence of seismic shaking, tsunami and maybe coastal elevation changes within a single chemo-stratigraphic framework.

A continued long history of earthquakes and Chilean lakes

In recent years, a wealth of lacustrine paleoseismic studies has emerged around the world, providing often long and highly-sensitive shaking records. These are particularly powerful in regions where more traditional paleoseismic techniques such as trenching or reconstructions of land-level changes are not feasible, or cannot completely and reliably grasp the manifold of seismic hazards that exist in these settings. In this respect, the south-central Chilean subduction zone has been extensively studied, resulting in the identification of sedimentary shaking imprints in no less than 20 lakes and fjords. Correlation of these records and integration with other coastal paleoseismic and -tsunami archives provided qualitative estimates of the recurrence mode for different types of rupture sources, notably for megathrust earthquakes. Full-segment ruptures, like the M_W 9.5 1960 Valdivia earthquake, occurred repeatedly in the last two millennia. Additionally, numerous partial ruptures and a rupture cascade have been identified alongside a notable seismic quiescence of ~400 years. Long shaking records are however still lacking in a large portion of the along-strike extent of this subduction zone segment, resulting in a knowledge gap of over 600 km long and thus often ambiguous cross-correlations. Also, quantitative estimations of the timing and spatial extent of these events are still lacking due to large uncertainties. These arise from inconsistencies in the applied dating techniques, variable age precision, and the mostly unclear relationship between depositional earthquake imprints and rupture characteristics. The new '*QuakeScene Chile*' project aims to push the frontiers of subduction-zone paleoseismology by i) retrieving additional records from several lakes in the Chilean lake district and on Chiloé Island to fill the knowledge gap, ii) developing a new chronological toolbox to improve synchronicity assessment between different sites and archives, and iii) applying ground-motion modelling to establish the missing link between sedimentary shaking evidence and seismological earthquake parameters. We present an overview of past and ongoing work within the framework of this project.

Hydroacoustic and bathymetric data of the Japan Trench collected during IODP Expedition 386

Prof. Myra Keep [1]***, Dr. Arata Kioka*** [2]***, Prof. Michael Strasser*** [3]***, Dr. Ken Ikehara*** [4]***, Dr. Jeremy Everest*** [5]***, Dr. Lena Maeda*** [6]

Expedition 386 “Japan Trench Paleoseismology” (13th April-1st June 2021) collected giant piston cores, hydroacoustic data and high-resolution bathymetry from 11 trench-fill basins along the Japan Trench. Cores were collected in water depths of 7,445-8,023 m below sea level.

The objectives of Expedition 386 were to: (1) Identify the sedimentological, physical, chemical, and biogeochemical proxies of event deposits in the sedimentary archive that allow for confident recognition and dating of past MW 9 class earthquakes; (2) explore the spatial and temporal distribution of such event deposits to investigate along-strike and time-dependent variability of sediment sources, transport and deposition processes, and stratigraphic preservation; and (3) develop a long-term earthquake record for giant earthquakes.

The cruise collected bathymetry and 575 line kms of sub-bottom profiles (as grids) in the 11 basins. Preliminary observations indicate that northern Japan Trench basins have a different bathymetric and hydroacoustic character to the central and southern Japan Trench basins. Bathymetric character in the northern basins is more diffuse than in basins in the central and southern areas, which tend to have sharp topographic ridges bounding the basins to the east and west. The northern basins also tend to have thick (>10m) packages of acoustically transparent materials forming marker horizons between basins, whereas the central and southern basins tend to have thinner, isolated acoustically transparent layers. Evidence of faulting is preserved in one of the northern basins, and there are some interesting relationships between basal highs and basin fill that indicate fluid mobilization.

Work is ongoing in correlating our data to the piston cores of upper Pleistocene to Holocene stratigraphic successions. Preliminary results reveal several potential giant earthquake-related event beds.

Relative sea-level (RSL) changes in northwest America (from British Columbia to Oregon) are influenced by both glacial isostatic adjustment (GIA) and earthquake cycles, on timescales of decades to millennia. Those processes are crucial to understanding the drivers of RSL changes temporally and spatially, because the region sits close to the North American ice sheet complex (Cordilleran and Laurentide ice sheets) of the last glacial period and is home to a convergent plate boundary (the Cascadia subduction zone). Here, we focus on the signal from earthquake cycles.

To study the contribution of earthquake cycles to RSL changes, a geodynamic model which can accurately simulate the vertical deformation throughout a cycle is needed. In this study, we aim to reproduce the coseismic, postseismic and interseismic deformation after the 1700 Cascadia megathrust earthquake with a 3-D viscoelastic finite-element model, which includes a realistic subduction zone geometry, realistic mechanical properties (elastic, viscous, and frictional), and heterogenous rupture patterns. Model-predicted interseismic deformation (both vertical and horizontal) is compared to contemporary geodetic observations to evaluate model performance and constrain its mechanical properties.

This study not only serves as a stepping stone to quantify earthquake cycles' contribution to RSL changes on the longer timescales, but it also provides a tool to potentially tackle earthquake-cycle-related problems (e.g., determination of earthquake recurrence intervals and rupture patterns) at subduction zones.

Testing the hypothesis of a nonpersistent rupture boundary at Sitkinak Island, Alaska.

Spatial and temporal patterns of megathrust ruptures prior to the 20th century remain unclear. Geological approaches using coastal sediments provide alternative means for constraining the chronology and characteristics of earthquakes over millennial timescales. Sharp lithological contacts indicating rapid changes in environment are key indicators of vertical land-level changes. Extensive palaeoseismic research has been conducted along the Alaska-Aleutian subduction zone in the eastern extent of the great 1964 (M_W9.2) rupture, and recent reconnaissance investigations southwest of Kodiak Island have begun to illuminate patterns of deformation including the possibility of nonpersistent rupture boundaries. At Sitkinak Island, southwest of Kodiak Island, observations by eyewitnesses during the 1964 rupture have been interpreted to suggest uplift on the northeast coast, while palaeoseismic evidence suggests subsidence in the southwest. This difference and variations in uplift and subsidence from palaeoseismic records prior to 1964 at the south lagoon have been interpreted as evidence of a nonpersistent rupture boundary where subsidence is interpreted to record ruptures arresting close to Sitkinak Island, and uplift indicates rupture through the boundary between the Kodiak and Semidi sections. Coastal geomorphology also hints at longer term differences between the coasts, with evidence of coastal marsh submergence on the southwestern side of Sitkinak Lagoon and emergence on the northeastern side. To further test the nonpersistent rupture boundary hypothesis, we present two sediment cores (~1.3 m) collected from a ~350m bank exposure at the northern lagoon. Sedimentology of the section reveals alternating peat and silt units that may indicate land-level changes from prehistoric earthquakes as well as tephra deposits that may aid in correlations. The peak in Cs^{137} occurring in AD 1963 is recorded in the sediments. This suggests that the record captures 1964, although there is no clear stratigraphic evidence for co-seismic uplift or subsidence associated with this earthquake at the site. Eight new radiocarbon dates indicate that the site dates to 2340-2433 cal yr BP. Additional microfossil, geochemical, and sedimentological analysis will be conducted to understand the deformation history of the northern coast of Sitkinak Island over the past ~2500 years and compare it to the existing palaeoseismic record ~6 km southwest.

Geological evidence of an unreported Chilean tsunami highlights the importance of combining geological and historical records in tsunami hazard assessment

***Dr. Emma Hocking* [1], *Dr. Ed Garrett* [2], *Dr. Diego Aedo* [3], *Dr. Matías Carvajal* [4], *Dr. Daniel Melnick* [5]**

Núcleo Milenio CYCLO, Valdivia, Chile

Assessing seismic and tsunami hazards commonly relies on historical accounts of past events. While such chronicles are often too short to account for variability in earthquake size, rupture style, tsunamigenesis and the existence of supercycles, even where long written histories exist, records may be biased by temporal gaps due to historical circumstances. We demonstrate that this is the case for the area affected by the magnitude 9.5 1960 Chile earthquake. Historical records document four great earthquakes (M8+) in the last 450 years in this region, but while devastating tsunamis are known to have accompanied earthquakes in 1575, 1837 and 1960 CE, there is no such record of inundation in 1737. The lack of reports of tsunami inundation from the 1737 south-central Chile earthquake has been attributed to either civil unrest or a small tsunami due to deep fault slip below land. Here we cross-check the historical record using a coastal sedimentary record from Chaihuín, a tidal marsh 15 km southwest of Valdivia, close to the region of maximum 1960 slip. Tidal marshes are low energy intertidal settings that may preserve evidence for abrupt co-seismic changes in land level and inundation by extreme waves. We conduct sedimentological and diatom analyses of tidal marsh sediments within the 1737 rupture area and find evidence for a locally-sourced tsunami consistent in age with this event. The evidence is a laterally-extensive sand sheet coincident with abrupt, decimetric-scale subsidence. Coupled dislocation-tsunami models place the causative fault slip mostly offshore rather than below land, as had previously been assumed from the absence of historical accounts of a tsunami. Whether associated or not with the 1737 earthquake, our findings reduce the average recurrence interval of tsunami inundation derived from historical records alone, highlighting the importance of combining geological and historical records in order to obtain robust long-term patterns to inform seismic and tsunami hazard assessment.

Submarine Landslide Controls and Outer Wedge Variations in the Negros–Sulu Trench System, Philippines

Mr. Lyndon Jr Nawanao [1], ***Dr. Noelynna Ramos*** [1]

1. Geomorphology and Active Tectonics Research Laboratory, National Institute of Geological Sciences, University of the Philippines Diliman, Quezon City, Philippines

Many catastrophic earthquakes and tsunamis have occurred along active trenches, and some of these tsunami events were found to either be amplified or induced by earthquake-triggered submarine landslides. In the Philippines, one of the less-recognized active subduction zones is the Negros–Sulu Trench System (NSTS) in the Sulu Sea that is capable of generating strong earthquakes and tsunamis. In this study, we characterized the outer wedge variations in the forearc margin of the NSTS and delineated submarine landslides and their morphometric parameters, submarine canyons, and lineaments. Terrain and morphometric analyses were performed using 20-m resolution local bathymetry data to delineate these submarine features. Lineaments are mainly distributed along the outer wedge, in which previous seismic profiles revealed thrusted sediments and high-angle reverse faults. The NSTS is divided into four segments based on orientation and width variations of the outer wedge. Heterogeneous sediment influx, convergence rates, and subduction processes are inferred to influence these variations. With more than 1,200 submarine landslides delineated, the L function suggests significant clustering at various distances, indicating heterogeneity and underlying geological and geomorphological controls. Matrix correlations of kernel density bands indicate that submarine canyons strongly influence the occurrence of submarine landslides as these conduits of terrestrial sediments induce rapid loading that preconditions slope failures. Getis-Ord Gi* reveals significant localized clusters of large- and small-volume submarine landslides and those with high and low length-to-width ratios (L/W). Regions with significantly low volume and high L/W occur in submarine canyon systems, whereas those with low L/W often occur along the outer wedge and abyssal plain. Significantly large-volume submarine landslides are clustered in various areas but are generally found on steeper slopes and at relatively deeper portions than those with significantly small volume. Oversteepening of the outer wedge due to seamount collision of the Cagayan Ridge is interpreted to induce the large-volume submarine landslides clustered in the northern Negros Trench segment. This new information on the spatial distribution and controls of submarine landslides in the NSTS is essential in hazard assessment of coastal areas susceptible to tsunamigenic submarine landslides.

Shaking-induced lake processes identify a previously unrecognized earthquake-triggered carbon sink and suggest potential use as paleoseismograms

Dr. Ann E. Morey Ross [1]

1. Cascadia Paleo Investigations

Recent research on the historic portion of the sedimentary record from a small lake near the California/Oregon border reported micron-scale sedimentological changes through disturbance deposits allowing them to be attributed to floods, an inslab or crustal earthquake, and a subduction earthquake. Changes through the earthquake deposits suggest that lake processes in response to ground motions can be identified from these sedimentological characteristics. Whereas the inslab or crustal earthquake, interpreted as a ~M7 from historic felt reports, caused the landslide dam to fail as represented by lake-wide slope failure deposits, the subduction earthquake, interpreted as a ~M9 based on paleoseismic evidence and historic data, resulted in a deposit interpreted to be the result of liquefaction. Evidence also suggests that sustained ground motions from the subduction earthquake resulted in flocculation of organics in the water column, producing a long organic-rich tail , a previously unknown earthquake-triggered carbon sink in lakes. This presentation summarizes how these lake processes can be used to bracket earthquake ground motions to better understand the spatial pattern of ground motions, and potential hazards, at inland locations throughout Cascadia where the hazard potential is greatest.

Recognizing megatsunamis in Mediterranean deep sea sediments based on the massive deposits of the 365 CE event

Dr. Alina Polonia [1]***, Prof. C. Hans Nelson*** [2]***, Prof. Stefano C. Vaiani*** [3]***, Dr. Ester Colizza*** [4]***, Prof. Giorgio Gasparotto*** [3]***, Dr. Giulia Giorgetti*** [1]***, Prof. Carla Bonetti*** [5]***, Dr. Luca Gasperini*** [6]

1. *CNR-ISMAR Bologna,* ***2.*** *CSIC, Instituto Andaluz de Ciencias de la Tierra, Granada, Spain,* ***3.*** *Department of Biological, Geological and Environmental Sciences, University of Bologna,* ***4.*** *Department of Math and Geosciences, University of Trieste,* ***5.*** *Universidade Federal de Santa Catarina, Florianopolis, Brazil,* ***6.*** *CNR - ISMAR*

The Mediterranean Sea hosts two subduction systems along the convergent Africa-Eurasia plate boundary that have produced strong ground shaking and generated tsunamis. Based on historical descriptions and sedimentary records, one of these events, in 365 CE, impacted a broad geographical area, including tsunami evidence for distances of 700-800 km from the source event, qualifying it as a ‘megatsunami’. Understanding how megatsunamis are produced, and where they are more likely, requires a better understanding of the different secondary processes linked to these events such as massive slope failures, multiple turbidity current generation, and basin seiching.

Our sedimentary records from an extensive collection of cores located in distal and disconnected basins, identify turbidites which are analyzed using granulometry, elemental (XRF), micropaleontological, and geochemical data in order to reconstruct their coastal or marine source. The depositional units of the 365 CE event, when viewed across multiple geomorphological locations of the marine depositional sites (canyon mouth, abyssal, isolated higher basin), demonstrate a complex sequence of processes triggered by the megatsunami wave propagation.

The 365 CE basin floor sediments are a mixture of inner shelf and slope materials implying that the tsunami wave produced multiple far-field slope failures that resulted in stacked basal turbidites. The sediment from the European and African margins was remobilized and transported by tsunamis to abyssal depositional sites and isolated basins during the catastrophic event. Sediment content from terrestrial and coastal sources, as shown by C/N and $\delta^{13}C_{org}$ data and abundant shallow water components in isolated basins, indicates that tsunami backwash or tsunami triggered slope failure processes entrained coastal/inland sediment and transported it into the deep sea even in the absence of canyons, probably through large-scale sheet-like flows. The tsunamigenic origin of the deposit is supported by coastal effects of the 365 CE Crete tsunami because resedimented deposits, erosional features and transported boulders with similar age, are reported around the Mediterranean Sea.

This is significant for rectifying and resolving where risk is greatest and how cross-basin tsunamis are generated. Based on these results, estimates of the underlying deposits from the same locations were interpreted as possible older megatsunamis.

Is rapid climate warming causing hypolimnetic anoxia in lakes? Exploring the climate-anoxia link in the Late-Glacial sediments of Soppensee, Switzerland

Mr. Stan J. Schouten [1], ***Dr. Petra Zahajská*** [1], ***Dr. Paul D. Zander*** [2], ***Dr. Luyao Tu*** [3], ***Prof. Martin Grosjean*** [1]

1. Institute of Geography & Oeschger Centre for Climate Change Research, University of Bern, Bern, Switzerland, 2. Climate Geochemistry Department, Max Planck Institute for Chemistry, Mainz, Germany, 3. College of Marine Science and Engineering, Nanjing Normal University, Nanjing, China

Recently, many lakes transitioned into stratified eutrophic systems due to nutrient additions from their catchments. Associated hypoxia typically deteriorates lake water quality, threatening aquatic ecosystems and water resources. Often, hypoxia and anthropogenic eutrophication interact in a positive 'chemical feedback' in which eutrophication-induced hypolimnetic anoxia prompts internal phosphorous (P)-loading which, in turn, sustains eutrophication. It is poorly understood whether this 'chemical feedback' also operated under natural pre-anthropogenic conditions and to what extend such events were reversible.

We test the existence of a pre-anthropogenic chemical feedback in well-studied Soppensee, a postglacial kettle-hole lake in Switzerland. Here, the Bølling warming (~14,700 cal. yr b2k; GI-1*e*) prompted an event with hypolimnetic anoxia. We investigate the sequence of biogeochemical lake responses –eutrophication, hypolimnetic anoxia, dynamics of algal communities, nutrient cycling, and chemical feedback – throughout Greenland Interstadial GI-1*e* which ended by abrupt cooling in the Older Dryas (~14,080 cal. yr b2k).

Our methods include XRF (elemental composition), hyperspectral imaging (bulk sedimentary pigments), HPLC (specific sedimentary pigments) and sequential extraction of phosphorous. We interpret total chlorophylls and diagenetic products (TChl) as a proxy for aquatic productivity and bacteriopheophytins (Bphe-*a,e*, purple and green sulphur bacterial biomarkers) as a proxy for hypolimnetic anoxia and (semi)-permanent lake stratification. The Redox-labile Fe-P preserved in sediment is a qualitative indicator for reductive dissolution of Fe-(oxyhydr)oxide bound P and internal P-cycling.

Preliminary results show that, before the Bølling, TChl, Bphe and all phosphorous fractions were low, suggesting oligotrophic well-mixed conditions. With the beginning of the Bølling warming, we observe an immediate increase of TChl with strong eutrophication. With a delay of a few years, Bphe-*a,e* peaked and permanent stratification with hypolimnetic anoxia was established. All sedimentary P fractions remain low suggesting that P is mainly recycled. After the warm Bølling (~700 years, ending in the Older Dryas cooling), eutrophication and lake stratification broke abruptly, and sedimentary Fe-P and Ca-P concentrations increased simultaneously. Although less pronounced, this cycle repeated in the Allerød, suggesting that past anoxia events were partly reversible. In our case study, we conclude that the eutrophication-anoxia chemical feedback also operated in Late-Glacial times and was triggered by rapid climate warming.

Synchronizing the Western Gotland Basin (Baltic Sea) and Lake Kälksjön (central Sweden) sediment records using common cosmogenic radionuclide production variations

Dr. Markus Czymzik [1]***, Prof. Achim Brauer*** [2]***, Dr. Marcus Christl*** [3]***, Dr. Olaf Dellwig*** [1]***, Dr. Markus J. Schwab*** [2]***, Dr. Daniela Müller*** [2]***, Dr. Jerome Kaiser*** [1]***, Dr. Carla Nantke*** [1]***, Prof. Raimund Muscheler*** [4]***, Prof. Helge Arz*** [1]

1. *Leibniz Institute for Baltic Sea Research Warnemünde - IOW, Marine Geology, Rostock, Germany,* ***2.*** *GFZ - German Research Centre for Geosciences, Climate Dynamics and Landscape Evolution, Potsdam, Germany,* ***3.*** *ETH Zurich, Laboratory of Ion Beam Physics, Zurich, Switzerland,* ***4.*** *Lund University, Department of Geology, Lund, Sweden*

Multi-archive studies of leads and lags in the climate system, as well as archive-specific thresholds require synchronous time-scales. Aligning common variations in short-term cosmogenic radionuclide production via curve fitting methods provides a tool for the synchronization of natural environmental archives. Based on this approach, we synchronize ^{10}Be records from brackish Western Gotland Basin (WGB, Baltic Sea) and Lake Kälksjön (KKJ, central Sweden) sediments to the ^{14}C production rate time-series inferred from the IntCal20 calibration curve during the period ~6400 to 5200 a BP. Before the synchronization, we assess and reduce non-production variability in the ^{10}Be records using ^{10}Be/^{9}Be ratios and common variability with the significantly correlated TOC record from KKJ sediments based on regression analysis.
The synchronizations to the IntCal20 ^{14}C production time-scale perform decadal to multi-decadal refinements to the WGB and KKJ chronologies. These refinements place the investigated WGB and KKJ sediment records on the IntCal20 ^{14}C time-scale and reduce the previously centennial-scale chronological uncertainties between both records to about ± 20 years. Placing the WGB and KKJ sediment records on one time-scale with minimized chronological uncertainties opens the possibility for the investigation of possible time-transgressive environmental changes in the marine-terrestrial Baltic ecosystem, with high temporal precision.

Using a multiproxy approach to interrogate the terrestrial impacts of the Laschamps geomagnetic excursion (ca. 41 ka BP) at Ioannina, NW Greece.

Ms. Megan Edwards [1], ***Dr. Amy McGuire*** [1], ***Dr. Alistair Seddon*** [2], ***Dr. Tim Heaton*** [3], ***Prof. Edouard Bard*** [4], ***Prof. christine lane*** [5], ***Prof. Chronis Tzedakis*** [6], ***Dr. Natasha Barlow*** [1]

The palaeoenvironmental archive at Lake Ioannina presents an important opportunity to study vegetation responses to past changes, including climatic variability and changes in the Earth's systems. A new, high-resolution pollen study between 46 and 40 ka BP reveals vegetation changes in response to climate variability on millennial timescales. Overprinting this climatic variability is an abrupt, sub-centennial, disturbance event dated to ca. 41.5 ka BP. Here, we utilise a decadally-resolved, multiproxy reconstruction to identify potential drivers of this vegetation disturbance event at Ioannina. Through study of pollen geochemistry, we reconstruct changes in terrestrial UV-B between 46 and 40 ka BP to see if the collapse in tree populations observed at Ioannina is related to changes in the Earth's magnetic field intensity associated with the 41 ka BP Laschamps geomagnetic excursion. Additionally, we use detailed micro and macro-charcoal analysis to determine whether simultaneous changes are observed in the fire regime at the site. Finally, we present the results of diatom analysis to reconstruct changes in the hydrological system to rule out a local climatic or hydrological driver for the vegetation disturbance. Through our detailed study, we aim to provide some of the first insights into the environmental response to changes in strength of the Earth's magnetic field around the timing of the Laschamps excursion, and potential subsequent impacts on human life.

Warm Younger Dryas summer temperatures in the South Carpathians

***Mr. Zoltán Szabó* [1], *Dr. Oliver Heiri* [2], *Dr. Sabine Wulf* [3], *Dr. Gabriella Darabos* [1], *Ms. Ivett Pálfi* [1], *Dr. Mihály Molnár* [4], *Dr. János Korponai* [5], *Prof. Enikő Magyari* [1]**

1. *ELTE Eötvös Loránd University, Institute of Geography and Earth Sciences, Department Environmental and Landscape Geography, Budapest H-1117, Hungary,* ***2.*** *University of Basel,* ***3.*** *School of the Environment, Geography and Geosciences, University of Portsmouth, Portsmouth, United Kingdom,* ***4.*** *Isotoptech Zrt - ATOMKI, Debrecen,* ***5.*** *Department of Water Supply and Sewerage, Faculty of Water Science, National University of Public Service, 6500 Baja, Bajcsy-Zs. str.12-14. Hungary*

Assessment of Late Glacial (LG) summer climate change suggests that the south-eastern part of the European continent experienced lower amplitude summer temperature fluctuation during stadial-interstadial transitions in comparison with NW Europe. In this study we present a new LG and Early Holocene summer temperature record based on fossil chironomid assemblages. The study site, Lake Latoritei (Pareng Mountains, 1530 m a.s.l.) was analysed at high resolution for chironomid and other paleoecological indicators. Using the joint Norwegian – Swiss transfer function, the reconstructed chironomid-inferred temperature pattern shows some differences from the NGRIP $\delta^{18}O$ record and other European chironomid-based reconstructions; however, it is consistent with the chironomid results of Lake Brazi (Retyezat Mountains, 1740 m a.s.l.). Summer air temperature at Lake Latoritei increased by ~ 3°C at the Oldest Dryas/Bølling transition (GS-2/GI-1) and reached 8.1-10.8°C during the LG interstadial. The Younger Dryas (GS-1) climate reversal is shown by only a weak decrease (~1 °C), while a slow temperature increase (9.7–11 °C) is observed in the second half of the period. We also performed cryptotephra analysis for the GI-1-GS-2 period showing that the region was reached by the ash fall of the Vedde Ash eruption (12,140 ± 40 cal BP), as well as by several unknown tephra. In other European sections, where the Vedde Ash eruption was found, the onset of the YD summer mean air temperature decline started at ~12,710 cal BP (Lake Kråkenes, Norway), at ~12,650 cal BP (Soppensee, Switzerland), at ~12,730 cal BP (Lake Bled, Slovenia), while in our record the chironomid-based T_{July} decline is dated to 12,500 cal BP. However, the old age effect detected during radiocarbon dating caused large uncertainties in the determined ages. At the Holocene transition a T_{July} temperature increase of ~2 °C was observed within 50 years. Prior to the Preboreal Oscillation (PBO), the mean summer air temperature was 12.5 °C. During the PBO, the temperature reconstruction shows a decrease of 1.8 °C. This cold event coincides with cooling in the Greenland ice core records and other European temperature reconstructions. Following the PBO, summer air temperatures increased to ~12.8 °C in the Early Holocene.

Assessment of the effect of soil salinity on bacterial diversity and community structure in a semi-arid area of Northern Tunisia

Mr. Mohamed Mdaini [1], ***Ms. Oumayma Hmidi*** [2], ***Dr. Eva Lloret*** [1], ***Dr. Nadhem Brahim*** [2], ***Prof. Raúl Zornoza*** [1], ***Prof. Najet Shimi*** [2]

1. *Universidad Politécnica de Cartagena,* ***2.*** *1. Department of Geology, University of Tunis El Manar, 2092, El Manar, Tunis, Tunisia*

Due to climate change, water resources in many regions have reached their natural limits, resulting in environmental and socio-economic problems such as agricultural drought and soil salinization. Therefore, soil salinization is likely to increase further in irrigated perimeters in arid and semi-arid areas worldwide. However, soil is a dynamic system whose functionality is related to the relationships between physicochemical properties and soil microorganisms. Most studies are limited to the top 30 cm of soil, but few works have been made about this topic in soil depth, particularly in semi-arid regions. This study aims to assess the effect of soil salinity on the bacterial community structure in upper and deeper soil horizons from an agricultural land in Northern Tunisia dedicated to apple and pear growth.

Twenty-three samples from the soil surface (0-10 cm) and subsurface (30-50 cm) were randomly taken in the study area. The study site is in the lower Medjerda River valley basin, Manouba, Tunisia, and is characterized by Quaternary deposits composed of sand and clay. Results showed that electrical conductivity ranged in soil from 0.6 mS. cm-1 and 5.0 mS. cm-1, pH ranged between 7.9-8.7, and soil organic C between 0.59-2.85 %. There were differences in the diversity and relative abundance of bacteria in the topsoil and deeper soil layers, assessed by DNA metabarcoding. Bacterial community was strongly related to soil physicochemical properties, including soil salinity.

Thus, studying the interrelationships between soil physicochemical properties and soil microorganisms could be an effective tool to understand the dynamics of microorganisms, and to determine the mechanisms of their adaptation to soil salinity.

Geochemical characterisation of tephra to improve marine, terrestrial and ice core chronologies in Antarctica

Ms. Anjali Dhunna [1]***, Prof. Simon Blockley*** [2]***, Dr. Bethan Davies*** [3]***, Dr. Stephen Roberts*** [4]***, Dr. Liz Thomas*** [4]***, Prof. Dominic Hodgson*** [5]

1. *Royal Holloway, University of London,* ***2.*** *Department of Geography, Royal Holloway University of London, London, United Kingdom,* ***3.*** *Newcastle University,* ***4.*** *British Antarctic Survey (BAS), Natural Environmental Research Council (NERC), High Cross, Madingley Road, Cambridge CB3 0ET, UK.,* ***5.*** *British Antarctic Survey*

Global compilations of paleoclimatic change currently exhibit a northern hemisphere bias. This challenges our ability to use these datasets to validate, evaluate and calibrate models of past climate change and to understand regional to hemispheric patterns of atmospheric and oceanic circulation changes. Antarctic paleo records have made significant contributions to understanding past changes in atmospheric CO2, temperature, ice sheet thickness and extent as well as ocean dynamics. Linking these changes and investigating leads and lags across ice, marine, lake and terrestrial records requires well-defined chronological reference points such as discrete tephra, produced by significant volcanic eruptions.

Whilst tephrochronology has been applied to a variety of Antarctic records, few studies systematically cross-correlate tephra across lacustrine, marine and ice core records in this region. This project aims to form a tephrochronological framework for Antarctica using numerous cores extracted from these environments and improve the chronologies of proxy temporal records of past climate change from the Antarctic Peninsula and the Sub-Antarctic Islands in the Southern Ocean.

We will identify suitable records for tephrochronology by scanning through cores and identifying peaks of tephra and undertake geochemical analyses using EPMA and LA-ICP-MS techniques for shard-specific chemical assay. Correlation of geochemical signatures of the tephra peaks will be conducted using reference material from known eruptions and deposits to build a tephrostratigraphic framework.

Integrated stratigraphy of the NDT-09 marine record: a ~15 ka-long depositional history in the epiclastic-volcanoclastic domain of the Marsili Basin (southern Tyrrhenian Sea)

***Dr. Luca Bellucci* [1], *Dr. Sergio Bonomo* [2], *Ms. Laura Bronzo* [3], *Prof. Antonio Caruso* [4], *Dr. Antonio Cascella* [5], *Dr. Annamaria Correggiari* [1], *Dr. Alessio Di Roberto* [5], *Dr. Donatella Insinga* [6], *Prof. Fabrizio Lirer* [7], *Dr. Renata Lucchi* [8], *Dr. Giulia Margaritelli* [9], *Dr. Stefano Miserocchi* [1], *Prof. Maurizio Petrelli* [10], *Dr. Bianca Scateni* [5], *Dr. Alessandra Smedile* [11], *Dr. Patrizia Macrì* [11]**

***1.** CNR-ISMAR, Via Gobetti 101, I-40129 Bologna, **2.** Consiglio Nazionale delle Ricerche, Istituto di Geologia Ambientale e Geoingegneria (IGAG), **3.** Department of Earth Sciences, University of Florence, **4.** Dipartimento di Scienze e Tecnologie Biologiche, Chimiche e Farmaceutiche, Università di Palermo, Italy, **5.** Istituto Nazionale di Geofisica e Vulcanologia (INGV), **6.** CNR-ISMAR, Napoli., **7.** Department of Earth Sciences of Sapienza University of Rome, **8.** National Institute of Oceanography and Applied Geophysics OGS, **9.** Consiglio Nazionale delle Ricerche, Istituto di Ricerca per la Protezione Idrogeologica (IRPI), **10.** Department of Physics and Geology, University of Perugia, **11.** Istituto Nazionale di Geofisica e Vulcanologia, Rome (Italy)*

This research presents preliminary results obtained from an integrated stratigraphic study of core NDT-09, carried out in the frame of INGV-AMUSED (*A MUltidisciplinary Study of past global climatE changes from continental and marine archives in the MeDiterranean region*") project activities. The core was recovered by CNR-ISMAR (former IAMC) during the oceanographic cruise NextData2016 in the western rim of the Marsili Basin at a water depth of 3359 m. The succession is 5,7 m long and it is characterized by hemipelagic mud sediments frequently interrupted by primary and secondary tephra deposits along with turbidites. The record has been studied by means of micropaleontology (calcareous nannoplankton, planktonic and benthic foraminifera), sedimentology, petrophysics, paleomagnetism and geochemistry (X-Ray Fluorescence, cosmogenic radionuclides, oxygen isotope). The chronological framework is provided by ^{14}AMS datings and tephrochronology (macro- and cryptotephra). The occurrence of the Neapolitan Yellow Tuff related tephra dates the bottom of the succession at ca.15 ka, whereas the decrease of the abundance of *Emiliania huxleyi* >4 µm at 480 cm and the increase of *Florisphaera profunda* at 430 cm indicate the onset of the Holocene interstadial period. The stratigraphic approach allowed us to "integrate" all the obtained data, to combine proxies (eg. total coccolith abundance vs Ca/Fe and Ca/Ti profiles to identify low and high detritic inputs) and to define a sequence of depositional events along the record. This latter is characterised by a prevailing epiclastic-volcanoclastic sedimentation (locally exclusive) due to the significant influx of deposits from the Aeolian Arc, the Neapolitan volcanoes and Ischia Island. Chemistry of single glasses of volcanic turbidites, in particular, reveals a homogenous trachytic to latitic composition, typical of distinctive Campi Flegrei products, thus suggesting a recurrent reactivation of flow transport from a single or multiple source areas.

The Holocene and terminal Pleistocene tephrochronological record from annually resolved lakes in East Anglia: implications for the integration of palaeoclimate, palaeoenvironmental and archaeological records in the North Atlantic and Northwest Europe

Tephrochronology has become a key tool in the synchronisation of a range of palaeo-records, from past climate to archaeology. Much of the work on lake records has mostly focussed on the last glacial period but recently several lake records, some of them annually laminated, have started to show the potential for far travelled tephra to be a key tool in the synchronisation of Holocene records in the North Atlantic and Northern European realm. This builds on the long history of analysing peat sequences in areas such as Scotland and Northern Ireland. Here we present a complete tephrostratigraphic record for the whole Holocene and end of the Last Glacial from East Anglia, along with a complete Holocene Bayesian age model for a critical varved lake record from the region, Diss Mere, Norfolk. This region has demonstrated that it is pivotal for understanding the potential for tephra dispersal from multiple volcanic sources across Northwest Europe and the North Atlantic, as it receives tephra from multiple volcanic sources. We present a total of 11 new tephra from the late Holocene and the terminal Pleistocene from Diss and other sites in the region, to add to the currently published tephra record from Diss. This takes the Holocene tephra record of East Anglia to 28 tephra (all but one of which has been found in Diss among other sites), all successfully correlated to either known tephra or to volcanic centres, using major and trace element chemical analyses. We show that Diss, along with a nearby site known as the Lay, contain tephra from Iceland, the Azores, Italy and North America. We also present a high-resolution chronology for this East Anglian tephra record, based on varve counting, ^{14}C and ^{210}Pb dating, and ^{10}Be synchronisation and historic age tephra. We then use this to demonstrate the significant potential for the integration of wider records across the whole Holocene.

Impact of extreme events related to climate change on mountain areas: preliminary results from the Abruzzo region (central Italy)

Dr. Andrea Sembroni [1]***, Prof. Paola Molin*** [1]

1. *Department of Science, Roma Tre University*

In the last decades, the interest of the scientific community on the coupling between extreme weather events and hydrogeological hazard has increased significantly. Given predictions about future climatic trends, a deeper understanding of the climatic influence on geomorphological phenomena is crucial to properly mitigate the hazard and the associated risk. Despite the numerous studies, the complexity of the interactions between climatic forcing and landscape still leaves many open questions about the triggering mechanisms of hazardous geomorphological processes like mass wasting. What is certain is that extreme rainfall events play an important role in the spatial-temporal distribution of high-elevation mass-movement events.

In recent decades Italy has been the scene of numerous extreme weather events, usually followed by phenomena such as landslides and floods that had a significant economic and social impact.

In this study we investigate the impact of extreme events on the mountain areas of the Abruzzo region (central Italy). The aim is to understand how the variation in frequency, intensity and spatial distribution of extreme events and the modification of meteorological parameters can affect the natural environment and human activities.

We collected the precipitation data of 202 stations for the period 1918-2021. The data were statistically analyzed to individuate the extreme events. In particular, we used the percentile method considering that a weather event is defined extreme if it is as rare or rarer than the 90th percentile. Successively, a landslides database has been realized by specifying the type, the date, and the geographic coordinates. Producing a landslide density map, we extracted landslides and stations located in areas with values greater than 0.4 landslides/km^2. Each landslide was paired with the nearest weather station and the precipitation values up to 30 days before the event were extracted to calculate the rainfall threshold.

The preliminary results allowed to individuate critical areas where to perform a field investigation to define the landslides predisposing and triggering factors and the local-scale impact of climate variations. This will lead to the assessment of the susceptibility of the study area to geomorphological phenomena and a better land management and resilience policies with respect to climate change.

From earthquake-triggered landslide inventories to intensity assessment: methodological workflow and preliminary results

Ms. Eliana Muccignato [1], *Dr. Francesca Ferrario* [1], *Dr. Aadityan Sridharan* [2]
1. *Università degli Studi dell'Insubria, Como,* **2.** *Amrita Vishwa Vidyapeetham*

Earthquakes commonly trigger secondary effects, including landslides; earthquake-triggered landslide inventories are available for tens of case histories and are a key input data for hazard assessment. The spatial distribution of landslides is commonly analyzed in terms of density or areal percentage, and compared to geological, geomorphological and seismic parameters.
Here we describe a methodological workflow to derive a macroseismic field, given a polygonal landslide inventory. We express intensity using the ESI-07 (Environmental Seismic Intensity) scale, which is based only on the effects on the natural environment. ESI-07 values are assigned to each mapped landslide based on the mobilized volume, which in turn is obtained from available area-volume scaling laws.
We apply the method to more than 20 earthquake-triggered landslide inventories on a global scale, adopting a grid-approach: the study area is divided into a regular grid of 1-km2 cells and ESI-07 values are derived for each cell. We apply several area-volume scaling relations, exploring the epistemic uncertainty and either the inter-event and intra-event variability. We also derive original relations between ESI-07 and LND (Landslide Number Density) or LAP (Landslide Area Percentage).
To date, the scientific communities dealing with i) realization of earthquake-triggered landslide inventories and ii) the application of the ESI-07 scale cooperates only sporadically. We argue that the easy-to-use, standardized method proposed here provides the ground for an enhanced collaboration, with mutual benefits. Indeed, landslide inventories derived from satellite or aerial imagery usually have a high spatial resolution and allow to systematically investigate wide territories; on the other hand, the ESI-07 scale allows to compare different earthquakes in space and time.

November 23, 1980 - M6.9, Irpinia-Basilicata Earthquake, southern Italy: An updated dataset of environmental seismic effects

Dr. Marco Pizza **[1]*, Dr. Francesca Ferrario* [1]*, Prof. Alessandro Michetti* [2]*, Dr. Rosa Nappi* [3]*, Dr. Sabina Porfido* [4]**

1. *Università degli Studi dell'Insubria, Como,* ***2.*** *Università degli Studi dell'Insubria, Como; and INGV OV,* ***3.*** *Istituto Nazionale di Geofisica e Vulcanologia, Sezione di Napoli Osservatorio Vesuviano, Naples,* ***4.*** *ISA-CNR, Avellino; and INGV OV*

The Mw 6.9 earthquake of November 23, 1980, known as the Irpinia-Basilicata Earthquake, was the strongest seismic event to hit Italy in the last century. There were 2,914 victims, 8,848 injured and about 280,000 homeless. The earthquake also induced numerous effects on the natural environment, both primary, surface faulting, and secondary, such as gravitational phenomena, ground fractures, liquefactions and extensive hydrological changes related to the flow rate of springs and rivers. The epicentral intensity is I=X either using the MCS (Mercalli – Cancani – Sieberg) macroseismic scale, or the ESI-07 (Environmental Seismic Intensity) scale, which is based only on environmental effects. Currently, there is a fair amount of knowledge about seismically induced environmental effects. There are also published compilations of effects, sorted by location, but without precise spatial location of each phenomenon. Several efforts have been made to document the environmental effects observed at the time of the earthquake, but a unified view integrating all available data is still lacking. This work aims at collecting all available data and build a comprehensive geodatabase, including information on the spatial location of these phenomena with the best possible accuracy. Data on Earthquake Environmental Effects (EEE) are collected from scientific papers, local professional geological reports, and are integrated with original field surveys. Environmental effects are then catalogued according to the ESI-07 scale guidelines. Results of paleoseismological trenching conducted across the earthquake ruptures are also included. The ultimate goal is to create a homogeneous and accurate dataset containing all the environmental effects induced by the 1980 Irpinia-Basilicata Earthquake, to fed and update extant catalogues (e.g., EEE Catalogue managed by Ispra, Geological Survey of Italy). In this way, it is possible to carry out a more complete analysis of the local seismic hazard and the environmental effects induced by it; moreover, it is possible to compare the effects induced by this earthquake with those of other earthquakes, even in other dynamic contexts, contained in similar catalogs (e.g. Catálogo de los efectos geológicos de los terremotos en España).

Understanding Earthquake-related Hydrogeochemical Responses: Results from a Long-term Monitoring Study Applied to the 2020's Monte Cristo Seismic Sequence (Nevada).

Dr. Sara Trotta [1], ***Dr. Gilberto Binda*** [2], ***Dr. Dylan Morlang*** [3], ***Prof. Paula J Noble*** [3], ***Prof. Andrea Pozzi*** [1], ***Prof. Simon Poulson*** [3], ***Prof. Lisa L. Stilling*** [4], ***Prof. William C. Hammond*** [3], ***Prof. Alessandro Michetti*** [5]

1. *Università degli Studi dell'Insubria,* ***2.*** *Norwegian Institute for Water Research, Oslo,* ***3.*** *University of Nevada-Reno,* ***4.*** *U.S. Geological Survey, MS-176 University of Nevada Reno,* ***5.*** *Università degli Studi dell'Insubria; INGV OV*

Earthquakes are well known to affect regional surface and groundwater systems, inducing changes in water chemistry and availability. However, the mechanisms behind aquifer responses are still unclear, due to the limited and short-term data available and the other factors affecting water quality.

To overcome this issue, we undertook an 18-month hydrochemical monitoring program in the epicentral area of the Monte Cristo Range seismic sequence, which struck Nevada between May and December 2020. The monitoring network included four locations at different distances from the epicenter, presenting different hydrogeological settings. This setup allowed us to determine seismic-related anomalies in different contexts and helped us point out factors affecting changes. We measured physicochemical parameters (T, EC, pH, alkalinity, and flow rates) and collected water samples for major ions, trace elements, and water isotope analysis. We then highlighted anomalous chemical changes (i.e., above or below the average ± standard deviation range) along the seismic sequence using time series plots.

The most marked anomalies occurred at the closest site to the epicenter (*Columbus Salt Marsh):* we observed an increase in SO_4, Ca, K, Fe, Zn, and Cu coinciding with a decrease in Na, Cl and Li during the period of May and November 2020. These changes suggested a possible mixing of water within the aquifer as the main driver. A similar but less marked trend was observable after the May shock in *Fish Lake Valley*, where we assessed a slight decrease in Cl, Na and a concomitant increase in SO_4, Ca and Ba. *Willow Ranch* site, close to *Fish Lake Valley*, presented scattered changes in major ions during the whole monitoring period. However, anomalous peaks in temperature and trace elements were observed during November aftershocks, mirroring a possible upwelling of geothermal waters from which the Fish Lake Valley hot well is sourced. Finally, the furthest site from the epicenter (*Mina Dump*) did not reveal any relevant effects on water chemistry, possibly due to the reduced seismic stress affecting this area.

Our results confirmed the complexity of earthquake-related hydrogeochemical responses, influenced by hydrogeological and seismic features.

Biotite chloritization triggers seismicity: Coupling geochemistry with seismology

Mr. PIYAL HALDER [1], Dr. Matsyendra Shukla [2], Dr. Kamlesh Kumar [3], Dr. Anupam Sharma [1]

***1.** Birbal Sahni Institute of Palaeosciences (DST, Govt. of India), Lucknow-226007, U.P.; Academy of Scientific and Innovative Research (AcSIR), Ghaziabad-201002, U.P.,India, **2.** Govt. of India, Ministry of Earth Sciences (MoES), Borehole Geophysics Research Laboratory (BGRL), Karad-415105, Maharashtra, India, **3.** Birbal Sahni Institute of Palaeosciences (DST, Govt. of India), Lucknow-226007, U.P.; Academy of Scientific and Innovative Research (AcSIR), Ghaziabad-201002, U.P., India*

Numerous small to medium-scale tremors have been felt in the Koyna-Warna Seismogenic region during the last five decades since the impoundment of the Koyna Dam in 1962. The largest earthquake with a magnitude ~ 6.7 occurred in 1967 in this small region which is bounded by the Koyna River fault zone to the west and NE-SW trending Patan fault to the east. The bulk and clay mineralogical XRD of the fracture and fault zone material of the basement granitoid of the Koyna-Warna region have revealed the occurrences of chlorite, illite, and epidote, and precipitation of calcite. Subsequent optical microscopic studies have shown the biotitic remnants within the neoformed chlorite in close association with the epidote indicating the formation of chlorite and epidote from biotite due to the reaction of element-rich fluid with host rocks.

Biotite + Al^{3+} + Mg^{2+} + Fe^{3+} + Ca^{2+} + H_2O + H^+ $\rightarrow$ chlorite + epidote + TiO_2 + H_4SiO_4 + K^+

Besides, the dissolution of plagioclase has been observed supporting the formation of illite at certain depths and the precipitation of calcite along several thin and thick fractures. Earlier studies have also revealed that this plagioclase dissolution is associated with the chloritization of biotite.

Plagioclase + Fe^{2+} + Mg^{2+} + K^++ H_2O $\rightarrow$ albite + illite + Ca^{2+} +Al^{3+}

Thus, the fluid-rock interaction promoting secondary mineralization basically resembles propylitic kind of hydrothermal alteration in the basement rocks of the Koyna Seismogenic Region. In addition, the presence of chlorite and illite-like hydrophilic clay minerals in fault and fracture zones may be responsible for triggering the seismicity in this Seismogenic Region because the absorption of water increases fluid pressure (P_f) and reduces the effective normal stress (σ_n). As a result, Critical Shear Stress (τ_c') becomes less than the effective shear stress which facilitates steady fault creep resulting in small recurring tremors.

In general, $\tau_c = (\mu \times \sigma_n) + c$

In our case, $\tau_c' = \mu \times (\sigma_n - P_f) + c$

On the other hand, the epidotes present here increase frictional strength under hydrothermal conditions and may promote unstable sliding with a large-magnitude earthquake in the future as experienced in 1967.

New hints of paleoliquefaction events across the external front of the Eastern Southern Alps in Veneto and Friuli (NE-Italy)

Dr. Giulia Patricelli [1], ***Prof. Maria ELIANA POLI*** [1], ***Dr. Giovanni Paiero*** [1]

1. University of Udine - Department of Agricultural, Food, Environmental and Animal Sciences - Udine, Italy

Among the secondary coseismic effects, liquefaction phenomena associated to medium-to strong earthquakes are often documented in wide areas around the epicentre. Paleoseismological studies certainly represent a fundamental key to unravel liquefaction episodes of the past, beyond the historical time interval.

The paleoseismological studies conducted in the north-eastern Italy (partly in the framework of the Italian Seismic Microzonation Project), allowed to detect many unpublished case-studies of paleoliquefaction events. The investigated sites are located across the Plio-Quaternary external front of the Eastern Southalpine Chain, a SSE-verging fold and thrust belt extending all along the Veneto and Friuli prealpine border. Numerous damaging earthquakes (Mw > 5.5) struck the study area in historical times: 1511 Mw 6.3, 1695 Mw 6.4, 1873 Mw 6.3, 1928 Mw 6, 1936 Mw 6. Despite the medium-to-high seismicity, the record of paleoliquefaction evidence in the literature are scarce. However, if considering the most recent seismicity, many liquefaction events associated to seismic shaking were registered in the epicentral area of the Friuli 1976 earthquake (Mw 6.5).

In this work we present the results of paleoseismological analysis conducted along the Veneto-Friuli prealpine border aimed at the characterization of active and capable faults. The paleoliquefaction features detected in trenches involve both fine and gravelly sediments and mainly include dikes filled by sand or silt and sand blows with sparse foundered clasts. Despite the presented data are preliminary results which should be further analysed, they provide important hints for the Italian Seismic Microzonation and Seismic Hazard Assessment of the Veneto - Friuli region.

Quaternary scientific papers production in Africa, a review.

Mr. Ahmed Serkhane [1], ***Dr. BOUHADAD Youcef*** [2], ***Prof. Mohammed Said GUETTOUCHE*** [3], ***Mr. Rabah DJEDDI*** [1], ***Mr. menad SADI*** [4], ***Mr. Yazid RABAH*** [4]

1. *Algerian geological survey agency/ University of sciences and technology houari boumediene,* **2.** *CGS,* **3.** *University of sciences and technology houari boumediene,* **4.** *Algerian geological survey agency*

Many studies have examined the impact of African scientists and their contribution to the worldwide scientific research, through the quantity of their publications in peer-reviewed journals. These studies have highlighted that the impact of African researcher in terms of scientific production and the quality of international publications is still under what it should be. In this study we propose to shed light on the African researcher contribution in quaternary sciences research such as surface process and quaternary geology, through a statistical analysis of African scientists contribution in comparison with worldwide scientists work.
For this purpose, we examined the representation and contribution of African and other authors using a bibliometric study of international geoscientific impact journals in the Web of science over a period of 25 years (1996 to 2021).
The results show a very low rates of scientific production of African authors for the examined period. Nevertheless, the number of publications has continuously increased, but it is still far from worldwide scientists production of the developed countries.
Indeed, some countries in the world such as USA, Japan, China, UK and Netherlands published alone more than all African countries combined.
Therefore, African countries should fil the gap in this field by developing research infrastructures and education as well as by enhancing the annual budget devoted to upgrade their research capacities.

Traps ‘n’ Maps: collecting modern pollen data across Australia to better reconstruct its ancient landscapes.

Mr. Alexander Wall [1]***, Dr. Cassandra Rowe*** [2]***, Dr. Janelle Stevenson*** [1]***, Dr. Tahlia Perry*** [3]***, Ms. Annie Nguyen*** [4]***, Dr. Haidee Cadd*** [5]***, Ms. Kelsey Boyd*** [5]

1. *ARC Centre of Excellence for Australian Biodiversity and Heritage, School of Culture, History and Language, The Australian National University,* ***2.*** *ARC Centre of Excellence of Australian Biodiversity and Heritage and Centre for Tropical Environmental and Sustainability Science, James Cook University, Cairns, Queensland, Australia,* ***3.*** *ARC Centre of Excellence for Australian Biodiversity and Heritage; School of Biological Sciences, University of Adelaide,* ***4.*** *ARC Centre of Excellence for Australian Biodiversity and Heritage; School of Natural Sciences, University of Tasmania,* ***5.*** *ARC Centre of Excellence for Biodiversity and Heritage, School of Earth, Atmospheric and Life Sciences, University of Wollongong*

Pollen is an important proxy for past vegetation. In Australia, the relationship between vegetation and pollen is not well constrained, even in the modern. Thus quantitative reconstructions of past plant abundance and land-cover based on palynological records cannot be precise. Traps ‘n’ Maps is a project by the Australian Research Council’s Centre of Excellence for Biodiversity and Heritage (CABAH) to establish a pollen monitoring network across major climate and biogeographic zones in Australia.

This project will help palaeoecologists move from describing “what was there” to “how much was there”. This will add a new dimension to understanding across a variety of disciplines that examine Quaternary Australia. Interactions between people, fire, fauna, and the climate are mediated by, and are reflected in, vegetation. Data will be collected using pollen traps installed and vegetation surveys conducted in transects spanning many hundreds of kilometres across the Australian continent. Collaboration with the Terrestrial Ecosystem Research Network will allow the use of existing long-term vegetation surveys.

Citizen science is also a major component of this project. Researchers are conducting a travelling “road show” in regional schools, highlighting the science being done in students’ backyards. An app is in development that will guide participants to construct a pollen trap of their own from readily available hardware and conduct a basic vegetation survey. Ultimately, Maps ‘n’ Traps will contribute a leap forward in our ability to reconstruct past Australian landscapes and create a powerful tool for public engagement.

: Rethinking data sharing in phytolith research: from FAIR phytoliths to key insights for the future

Prof. Marco Madella [1]***, Prof. Carla Lancelotti*** [2]***, Dr. Emma Karoune*** [3]***, Dr. Javier Ruiz-Pérez*** [4]***, Dr. Juan José García-Granero*** [5]***, Dr. Cèline Kerfant*** [6]

1. *CaSEs – Department of Humanities, Universitat Pompeu Fabra, Spain; School of Geography, Archaeology and Environmental Studies, The University of the Witwatersrand, South Africa,* ***2.*** *ICREA - CaSEs, Department of Humanities, Universitat Pompeu Fabra,* ***3.*** *The Alan Turing Institute,* ***4.*** *Texas A&M University,* ***5.*** *Spanish National Research Council,* ***6.*** *CaSEs, Department of Humanities, Universitat Pompeu Fabra*

Our project 'Increasing the FAIRness of phytolith data', funded by EOSC-Life, is striving to set the basis for implementing the FAIR (Findable, Accessible, Interoperable and Reusable) data principles within the phytolith research community. Phytoliths are micro-botanical remains that are formed within the cells of living plants. They can be used to address archaeological questions concerning anthropogenic plant exploitation and landscape changes.

The phytolith community has been making efforts to standardise data through the development of a common nomenclature and other guidelines. However, the routine adoption of these standards has not been straightforward. Data sharing is minimal and data is often exclusively within paywalled published articles rather than in open repositories.

An assessment of open science practises in phytolith research (Karoune 2020) found that only a small percentage of research provided reusable data. These findings initiated the FAIR Phytoliths project to take the first steps along the FAIRification journey.

The FAIR Phytoliths project has engaged with our community to find shared views on opening up research. We have also conducted an assessment of publications containing primary phytolith data and associated methods to fully investigate the key variables needed to improve data sharing in line with the FAIR principles.

This presentation will share the results of this work and the FAIR guidelines that we have drawn up with community support. We will discuss what this means for future phytolith research and the wider learnings that can be taken from this project for the archaeological community. We hope this work will initiate more sustainable data sharing practices in the future for phytolith research and related disciplines.

Geochemistry of Middle Pleistocene fossil termite nests (Calitzdorp, Western Cape,South Africa)

Ms. Rabia Jacobs [1]***, Dr. Miengah Abrahams*** [1]***, Prof. Chris Harris*** [1]

1. *University of Cape Town*

Fossil termite nests (termitaria) are commonly replaced by calcium carbonate and preserved as resistant, dolomitised material. A typical process for precipitation in pedogenic carbonates is the downward migration of saturated carbonate solutions from the vadose zone (which lies between the groundwater and water table). Carbonate chemistry can therefore be used to comment on palaeoenvironmental conditions like vegetation and climate. In South Africa, carbonates from fossil termite mounds (Heuweltjies) interpreted to have been made by termite activity, have successfully been studied to determine palaeovegetation and palaeoclimate trends using carbon and oxygen stable isotopes. Here, we evaluate two calcretised Middle Pleistocene termitaria preserved in a well-developed soil profile near Calitzdorp (Western Cape, South Africa) to determine their palaeovegetation and palaeoclimate signals. The bulk rock mineralogy and geochemical analysis indicates that the fossil nests comprise 27 wt.% of carbonate minerals, 25% of which is dolomite and 2% calcite. Targeting carbonate precipitate enriched zones of the nest specimen, which are interlayered with clastic sediments, we assessed their δ13C and δ18O values. δ13C ranges between -3.45‰ to -0.69‰ PDB and δ18O ranges between 28.49‰ to 31.33‰ SMOW. These δ13C signatures suggest a dominance of plants with a C4 photosynthetic pathway at the time of calcretisation. C4 plants prefer warmer climates regimes which is supported by the range δ18O values which suggests that the climate in Calitzdorp was likely warmer than today.

Morphology, radiocarbon dating and stable isotopes analysis from eggshell of extinct ostrich from Central Tapi River Valley, India: Paleoanthropological significance

Dr. Prabhin Sukumaran [1]***, Prof. Stanley Ambrose*** [2]***, Dr. Parth Chauhan*** [3]

1. Charotar University of Science and Technology, 2. Department of Anthropology, University of Illinois, Urbana, USA, 3. Department of Humanities and Social Sciences, IISER-Mohali, Punjab

The ostrich is important for Quaternary scientists trying to understand human adaptations, cultural practices, and Late Pleistocene extinction patterns. Modern ostrich is adapted to open, arid environments in Africa and southwest Asia. Their range extended to South Asia and arid northwest China until 7500 years ago. The Central Tapi River Valley (CTRV) is important because among hundreds of ostrich eggshell (OES) fragments recovered from archaeological and paleontological sites across India, three from CTRV preserved intentionally engraved designs similar to cultural specimens from Africa and elsewhere. They represent the earliest dated, engraved artistic expression of prehistoric humans in India. These artefacts compliment the evidence for manufacturing drilled beads on ostrich eggshells from sites up to 50,000 years old (ka) in Africa, India, and China. The eggshell inner (columnar crystal/mammillary) layer is resistant to diagenesis. This layer provides reliable radiocarbon dates, and its stable carbon and oxygen isotopes of OES are valuable proxies for reconstructing paleoenvironmental conditions. Ostrich is herbivorous, so OES $\delta 13C$ reflects the average dietary proportions of C4 and C3 plants during the breeding season. Ostrich is not obligate drinkers, so they acquire most water from plants. Leaf water transpiration results in high enrichment in leaf $\delta 18O$ particularly when there is low humidity. OES $\delta 18O$ thus reflects relative humidity.

We report the discovery of an OES fragment from the CTRV. The specimen was subjected to various analytical procedures, including the microscopic study of surface morphology, thin section analysis under a polarizing microscope, radiocarbon dating, and stable carbon and oxygen isotope analysis. The analysis of this specimen, dated to 53,200 ± 1200 cal bp, was compared with reported records of OES, including modern and extinct species, and regional geologic and archeologic records to understand its paleoanthropological and paleoenvironmental significance.

New information on mortuary practices and subsistence of terrestrial hunter-gatherers from the highlands (Cerro Guido/Sierra Baguales) during the late Holocene in southern Chilean Patagonia

Dr. Victor Sierpe [1] ***, Prof. Cristóbal Palacios*** [2]***, Dr. Fabiana María Martin*** [1]***, Dr. Luis Alberto Borrero*** [3]***,***
Ms. Francisca Caravantes [4]***, Ms. Constanza Arecheta*** [5]

1. *Centro de Estudios de Historia y Arqueología, Instituto de la Patagonia, Universidad de Magallanes,* ***2.*** *Programa de Doctorado en Antropología UTA/UCN, Universidad de Tarapacá,* ***3.*** *Universidad de Buenos Aires e Instituto Multidisciplinario de Historia y Ciencias Humanas (IMHICIHU-CONICET), Buenos Aires,* ***4.*** *Universidad Alberto Hurtado, Santiago de Chile,* ***5.*** *Programa de Master Universitat Rovira i Virgili, Tarragona, Cataluña*

The geographical area of Cerro Guido and Sierra Baguales (Province of Última Esperanza, Magallanes, Chile) is a territory characterized by low steppe or pampa plains, large ravines, current ephemeral watercourses and others with large tributaries, as well as mountains with high accessible plateaus and summits that are difficult to access. In summer the territory is open and easily accessible, while in winter snow covers every space. Results obtained during the 2020-2022 archaeological campaigns give so far an antiquity in the human occupation of the sector of up to ca. 2400 years BP. The main characteristics observed have been the supply of varied and good quality lithic raw materials in high mountain range sectors (~ 1500 masl) and the hunting and gathering of large fauna in ravines and valleys with the main use of the guanaco (Lama guanicoe) as the most exploited species. Previous antecedents on the customs of these human groups indicate mortuary practices with the recurrent use of high areas for the burial of individuals in chenques, being the most recognized the one called “Chenque de Cerro Guido” or “Guido 1”, arranged in the highest point of the homonymous hill and characterized by multiple burials having been reused in a period between ca. 500 and 1150 years BP. New antecedents have allowed us to recognize the use of other spaces for the burial of skeletons evidenced through the use of a rock shelter, allowing us to broaden the vision of funerary practices in this sector. The components discovered so far help to improve the information about the customs and lifestyles of terrestrial hunter-gatherer groups from the interior to the extreme south of Patagonia.

Unique Zoological Nomenclature for World-Wide Databases, is it possible?

Dr. Joaquin Arroyo-Cabrales [1] ***, Prof. Raffaele Sardella*** [2]

1. *Instituto Nacional de Antropologia e Historia,* ***2.*** *Department of Earth Sciences, Sapienza University of Rome*

Paleoenvironmental research data are a resource that must be managed in a way that provides the entire global-change research community with the tools to find, access, and manipulate quickly the data needed for a particular investigation. Much of the research into the responses of species and communities to climate change is based on recent historical data, and although climate has changed significantly since the start of the Industrial Revolution, a broader suite of global climatic changes have occurred in the past. It has identified several types of data that need to be given high priority for global change studies. The first priority is the original "raw" or primary paleoclimatic, paleoecologic, and paleoceanographic data, including associated chronological information. The power of paleoecological data lies in the temporal dimension: fossil deposits contain repeated samples through time, drawing from different climatic and environmental contexts. For creating a complete database that could include much of above data, several criteria have to be decided, like locality (how much information is needed?), chronology (absolute, relative, etc.), and taphonomy (qualitative and/or quantitative ecofats) issues, but one contentious issue, mostly for the great importance for any database, are the taxonomic names assigned to the specimens. Establishing a conventional and unique zoological nomenclature used for a database, considering similarities and differences between New and Old worlds systems, is necessary for a database have World-wide usefulness. Species names for extant species could follow ASM recent database, but those for the fossil record are still awaiting a unique endeavour, in agreement with current taxonomic practices.

A MaxEnt predictive modelling for palaeontological sites in the Siwalik Hills: A case study from the Pinjore Formation of the Siwalik Hills north of Chandigarh, northern India

Ms. Anubhav PreetKaur [1]***, Dr. Matthew Sisk*** [2]

1. Indian Institute of Science Education and Research Mohali, 2. Lucy Family institute for Data & Society, University of Notre Dame, USA

The Pinjore Formation of the Upper Siwalik Hills north of Chandigarh, northern India, is India's only continuous and most extensive Early-Middle Pleistocene deposit. It is well-known for its rich deposits of fossilised vertebrate faunal remains, chronologically ranging from 2.58-0.63 Ma. However, most have been reported as surface finds of an unconfirmed geological association. In order to better understand the Pinjore biostratigraphy, new surveys were initiated in the region in November 2020. A MaxEnt predictive model was generated to guide the surveys in the region. The main objectives of this model were: 1) to identify new fossil scatters closer to the context. 2) to evaluate the applicability and accuracy of predictive models generated using MaxEnt for identifying fossil localities in the Siwalik Hills region. 3) to generate a replicable predictive model through this case study. Primary data consists of environmental variables that include slope, aspect and NDVI (vegetation index). The input data used 14 previously known fossil localities from the study area. The model's accuracy was evaluated through field surveys concentrated around regions predicted with a high-moderate possibility for the presence of fossil sites. As a result, six new fossil localities, with multiple scatters, have been identified in the Pinjore Formation of the Siwalik Hills north of Chandigarh. Further efforts are now being directed towards improving the model enhancing its spatial resolution.

Hunter-gatherers of the central Narmada Basin: a unique and prolonged survival

Dr. Nupur Tiwari [1]

1. *Department of Humanities and Social Sciences, IIT Bombay*

The region of central Narmada Basin (CNB) is bounded by heavily forested zones of Vindhyans and Gondwanas, famously known as the Satpura forest. Sitting in the centre of India, the region is home to diverse flora and fauna. CNB was explored, surveyed and excavated during 2015-2019 for the author's doctoral work. The project aimed to locate open-air sites and microlithic occupations in this region. Extensive surveys covered a 326 km area, bringing to light a high number of (225) microlithic occurrences. The unique ecological setting of this forested area yielded 15000 non-geometric microliths indicating primarily hunting-based subsistence. Eighteen major sites were selected for microlithic collections, which were later morphometrically analysed in the lab. Luminescence dating has been carried out at six sites from this region, supporting the sustenance of these prehistoric Homo *sapiens* in the CNB. This ecological niche supported the hunter-gatherer lifeways for at least ~50-1kya, i.e. Late Pleistocene to Late Holocene. It is possible that this ecologically resourceful region provided these hunter-gatherer communities to sustain in this zone with microlithic technology mostly isolated from the surrounding regions. The region has not yielded any cultural artefacts other than the lithics from Lower Palaeolithic to microlithic. It is indeed a unique ecological and geological niche that prolonged the existence of microlithic-producing hunter-gatherers commonly thought to have transitioned into an agriculture-based economy mainly after the 8kya (Mesolithic period). Such a detailed study of this region provides a balanced approach to understanding microlithic sites in an open-air context and their prolonged use by the hunting-gathering communities. This paper/poster aims to represent a wholesome result-oriented research that speaks about a human-ecology-landscape-technology relationship in the central Narmada Basin.

Ostracods as proxies in Lake Stechlin, NE Germany – an actualistic approach

Ms. Ella Quante [1], **Prof. Peter Frenzel** [2]

1. Department of Archaeology, Max Planck Institute for Geoanthropology, 2. Friedrich Schiller University Jena, Institute of Earth Sciences

Actualistic studies are a necessity for the development and improvement of proxies for palaeoenvironmental reconstructions. For ostracods, several proxies that have been established and used frequently in, e.g., palaeoenvironmental, palaeoclimatological or geoarchaeological studies, have never thoroughly been approved statistically (e.g., adult/juvenile-ratios, carapace/valve ratios). To do this, an actualistic investigation of the ostracod fauna and its taphonomy was carried out in Lake Stechlin, NE Germany.

Lake Stechlin is an almost 70 m deep, slightly eutrophic, groundwater dominated lake without any other inflows. Due to the operation of a nuclear power plant from 1955-1990 on the west shore, the lake environment has been thoroughly monitored since the 1960's, and it is therefore an excellent location for testing the analysis of ostracod records.

The modern ostracod fauna and distribution was analysed at several localities, to investigate potential differences at hydrogeological factors, anthropogenic impacts (trampling, boat landing stages, fish farms) and climatic conditions. Species occurrences and distributions were analysed for each locality, as well as abundances of species, adults and juveniles, and carapaces and single valves.

Preliminary results show that the depth distribution of adult/juvenile valves and carapace/single valves in a depth transect may only to some degree follow the expected trends in the particular lake environment. Factors such as macrophyte coverage, substrate type, shore line morphology and fish activity significantly affect the distribution of ostracods in the littoral zone, and make these proxies more difficult to interpret. Further, oxygen deficiency and carbonate dissolution in depths of ca. 11 m in the lake lead to absence of ostracods in the deep lake sediments and are another important detriment for ostracod proxies.

Abundances and assemblages vary strongly in the human impacted areas, e.g., showing high occurrences of *Cypridopsis vidua* at a fish farm, high frequencies of *Darwinula stevensonii* and *Limnocythere inopinata* at the landing stages of a boat rental, and lower diversity at the beach site compared to an undisturbed locality. Although these differences may be significant, they underline the necessity for samples for comparison from other areas, as the fauna in human affected areas may look natural.

The measurement of open apices of lower dentition as ontogenetic indicator for Pleistocene hyenas

The study of age at death can be used to investigate modes of accumulation of fossil assemblages, including predation and the behaviour of ancient non-human and human populations. In Palaeontology, the most common analyses to estimate age are dental wear, tooth replacement or dental annuli count. However, these have some limitations because they may be affected by taphonomic biases or variation in between individuals. In physic anthropology, age estimation in humans is commonly assessed by dental development due to it is less affected by these processes. One of the most widely used methods is based on obtaining growth indices by measuring the opening of root apices in the permanent dentition. The main objective of this study is to develop a quantitative methodology for estimating age at death in Pleistocene hyenas centred on dental development. We applied X-rays on mandibles and isolated teeth corresponding to several Pleistocene sites such as Galería de la Estatuas and Galería Baja (Sierra de Atapuerca, Burgos, Spain), Cueva del Camino (Pinilla del Valle, Madrid, Spain) and Terrasses de la Riera del Canyars (Gavà, Barcelona, Spain). The radiographs were used to calculate growth indices in dental elements. The results show that this method is accurate for classifying hyena individuals through developing permanent teeth. The teeth were compiled in 2 categories for juveniles, one for sub-adults, one for adults and one for olds. Furthermore, these categories are associated with important milestones in the behaviour of individuals. The application of this method helps to the classification of isolated teeth, the most common element found in hyena assemblages, resulting in more precise mortality profiles.

Morphological study of Canis mosbachensis mandibles from Early and Middle Pleistocene European localities

The origin of *Canis lupus* Linnaeus, 1758 probably took place in the Middle Pleistocene of Beringia and it dispersed into Europe during the late Middle Pleistocene. *Canis mosbachensis* Söergel, 1925 is a small wolf which is frequently found in Eurasian early Middle Pleistocene sites, although it is already known in the Epivillafranchian, at about 1 Ma ago. Although the Mosbach wolf is considered the ancestor of *Canis lupus* , its phylogenetic position is still subject to debate, and different classifications are suggested: as a species, subspecies of *C. lupus* or subspecies of *C. etruscus*. Considering the taxonomical problems on the lineage of this canid, more analysis are necessary to understand which is the more useful anatomical information that allow us to discriminate between the different species.
Mandibles are complex biological forms with diet-related adaptations that respond quickly to selective pressures. This work aims to analyze mandibular features of *Canis mosbachensis* remains from Vöigstedt and Untermaßfeld (Thuringia, Germany) as well as from Trinchera Dolina (Sierra de Atapuerca, Spain) sites. Here, we provide a preliminary morphological and biometrical analysis to discriminate *C. mosbachensis* from modern Iberian wolves (*Canis lupus signatus*) that allow us differentiating and characterize them in descriptive visual and numeric terms. The carnassial (M_1) and the P_4 are two diagnostic characters to distinguish between both. We used 2D Geometric Morphometry (GM) techniques for a better understanding on the mandibular variation on *Canis* evolutionary processes. This method allows us a better observation of shape changes, trough visual representations of morphological variation.
The fossil remains from Trinchera Dolina and Untermaßfeld are almost complete, however, the mandibles from Vöigstedt are scanty and fragmentary. We have initially studied the complete specimens to subsequently focus on the fragmentary remains with special attention to the P_4 and M_1.

Important findings from the TephroMed project II: The glass geochemistry of key visible tephra layers from Lake Van, eastern Anatolia

The lake sediments of Lake Van, eastern Anatolia, are an important archive of past environmental and climatic conditions. Located in the eastern Mediterranean region, the lake is critically located between the humid Mediterranean climate and the Saharo-Arabian desert belt. Previous investigations on the record have shown major shifts in precipitation regimes throughout the last glacial to glacial period (130-30kya). The sediment core also contains visible tephra (volcanic) layers, a record of past eruptions from the volcanoes located very close to the lake. Two of which, Nemrut and Süphan, are known to have been extensively active throughout this time period. Dating of this archive has been undertaken through radiocarbon, ^{10}Be palaeomagnetism, ^{40}Ar/^{39}Ar on certain tephra layers (via proximal deposits), and wiggle matching. However, problems of large dating uncertainties and lack of independent dating has prevented insight into regional climatic (a)synchronies, particular between other palaeoclimatic records (e.g. The Dead Sea, Israel).
Here we present new single glass shard chemistry for fourteen important visible tephra layers from the ICDP PALEOVAN Ahlat Ridge (AR) record, part of the TephroMed project. These fourteen layers were chosen due to being stratigraphically positioned at major climatic transitions during the time period investigated. Extensive major and minor element data has allowed each volcanic layer to be geochemically characterised. Additional chemical information is provided with trace elements (LA-ICP-MS) as well as glass shard morphology for the fourteen layers. This new data provides important information for eruptions from Nemrut and Süphan (and other proximal volcanoes). Crucially, direct geochemical correlations between tephra layers found in distal palaeoenvironmental records (The Dead Sea) and archaeological archives in the region can now be made confidently made with Lake Van. This provides insight into the timing of major regional environmental and climatic shifts as well as with human occupation and cultural changes in the region.

Insights for restoration: Reconstructing the long-term responses and resilience of vegetation, hydrology and peat conditions to fire events in a tropical peatland in Central Kalimantan.

Ms. Khairun Ramdzan [1]

1. *University of Queensland*

Fire events in tropical peatlands are often related to dry peat conditions associated with climate variability (drought) and anthropogenic-driven ecosystem degradation. However, drought is not the only driver to long-term fire events and peatland ecosystem changes. This study used palaeoecological and geochemical proxies to investigate the long-term drivers in fire severity (FS) and the associated responses of the peatland ecosystems in Central Kalimantan, Indonesia. The results showed FS has increased from ~2300 cal. yr BP to present, and possible drivers include changes in sea level, increased frequency of El Niño events, increased biomass, and anthropogenically-driven ecosystem degradation. In response, the vegetation composition changed from a mix of peat swamp forest (PSF) and open vegetation (OV) during the late Holocene (2284 to 1129 cal. yr BP), to predominantly PSF from 1128 to 375 cal. yr BP, dry lowland mixed with swamp forest (LMS) and open vegetation (OV) from 374 to 135 cal. yr BP, and predominantly OV and FSF from 134 to -62 cal. yr BP. The drivers of the vegetation turnover were hydrological conditions and the fertilising effect from the combustion of organic matter (i.e. N release) during low FS, while the responses of vegetation turnover affect the accumulation of recalcitrant organic matter in peat. The resilience of the peatland ecosystems over longer-term timeframes provided the following restoration insights: 1) PSF species (i.e. *Eurya* and *Ilex*) had FS tolerances of up to ~23 $mm^2cm^{-3}yr^{-1}$ while LMS and OV species had lower FS thresholds of ~13 $mm^2cm^{-3}yr^{-1}$; 2) PSF expanded during periods of wet conditions and higher peat nutrients (i.e. TN- enriched from low FS); and 3) Future revegetation in the region can focus on taxa such as Araceae, Restionaceae, *Myriophyllum*, and *Ficus* as they were historically able to thrive in present baseline conditions of high FS and dry hydrological conditions.

Seasonal climate signals and temperature changes recorded by oxygen isotopes in the shells of Anularya mansuyi

Dr. Guoliang Lei [1]

1. School of Geographical Sciences, Fujian Normal University

The oxygen isotopic composition of carbonate in mollusk shell is closely related to the surrounding water environment and become an important archive for reconstructing paleoclimate. *Anularya mansuyi* is a viviparid freshwater snail genus endemic to the lakes of Central Yunnan and has large size. It is widely distributed in the Quaternary lakeshore terrace in Central Yunnan. However, it is still unclear whether the oxygen isotope of its shell can be used to reconstruct the regional seasonal climate signal. In this study, the living shell of *Anularya mansuyi* in Qilu Lake was collected and sampled continuously along the spiral growth direction of the shell to test the shell $\delta^{18}O$ value, the relationship among the shell $\delta^{18}O$ and lake water temperature and lake water $\delta^{18}O$ is analyzed and discussed. The results show that (1) The oxygen isotope in the shell of *Anularya mansuyi* along the growth direction has significant seasonal fluctuation characteristics. (2) The oxygen isotope characteristics of shell carbonate shows that shell was precipitated under the condition of equilibrium with lake water, $\delta^{18}O$ value of shells is closely related to lake temperature and water$\delta^{18}O$. (3) The fluctuation of $\delta^{18}O$ values in modern *Anularya mansuyi* shell in Qilu Lake are mainly controlled by the seasonal change of temperature. With the measured $\delta^{18}Ow$ value, regional seasonal lake water temperature change can be reliably reconstructed based on shell $\delta^{18}O$ value, the temperature reconstructed by $\delta^{18}Ow$ value of summer lake water is more consistent with the regional atmospheric temperature.

A chrono-ecological framework for the Middle Stone Age and Late Stone Age of Northwest Africa

Ms. Solène Boisard [1]***, Dr. Eslem Ben Arous*** [2]***, Dr. Colin Wren*** [3]***, Prof. Ariane Burke*** [1]

1. *Université de Montréal, Hominin Dispersal Research Group,* ***2.*** *Max Planck Institute for Geoanthropology, Pan-African Evolution Research Group,* ***3.*** *University of Colorado at Colorado Springs, College of Arts and Sciences*

In Northwest Africa, the distribution of Middle Stone Age (MSA) and Late Stone Age (LSA) archaeological sites spans an extensive area from Morocco to Libya, raising questions about the spatial and temporal relationship between distant sites. MSA/LSA sites include assemblages attributed to several taxonomic units - Aterian/Mousterian/Dabban/Iberomaurusian - defined by their lithic technology and typology and the presence or absence of diagnostic types in the archaeological assemblages. Technological variability within each taxonomic unit is often defined in relation to geographical and ecological factors. This task is complicated because of numerous biases (taphonomic, methodological, historical), however, making comparative analyses difficult. In this paper, we adopt a macroscale approach to the MSA and LSA. We pay special attention to the chronological evidence from individual sites and map their spatial and temporal distribution across Northwest Africa. Our goal is to establish an updated dataset of archaeological sites; assess the validity of published dates and model the pattern of human occupation diachronically by Marine Isotopic Stages. We then compare site distributions by timeframe to available landscape reconstructions based on ecological proxies and climate model outputs. This approach allows us to explore the role of climactically driven environment change as a driver of broad cultural processes such as technical change and human persistence in North Africa.

Comparing Neanderthal and Homo sapiens subsistence behaviours at Riparo Bombrini (Liguria, Italy)

Dr. Geneviève Pothier-Bouchard [1], ***Prof. Ariane Burke*** [2], ***Prof. Fabio Negrino*** [3], ***Dr. Michael Buckley*** [4], ***Prof. Julien Riel-Salvatore*** [2]

1. *Université Laval,* ***2.*** *Université de Montréal,* ***3.*** *Department of Antiquities, Philosophy, History, University of Genova,* ***4.*** *University of Manchester*

Located in the Balzi Rossi Paleolithic site complex, Riparo Bombrini documents one of the latest Mousterian occupations in Liguria (Italy), along with early Protoaurignacian occupations. Previous studies on the late Mousterian (MS) and Protoaurignacian (A1, A2) levels have revealed distinct mobility and technological organizations associated with changing paleoenvironment signatures. This makes Bombrini a key site to document the subsistence adaptations and human-environment interactions of the last Neanderthals and the subsequent arrival of modern humans in Western Europe.

We present the results of a complete ZooMS-informed zooarchaeological and taphonomic analysis conducted on levels MS, A1 and A2 at Bombrini, which provide the first high-resolution study of human subsistence during the Middle-Upper Paleolithic transition (43-36 ky cal BP) in the Liguro-Provençal arc region. These data allow us to test for the possible existence of inter-population differences in behaviour and adaptation in the context of rapid climate change on the European continent.

Palaeotempestology: understanding coastal flood mechanisms in Middle Lake, Alabama, USA

Dr. Joanne Egan [1], ***Dr. Claire Jones*** [1]

1. *Edge Hill University*

Hurricanes are one of world's most deadly and destructive natural hazards. It has been suggested the frequency and the intensity of hurricanes are increasing in recent years. As instrumental data of hurricanes only extend back to around 170 years ago, it is essential to analyse the past to aid in future predictions. Palaeotempestology is a relatively new field of study which involves analysing a series of physical, chemical and biological proxies to identify hurricane occurrence and intensity in the past. This study examines hurricane occurrence throughout the Holocene from Middle Lake, Alabama, U.S.A. Two lake sediment cores were extracted from Middle Lake in May 2018. The cores were transported back to the U.K. and organic matter content, carbonate content, particle size, water content and ITRAX XRF analysis was conducted on both cores, and pollen and diatom analysis is underway. Both cores display a number of sand layers, which is furthered by declines in organic matter content and increases in particle size. Therefore, it is hypothesised that these sand layers are hurricane events throughout the Holocene. However, it is unclear whether the flooding associated with the hurricane events is due to storm surges, or terrestrial flooding from high rainfall. The use of non-destructive XRF core scanners in the identification of hurricane events and the nature of the flooding has been especially useful to confirm this hypothesis. This study analyses several ratios to analyse hurricane occurrence throughout the core and displays that an increase in the ratio Cl/Br is a good indication of hurricane presence with storm surges being the flooding mechanism. However, there is not a consistent pattern, and so the pollen and diatom analyses will confirm the origin of the flood deposits further. Both cores also show a significant shift throughout the core from a more marine dominated catchment source to a terrestrial. Change within the core marks a shift from a lagoonal area to a fresh-water lake. These multi-proxy analyses will further our understanding of the lake ontology and coastal flooding events.

Biofossils in borehole unravel tsunamis caused by submarine volcanic eruptions

Dr. Hoil Lee [1] ***, Dr. Yire Choi*** [1] ***, Dr. Ji Hye Han*** [2] ***, Dr. Sang Deuk Lee*** [2] ***, Dr. Sujeong Park*** [3] ***, Dr. Jin-Hyuck Choi*** [1]

1. *Korea Institute of Geoscience and Mineral Resources (KIGAM),* ***2.*** *Nakdonggang National Institute of Biological Resources,* ***3.*** *Hanyang University*

It is important to assess geologic hazards associated with tsunamis on the east coast of the Korean Peninsula because of nuclear power complexes, populated cities, active faults, and volcanos under the East Sea. Although tsunamis in the east coast areas were reported in historical documents, there have been no studies detecting the geological record of tsunami sediments. Here we first show three tsunami events from core samples of the lagoon. In the bacterial diversity analysis, the *Sulfurimonadaceae* known to inhabit mainly hydrothermal vents characteristically distributed only at about 0.3–2.5 ka (Event III), 6.5–7.8 ka (Event II), and 8.3–8.8 ka (Event I). The *Dictyocha byronalis*, a pelagic species, also reported in hydrothermal vents is dominant around Event I. These paleo-archive results are supported by the Fe/S ratio in the coreXRF data to confirm the Fe fluctuation trend related to volcanism. Coincidentally, Event I coincides with the volcanic activity period of Ulleung Island located in the East Sea, suggesting volcanic activity occurred on Ulleung Island and its surrounding seabed for 8.3–8.8 ka, which caused a tsunami. In addition, the rest of the periods can be used as evidence to reveal the timing of the submarine volcanic activity around Ulleung Island.

Application of sedimentary ancient DNA to 1755 Lisbon tsunami and palaeostorm deposits in Martinhal, southern Portugal

Mr. Piotr Rozwalak [1], ***Prof. Witold Szczuciński*** [1], ***Prof. Jan Pawłowski*** [2], ***Ms. Kristina Cermakova*** [3], ***Ms. Inés Barrenechea Angeles*** [4]

__1.__ Geohazards Research Unit, Institute of Geology, Adam Mickiewicz University in Poznan, __2.__ Institute of Oceanology, Polish Academy of Sciences, Sopot, __3.__ ID-Gene Ecodiagnostics, 1202 Geneva, Switzerland, __4.__ Department of Earth Sciences, University of Geneva

One of the significant problems in coastal geology is differentiating between tsunami and storm deposits. So far, there is no unique set of features applicable globally to identify these deposits. Recently a promising novel technique applying ancient sedimentary DNA was suggested as a potential key to distinguishing palaeostorms and tsunamis. Thus, the present study aimed to use the palaegenomic approach for the 1755 Lisbon tsunami and younger palaeostorm deposits from the same coastal setting of the seasonal coastal lagoon in Martinhal, southern Portugal. We performed an analysis based on a specific marker for foraminifera (18S 37f) and a universal marker for eukaryotes (18S V9) in 96 samples taken from event deposits, beach, dune, shallow seabed, and freshwater stream sediments. We found that the sedimentary DNA was preserved in all the samples. While, the DNA of marine organisms was preserved in samples of modern marine sediments, the 1755 Lisbon tsunami, and several younger storm deposits. Our results confirmed the usability of metabarcoding in coastal geology. They demonstrated that ancient DNA might be preserved in harsh and unstable conditions of the temporarily flooded lagoon in the warm and arid climate in southern Europe. Thanks to the presence of tsunami and storm deposits in the same location, the results provided ground for further discussion on the advantages and limitations of metabarcoding in interpreting the coastal sedimentary record.

The research was funded by the Polish National Science Centre grant No. 2020/37/B/ST10/03677 (TSUNASTORM).

A Quantified Historical Data Framework (QHDF) for reconstructing historical storms and tsunamis from archival records

Prof. Adam Switzer [1]***, Dr. Joseph Christensen*** [2]

1. *Earth Observatory of Singapore, Nanyang Technological University Singapore,* ***2.*** *School of Humanities, Discipline of History, The University of Western Australia*

Risk assessments for coastal hazards including tsunamis or storm surges are often based on short-term instrumental records that in almost all cases fail to reflect the full range or magnitude of possible events. As such methods for accurately assessing natural hazard recurrence are becoming increasingly important as clearly such short records are inadequate for determining the natural variability of a hazard at multi-decadal timescales. While it is well known that the historical record is fragmentary, incomplete and limited in spatial balance, the historical record does provide a key link between instrumental datasets and the prehistoric record that allows for the detailed reconstruction of past events. Here, using a method developed for the study of 1921 cyclone in Western Australia we present a Quantified Historical Data Framework (QHDF) that provides a method to assess the quality of the historical information. The QHDF examines historical accounts using a five-dimensional assessment along axes of 'proximity', 'immediacy', 'accuracy', 'impartiality' and 'provenance' that can either be given equal weighting or weighted in terms of importance. The successful reconstruction of historical events is underpinned by the quality of the historical data. In this example the historical data allowed the reconstruction of a historical cyclone that implies that the event was much bigger than previously thought.

A comparison of instrumental and geologic records of storm activity in northern New Jersey, USA: Implications for extreme sea level recurrence intervals

***Dr. Kristen Joyse* [1], *Dr. Jennifer Walker* [2], *Prof. Linda Godfrey* [2], *Prof. Margaret Christie* [3], *Dr. Timothy Shaw* [1], *Prof. Reide Corbett* [4], *Prof. Robert Kopp* [2], *Prof. Benjamin Horton* [1]**

1. *Earth Observatory of Singapore, Nanyang Technological University Singapore,* ***2.*** *Department of Earth and Planetary Sciences, Rutgers University, NJ, USA.,* ***3.*** *McDaniel College, Westminster, USA,* ***4.*** *Department of Coastal Studies, East Carolina University, Greenville, North Carolina, US*

Determining the recurrence interval for overwash events requires a robust record of extreme storm activity. Geologic records of extreme overwash events can extend the record of landfalling storm activity beyond short instrumental records. However, the completeness of these geologic records is currently not well understood. Moreover, developing these geologic records can be difficult near urban centers, where the environments in which such records are found are often disturbed by anthropogenic activities.

Here, we develop a geologic record of overwash events from a salt marsh in Cheesequake State Park in northern New Jersey, which is adjacent to New York City that was impacted by Hurricane Sandy in 2012. We infer eight deposits within the marsh to extreme overwash events from storms. The overwash deposits are identifiable in stratigraphy by their fan-shaped morphology across the marsh and coarser mean grain size (2.7 ± 0.4 φ) compared to the salt marsh sediments (5.1 ± 1.2 φ) in which the overwash deposits are embedded. Age-depth modeling based on modern chronohorizons (bulk Pb, ^{206}Pb:^{207}Pb, ^{137}Cs, and pollen) and radiocarbon dates provides age constraints for each of the overwash deposits. The youngest of the deposits is attributed to Hurricane Sandy, while the oldest deposit is estimated to have originated from an event that made landfall between 1584 and 1658 CE (2σ).

We compare the last ~100 years of the Cheesequake geologic record with extreme sea-level events captured by nearby Sandy Hook and Battery tide gauges. Eight and ten extreme water level events above the 10 % probability of annual exceedance (AEP) level are recorded at the Sandy Hook and Battery tide gauges, respectively, and are attributed to extreme storm events. Of these events, four were also captured by the geologic record at Cheesequake. Thus, we find the Cheesequake geologic record has a 40 to 50 % preservation rate of extreme sea-level events above the estimated 10 % AEP level calculated from the tide gauge records. This implies estimates for the recurrence interval of extreme sea-level events from the geologic record would underestimate the true number of extreme events without consideration of this preservation bias.

Varying seasonal patterns of NE Atlantic storminess inferred from a 1500-years sediment record on the Shetland Islands (UK)

Ms. Katharina Hess [1], *Dr. Max Engel* [2], *Dr. Tasnim Patel* [3], *Dr. Polina Vakhrameeva* [1], *Dr. Andreas Koutsodendris* [1], *Prof. Eckehard Klemt* [4], *Dr. Thor Hansteen* [5], *Dr. Philipp Kempf* [6], *Prof. Sue Dawson* [7], *Prof. Isa Schön* [3], *Prof. Vanessa M.A. Heyvaert* [3]

1. *Institute of Earth Sciences, Heidelberg University,* **2.** *Universität Heidelberg,* **3.** *Royal Belgian Institute of Natural Sciences,* **4.** *Ravensburg-Weingarten University,* **5.** *GEOMAR Helmholtz Centre for Ocean Research Kiel,* **6.** *Institute of Geological Sciences, Freie Universität Berlin,* **7.** *University of Dundee*

The coasts of northwestern Europe are exposed to severe storm surges with the potential for high socio-economic losses. Therefore, high-resolution records of past storminess in the North Atlantic are needed to find answers to key questions such as (i) has storm activity increased over the last decades? and (ii) what risks may arise from storm surges in the future? The most destructive storms passing over Europe originate in the North Atlantic. Therefore, the Shetland Islands primely located in the northeast Atlantic serve as a window to the past frequency and intensity of storms. This study aims to reconstruct storm-induced overwash processes in lacustrine sediment cores from the coastal freshwater lake Flugarth. The variability of storm overwash is revealed by thin coastal sand layers serving as a contrast to the dark, organic-rich peat.

This multi-proxy study uses approaches including both sedimentological (grain size) and geochemical (XRF, TOC) data, and applies multivariate statistical analyses to determine the origin of the sand and peat layers within the sediment core. The resulting age-depth model is based on Bayesian AMS-^{14}C and ^{137}Cs data. Icelandic cryptotephra analyses and re-analysis of historical data were used to further calibrate the sedimentary record.

The results of our XRF Si/Ti ratio and the unimodal grain-size distribution clearly show that the sand layers originated from the beach. Phases of higher storminess with a prevailing northwesterly origin were documented between: 980–1050, 1150–1300, 1450–1550, 1820–1900 and 1950–2000 AD. These documented periods correlate with a positive North Atlantic Oscillation (NAO) mode and an increased subtropical water inflow into the northeast Atlantic. During these warm phases of the last 1500 years, storms occurred mostly in winter and their track shifted towards the northeast Atlantic. However, during the Little Ice Age (LIA, ca. 1400–1850 AD) high-intensity storms were predominantly from other directions than north(west), and a southward shift of storm tracks dominated along with storms occurring mostly in autumn and spring. These findings support IPCC forecasts of future storm track changes and an expected increase in winter storminess in the northern North Sea.

Impact on the German North Sea coast by the Storegga slide tsunami around 8150 cal BP

The Storegga slide tsunami (SST) at ca. 8100 ± 100-250 cal BP is known to be the largest tsunami that affected the North Sea during the entire Holocene. Geological traces of tsunami landfall were discovered along the coasts of Norway, Scotland, England, Denmark, the Faroes and Shetland Islands. So far, the German North Sea coast has been considered as being well protected due to the wide continental shelf and predominant shallow water depths, both assumed to dissipate tsunami wave energy significantly, thus hindering SST propagation dynamics. The objectives of our study were to clarify if the SST reached the German Bight and if corresponding sediment markers can be found. Our research was based on a 20 m long sediment core (GAR 1A) recovered from Eiderstedt Peninsula near Garding in North Frisia. High-resolution Direct Push sensing data and results of multi-proxy analyses of the sediment material were used to reconstruct palaeoenvironmental as well as palaeogeographical conditions.

We identified a high-energy event layer with sedimentological (e.g. erosional unconformity, rip-up clasts, fining upward), microfaunal (e.g. strongly mixed foraminiferal assemblage) and other features (e.g. upward increase of organic matter) typical of tsunami influence and identical in age with the SST. The event layer was deposited at or maximum ca. 1-1.5 m below the local contemporary relative sea level and minimum 40 km inland from the coastline within the palaeo-Eider estuarine system beyond the reach of storm surges. Tsunami facies and geochronological data correspond well with SST signatures identified on the nearby island of Rømø. SST deposits identified at Garding represent the southernmost proof of this event in the southern North Sea. They give evidence, for the first time, of high-energy tsunami landfall along the German North Sea coast and tsunami impact related to the Storegga slide.

It is suggested that the SST was not essentially weakened across the shallow continental shelf of the North Sea, but largely intruded the estuarine systems in North Frisia by tens of kilometres inland.

The sedimentary imprint of the ~8.1ka Storegga tsunami in Northumberland, northern England

Coastal sites in Scotland and Norway provide extensive evidence for the occurrence, timing and impacts of the Storegga tsunami, the largest tsunami to have struck North Sea coastlines during the Holocene. Sedimentary evidence from English shores has been less widely reported, likely due to erosion and submergence of the deposit by subsequent relative sea-level rise. Nevertheless, in northern Northumberland, the comparative stability of sea levels over the mid and late Holocene offers the potential for enhanced preservation of Storegga tsunami deposits. Here, we provide a detailed characterisation of a laterally extensive sand sheet at Broomhouse, approximately 10 km south of Berwick and 2 km inland from the modern coastline. Sea-level research at the site in the late 1990s identified that this layer abruptly interrupted supratidal deposits. Based on an extensive new stratigraphic survey, we trace the layer to a maximum elevation of more than 6.8 m above our estimate of contemporaneous sea level. Radiocarbon dating strongly supports the association of the deposit with the Storegga tsunami and we identify a range of sedimentological characteristics that further corroborate the origin of the layer. We use a multi-resolution finite element numerical model to explore the implications of the elevation, extent, and grain size of the Broomhouse deposit for understanding the characteristics of the incoming wave and aspects of the inundation of the coast of northeast England.

New sedimentary evidence for the ~1500 BP tsunami on the Shetland Islands

Dr. Max Engel [1]***, Ms. Katharina Hess*** [2]***, Dr. Tasnim Patel*** [3]***, Dr. Philipp Kempf*** [4]***, Dr. Andreas Koutsodendris*** [2]***, Dr. Polina Vakhrameeva*** [2]***, Prof. Eckehard Klemt*** [5]***, Prof. Sue Dawson*** [6]***, Prof. Isa Schön*** [3]***, Prof. Vanessa M.A. Heyvaert*** [7]

Tsunami deposits are required to assess the long-term hazard of tsunamis, in particular in regions with a short and fragmented historical record. In the North Sea region, historical evidence of tsunamis is scarce. However, the Shetland Islands are an exception, as they provide abundant sedimentary evidence of the Storegga tsunami 8200 BP, and more fragmented evidence of younger events ~5500 and ~1500 BP. Sediments of the 1500 BP tsunami have only been found in two sites so far, as thin landward fining and landward thinning sand sheets which are vertically confined by peat.

Here, we present sedimentary evidence for the ~1500 BP tsunami from the small coastal lake of Loch Flugarth, northern Mainland. Three gravity cores of up to 91 cm length were taken behind the barrier separating the lake from a marine embayment. The cores show organic-rich background deposition with many (sub)mm-scale sand layers in between, reflecting recurring storm overwash and a sediment source limited to the active beach and shallow embayment. A basal 13 cm-thick sand layer, dated to 426–787 cal yr CE based on ^{14}C-AMS and ^{137}Cs and Bayesian age-depth modelling, was found in all three cores. High-resolution grain-size analysis identified four normally graded sublayers with inversely graded traction carpets in the two lower sublayers. A mud drape and mud cap cover the upper two sublayers, which also contain a rip-up clast. Endmember modelling of grain-size distributions shows a difference between the basal sand layer and the thin storm layers, which are coarser and better sorted. Principal component analysis of XRF core scanning data also distinguishes both sand units, mostly driven by Zr and Fe in the basal sand. This, in combination with increased magnetic susceptibility, may be related to higher heavy mineral content reflecting a deeper additional sediment source for the tsunami deposit. The source of the ~1500 BP tsunami is unknown, but it is estimated to be of local origin as associated deposits have not been found outside the Shetlands. The size of the tsunami is estimated to be smaller than the Storegga tsunami, which affected most of the North Sea basin.

Geomorphological features of storm-induced depositional landforms in the SE Baltic Sea coastal zone

Storm surges influence sediment distribution along the sandy barriers. If the water level reaches the top of the dunes, sediment is moved to the back-barrier environment through breaches, forming washovers. These landforms are the direct result of contemporary storm surge events. In favourable conditions, sediments related to storm events are also preserved in the sedimentary record and become a valuable archive of past coastal floods. Thus, information on washover's shape, internal structure and properties of deposits may help better understand processes that lead to their formation and preservation in the sedimentary record.

The Southeastern Baltic Sea coastal zone (of a semi-enclosed, nearly tideless water reservoir) was subjected to the analysis of washover features. The fieldwork comprised hydroacoustic surveys using a Multibeam Echosounder (MBES) and Unmanned Aerial Vehicle (UAV) equipped with a photogrammetric camera, a laser scanner, and a multispectral camera. Surface data on morphology was supported by Ground Penetrating Radar (GPR) and surface sampling to obtain information about sediments. The gathered dataset was processed in QINSy, Pix4DMapper and CHCNV software. Secondary feature datasets were generated using ArcGIS, Matlab, R, and eCognition software.

The preliminary results allow us to compare dimensions of washovers formed at the coasts that differ in the basic geomorphological setting. In general, the slope of the nearshore zone, the height of dunes, surface sediment distribution and beach morphology influence the efficiency of sediment transfer to the back-barrier environment. The results also indicated incoherence of surface sediments traceable with a multispectral camera and possible application of this sensor to study surface sediment dynamics in the coastal zone.

The study is a part of the STORMLINK project funded by the National Science Centre, Poland, SONATA grant 2021/43/D/ST10/00185

An unexpected record of the 1922 Atacama tsunami. Historical and micropaleontological evidence in Carrizal Bajo (southern Atacama Desert)

On November 10th, 1922, at 23h 53m Chilean time, the Mw8.6 Atacama earthquake shook generating a highly destructive transoceanic tsunami with flood depths in the coastal cities near the epicenter of 7 to 9 m. There is no historical description of the tsunami arrival time to Carrizal Bajo (Atacama, Chile) but the chronicles report that two waves hit the port a few minutes later. The first wave razed the docks, the ships, the port offices as well as the train terminal station and workshop. The second one destroyed several buildings, the power station and residential houses reaching a flood height of 6 m above the mean sea level. The waves penetrated inland between 1.5 and 2 km washing away a locomotive and its train cars, tearing the electric engines off their foundations and scattering and burying the petrol barrels a kilometer away from the installation.
Inside of what we have identified as the half-buried locomotive boiler, located more than 600 m from the present coastline, a moderately sorted, medium to fine sand deposit appear. It is partially cemented by iron oxides and together with this rust its analysis has revealed the presence of foundry slags, metallic spherulites and coal that record the destruction and landward transport of the railway and metallurgic infrastructures originally located near the port. Its micropaleontological study has shown very common marine specimens such as siliceous sponge spicules, echinoderm radioles, bony fish teeth, benthic foraminifera (e.g., *Buccella peruviana*, *Quinqueloculina seminula*, *Cibicides ornatus*) and ostracods (e.g., *Xestoleberis chilensis, Cyprideis beaconensis*) with some fragments of calcareous nannoplankton (e.g., *Thoracosphaera*). Occasionally, freshwater organisms appear as charophyte girogonites, gastropods (*Heleobia copiapoensis*) and amoebas (Arcellinidae) with some brackish ostracods (e.g., *Cyprideis beaconensis*). Altogether, the locomotive and the sandy sediment within represent an exceptional archeological-historical-geological record of the last large tsunami recorded in the southern edge of the Atacama Desert. The strong onshore flow was able to displace tens of meters an iron locomotive ant its railcars, accompanied by high volume of sandy sediments eroded from the subtidal, intertidal and the wetland zones during the marine flooding.

The morpho-sedimentary record of the 1922 Atacama tsunami in the Copiapó coastal wetland (Southern Atacama Desert)

***Dr. MANUEL ABAD* [1], Dr. Tatiana Izquierdo [1], Mr. Maximiliano Forch [2], Mr. Nelson Pereira [3], Ms. Elena Cuesta-Hernández [4], Ms. Irene Damas-Fernández [4], Ms. Marina G. Herrero [4], Dr. Francisco Ruiz [5]**

The November 10th 1922 earthquake (Mw~8.5–8.6) is considered to be the second largest seismic event occurred in Chile during the 20th century after the 1960 Valdivia earthquake (Mw 9.5). The earthquake had a rupture close to 500 km long and it was felt in most of Chile and South America. It generated a destructive transoceanic tsunami with maximum wave heights of 7 to 9 m close to the epicenter that not only caused damages along the Chilean coast but also hit Perú, Hawaii, Samoa Islands, Taiwan, and Japan. Despite its magnitude, the geological record of this recent event is poorly studied, on the one hand, because of the low preservation potential of the tsunami deposits on arid coasts and on the other, due to the irregular and steep configuration of the southern Atacama Desert coast.

In this work we present the first evidence of the marine flood generated by this tsunami in the Copiapó coastal wetland. We focus on its northern sector where a narrow strip of wetlands and small coastal lagoons occur parallel to a foredune (heights >2.5 m) and beach systems. The geomorphological analysis of the area has shown several breaches of the littoral dune ridge and the formation of washover fans over older saltwork structures. The excavation of trenches has revealed a sandy layer 2 to 11 cm thick at 20 cm below the surface. It is formed by massive and well sorted fine sands with erosive base interbedded with argilite, peat and sandy shale deposits, as well as paleosoils interpreted as flood and arid marsh facies. In addition, a few specimens of sponge spicules, fragments of ostracods, diatoms, and marine benthic foraminifera have appeared in this tsunami deposit. Channelized return flow incised the initial breach opening and formed the small lagoons, with a V-shape oriented toward the sea, that are now disconnected from the beach. These last forms constitute the only obvious evidence that have been preserved in the landscape of the 1922 tsunami, although they continue acting as preferred discharge zones toward the sea during extreme fluvial floods in recent times.

Portuguese offshore tsunami deposits - a hydroacoustic survey

The 1755 CE Lisbon tsunami caused widespread destruction along the Portuguese, Spanish and Moroccan coasts. In Portugal, this event's onshore record is particularly well-studied. The offshore record, on the other hand, is until now sparse and not well understood. RV METEOR cruise M152 sailed to study offshore imprints of the 1755 CE Lisbon tsunami and possible preceding events on the southwestern Algarve continental shelf, southern Portugal. Deposits of the 1755 CE Lisbon tsunami and of an older event dated to around 3400 years BP, were identified in the sediment cores. Especially the deposits of the the latter event are represented by an extraordinarily strong reflector in the recorded sub-bottom profiles.

Here, we present an interpretation of sub-bottom and seismic profiles recorded during cruise M152 and one additional cruise which extended the original profiles into shallower waters. During cruise M152, an Atlas Parasound echo-sounder was used, while the additional cruise included a sub-bottom survey with a parametric echo-sounder and 2D single-channel seismics. The Late Quaternary sedimentary record of the southwestern Algarve shelf was in the focus. Most of the study area is characterized by rough erosional seafloor and exposures of bedrock with only thin sedimentary cover. In some areas, one or more strong reflectors were recorded and, where possible, correlated to the stratigraphy of the sediment cores. Mapping of the strong reflector related to the 3400 years BP event revealed its lateral distribution on the shelf. Only the strong compositional contrast between the event layer and the surrounding sediments in water depths between 30-70 m is capable of producing an extraordinarily strong reflector. But in the cores, deposits of the 3400 years BP event extend further until around 90 m water depth. In the deeper cores, a thinning and fining trend of the event layer is observed.

Our study demonstrates the advantages of using hydroacoustic profiling to study the Late Quaternary sediment cover of the Algarve shelf to better reveal the spatial extent of offshore tsunami deposits.

Deciphering high energy wave-induced sediment deposits using spectroscopic technics

In the last two decades, several devastating wave-induced events such as the 2004 Indian Ocean tsunami, 2011 Tohoku tsunami and the 2018 Palu tsunami, demonstrated the need for reliable information on the magnitude and recurrence interval of such events. Sediment archives are a major source of data on extreme palaeoenvironmental events. However, despite a considerable progress in tsunami research, the multi-proxy characterization of tsunami deposits for reliable identification of changes in sediment provenance remains a major scientific challenge because it provides insights into source materials and their environmental context at the time of the event. The increasing reliance of such studies and the need for robust identification and characterization of sediment deposits, motivated the research of reliable, time-saving analytical tools and procedures. Here we compare four rapid (1sec – 2min), non-destructive and accurate spectroscopic technics for semi-quantitative mineralogical, geochemical and bio-chemical characterization of sediments. Portable visible spectrocolorimetry, benchtop mid infrared spectroscopy (Fourier Transform attenuated total reflectance and diffuse reflectance) and portable X-Ray fluorescence were used to characterize and discriminate high energy wave-induced sediment deposits. Sediment deposits were collected from 7 ka year record of high-energy deposits recorded in a coastal cave along the north-western coast of Sumatra (Indonesia). Compared to more conventional technics such as atomic absorption spectroscopy, inductive coupled plasma mass spectroscopy, scanning electron microscopy, visible (VIS) and infrared spectroscopy (MIR) analytical approaches used in this study are faster and less costly. Compared to conventional X-Ray diffraction, MIR spectroscopy is not subject to analytical biases introduced by the differential settling or preferred orientations of minerals, allows identifications of amorphous phases and only requires small samples (> 20 mg) and brief measurement times (~1 min). Due to its wide range of wavenumbers (VIS, 400-700 nm; MIR, 4000-450 cm^{-1}), spectra are highly discriminant and allow strong source to sink determination using multivariate statistics and machine learning. The results show strong discrimination between the subsequent high-energy events, suggesting significant environmental differences of source materials and their palaeoenvironmental (inland, offshore) and geomorphological context (lagoon-mangrove, dune, beach etc.). The advantages, the limits and the wider significance of the methods are discussed.

Tsunami potential source in the eastern Sea of Marmara (NW Turkey), along the North Anatolian Fault system

Tsunamis could be generated by direct displacement of the seafloor due to a fast motion during an earthquake, or by mass failure as a consequence of earthquake shaking or other natural/anthropogenic causes, resulting in so-called “landslide tsunamis”. Although in different proportions, both mechanisms can play a role during most tsunami events, particularly those generated close to continental shelves.
The Sea of Marmara is particularly prone to landslide tsunami hazards for multiple reasons. First, it experiences large-magnitude, relatively shallow earthquakes, along active segments of the North Anatolian Fault (NAF) system, one of the most seismogenic structures on Earth. Second, it is bounded by steep fast-subsiding slopes, favoring relatively thick and unstable sedimentary sequences piling up over natural sliding planes. Third, it has been affected by dramatic water-level changes during the Pleistocene/Holocene transition, and most probably during previous glacial/interglacial cycles, primarily controlled by the natural Dardanelles and Bosphorus sills primarily controlled by the natural Dardanelles and Bosphorus sills. This peculiar physiographic setting could have favored catastrophic inundations, mega-turbidites, and slope instability during eustatic transitions and/or variations of hydrostatic pressure conditions. In the Sea of Marmara, gravitative failures could also be enhanced by the presence of geological fluids in the sediments.

Several oceanographic expeditions carried out in the Sea of Marmara after the *Mw*=7.6, 1999 İzmit earthquake highlighted the effects of gravitative instability and landslides, shown by slumping scars, actively gliding masses, or chaotic deposits in the sediments. In this general framework, high-resolution marine geophysical data led us to recognize a sizeable potential landslide mass in the Çınarcık Basin (eastern Sea of Marmara), close to the entrance of the Gulf of İzmit, which we called the South Çınarcık Landslide (SCL). This submarine landslide body could represent a potential hazard for the Sea of Marmara coasts, particularly in the NE sector between the Armutlu Peninsula and Istanbul. Our work attempts to define possible scenarios in case of a massive failure of this body due to future earthquakes or other causes and could be used as an example of a multidisciplinary study towards understanding and mitigation of landslide tsunami risk in other regions.

Storm or tsunami, that is the question - the sedimentary record of the 1755 Lisbon tsunami and palaeostorms in Martinhal (southern Portugal) revisited

One of the significant problems in coastal geology is differentiating between tsunami and storm deposits. Addressing this issue, studies comparing characteristics of event layers formed by various mechanisms on the same coast are particularly important, because many local factors (topography, bathymetry, sediment sources, climate, etc.) may affect sediment deposition from extreme coastal flooding. Such an approach was previously used by Kortekaas and Dawson (2007, Sedimentary Geology 200: 208–221) for a coastal lowland in Martinhal nearby Sagres in southern Portugal, where 1755 Lisbon tsunami deposits and several palaeostorm layers were documented. We have extended this previous work by multidisciplinary investigations, including detailed field mapping (DGPS based) and investigation of sedimentary records in over 70 sites, mainly in up to 90 m long trenches, providing new insight into a thus far complex stratigraphy. The sampling of the trenches was supplemented by hand coring and a collection of endmember samples from potential sediment sources: continental shelf, nearshore, beach, dune, river channels, and local soils. To reconstruct the evolution of the coastal lagoon and the nearby plain of Martinhal, the impact of catastrophic floodings (tsunami and storms), and the specific characteristics of event deposits, we applied a wide range of methods. The latter included geochronology (^{210}Pb, ^{137}Cs, and ^{14}C), sedimentology (sediment architecture, sedimentary structures, grain size analyses), geochemistry (XRF, ICP MS, LOI), mineralogy (heavy minerals, magnetic susceptibility), micropaleontology (diatoms, dinocysts, foraminifera, Tardigrada, Cladocera) and sedimentary ancient DNA. We carefully assessed the application of these proxies in the context of differentiating tsunami and storm deposits. We underline that changes in the coastal systems in time, particularly after extreme events (e.g., changes in coastal barrier height and shape), must be considered when interpreting the type and frequency of event deposits. This research was funded by the Polish National Science Centre grant No. 2020/37/B/ST10/03677 (TSUNASTORM).

Resilience of coastal peatland to the tsunami based on palaeoecological study of 1929 Grand Banks tsunami impact in Newfoundland

Extreme marine inundations such as tsunamis and storm waves drive changes to coastal environments worldwide. Their frequency and magnitude are going to change in the future along with rising sea-level, and will significantly impact ecosystems of coastal peatlands, influencing their hydrology, structure, vegetation, microorganisms, and carbon burial rate. Despite the increasing number of studies, the specific response of coastal peatland to extreme and short-term events like a sudden increase in salinity due to extreme marine flooding, combined with delivery of sand and organics, as often caused by a tsunami, is largely unknown. The aim of this study is to determine 1) what is the response/resistance of coastal peatland to an inundation, 2) how quickly does coastal peatland recover after burial with tsunami deposits, and 3) how palaeoecological data can inform studies of peatland recovery after a tsunami. Hence, we conducted high-resolution analyzes (0.5 to 1 cm) of two peat cores from the Burin Peninsula (Newfoundland, Canada). The 210Pb and 137Cs dated cores were collected from the blanket bogs affected by the 1929 Grand Bank tsunami that can be traced in our record by thick sand layers interbedded in organic sediments. We used testate amoebae analysis to reconstruct long-term hydrological dynamics and track the changes in the community of testate amoebae, and plant macrofossils to reconstruct changes of the local vegetation. Despite a significant tsunami impact, peatland recovery occurred within the following decades and led to the development of a fully functional peatland ecosystem. The research is carried out as a part of an OPUS project (2020/37/B/ST10/02614) financed by the Polish National Science Center.

Sedimentary traces of tsunami events recorded in the Sea of Marmara during the last millennium (Kumlubent Lagoon, NW Turkey)

Dr. Ufuk Tari [1], ***Dr. Nazli Olgun Kiyak*** [2], ***Dr. Ulas Avsar*** [3], ***Prof. Cenk Yaltirak*** [1], ***Prof. Gursel Sunal*** [1]

1. Department of Geological Engineering, Faculty of Mines, Istanbul Technical University, 34469, Istanbul, Turkey, 2. Climate and Marine Sciences Division, Eurasia Institute of Earth Sciences, Istanbul Technical University, 34469, Istanbul, Turkey, 3. Department of Geological Engineering, Middle East Technical University, 06531 Ankara, Turkey

The Sea of Marmara and its coastal regions are one of the few areas in the world with a thorough earthquake history. Lagoon environments that are separated from the sea by a narrow strip of sandbar can provide protection from post-depositional erosion and hence are critical coastal areas hosting traces of earthquake-related tsunami events. However, most of the coastal regions in the Marmara Region have been under rapid urbanization, and only a very few areas preserve original coastal sediment successions. This study provides the first multi-proxy sediment core analyses of a lagoon on the Marmara coast that is located in the Kumlubent coastal region in Gelibolu Peninsula, Çanakkale. Two sediment cores, retrieved from the Kumlubent lagoon were 3.40 m and 2.78 m long, respectively. The ITRAX micro-XRF scanner is used to obtain 0.2 mm-resolution radiographic images and 1 mm-resolution XRF data for the element distributions of twenty-five elements including Al, Si, P, S, Cl, Ar, K, Ca, Ti, Cr, Mn, Fe, Ni, Cu, Zn, As, Br, Rb, Sr, Y, Zr, Ba, Ce, Pr, Pb. Further geochemical analyses including TOC, $\delta^{18}O$, and $\delta^{13}C$ in the carbonate shell material will be investigated in order to understand the past oceanographic changes in the region that could be related to the events encountered in the sediment cores. The age model will be done by using AMS ^{14}C dating together with ^{210}Pb to obtain high-resolution age data. Our results showed that gray sandy sediment deposits of the Kumlubent lagoon are intercalated with several event-type sediment deposits including the variable thickness of; brownish gravel layers of terrestrial origin, gray gravels of marine origin, layers with high contents of marine bivalves and gastropods (*e.g. Turritella communis*) of pelagic origin, and black sapropels with high organic content and liquefaction structures. Geochemical and biostratigraphic analyses pointed out strong evidence of terrestrial and pelagic events which can be related to past tsunami and earthquake events as well as flood and storm events. These event-type sedimentary units are discussed within the historical records in order to understand the timing and influence of both the tectonic and paleoceanographic history of the region.

Coastal calc-arenites as a new archive of Holocene storminess in the SW Indian Ocean

Ms. Michaela Falkenroth [1]***, Prof. Andrew Green*** [2]***, Prof. Andrew Cooper*** [3]

1. *TU Darmstadt,* ***2.*** *University of KwaZulu-Natal,* ***3.*** *University of Ulster*

Because of their violent nature, extreme-wave events leave a trace in the sedimentary record in the form of sediment layers, erosional surfaces or both. Identifying and dating these traces is used to gain an understanding of recurrence intervals and magnitudes of extreme-wave events over geological timescales. Unlike for the Atlantic and Pacific Oceans, there is no robust record of extreme-wave events for the SW Indian Ocean. In a recent study based on a record of shelf-hosted tempestites, it was revealed that Holocene storminess along the SE African margin was higher than previously thought (Green et al. 2022). In the context of coastal deposits, we expand this record of storminess to include coastal calc-arenites, like beachrock, that also comprise archives of extreme-wave events in the region. At Mission Rocks on the KwaZulu-Natal coastline of South Africa a narrow beach with isolated sand patches occupies low points of an otherwise continuous 3 m-thick, raised shore platform of sandy and gravelly beachrocks. Here tempestites occur as poorly sorted pebbly sandstones with erosional bases. Individual beds contain convex down shells, exotic shell content and cobble sized clasts of the underlying calcarenite layers. Based on the sedimentological facies analysis, radiocarbon dating, petrography and isotope geochemistry, we unravel the timing and magnitude of event layers along the coastlines of NE South Africa. Our work adds to a more complete understanding of marine flooding hazards for the region, to which we link to known fluctuations in the region's climatic drivers.

Applications of 210Pb and other gamma-emitting radioisotopes for studies of tsunami and storm deposits – insights from the coastal plain, lagoon, and continental shelf deposits

Prof. Witold Szczuciński [1], ***Ms. Hanna Machejek*** [2], ***Dr. Krzysztof Pleskot*** [2], ***Ms. Paulina Romel*** [3], ***Prof. Karl Stattegger*** [2], ***Ms. Roksana Śliwińska*** [2]

1. Geohazards Research Unit, Institute of Geology, Adam Mickiewicz University, 2. Geohazards Research Unit, Institute of Geology, Adam Mickiewicz University, Poznań, Poland, 3. Institute of Geology, Adam Mickiewicz University, Poznań

Geochronology applying ^{210}Pb and ^{137}Cs is commonly used to date sediments back in time to over 100 years ago. However, these isotopes may reveal more than the age model of a sediment core. They also provide essential insights into the sediments and sedimentary processes. The present paper aims to highlight some of these opportunities (and also limitations) based on case studies from the tsunami and storm-affected environments: the coastal plain and lagoon at Martinhal (southern Portugal), the coastal plain and lakes of Newfoundland (Canada), and Andaman Sea continental shelf deposits. These sites were affected by major tsunamis (e.g., the 1755 Lisbon tsunami, the 1929 Grand Banks tsunami, and the 2004 Indian Ocean tsunami) and storms, hurricanes, and typhoons. The application of ^{210}Pb and other gamma-emitting radioisotopes helped in addressing significant problems in coastal geology, namely the identification of event deposits and tracing the impacts of tsunamis and storms on coastal ecosystems. On the examples of the new data, we presented typical activity-depth profiles for gamma emitting isotopes (e.g., ^{40}K) and excess ^{210}Pb. We highlighted the potential to assess event deposition, erosion due to extreme events, and changes in local sedimentary systems leading to changes in sediment accumulation rates. We concluded that in some cases, the change in radioactivity profile may be the key to identifying event deposits in the offshore record. Moreover, radiochemistry may provide insights into areas of sediment bypassing and sediment sinks, as well as reveal sediment provenance. The simultaneous application of the radiochemical methods along with sedimentological, geomorphological, and geochemical approaches may provide very valuable insights into the interpretation of extreme marine flooding events and their impacts. This research was funded by the Polish National Science Centre grants No. 2020/37/B/ST10/03677 (TSUNASTORM) and 2020/37/B/ST10/02614.

Coastal boulders in Cuba: implications for paleotempestological research in the Caribbean

Instituto de Meteorología*

Boulders transported and/or moved by high-energy wave events have been the subject of research in different regions of the planet, including the Caribbean, which has historically been affected by hurricanes and tsunamis (the former more frequent than the latter). In Cuba, there are numerous areas with such boulder deposits; however, their origin (whether due to paleohurricanes or paleotsunamis, is unknown. The conditions that favor the deplacement of boulders, their different spatial distribution, size, and distance from the coast were studied and are presented here. The transport and deposition of boulders is likely the result of different factors, including the lithological characteristics of marine terraces (submerged and emerged), the presence (or absence) of coral reefs, and geomorphological factors (e.g., sea depth, underwater slope inclination, distance between the coastline and the island slope, and coastline orientation). On the south coast of Cuba, these accumulations are more common, and are characterized by blocks that are larger than elsewhere (mean volume between 5 and 50 m^3); on the north coast, the average volume has values from 1 to 5 m^3. These results are important because they are related to extreme wave events that have impacted the Cuban coastline, both in the past and in the present, and provide a new potential source of information for paleotempestological research in the region, which may help prevent hazards and disasters in the future.

Differentiating tsunami and storm deposits – application of heavy minerals analysis

Dr. Robert Jagodziński [1], *Dr. Beata Sternal* [1], *Prof. Witold Szczuciński* [2], *Dr. Karolina Leszczyńska* [3], *Prof. Karl Stattegger* [1], *Prof. Pedro JM Costa* [4]

Although distinguishing tsunami and storm deposits affected by postdepositional changes may be possible by using a multi-proxy approach, their identification is often difficult because they are dependent on multiple factors and there exists no unique set of features which could be applied. One approach to distinguish these deposits is to apply heavy mineral analysis. The presence of heavy minerals (HM) has been frequently noted in tsunami and storm deposits, but they have hitherto received little attention. However, HM analyses may be useful in finding sediment provenance (e.g. marine), and trends (vertical and spatial) in HM assemblages within tsunami and storm deposits resulting from hydraulic sorting processes acting during the tsunami or storm. To test the applicability of HM analysis, modern tsunami deposits left by the 2004 Indian Ocean tsunami on Kho Khao Island, Thailand and by the 2011 Tohoku-oki tsunami on Sendai plain, Japan, were studied. The study of heavy minerals in storm sediments was tested on the southern coast of the Baltic Sea. In turn, the test area for both tsunami and storm sediments was the study of sediments in the Bay of Marthinal, on the SW coast of Portugal. The HM fraction content and mineral assemblages significantly differ between the individual case studies. The content of the fraction ranges from less than 1% in storm sediments of the southern Baltic Sea to over 30% in the sediments of the Tohoku-oki tsunami. Differentiation is also observed in the composition of HM. While the mineral assemblages of transparent HMs depend on the available source rocks, the presence and distribution of mica and opaque, particularly limonites, are a good indicator of the mode of transport. Thus, HM analysis may be a useful supplementary tool in tsunami deposit studies, however, the interpretation must always be put into the local geological context and evaluated in tandem with other proxies such as diatoms.

The research was funded by the Polish National Science Centre grant No. 2020/37/B/ST10/03677 (TSUNASTORM) and grant No. 2018/29/B/ST10/00042 (CatFlood).

In search of high energy marine deposits in coastal archaeological sites: first results from the ancient Greek-Roman town of Elea-Velia (Campania, Italy).

Dr. Alessandra Smedile [1]***, Dr. Vincenzo Amato*** [2]***, Dr. Paolo Marco De Martini*** [3]***, Dr. Mauro Di Vito*** [4]***, Dr. Domenico Doronzo*** [4]***, Dr. Patrizia Macrì*** [1]***, Dr. Valerio Materni*** [5]***, Dr. Vincenzo Sapia*** [5]***, Dr. Francesco Uliano Scelza*** [6]***, Dr. Tiziana D'Angelo*** [6]

The Mediterranean region is particularly rich in paleotsunami data, thanks to the availability of historical records that provided precious clues to geologists and archeologists in search for "the direct evidence of tsunamis" (e.g. sediments, morphological signatures, destruction layers). Tsunamis in the Mediterranean may originate from large earthquakes as well as active volcanoes and significant submarine landslides. Some evidence for past tsunami, associated to volcanic eruption (e.g. 79 CE Vesuvius eruption as reported by the ITED database) and related landslides of the Vesuvius, Phlegrean Fields and Ischia volcanoes, are reported in some archaeological excavation along the coastline of the Campania region highlighting significant tsunami hazard along one of the most populated coastal areas in Italy.

We report preliminary results from a multisciplinary study conducted in the Greek-Roman archeological site of Elea-Velia, located along the Cilento coast in southern Italy, carried out in the frame of the INGV-Ricerca Libera 2019 project and the scientific Memorandum of Understanding between INGV and the Paestum-Velia Archeological Park.

Recent archaeological excavations conducted in the Roman necropolis (1st-2nd century CE) and in the southern part of the town, reported a volcanoclastic deposit referable to 79 CE covered by a storm/tsunami deposit made of a thick layer of marine sands interbedded in a continental sequence.

ERT and GPR profiles, both located in the Roman Necropolis area and outside the city walls, were carried out in order to reconstruct the shallow subsoil setting and identify buried features covered by archaeological restoration. Based on geophysical outputs, ten cores were collected by means of a gasoline-powered percussion hammer equipped both with slotted and closed PVC pipe, down to the maximum depth of 6.20 m.

Preliminary results show a complex stratigraphy that points to the interplay between natural environments and human activities as far as back to the 3rd century BCE. Magnetic susceptibility on selected cores, highlight at least two volcanic ashes likely referable to 79 CE eruption. Further analyses are still in progress, aiming to characterize and date ash layers and the whole stratigraphy made by alternating of fine and coarse sediments full of pottery remnants, looking for potential tsunami deposits.

Progress and opportunities in ISROC: A Research Coordination Network targeting coastal boulder deposits

***Dr. Annie Lau* [1], *Dr. Max Engel* [2], *Prof. Rónadh Cox* [3], *Prof. Andrew Kennedy* [4], *Prof. Nobuhito Mori* [5], *Dr. Melissa Berke* [4], *Dr. Gregory Guannel* [6]**

__1.__ The University of Queensland, __2.__ Universität Heidelberg, __3.__ Williams College, __4.__ University of Notre Dame, __5.__ Kyoto University, __6.__ University of the Virgin Islands

Intertidal and supratidal coastal boulder deposits (CBD) result from extreme marine inundation on rocky shores. They are important for understanding long-term coastal wave hazards (both storm and tsunami), have potential predictive value for future events, and support assessment and planning for rocky coasts. However, there are at least two main obstacles to deeper understanding of CBD transport and applications: a lack of data on CBD worldwide, and discrepant approaches that lead to difficulties in comparing data from different sites. Building community and interaction among CBD researchers, and awareness of CBD as research targets, can help grow our knowledge and our ability to tackle these questions.

ISROC—Inundation Signatures on Rocky Coastlines—is an NSF-funded Research Coordination Network started in 2021 to define the CBD problem chain and identify research gaps by developing a broad and diverse network of researchers. The authors of this abstract are the ISROC PIs and steering group. Our goals are to extend the community of researchers to include underrepresented groups; to facilitate the development of standards and best practices for gathering and archiving CBD data; to develop cyberinfrastructure for uploading, visualizing, and analyzing data; and to train the next generation of CBD researchers. Understanding CBD and using them as a tool to reconstruct coastal inundation history and extreme climatological states is a prime example of convergence research that one discipline cannot solve. Thus, we create opportunities for cross-disciplinary collaboration and exchange. The ISROC network includes geologists, geographers, oceanographers, engineers, hydrodynamicists, geophysicists, climatologists, and paleoclimatologists. ISROC activities include meetings, student training, exchanges; sessions at major conferences in geoscience and coastal engineering; consolidation of survey/mapping approaches; and building a global database, including user-friendly, fully accessible online data archiving. Understanding past inundation and how CBD form and evolve will help quantify present-day risk and provide guidance for what to expect from future climate and sea levels.

New intensity map for the Mw7, November 19, 1912, Acambay earthquake, Mexico: a re-evaluation of the EEE's by ESI-07 scale

Dr. Magdalena Velázquez-Bucio [1], ***Dr. Pierre Lacan*** [1], ***Prof. Alessandro Michetti*** [2]

1. Centro de Geociencias, UNAM, Queretaro, 2. Università degli Studi dell'Insubria; INGV OV

The 1912 Acambay seismic event is the best documented historical crustal earthquake associated with surface rupture within the Trans-Mexican Volcanic Belt. It was accompanied by both primary and secondary environmental effects on the Acambay graben and nearby central Mexico. However, inaccuracies and contradictions in historical documents have led to different interpretations about the tectonic surface ruptures and other coseismic effects such as landslides and liquefaction. We revisited the sites first described by contemporary sources, and revised trench investigation conducted across the coseismic ruptures. This allowed us to obtain a new and more precise map of the distribution of environmental effects and ESI-07 epicentral intensity.
A detailed review of documents (historical archives, photographs, newspapers, reports), assisted by fieldwork, interviews with inhabitants, and paleoseismological studies, provided new data allowing a better characterization of the earthquake and its effects on the natural environment. The classification and re-evaluation of the primary and secondary effects led to reinterpret the macroseismic field and the intensity distribution within the graben. The ESI-07 isoseismals of maximum intensity values correlate with the location of the surface ruptures, showing that the rupture occurred A) at the northern border of the graben, in the Acambay-Tixmadejé fault; B) at the southern border, in the Pastores fault and; C) along the central fault system, involving the Temascalcingo and San Pedro faults. The above suggests that multifault rupture event scenarios, with related higher magnitudes, have to be considered on Central Mexico, a region with significant urban and infrastructural development that concentrates more than 50% of the population of the country.
This study highlights the importance of considering the EEE's in order not to underestimate the intensity values in the epicentral area, and also suggests the use of the ESI-2007 scale as an effective tool to assess seismic hazard.

The Trans-Mexican Volcanic Belt and its active faults: creation of an update database through geomorphic analysis, heavy bibliographic compilation and extrapolation of coherent values

Mr. Andrés Núñez Meneses [1] ***, Dr. Pierre Lacan*** [1]

1. *Centro de Geociencias, UNAM, Queretaro*

The Trans-Mexican Volcanic Belt is a continental volcanic arc that crosses central Mexico from the Gulf of Mexico to the Pacific Ocean. Despite being affected by different active crustal fault systems responsible for several destructive historical earthquakes, more than 50% of the Mexican population lives in this geological province, in megacities, increasing the seismic risk.

More than 600 fault segments have been mapped in the Trans-Mexican Volcanic Belt, but only 5% of these structures have been studied enough to characterize their seismogenic potential.

Several works are disponible on literature using different approaches such as structural geology, geochronology, tectonics, historical crustal seismicity, paleoseismology, geophysics and seismic hazard assessment, and could be compile to form an updated database with all the necessary parameters to incorporate faults data within seismic hazard assessment.

We present here this compilation and how we used it, extracting relevant information on the ages of rocks displaced by the activity of faults within the Trans-Mexican Volcanic Belt, slip rate, displacement speeds, height of the escarpments, among others. In addition, an extrapolation of the data found in the literature for other fault segments within the same system and with similar characteristics is proposed. For this, a geomorphic study has been performed using digital elevation models, satellite images and different types of maps in Qgis software. Key parameters for future risk analysis are established, such as the length of the fault trace, azimuth, coordinates of the extremes, proximity to large cities, as well as important or dangerous infrastructures (dams, oil pipelines, etc.). With this work, a new database is proposed where punctual information for the different segments or fault systems with potential seismogenic activity is organized and quantified. This new database will allow the incorporation of cortical fault data in seismic hazard assessment at the scale of the Trans-Mexican Volcanic Belt.

PASTORA: An example of inclusion of gender perspective in geosciences research

***Dr. Penelope Gonzalez-Samperiz* [1], *Dr. Graciela Gil-Romera* [2], *Dr. Federico Fillat* [3], *Mr. Javier Lara-Recuero* [3], *Dr. Lourdes Montes* [4], *Dr. Carmen Mayoral* [5]**

***1.** Pyrenean Institute of Ecology-CSIC, **2.** ARAID Researcher - Pyrenean Institute of Ecology - CSIC, **3.** Pyrenean Institute of Ecology - CSIC, **4.** Dept. of Antiquity Sciences (Prehistory), University of Zaragoza, **5.** Women and Science CSIC Commision*

The inclusion of the gender and/or sex dimension in research (IGAR) renders higher quality, more correct scientific results, and avoids adverse effects, as recommended by the Gendered Innovations Program (European Commission in collaboration with Stanford University), and by the National Science Foundation of the United States. For those research areas where human beings are not directly involved, as in Geosciences, IGAR tools suggest to explore the extent at which men and women can also be the object of research when considering potential final users of the findings, and customers, workers or citizens.

In this contribution the gender perspective in the PASTORA project is explored. The research project aims to determine the patterns of resilience and use over time of different pastures in high altitudes of the Central Pyrenees (NE Iberia) using paleoenvironmental, palynological, archaeological and modern ecology techniques. The approach is focused on the analysis of grazing impacts on mountain ecosystems from the Prehistory to assist in the design of appropriate subalpine pasture conservation policies and strategies. The gender perspective is important, firstly, in the study of the prior knowledge of ancient pastoralism practice and sexual division of labor in the past. We are aware that part of this traditional and ancestral profession has included, includes, and will include in the future, women shepherds. Also, it is proposed that recent efforts made to maintain traditional practices, interests and visions, should include women shepherds in activities or projects, with the support of society, public administrations, and scientific research. And finally, results diffusion and outreach activities are designed to reach not only local networks and stakeholders as rural women entrepreneurs, but also institutional bodies involved in reverting depopulation.

The research team of PASTORA project (whose acronym in fact means ‘women shepherd’), with an approach focused on the past, present and future of the mountain and its culture, is highly committed to gender perspective, with active presence in skilled commissions that investigate women involvement in Geosciences and participation in evaluation panels, with the final purpose to reach real gender equality in academia.

Identifying and tackling microaggressions within the Quaternary Sciences at levels implementable by individuals

Dr. Daniel Schillereff [1], ***Dr. Kathryn Adamson*** [2], ***Prof. Jane Hart*** [3], ***Dr. Naomi Holmes*** [4]

1. *Department of Geography, King's College London,* ***2.*** *Manchester Metropolitan University,* ***3.*** *School of Geography and Environmental Science, University of Southampton,* ***4.*** *Department of the Natural and Built Environment, Sheffield Hallam University*

Microaggressions are seemingly insignificant words or actions that belittle, stigmatise or stereotype certain individuals, often without the person delivering the slight being aware or intending it to have a harmful impact. Microaggressions stem from (unconscious) bias or prejudice and reinforce feelings of exclusion and being an outsider. Individuals from under-represented groups in society are most likely to experience subtle, everyday microaggressions, bringing deleterious cumulative effects on well-being as well as participation and engagement in social and professional settings.

Discussions and proposals to increase diversity within the geosciences mostly consider systemic barriers within academic settings. Whilst these represent positive progress, the pervasiveness of microaggressions in the scientific community is rarely discussed. Virtually nothing is published publicly about identifying and tackling microaggressions within the Quaternary Science community.

This presentation therefore has two goals: (i) to formally and openly draw attention to microaggressions that are likely to be common in research environments, and indeed that someone may be experiencing right now in this conference centre; and (ii) propose some straightforward measures to address microaggressions and foster more positive, inclusive research cultures that are implementable at levels at which we as individual researchers have direct influence, such as within research groups or Society committees.

Drawing on collective insight and observations from initiatives the authors have implemented, participated in or commissioned reports into, we explore how to identify and tackle four forms of microaggression that may play out in the field, laboratory, classroom or at meetings: (i) mispronunciation of names; (ii) questioning one's heritage or ancestry; (iii) complimenting the sophistication of a researcher's scientific output or the eloquence of their spoken or written English and (iv) comments on visual appearance.

Democratizing palaeosciences for effective bidirectional communication

Dr. Morthekai P [1]

1. Birbal Sahni Institute of Palaeosciences

Palaeosciences deals with disconnected past and it differs slightly from geoscience/Earth science as it is temporally in continuum with the past (Morthekai, 2019. Philosophies for the palaeosciences – a review. Proceedings of Indian National Science Academy 85 (1), 95 - 120). Although the 'present' is not the focus of palaeosciences, it is a methodologically required key to unlock the past. Considering the complexity in the palaeoscientific investigations, epistemological pluralistic approach is suggested where not only different disciplines come together but also people from various walks of life (with their own situated knowledge) should be involved in research activities in palaeosciences. It assumes implicitly that no lay persons, how marginalized they are, should be excluded. If excluded, the objectivity of the approach is skewed which lead both 1) to an incomplete knowledge of the present (loss for the palaeoscientists) and 2) to a degraded society in terms of scientific temper, and deprived of informed decision making on S & T projects (loss for the local civil society). This democratic participation of local civil society in palaeoscientific research activities is not only a good strategy to outreach (not only the majority ablests but all, possible) with an effective communication capacity but also society's valuable contribution back to palaeosciences.

Further, this type of democratic participatory nature of research activities has the potential to increase the adaptive capacity of the local civil society towards extreme climate events, because that is not only aware but also feel the responsibility to act towards mitigation and prevention.

Quaternary Quandaries: Transdisciplinary research and pedagogy in the India

Prof. Shanti Pappu [1]***, Dr. kumar akhilesh*** [2]

1. *Sharma Centre for Heritage Education & Krea University,* ***2.*** *Sharma Centre for Heritage Education*

This paper seeks to discuss issues in the transdisciplinary and international nature of academic interactions in Quaternary palaeosciences with a specific focus on research within South Asia. We trace the evolution of interactions between Indian and foreign prehistorians and Quaternary scientists from the 19th c onwards, discussing the evolution of concepts and the impacts this had on the methodologies adopted to investigate the past. We also highlight issues related to the structure of research projects, sources of funding and resulting publications arising from such studies that have influenced perceptions of prehistory. We discuss the current state of research in prehistory and the impact of collaborative research on the same. We then move on to issues in pedagogy in the Indian context discussing the extent to which prehistory is incorporated into courses where other Quaternary palaeosciences are taught. We highlight the efforts of our Institute (Sharma Centre for Heritage Education, India), which has focused on holistic approaches towards understanding the past in the form of courses and workshops that stressed interdisciplinary participants and course structures. We conclude by discussing legal issues related to national and international collaboration within the country and issues therein, suggesting innovative ways in which these relationships may be fostered for the benefit of developing research and skills training within the nation. We conclude by discussing the need for the creative development of hybrid modes of pedagogy exploiting the vast potential for online modes of education, skills development and exchange of knowledge, thereby facilitating more comprehensive outreach and breaking barriers created by established hierarchies and funding.

Traces of Holocene extreme wave events in the Alykes coastal plain, Corfu Island

Ms. Tina Georg [1]***, Dr. Lea Obrocki*** [1]***, Dr. Peter Fischer*** [1]***, Dr. Timo Willershäuser*** [1]***, Dr. Björn R. Röbke*** [2]***, Dr. Kalliopi Baika*** [3]***, Prof. Andreas Vött*** [1]

Corfu Island is the northernmost of the Ionian Islands located in the eastern Mediterranean Sea. As a result of the collision of the African and the Eurasian plates, the island lies within an area of exceptional tectonic stress with all plate boundaries in its proximity. In the Adriatic Sea north of Corfu, the Adriatic microplate collides with the Eurasian plate, and to its south, in the Ionian Sea, the African oceanic plate is subducted beneath the Aegean microplate forming the Hellenic Arc. Earthquakes and co-seismic crustal movement which can cause extreme wave events have been recorded for the area. This paper presents geomorphological, sedimentary and microfaunal evidence of repeated tsunami landfalls in the Alykes coastal lagoon at the southwestern coast of Corfu Island. Using the radiocarbon dating approach, the beginning of the lagoon was dated back to at least the 6th millennium BC. Siltation of the lagoon was repeatedly interrupted by high-energy tsunami impacts. The most prominent tsunami traces were found for time immediately before 5.7 ka cal BC and the time between 5.2-5.0 ka cal BC. The ages of the tsunami events correspond well with local, regional, and supra-regional tsunami signatures found along the northwest and the west coasts of Greece. Subordinate traces for younger extreme wave events described by previous studies for the Gulf of Corfu were also detected in the Alykes palaeotsunami archive and seem to be partly related to co-seismic movements of the southern part of Corfu Island in the 4th century BC. The current study contributes to the understanding of the environmental effects of palaeotsunami impacts and underline a strongly non-uniform neotectonic behaviour of Corfu Island as a whole.

SW Atlantic intermediate to deep water flow changes from MIS4 to Holocene: a sortable silt perspective

Prof. Michel de Mahiques [1]***, Prof. Renata Hanae Nagai*** [2]***, Ms. Rafaela Nogueira Mendonça Mendes*** [1]***,***
Prof. Silvia Helena Mello e Sousa [1]***, Mr. Gilberto Dias*** [1]***, Prof. Rubens Cesar Lopes Figueira*** [1]

1. *Universidade de São Paulo,* ***2.*** *Federal University of Paraná*

Understanding the formation and circulation patterns of intermediate to deep water masses on different time scales is crucial for understanding the global thermohaline overturning circulation impacts on the Earth's climate. On the SW Atlantic continental margin, the northward flow of the Antarctic Intermediate Water (AAIW) and the Upper Circumpolar Deep Water (UCDW) is driven by the Intermediate Western Boundary Current (IWBC). In this study, we investigate intensity variations in the transport of AAIW and UCDW over the last c.a. 80,000 years, using the concept of sortable silt, a reliable proxy for current speed on the continental slope. We used grain-size data from three sedimentary records collected on the SW Atlantic slope, located at 840 mbsl (meters below sea level; modern AAIW and IWBC depth core), 1343 mbsl (current UCDW depth upper limit), and 1588 mbsl (modern UCDW depth core).

The results indicate that the average speed of the IWBC core (AAIW depth transport) is at least 15 $cm.s^{-1}$ faster than at the lower IWBC limit, where UCDW is transported. The minimum (15.5 $cm.s^{-1}$) and maximum (24.2 $cm.s^{-1}$) speed values obtained for the record under the IWBC modern core depth are compatible with those calculated for the current oceanographic setting. The results show abrupt changes in sortable silt (interpreted as changes in flow speed) in the transition between Marine Isotope Stage 4 (MIS4) and MIS3 and during MIS3, exclusively for the record retrieved at 840 mbsl. In addition, there is a clear coarsening of sortable silt from the Deglacial to the Holocene, indicating an intensification of the northward transport of the AAIW along the SW Atlantic margin. These results highlight a prevailing positive relationship between the northward carrier of the AAIW and the Atlantic Meridional Overturning Circulation over the last 80 kyr, with an antagonistic relationship at the beginning of MIS3 and over the Holocene.

For the cores located under the UCDW, the low average speed values (5.3 to 6.4 $cm.s^{-1}$) are compatible with the transition between the IWBC and the Deep Western Boundary Current (DWBC), which transports the North Atlantic Deep Water (NADW) towards the south.

The Holocene onset of the Plata Plume Water on the southeastern South American Shelf: a grain-size approach

***Ms. Gabrielle Bonifatto* [1], *Dr. Samara Cazzoli y Goya* [1], *Mr. Edilson Oliveira Faria* [1], *Ms. Irys Ventura* [1], *Mr. Mascimiliano Maly* [1], *Prof. Michel de Mahiques* [1]**

***1.** Oceanographic Institute of the University of São Paulo*

On the southeastern South American shelf, the discharge of the Río de la Plata, together with those from the Uruguayan and southern Brazilian lagoons, lead to the formation of a low-salinity water mass, the Plata Plume Water (PPW). This water mass presents a conspicuous seasonal regime, determined more by the intensity of the southerly winds than by the river discharge. In this sense, the knowledge of the plume´s variation is a valuable tool for recognizing the wind dynamics in the South Atlantic. This study aims to identify the input and variations of the PPW on the southeastern South American shelf by analyzing the grain-size end members.

We used two sediment cores collected on the southern Brazilian continental shelf in areas directly affected by the current flow of the Plata Plume Water (PPW). Both cores were radiocarbon-dated, and age-depth models were created for them. Grain-size analyses on decarbonated samples were made every 2 cm. From the grain size results, we performed grain-size end-member analyses.

The results allowed us to recognize a silty end-member, presenting a trend of increasing values towards the top of the cores. This silty fraction was interpreted as the distal, fine grain size fraction delivered from the Río de la Plata basin and associated with the sediments transported by the PPW. These sediments started to be deposited at ca. 8,000 cal BP when the Holocene sea level reached heights equivalent to the current times. The main change in sedimentation was observed at ca. 2,800 cal BP when the coastline position and the current oceanographic conditions were established in the southwestern South American region. Apart from the oceanographic control, we recognized the role played by the Holocene relative sea-level variations in the establishment and variations of the PPW. Our results agree with the conclusions raised by independent proxies in the same area.

Climatic temperature gradients during the Younger Dryas Stadial (GS-1) across the British Isles in chironomid-inferred temperature records

Dr. Christopher Francis [1]***, Prof. Ian Candy*** [1]***, Dr. Stefan Engels*** [2]***, Dr. Ian Matthews*** [3]***, Dr. Adrian Palmer*** [1]

1. *Department of Geography, Royal Holloway University of London, London, United Kingdom,* ***2.*** *Birkbeck, University of London,* ***3.*** *Royal Holloway, University of London*

The Younger Dryas stadial (GS-1; c. 12.8 to 11.7 kyrs ago), the last major abrupt cooling event in the North Atlantic region at the end of the last glaciation, provides an excellent opportunity to investigate the timing and nature of climatic changes. Knowledge of spatial variations in temperature in response to abrupt climatic transitions is essential to understand potential future climatic change. Numerous studies, with varying degrees of chronological control and sampling resolution, have described two or more phases during the Younger Dryas from records around the North Atlantic region based on reconstructions of sea surface temperatures, hydrological change, and windiness. It is critical that the climatic structure of the LLS/YD is better understood as numerous forcing mechanisms and processes have been proposed to explain the multiple phases observed. These include changes in AMOC strength, sea-ice extent, polar jet stream location and Westerly strength.

Relatively little attention has been given to temperature variations expressed in chironomid-inferred temperature (CI-T) records during the Younger Dryas, yet they can provide high-resolution (decadal-scale) mean July air temperature estimates. In this study, chironomid analysis was applied at a high temporal resolution to a number of lake sequences from spatially diverse locations across the British Isles, including Old Buckenham Mere in the southeast of Britain, Llangorse in south Wales and Crudale Meadow in the Orkney Isles. The new C-IT records are combined with previous studies to generates a palaeoclimatic database. These records lie on W-E and N-S transects across the British Isles allowing the spatial variability of the structure and magnitude of temperature change to be explored. All three of the new sites display a three-phase structure. Old Buckenham Mere displays this most clearly with an initial cool period (c. 11 °C) from 12.7-12.5 kyrs ago, warmer temperatures (c. 13 °C) then occurred between 12.7-12.4 kyrs ago, followed by a return to cold (c. 10 °C) and gradually warm into the Holocene. Our new records suggest that there is greater variation in temperature change during the LLS than previously observed.

Changes in the global ocean during the last deglaciation from a model-data perspective

The early last deglacion (~19-15 ky BP) was a period of rapid climate change. It is characterized by the onset of atmospheric CO2 raise and land ice reduction that eventually lead to the Holocene climate state. The ocean processes involved in deglacial climate change are still under debate, with freshwater fluxes in different basins, changes in winds, ocean circulation, and biogeochemistry, as possible drivers of carbon transfer from the deep ocean to the atmosphere. Carbon isotopes in benthic foraminifera samples from sediment cores show variations during the early last deglaciation, that act as tracers of changes in deep water mass structure, ventilation, and export production. Here we compare the global deglacial benthic foraminifera δ13C database from the Ocean Circulation and Carbon Cycling (OC3) project with different transient global, isotope enabled, ocean model simulations. The goal is to constrain the different ocean changes that can explain variations in δ13C during the early last deglacation. This is the first time that a global synthesis of benthic foraminifera δ13C is compared one-to-one with modeled δ13C from transient simulations, with both spatial and time dimensions taken into account in a four-dimensional analysis.

Chironomid-based reconstruction of Holocene July temperatures: new training set from Eastern Europe and its application

Ms. Varvara Bakumenko [1], Prof. Tomi Luoto [2], Dr. Neringa Gasteviciene [3], Dr. Mateusz Płóciennik [4], Dr. Bartosz Kotrys [5], Dr. Simon Belle [6], Prof. Siim Veski [7]

__1.__ Early Stage Researcher - Division of Quaternary Geology: Department of Geology, Tallinn University of Technology, __2.__ Adj. Professor of Paleolimnology, Faculty of Biological and Environmental Sciences, Ecosystems and Environment Research Programme, University of Helsinki, Niemenkatu 73, FI-15140 Lahti, __3.__ Researcher, Laboratory of Quaternary Research, Nature Research Centre, Vilnius, __4.__ University of Lodz, Department of Invertebrate Zoology and Hydrobiology, Lodz 90-237, Banacha st. 12/16, __5.__ Polish Geological Institute − National Research Institute, Pomeranian Branch in Szczecin, Szczecin, Poland, __6.__ Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences, Uppsala, __7.__ Tenured Full Professor, Head of Division - Division of Quaternary Geology: Department of Geology, Tallinn University of Technology

The life cycle of non-biting midges from the family Chironomidae (order Diptera) depends on the ecological conditions of the water body, where larvae live (trophic state, oxygenation level, etc.) along with climatic factors, mainly average July temperature. Therefore, sub-fossil Chironomidae remains deposited in lakes and bogs provide a record of the past terrestrial and aquatic environment and could quantitatively reconstruct the environmental conditions.

Collecting modern analogs training sets and producing transfer functions based on them is the primary approach in paleo-Chironomidae research. I have created new Baltic States training set which covers understudied territories of Estonia, Latvia, and Lithuania. July average temperature range Baltic States transect is 1,5 ^{o}C. New data was merged the already published Finnish training set. Furthermore, some published sites from Poland were added to the Finno-Baltic training set. The final Finno-Baltic-Polish dataset contains 121 sites and has a temperature gradient from 11,0 ^{o}C up to 19,0 ^{o}C.

Based on the Finno-Baltic-Polish training set developed a new inference model using weighted averaging-partial least squares (WA-PLS) regression outperformed with maximum likelihood regression. The normalized root mean squared error (RMSEP) of the training set performance is 0,43 ^{o}C, the maximum bias is 0,35 ^{o}C, and R2 is 0,94. The Finno-Baltic-Polish inference model was applied on several lake long cores from Baltic States (300-13500 years BP) and resulted in the July air temperature reconstruction with an average error of 0,82 ^{o}C. Thus, the new Finno-Baltic-Polish training set provides the best modern analogs of Chironomidae communities to perform paleo-temperature modelling in the Baltic States region.

Clipperton coral d13C variability and its relationship to the rate of anthropogenic CO2 uptake

Dr. Émilie Dassié [1], Mr. Aitu Raufauore [1], Ms. Karine Charlier [1], Dr. Myriam Khodri [2], Dr. Bruno Malaizé [1]

1. Univ. Bordeaux, CNRS, Bordeaux INP, EPOC, UMR 5805, F-33600 Pessac, France, 2. LOCEAN

Since the 1850s, human activities have released a large quantity of CO_2 into the atmosphere. Anthropogenic CO_2 is depleted in ^{13}C leading to a continuous decrease in atmospheric $d^{13}C$ as the atmospheric CO_2 concentration continues to increase. The ocean is one of the main global sinks of anthropogenic CO_2 emissions which contribute greatly to reduce the effect of the global climate warming. However, the flux of CO_2 between the atmosphere and the ocean is not spatially homogeneous, especially in the tropics, where a mosaic of CO_2 sinks and sources is observed. The effectiveness of these zones also varies over time mainly at the decadal timescale. A better understanding of the variability of this CO_2 pump over the last centuries would improve predictions of the future evolution of these areas according to the different scenarios proposed by the IPCC.
Variations in the surface Dissolved Inorganic Carbon $d^{13}C$ ($d^{13}C$-DIC) make it possible to estimate the oceanic uptake of atmospheric CO_2. Nevertheless, there is only a limited amount of instrumental data of $d^{13}C$ -DIC, covering short time periods that cannot resolve its variations at decadal timescales. It is therefore necessary to find a marker of the variability of $d^{13}C$ -DIC that allows us to reconstruct the variability of the oceanic absorption rate over the last centuries in key areas of the tropical band.
This study that builds up on previous work will present Clipperton atoll coral $d^{13}C$ data as a proxy of $d^{13}C$-DIC variability over the last centuries. These geochemical data coupled with a modelling approach will give insight into the temporal variability of the rate of oceanic absorption of the anthropogenic CO_2 signal in the South East Pacific area.

crestr: An R package to perform probabilistic climate reconstructions from palaeoecological dataset

Dr. Manuel Chevalier [1], ***Dr. Brian M. Chase*** [2]

1. Institute of Geosciences, Rheinische Friedrich-Wilhelms-Universität Bonn, 2. Centre National de la Recherche Scientifique

Quantitative climate reconstructions are fundamental to scaling past environmental changes. In particular, the proliferation of pollen-based reconstructions during the past decades has been instrumental in improving our understanding of past climate dynamics across various spatial and temporal scales. However, this knowledge has been mainly concentrated in North America and parts of Eurasia, and very few quantifications exist in the tropics. This global data imbalance is partly due to the sparser network of supporting pollen records in these regions and, in equal proportions, to the limitations of the most commonly used reconstruction techniques (e.g. the analogue technique or WA-PLS) in dealing with the specificities of tropical vegetation. To address this problem and produce the much-needed climate quantification from tropical regions, we propose using the probabilistic method CREST (Climate REconstruction SofTware) that uses probability density functions ('pdfs') fitted on modern occurrence plant data to reconstruct environmental parameters. CREST, which has been successfully employed in the Africa and South America, offers many advantages over the classical approaches, including 1) a higher flexibility of application, 2) a better capacity to estimate uncertainties, and thanks to the recent developments of a dedicated R package crestr that includes a global calibration dataset, 3) CREST is applicable in every environment where plants currently grow. Considering these advantages, the large-scale application of CREST to quantitatively reconstruct important climate parameters from the existing tropical fossil pollen records should 1) help better integrate and interpret regional proxy compilations, 2) shed light on the spatiotemporal climate variability of tropical regions, and 3) determine the main modes of tropical climate variability. With this contribution, we will showcase the use of the crestr package with a novel temperature reconstruction derived from the 270,000-year-long, high-resolution pollen record from Laguna Fùquene in Colombia, and discuss how this type of analysis could be generalised to determine spatial patterns of climate change from multi-record reconstructions

Variations in the strength of the Atlantic Meridional Overturning Circulation during the Holocene

***Mr. Meriadec Le Pabic* [1], Dr. Christelle Not [1], Dr. Benoit Thibodeau [2]**

1. Earth Science Department & Swire Institute of Marine Science, The University of Hong Kong, 2. School of Life Sciences, The Chinese University of Hong Kong

Based on the geochemistry of foraminifera shells, the past strength of the Atlantic Meridional Overturning Circulation (AMOC) can be indirectly reconstructed by sea surface temperature, sea surface salinity, and CO_2 trapped by deep-water formations. While the AMOC plays a key role in climate variability, precise variations of the AMOC strengths and climate-related responses are still equivocal. The Holocene is an ideal period to further develop our knowledge of the natural climatic and oceanic variability from well-preserved microfossils. The aim of this study is to reconstruct the AMOC in a deep-water formation area (e.g., surface and bottom water) to obtain high-resolution strength variations. To investigate these variations, we used benthic and planktic foraminifera assemblages and geochemistry. Our study focuses on Core U1314, located in the Iceland basin (56° 21.8' N, 27°53.3' W), which is one of three deep-water formation areas in the North Atlantic. The core has been divided into 3 cm sections, 5 cm apart, to obtain a final resolution of 300 years. Preliminary results reveal four dominant species (from the most abundant to the lowest): Globigerina bulloides, *Neogloboquadrina incompta*, *Neogloboquadrina pachyderma (s*) and *Globigerina quinqueloba*. The early Holocene shows a warming trend with an increase of *G. bulloides* (40% to 63%). Additionally, there is a decreasing trend in *N. incompta* (from 40% to 28%). Although the late Holocene is still dominated by G. bulloides (ranging from 37% to 54%), a brief dominance of *N. incompta* (49%) appears at 4.000 years B.P., which indicates a freshening at this time. Additional trace element analyses (Mg/Ca) and stable isotope analyses ($\delta^{18}O$ and $\delta^{13}C$) will be conducted on benthic (*Hoeglundina elegans*) and planktonic (*G. bulloides* and *N. incompta*) foraminifera to reconstruct paleotemperature of bottom water and sea surface. The expected results will provide 1) a high-resolution dataset of bottom and sea surface temperatures; 2) an overview of the AMOC millennial cycle; and 3) a better understanding of the feedback mechanisms that influence the AMOC in the Holocene and their impact on the global climate. Therefore, the reconstruction of the AMOC strength variations can provide insight into future global warming.

Using lakes as isotopic precipitation gauges to constrain inflow seasonality and evaporative enrichment

Dr. Sofia E. Kjellman [1], ***Dr. Elizabeth Thomas*** [2], ***Prof. Anders Schomacker*** [1]

1. *Department of Geosciences, UiT The Arctic University of Norway, N-9037, Tromsø, Norway,* ***2.*** *University at Buffalo*

Lake-water-derived proxies have the potential to store information about both large-scale circulation changes and catchment-integrated processes. Lacustrine carbonates, cellulose, and aquatic organisms incorporating the stable isotopic composition of lake water hydrogen (d2H) and oxygen (d18O) can indirectly archive the isotopic composition of precipitation in the geological past. However, despite similar precipitation input, the lake water isotope values may vary greatly within a region due to variable influence of inflow (precipitation) seasonality and evaporative enrichment. Moreover, the relative sensitivity of each lake to these controls may vary through time. One way to quantify spatial and temporal variation in lake water isotopic composition is modern lake water monitoring. Furthermore, studying present-day conditions allows us to directly link isotopic changes to observations of atmospheric circulation change. From 2018 to 2022, we have measured the stable water isotopic composition of 135 lakes in northern Norway, Finland, and Sweden through a sampling campaign in the first week of July each year. The sample collection is focused along a coastal-to-inland transect, extending from the Norwegian Sea in northwest to Bothnian Bay in southeast. We find that the lakes display variable sensitivity to changes in inflow isotopic composition and to evaporative enrichment, and that these controls vary in both time and space. The water isotopic composition of coastal lakes is mostly sensitive to distillation during moisture transport, whereas the isotopic composition of inland lakes also reflects evaporation. To estimate the inflow isotopic composition of evapo-concentrated lakes (d2HI), we used a Bayesian method. For instance, more depleted d2HI in 2020 than in 2019 indicated more 2H-depleted and/or more winter precipitation inflow to the lakes in 2020, explained by extremely positive Arctic Oscillation (AO+) conditions. We find evidence that lake water isotopic variability in this region reflects a combination of seasonal precipitation changes associated with atmospheric circulation changes, and catchment-integrated evaporation. Careful consideration of the variable sensitivity to these processes is essential when inferring past climate from lake water isotope proxies.

Oceanographic variability by SE Greenland over the past 2000 years

Dr. Inda Brinkmann [1], **Prof. Jens Hesselbjerg Christensen** [2], **Prof. Christine Hvidberg** [2], **Dr. Camilla S. Andresen** [1]

1. Department of Glaciology and Climate, Geological Survey of Denmark and Greenland, 2. Center for Ice and Climate at Niels Bohr Institute, Copenhagen University

The interdisciplinary GreenPlanning project addresses an important question in climate science: *Does Greenland ice sheet melt affect weather fluctuations in Europe*? Model studies suggest that certain climatic modes with blocking of high pressure systems can hinder warm moist air from reaching Northwest Europe, and that these conditions are instigated by changes to sea surface conditions near Greenland. To test this hypothesis, the GreenPlanning project will establish a 2000 year long record of changes to the modes of climate variability in the North Atlantic and a record of Greenland Ice Sheet melt water fluxes.

An important brick to this puzzle is the ocean variability near Greenland over the past 2000 years. The Atlantic waters may modulate the amount of ice sheet melt and in return have their temperature and salinity modulated by melt water from the ice sheet. Paleoceanographic data from the SE and W Greenland shelf region document that temporal changes to the sea surface temperature and flow of Irminger Current is transmitted to Greenland's shelf and can be reconstructed from shelf sediment cores. Thus, potentially providing additional insight into the Irminger Ocean sea surface temperature changes. Here we present an overview of the past 2000 years of variability in Atlantic waters on the SE Greenland shelf based on foraminifera assemblage analysis and alkenone paleothermometry.

Variations of bottom current activity in the Korea Gap, East Sea (Japan Sea) since 35 ka

Prof. Jang Jun Bahk [1], ***Mr. Junho Jang*** [1], ***Prof. Boo-Keun Khim*** [2], ***Dr. Yu-Hyeon Park*** [2], ***Dr. In Kwon Um*** [3]

1. *Chungnam National University,* **2.** *Pusan National University,* **3.** *Korea Institute of Geoscience and Mineral Resoiurces*

This study reconstructed variations of bottom current activity based on the changes in sedimentary facies and detrital grain-size distributions of the levee deposits at the bottom-current channel in the Korea Gap. Since the Korea Gap serves as a conduit of deep-water circulation between Japan and Ulleung basins of the East Sea (Japan Sea), it is suggested that bottom current activity in the Korea Gap have been regulated by the deep-water circulation changes. Based on sedimentary facies analyses, intermittent turbidite beds deposited by the turbidity currents from the surrounding slopes were discriminated from the normal background deposits by hemipelagic settling and bottom-current reworking. The age-model for the normal background sedimentation since 35 ka shows an extremely high sedimentation rate up to 46 cm/kyr during about 17 to 11 ka, which is ca. eightfold higher than that of the last glacial period (5.5 cm/kyr) and ca. fourfold higher than that of the Holocene (12 cm/kyr). Such abrupt increase in sedimentation rate suggests a vigorous bottom-current activity which might have facilitated erosion in the bottom current channel axis and rapid deposition of the reworked sediment in the channel levee during the late-glacial period. The mean size of "sortable silt" from the bottom-current deposits, representing the bottom current velocity, fluctuated significantly with *ca.* 0.34-0.70 kyr periodicity. Hence, deep-water circulation in the East Sea was very unstable during the late glacial period, varying with centennial periodicity

Luminescence chronology of point bars and their utilisation in Past discharge estimation in the Southern West Bengal.

Mr. Vibhuti Shivsager [1]***, Dr. Manoj K. Jaiswal*** [2]***, Mr. Belligraham Narzary*** [1]***, Mr. Mahadev Rawat*** [3]***, Dr. Saurabh Singh*** [4]

1. *Department of Earth Sciences, Indian Institute of Science Education and Research, Kolkata, 741246, West Bengal, India,* ***2.*** *Department of Earth-Science, IISER-Kolkata,* ***3.*** *Inter University Accelerator Centre, New Delhi,* ***4.*** *Dr.RammanoharLohia Avadh University, Ayodhya, Uttar Pradesh*

Point bars are sinuous accretionary wedges of sand and finer sediments deposited by laterally migrating meandering rivers. They provide an excellent means to study past environments due to their ability to preserve the sedimentary structures corresponding to alteration in energy conditions. At the same, the dimension of the meander loops is directly proportional to the discharge of the river and the type of sediment load. The present work aims to study the point bars in Southern West Bengal to calculate the past river discharge and thus reconstruct the past climate. Luminescence dating is applied on the point bars to build the chronology. Field investigations and grain size analysis of point bar sediments supported by luminescence ages have shown point bars as a potential proxy for paleoflood and paleodischarge estimation. The study reveals that the region received good rainfall during reported periods of intense monsoon (Medieval Warm Period, Sub Altantic Period, Sub Boreal Period) and remained devoid of discharge during cold or dry events. (Little Ice Age) and 4.2 ka dry event (Meghalayan aridification).

Reconstructing tropical South Pacific hydroclimate during the late Holocene using proxies and models

***Dr. Mark Peaple* [1], *Dr. Gordon Inglis* [2], *Prof. Peter Langdon* [2], *Prof. David Sear* [1]**

1. School of Geography and Environmental Science, University of Southampton, 2. University of Southampton

Hydroclimate in the tropical South Pacific is dominated by the South Pacific Convergence Zone (SPCZ), a region of low-level convergence responsible for providing fresh water to 11 million people. The SPCZ is known to change in orientation and intensity in response to interannual climate phenomena (e.g., ENSO), although the impact of decadal and centennial scale climate cycles on the SPCZ is unclear. As such, our ability to predict long-term changes in South Pacific rainfall is low, which is likely to hamper societal responses to future climate change. To increase our understanding of the mechanisms driving SPCZ variability, we have reconstructed changes in precipitation across the tropical South Pacific over the past 3.5 ka. We have used a combination of organic and inorganic geochemical proxies to generate decadal-scale precipitation records from 3 islands across French Polynesia to constrain changes in the eastern side of the SPCZ. Additionally, using previous proxy reconstructions and climate model simulations, we have performed a data model assimilation to evaluate how the SPCZ has changed in intensity and orientation over the late Holocene, allowing us to evaluate the relationship between decadal-scale global climate periodicities and tropical South Pacific precipitation.

Implementation of the Neodymium oceanic cycle in the iLOVECLIM model (EMIC)

Dr. Tristan Vadsaria [1]***, Dr. Mohamed Ezat*** [1]***, Prof. Didier Roche*** [2]***, Dr. Pepijn Bakker*** [3]***, Dr. Jean-Claude Dutay*** [4]***, Dr. Mohamed Ayache*** [4]***, Dr. Nathaelle Bouttes*** [4]

__1.__ Department of Geosciences, UiT The Arctic University of Norway, N-9037, Tromsø, Norway, __2.__ Department of Earth Sciences, Vrije Universiteit Amsterdam - LSCE/CNRS, Saclay, France, __3.__ Department of Earth Sciences, Vrije Universiteit Amsterdam, __4.__ LSCE-IPSL, Laboratoire des Sciences du Climat et de l'Environnement (CEA-CNRS-UVSQ), Paris-Saclay

An improved understanding of the mechanisms involved in the Neodymium (Nd) oceanic cycle is needed to better interpret past archives. Recently, climate and ocean models (e.g. FAMOUS-MOSES1, Bern3D, CESM1.3, COCO, OCIM-GNOM and NEMO-PISCES) incorporated the neodymium isotopic composition of seawater to have a broader view of these mechanisms, but also to simulate and understand neodymium isotopic composition as a tracer of the modern and past oceanic circulation .

Here, we aim to implement the Nd oceanic cycle in the Earth System Model of Intermediate Complexity (EMIC) *i*LOVECLIM. The Nd implementation in *i*lOVECLIM is following the state-of-the-art Nd scheme as implemented in previous studies, with the incorporation of the atmospheric dust source, the river source, the boundary exchange as well as the recently highlighted bottom sediment flux. We will also include the reversible scavenging for the sink term. Due to this computational efficiency of the *i*LOVECLIM model, numerous simulations will be carried out for a fine tuning of the key parameters, such as the scavenging efficiency and the bottom sediment flux.

Moreover, we aim to provide an improved framework on the interplay between Arctic Ocean, carbon cycle and the Atlantic Meridional Oceanic Circulation (AMOC) via an extensive data-model comparison, including new simulation and Nd isotope records for the Last Interglacial period and the Last two deglaciation.

Humid phases in western Europe since 5 ka and their synchronicity with Northern hemisphere climate changes, insight from neritic and coastal deposits

Dr. Frederique Eynaud [1], ***Dr. Florence Verdin*** [2], ***Mrs. Camille Culioli*** [2], ***Dr. Aurélie Penaud*** [3]

1. *Univ. Bordeaux, CNRS, Bordeaux INP, EPOC, UMR 5805, F-33600 Pessac, France,* ***2.*** *UMR AUSONIUS, 8, esplanade des Antilles, F-33607 PESSAC,* ***3.*** *Geo-Ocean, UMR 6538, Université de Brest, CNRS, Ifremer*

The detection and understanding of natural climatic modes appear to be critical for improving the predictive capacities of climate variations since the Anthropocene onset. This has recently led to major compilation and inter-comparison works on past climate series targeting the Holocene in particular. A key objective of paleoclimatology is indeed to supplement the short temporal extension of the instrumental data, in order to draw up an inventory of past climatic situations, analogous or contrasting with the current period, able to provide us with a better knowledge of the natural sensitivity of the climate (threshold periods, extremes, etc.).

The present work focuses on coastal and neritic archives from the inner margin of the Bay of Biscay off Aquitania and on the humidity signals that have been trapped within those sediment series along the five last millennia. Paleosoils especially, developed in the shore dune systems of the Bay of Biscay sand beaches, are since long attributed to the persistence of centennial humid climatic phases affecting western Europe border during the Holocene. Several attempts have been done to correlate the regional occurrence of those paleosoils to global climatic conditions, with sometimes an inverse approach targeting the datings of sand dunes and of their mobility episodes rather than the rich paleosoil records themselves. Here we revise the chronology of those deposits *a priori* related to wet climatic conditions and question their interpretation in terms of oceanic and atmospheric forcings. The coherence of the main humid events detected in this context will be tested at regional scales and their phasing with climatic oscillations detected at the boreal Atlantic scale will also be questioned.

Coccolith vital effects for the development of climate proxies

Dr. Alba González-Lanchas [1], *Dr. Karl Heinz Baumann* [2], *Dr. Rosalind E.M. Rickaby* [1]

1. University of Oxford, 2. Universität Bremen

To understand how coccolithophore calcification rates evolved, it is critical to disentangle which environmental parameters are responsible to modulate the flow of energy and resources from photosynthesis to calcification. The values of coccolith vital effects, the offset of the isotopic composition of coccoliths from abiogenic calcite equilibrium, are not yet unilaterally understood.

To explore the suitability of coccolith isotopic values to produce consistent estimations of calcification intensity under contrasted boundary conditions, we analyze the $\delta^{13}C$ values and coccolith vital effects recorded in size-separated coccolith fractions in the modern ocean across key environmental gradients, from core top sediments. Size separations are based in the application of the method by Minoletti et al. (2009) and serve to produce nearly monospecific isolated coccolith fractions.

We will investigate the variance of size-separated coccolith vital effects and PIC/POC (Particulate Inorganic Carbon/Particulate Organic Carbon) estimations with environmental change and independent indicators of coccolith calcification, obtained from the application of detailed coccolith morphometrical analysis with the use of different techniques of microscopy and image analysis.

Weaker North Atlantic surface circulation during Common Era centennial-scale cold anomalies associated with Caribbean salinification

***Dr. Anastasia Zhuravleva* [1], *Dr. Henning A. Bauch* [2], *Dr. Mahyar Mohtadi* [3], *Dr. Kirsten Fahl* [4], *Prof. Markus Kienast* [1]**

***1.** Dalhousie University, Halifax, **2.** Helmholtz Centre Alfred Wegener Institute for Polar and Marine Research c/o GEOMAR, Kiel, **3.** MARUM-Center for Marine Environmental Sciences, University of Bremen, **4.** Helmholtz Centre Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany*

Paleoceanographic reconstructions show pronounced centennial variability in sea surface temperature and salinity (SST, SSS), and circulation in the subpolar North Atlantic during the Common Era (CE). In particular, weakening of the surface circulation in the high latitudes associated with advection of Arctic sea ice into the Labrador Sea has been invoked to explain cold climate in Europe during the Little Ice Age. In contrast, upstream changes in the tropical Atlantic remain underrepresented due to the paucity of records covering the CE, rendering our understanding of interactions between these oceanic sub-basins incomplete. Here, we reconstructed centennial SST and SSS variability in the Caribbean Basin over the last two millennia using Mg/Ca and $\delta^{18}O$ in mixed-layer dwelling planktic foraminifera. The SST/SSS changes occur contemporaneously with (hydro)climate anomalies in the North Atlantic and Americas, suggesting a common forcing mechanism resembling the modern Atlantic Multidecadal Oscillation. Cold phases around 500-650, 750-900 and 1400-1600 CE were associated with Caribbean salinification and Gulf of Mexico freshening, implying that weaker North Atlantic surface circulation during these periods was associated with reduced northward transport of tropical salt. Our data suggest that changes in tropical ocean salinity played an important role in shaping subpolar and global-scale climate variability during the CE.

Reconciling the Antarctic temperature – δ18O relationship on different time- and spatial scales

Dr. Christo Buizert [1], **Prof. Zhengyu Liu** [2], **Dr. Chengfei He** [3]

1. Oregon State University, 2. The Ohio State University, 3. University of Miami

Water stable isotope ratios ($\delta^{18}O$, $\delta^{2}H$) in polar ice cores are a widely-used proxy for site temperature, yet their calibration has remained challenging. The temperature-$\delta^{18}O$ relationship is strongly dependent on the spatial or temporal scale under consideration. In Antarctica, spatial regression of $\delta^{18}O$ and surface temperature (T_S) yields a slope of ~0.8 ‰ K^{-1}; temporal regression using the seasonal cycle yields 0.21 to 0.57 ‰ K^{-1}; and the (site-dependent) glacial-interglacial temporal regression slope ranges from 0.8 to 1.45 ‰ K^{-1} in recent estimates. Precipitation isotopes are controlled by the condensation temperature (T_C) that is warmer than T_S owing to the strong near-surface inversion. The T_S - T_C relationship differs on spatial, seasonal, and glacial-interglacial scales, further complicating climatic interpretation of $\delta^{18}O$. A comprehensive description of Antarctic isotopes thus requires a description of the relationship between six different isotopic slopes ($\delta^{18}O$ variations on 3 spatial/temporal scales, each regressed onto T_S and T_C).
First, we will give a short overview of recent estimates of the glacial-interglacial $d^{18}O$-T_S regression slope based on borehole thermometry and empirical estimates of the gas age-ice age difference (Δage). Next, we combine isotope-enabled simulations using CESM (Community Earth System Model) with an analytical approach called *Unified Slope Equations* to provide a description of the relationship between the six aforementioned isotopic slopes. Surprisingly, our analysis suggests that the seasonal $\delta^{18}O$-T_C regression slope is a good estimate of the glacial-interglacial $\delta^{18}O$-T_S regression slope: indeed, at Dome C the former is 1.16 ‰ K^{-1} in observations (monthly averages, r = 0.9) while the latter is 1.14 ‰ K^{-1} borehole-based reconstructions. Our framework can reconcile the initially contradictory and disparate isotopic slope estimates found in the literature, and suggests a new observational way to calibrate the ice core isotope paleothermometer.

2000-year variability of the North Atlantic Current: Insights into AMOC dynamics?

Dr. Paola Moffa-Sanchez [1], *Prof. Ian Hall* [2]

1. Durham University, 2. School of Earth and Environmental Sciences, Cardiff University

Over the last 2000 years, the climate of the North Atlantic region was punctuated by centennial oscillations, which despite their small magnitude had important societal impacts, particularly in NW Europe. The most favoured explanations for this climate variability invoke changes in external forcings which were likely amplified by ocean-ice-atmosphere feedbacks. Traditionally, ocean changes, specifically the strength of the Atlantic Meridional Overturning Circulation (AMOC) have been invoked to explain some of this centennial climate variability. However, new research suggests that the strength of the subpolar gyre and its northward heat transport by the North Atlantic Current likely contributed to the climate variability recorded in Europe. In this study, we explore the hydrographic variability of the North Atlantic Current using four subdecadally to decadally resolved sediment cores that lie within the pathway of this watermass. New and published foraminiferal-based temperature and salinity reconstructions from these four locations are combined to study their common variability and obtain a robust reconstruction of the North Atlantic Current across the last two millennia.

Plant macrofossil-based Lateglacial temperature seasonality reconstructions for the Baltic States region – a methodological comparison

Ms. Liva Trasune [1], ***Dr. J. Sakari Salonen*** [1], ***Dr. Frederik Schenk*** [2], ***Dr. Minna Väliranta*** [3], ***Dr. Normunds Stivrins*** [4], ***Dr. Leeli Amon*** [5]

The Younger Dryas (YD; ca. 12.8–11.7 ka BP) represents an abrupt climate shift and is traditionally referred as a generally cold period in Europe. More recent studies have proposed that YD is rather linked to a distinct rise in temperature seasonality in Northern Europe due to an abrupt winter cooling and only modest cooling or even a slight warming in summer. However, a robust test of this hypothesis remains elusive, partly due to paucity of proxy data reliably recording winter temperature conditions in higher northern latitudes.

In this study we reconstruct temperature seasonality patterns of YD using plant macrofossil datasets from 13 sites of the Baltic States and surrounding region. Plant macrofossils, while representing local environment, typically face a high risk of incomplete data through false absences caused by low dispersal ranges and relatively high decomposition rates. This shortcoming is balanced by strengths including better taxonomic resolution and less noise from long-distance transport compared to commonly used pollen data. This has led to an increased interest in plant macrofossils as a climate proxy in the recent years. Consequently, a range of new species-based climate reconstruction approaches compatible with plant macrofossil data have been introduced. Here we compare multiple classical and novel climate reconstruction approaches to reconstruct January and July mean air temperatures using plant macrofossil assemblages. Methods tested here include the traditional Mutual Climate Range and recently developed CRACLE, CREST and Minimum Temperature Limit approaches. Additionally, we test the influence of different modern climate datasets and geographic calibration areas on the temperature reconstructions.

In the aggregate, the results of each method, when using the same calibration region, are similar to one another in relative temperature trends throughout the reconstructed time period, while their absolute values can vary by several degrees. Both summer and winter YD temperature trends are highly dependent on site data quality (species assemblages and sample resolution) and differ between calibration regions used. Nevertheless, our ensemble reconstructions from combined data of 13 sites indicate a strong tendency for increased YD seasonality with strong winter cooling and moderate to no summer cooling, when a global calibration is used.

Preliminary proxy data from a Pleistocene deep lake sediment core from eastern Romania

We present here the environmental context and preliminary results from the analysis of a recently retrieved 60 m long core from the Obanul Mare paleolake (Mangalia, Romania). The 300 m wide, fully closed Obanul Mare doline is part of a group of dolines that formed through the opening of underground voids. These dolines were subsequently flooded by groundwater and some of them still function as active lakes, the largest of them being Mangalia Swamp with a diameter of ~1 km.

Our aim is to extract multi-proxy information from these sediments and gain insights into the environmental conditions that prevailed during the sedimentation history of Obanul Mare. The most important aquifer feeding these type of lakes is mesothermal and sulphidic and its level is controlled by that of the nearby Black Sea. By identifying periods with sulphidic, meteoric or even sea water recharge, we would also be able to constrain periods of Black Sea level fluctuations.

Magnetic susceptibility and loss on ignition data indicate that deposition took place across several glacial-interglacial cycles of, probably, Pleistocene age. The sediment column comprises five main lithological units in which the fine fraction is dominated by the presence of silts (50%), while clays are the secondary component. These lithological units are: recent soil and brown clays from surface to 10 m, yellowish deposits (that could be interpreted as wind-blown material that deposited as loess in the surrounding region) from 10 to 15 m, a yellowish-reddish unit between 15 to 25 m, a dark grey unit until 42 m, and a light grey unit rich in gravels and limestone blocks between 42 and 60 m.

From the entire core length we analyzed a wide range of proxies, including polyaromatic hydrocarbons and microcharcoal, $\delta^{18}O$ and $\delta^{13}C$ from freshwater shell fragments, $\delta^{13}C$ and $\delta^{15}N$ in organic matter, as well as the chemical composition of these sediments.

This research was supported by a grant of the Romanian Ministry of Education and Research, CNCS - UEFISCDI, project number PN-III-P4-ID-PCE-2020-2282.

Palaeoenvironmental evolution of coastal ecosystems: La Janda (SW Iberia)

Ms. Cristina Val-Peón [1], Dr. José Antonio López Sáez [2], Dr. Juan I. Santisteban [3], Dr. Rosa Mediavilla [4], Prof. Klaus Reicherter [1]

Coastal ecosystems are shaped by the interplay of different factors, such as climate, tectonics, sea-level changes, human activities, etc., which make them highly dynamic areas that have undergone significant changes over time. Considering the sensitivity of the vegetation to these factors, its study from a long-term perspective may provide insights into the environmental evolution and serve as past analogues to understand the impact of natural and anthropogenic changes.

The study of several sedimentological cores drilled in La Janda (SW Iberia) allowed identifying a succession of different phases and environments during the Holocene in this region. The fluvial system existing during the Early Holocene was progressively transformed by the marine transgression and, after a period of transition, resulted in the development of a restricted bay. The reverse process occurred during the Late Holocene with a gradual silting up of the restricted bay until anthropogenic facies were recorded in the upper part.

Here we present the multiproxy research that was carried out in one of the cores, the S3, combining palynological, sedimentological, and geochemical analyses.

Quantitative reconstruction of Holocene vegetation and seasonal temperature change in Northeast China

The Holocene temperature conundrum has been the subject of intense debate in the studies of Holocene climate changes. Pollen-based quantitative reconstructions of seasonal temperature change in different regions provide an important approach to study this conundrum. Northeast China is located on the northern margin of the East Asian monsoon region yet has obvious gaps and deficiencies for quantitative reconstruction. Although studies of different archives in this region were conducted, the Holocene climatic history and mechanism remain debatable. Moreover, the high-resolution record that can reflect the decadal to centennial variability is rare. Here we reconstruct vegetation and climate changes during the last ~ 10000 years BP based on a high-resolution pollen record from Gushantun peatland, Changbai Mountains. Multiple quantitative reconstruction approaches were used and weighted averaging partial least squares regression (WA-PLS) was chosen as the most appropriate method to reconstruct Holocene temperature and precipitation time series and the history of seasonal temperature change was revealed. The reconstruction result shows that the Holocene Climate Optimum was in early to mid Holocene with ~2°C warmer than modern temperature in the coldest month and it gradually cooled during late Holocene with minimum -19.6°C. Cold events occurred around 9.2 ka BP, 7.8 ka BP, 5.8 ka BP and 2.3 ka BP with variation amplitudes from 1.5 to 3°C. The synthesized seasonal temperature time series and the comparison with other proxies show that the decreasing trend of mean annual temperature is not a seasonal bias caused by summer temperature change. This study provides evidence for seasonal temperature change on regional scale during the Holocene, reference for further understanding of the Holocene temperature conundrum and data support for the investigation of vegetation feedback and projection models of future climate change.

Temperature changes in southern France (Canroute, Massif Central) over the last 14,000 years: a quantitative reconstruction based on pollen and lipid tetraethers (brGDGT)

Ms. Léa d'Oliveira [1], *Mr. Lucas Dugerdil* [1], *Prof. Guillemette Ménot* [2], *Dr. Allowen Evin* [1], *Dr. Salomé Ansanay-Alex* [2], *Dr. Julien Azuara* [3], *Ms. Coline Bonnet* [1], *Dr. Laurent Bremond* [4], *Dr. Serge Muller* [1], *Dr. Odile Peyron* [5]

The climate of the southern Europe/Mediterranean area is characterized, during the Holocene, by a strong spatial and temporal heterogeneity whose patterns and mechanisms are still poorly understood. The proxies used to reconstruct quantitatively past climate changes are based most of the time on pollen, as well as a few speleothems and chironomids for terrestrial temperatures and alkenones for SSTs (Sea Surface Temperatures). Studies based on molecular biomarker data in the continental area are rare. Studies based on coupled pollen/molecular biomarker approaches are even more scarce, despite the interest in such multi-proxy studies. Here we propose an approach combining pollen and brGDGTs (branched Glycerol Dialkyl Glyceryl Tetraethers) applied to the Canroute well-dated peat sequence to document the climatic changes of the last 15,000 years in the south of Massif Central (France). We also compare the climate pattern inferred at Canroute from both proxies to the more regionally known climate pattern from surrounding climate archives. To achieve this, a pollen-based transfer functions approach is tested, combining three modern pollen dataset calibrations to four different models (MAT, WAPLS, RF and BRT). For molecular biomarkers, nine calibrations based on soil and peat calibrations are tested, and the more reliable is selected depending on the accuracy of the temperature quantified for surface samples.

The confrontation of the Canroute signal with those of various sites located in southern Europe shows a coherent climatic signal with a global warming trend during the Tardiglacial. The Holocene shows more contrasted trends between sites and proxies, but overall, the Canroute signal appears coherent with most of the regional signal. The presence or absence of a Holocene Thermal Optimum still cannot be confirmed although the Canroute signal seems to point to its presence for the south of the Massif Central. Results highlight the importance of considering environmental and ecological constraints to better understand pollen data and brGDGTs-inferred temperature reconstructions. Moreover, the multi-proxy approach points out the importance of investigating the evolution of the local environmental context for a better understanding of the reconstructed climate parameters, as local changes in environmental conditions could impact pollen records and the brGDGTs-producing bacterial community.

Tracking shifts in the westerlies at Baboon Lakes, central Sierra Nevada, California over the last 12,000 years

Ms. Meghan Spoth [1]***, Dr. Aaron Diefendorf*** [2]***, Ms. Megan Corcoran*** [2]***, Dr. Brenda Hall*** [1]***, Dr. Aaron Putnam*** [1]***, Dr. Jacquelyn Gill*** [3]***, Dr. Scott Mensing*** [4]

1. *School of Earth and Climate Sciences, University of Maine,* ***2.*** *University of Cincinnati,* ***3.*** *Climate Change Institute, University of Maine,* ***4.*** *University of Nevada, Reno*

Extreme drought has led to critical water shortages with increased fire activity in the American West and a need for more accurate climate predictions. The past hydrology of this sensitive region could afford unique insight into potential patterns and mechanisms of future water availability. Latitudinal migration of the westerly winds and associated storm tracks may play a primary role in controlling precipitation patterns over much of this region. However, few records have documented past shifts in wind patterns independently from precipitation variations. The Sierra Nevada are key for studying this problem as the mountains steer incoming storms either north or south of the range, depending on location of the westerlies. Thus, this region is not only a potential contributing factor to the spatial pattern of droughts, but also is ideal for isotopic tracking of the westerlies, because the isotopic difference in storm tracks between north and south-shifted positions is large.

Here, we use plant wax isotopes preserved in lake sediment cores from the high-elevation Baboon Lakes of the Sierra Nevada, California to reconstruct the relative position of the westerlies and hydrologic changes over the last 12,000 years. We pair these analyses with pollen and charcoal data to assess coeval variations in plant communities and fire history. An understanding of the westerlies' influence on regional precipitation patterns and the mechanisms behind shifts will inform models used to predict precipitation patterns and the snowpack levels of the Sierra Nevada more accurately.

The Baboon Lakes sediment record covers the last 12,000 years and documents fluctuations between low organic content clays and more organic-rich sediment. Sediments have high concentrations of plant-derived *n*-alkanes with chain lengths ranging from C21-C33 and terpenoids specific to conifers and angiosperms. The long-chain *n*-alkane $\delta^{13}C$ values are consistent with mixing of plant waxes derived from both conifers and angiosperms. Select *n*-alkane $\delta^{13}C$ values are high, suggesting the conifers grew under high water stress conditions. The $\delta^{2}H$ of these alkanes is underway to be used as a SHW position proxy. This will be tested with a pollen assemblage and compared to a charcoal record.

Bulk organic matter δ13C and δ15N data of a sediment core from Obanul Mare paleolake, SE Romania

Ms. Georgiana Grigore [1] ***, Dr. Virgil Dragusin*** [2] ***, Mr. Bogdan Ispas*** [1] ***, Dr. Viorel Atudorei*** [3] ***, Prof. Carmen Chifiriuc*** [1]

***1.** Faculty of Biology, University of Bucharest,* ***2.** Emil Racoviță Institute of Speleology, Romanian Academy, Bucharest,* ***3.** Earth and Planetary Sciences, University of New Mexico, Albuquerque*

We present here preliminary $\delta^{13}C$ and $\delta^{15}N$ measurements of bulk organic matter from a 60 m deep paleolake core. The sedimentary sequence was deposited over several glacial/interglacial cycles and consists of five clay and silt main units.
Bulk sediment samples from different depths were taken for isotopic analysis and were prepared following three different protocols. All the methods considered were based on the usage of aqueous-acid treatment and adapted to ensure complete removal of inorganic carbon and the prevention of organic carbon loss, especially for samples with low content of organic matter.
The samples were measured on a Nu Instruments Horizon 2 IRMS coupled to a EuroVector 3024 elemental analyzer. After acid treatment, an amount of ~20 mg was analyzed and we determined that the organic C content varies between 0.9% and 0.2%, while the N content varies between 0.09% and 0.02%, resulting in C/N ratios of 7 to 11.
Neighboring extant lakes, similar to Obanul Mare, are fed by underground mesothermal water rich in H_2S and CH_4 (methanotrophs form the basis of methane-driven food chain), sustaining chemoautotrophic ecosystems. By analyzing stable C and N isotope values we can constrain periods when the lake was fed by sulphidic water, whose level is controlled by the level of the nearby Black Sea.
Part of this research was supported by a grant of the Romanian Ministry of Education and Research, CNCS - UEFISCDI, project number PN-III-P4-ID-PCE-2020-2282.

Anthropogenic pollution impact and recovery of a Swiss run-of-the-river reservoir based on paleolimnological water quality indicators (diatoms, chironomids)

***Dr. Ieva Grudzinska-Elsberga* [1], Prof. Hendrik Vogel [2], Prof. Flavio Anselmetti [3], Dr. Oliver Heiri [4]**

***1.** University of Latvia, Institute of Biology, Laboratory of Geobotany, Riga, Latvia, **2.** Institute of Geological Sciences & Oeschger Centre for Climate Change Research, University of Bern, Bern, Switzerland, **3.** Univ. of Bern, **4.** University of Basel*

Wohlensee is a run-of-the-river reservoir created in 1920 by the construction of the Mühlberg hydroelectric power station and the damming of the Aare river, a mid-sized river originating in the Swiss Alps, downstream of the city of Bern (Switzerland). Wohlensee has been significantly affected by increasing anthropogenic and industrial pressures in the mid-20th century (population growth, agricultural and industrial development). Our aim was to investigate how and to what extent the diatom and chironomid communities, generally considered to be excellent indicators of water quality, have changed in the lake since the dam on river was built, and to what extent the discharge of untreated industrial and municipal wastewater into the Aare had an impact on species diversity within these indicator groups. Sediments were collected with a Piston-type corer in 2014 and dating of the sediments was based on ^{210}Pb and ^{137}Cs analyses.

The results of the analysis of chironomid larval head capsules indicate a very high level of organic pollution from ca 1940 to 1950, when the chironomid species composition changed completely. These changes suggest a high load of nutrients and organically degradable substances in Wohlensee. From about 1965, the chironomid larval community slowly recovered. A similar trend was observed in the diatom analyses. The proportion of planktonic diatoms increased significantly in the middle of the 20th century. This indicates an increase in the nutrient load in the water body, in which planktonic diatoms can only thrive under high growth rates and high nutrient availability due the low water retention time in this river-fed reservoir. The first signs of ecosystem recovery appear in the 1960s, but it was not until the very end of the 1980s that significant changes in the species composition of diatoms were observed. The composition of the modern group of chironomid and diatom species is still different from the original fauna and flora observed in Wohlensee observed immediately after the dam was built, suggesting that the ecosystem has not (possibly not yet) recovered back to its original state, although the observed taxa indicate a similar water quality as at the initiation of the lake.

Influence of oceanographic conditions on multidecadal sea surface temperature variability reconstructed from molecular proxies during the Last Interglacial sapropel deposition

Dr. Igor Obreht **[1]**, ***Dr. Lars Wörmer*** **[1]**, ***Prof. David De Vleeschouwer*** **[2]**, ***Ms. Devika Varma*** **[1]**, ***Ms. Jenny Wendt*** **[3]**, ***Dr. Hartmut Schulz*** **[4]**, ***Prof. Michal Kucera*** **[1]**, ***Prof. Kai-Uwe Hinrichs*** **[1]**

1. *MARUM, University of Bremen, Bremen, Germany,* ***2.*** *Westfälische Wilhelms-Universität Münster, Institut für Geologie und Paläontologie, Münster, Germany,* ***3.*** *MARUM, University of Bremen, Germany,* ***4.*** *Department of Geosciences, University of Tübingen, Tübingen*

Anthropogenic greenhouse gas forcing causes Mediterranean sea surface temperatures to increase at a faster rate than the global sea surface temperature, potentially leading to changes in oceanographic and environmental conditions that are unprecedented in the instrumental era. Thus, it is important to reconstruct climate-oceanographic interactions from past warmer-than-present periods, as partial analogs to future conditions.

The Last Interglacial (~129,000-116,000 years ago) is the most recent warmer-than-present period in Earth's history. Sapropel S5, deposited during this period, presents an excellent archive to study the high-resolution paleoclimate evolution of the Mediterranean region. We studied the S5 layer recovered in core M51/3-SL104 from the Pliny Trench region. This sapropel is varved for most of its extension and thus provides an opportunity to generate a precise relative age model.

We recently applied mass spectrometry imaging (MSI) to long-chain alkenones in order to reconstruct sea surface temperature (SST) changes during this period in annual to subdecadal resolution, and observed that the forcing of the SST was partly dependent on the oceanographic conditions. To provide a better understanding of the relation between SST and changes in oceanographic conditions, we here present MSI data from the same archive, but targeting an alternative SST proxy based on glycerol dialkyl glycerol tetraethers (GDGTs).

GDGTs are produced by planktonic archaea and are recognized as important biomarkers for paleoenvironmental studies. Changes in the relative abundance of GDGTs with different number of cycloalkyl rings is highly sensitive to ecological and environmental factors such as temperature and to a lesser extent nutrient concentration. Nevertheless, under the highly stratified nutrient-rich conditions prevailing during the Mediterranean sapropel S5 deposition, marine Thaumarchaeota may have resided at the chemocline and thus recorded a signal that is not representative of SST. In this poster, we will compare ultra-high resolution GDGT-based and alkenone-based SST records to obtain information about how ocean circulation influences SST reconstructions during sapropel S5 deposition. To do so, we will explore the variability and phase relationship between two different SST records in multidecadal to multicentennial time bands.

Early-mid Holocene hydroclimate records using stable carbon and oxygen isotopes of shallow marine benthic foraminifera from Singapore

Stable carbon (δ^{13}C) and oxygen (δ^{18}O) isotopes in carbonate from foraminifera are commonly used as a palaeoenvironmental proxy in Quaternary records. Here, we present high-resolution stable isotopic records from ~ 8.8 to 5.8 cal ka BP from the Kallang River Basin, Singapore. The records use three shallow benthic foraminifera species (*Ammonia* sp., *Elphidium* sp. and *Asterorotalia pulchella*). In equatorial coastal settings, the δ^{13}C value of foraminiferal carbonate is more representative of environmental variability, as high rates of evaporation (E/P) in the equatorial region can mask the δ^{18}O signals of rainfall changes. Our foraminiferal δ^{13}C records generally exhibit an increasing trend that follows Equatorial boreal summer insolation. Enrichment of the *A. pulchella* δ^{13}C values between 8.3 and 8.1 cal ka BP may indicate a drying period likely related to the 8.2 ka climate anomaly. Our work demonstrates that *Elphidium* sp. and *A. pulchella* may be more suitable candidates for environmental reconstruction in equatorial regions, as vital and microhabitat effects may mask the sensitivity of *Ammonia* sp. to environmental changes.

Ostracoda as proxies in sediments of subrosion depressions in Germany

Prof. Peter Frenzel [1]***, Dr. Anna Pint*** [2]

1. *Friedrich Schiller University Jena, Institute of Earth Sciences,* ***2.*** *University of Jena*

Subrosion is a common phenomenon in Central Germany and other regions. Subsurface evaporites of mainly Permian (Zechstein) and Triassic age are dissolved by groundwater. If the cavities created by this process collapse a crater-like structure can be formed at the surface, sometimes with dimensions of kilometres but mostly much smaller. Those depressions are regularly filled with water and act as sediment traps. Middle and Old Pleistocene sediments of Germany are often preserved in such subrosion depressions and provide important palaeoclimate archives.

Ostracoda are minute Crustacea with a calctitic bivalved carapace. The shells of such a carapace are easily fossilisable and appreciated as archives of palaeoenvironmental conditions and processes as well as index fossils for their stratigraphical age. They can be used in palaeoecological association analyses and shell chemistry approaches. The high diversity and often high abundance of ostracods highlight them as one of the most significant microfossil groups of Quaternary sediments.

The 197 Quaternary ostracod species reported by Fuhrmann (2013) for Central Germany contain 51 biostratigraphical index species allowing dating in a resolution of interglacial and glacial periods. Many taxa are palaeoclimatic indicators. Index species and the Mutual Ostracod Temperature Range method are the most used tools beside stable isotope analysis on ostracod shells for reconstructing summer and winter temperatures. A special phenomenon is the occurrence of marginal marine ostracod taxa in inland water bodies indicating elevated salinity. Examples are *Cyprideis torosa* and *Cytheromorpha fuscata* occurring in slightly saline lakes of Central Germany. Transfer functions enable quantitative salinity reconstructions indicating brine extrusion and a low precipitation/evaporation balance.

We present case studies of the application of Quaternary ostracods from subrosion depressions for showing their high value for indicating stratigraphical age and glacial-interglacial cycles, elevated salinity as result of protruding brines during active subrosion processes, size and structure of water bodies and aquatic habitats, as well as biogeographic relations. The study areas shown lay in Thuringia, Saxony-Anhalt and Nordrhein-Westfalia.

A 225-year gapless record from Lake Khamra based on diatom oxygen isotopes, diatom assemblages and biogeochemical analyses: Reconstructing hydroclimate extreme events in Siberia

Ms. Amelie Stieg [1], ***Dr. Boris K. Biskaborn*** [1], ***Prof. Ulrike Herzschuh*** [2], ***Dr. Jens Strauss*** [1], ***Dr. Hanno Meyer*** [1]

The northern landscapes are highly affected by global climate warming, but little is known about associated changes in hydrology. Recent drought events resulted in higher salinities of permafrost-affected lake systems, a major threat to local freshwater resources. The overall goal of this project is to understand the relationship between climate warming, hydrological extremes and water quality both in pristine and human-influenced lake systems in northeastern Siberia on decadal time-scales. The temporal focus is on the Early Holocene warming phase and the recent climate change to disentangle the natural and anthropogenic contributions.

Here we present a first high-resolution dataset of Lake Khamra (59.99° N, 112.98° E) located in south-west Yakutia, in a remote permafrost area in Russia. Established from a Pb/Cs dated sediment shortcore, a 225-years (2018 – ca. 1790 CE), gapless stable oxygen isotope record of diatoms ($\delta^{18}O_{diatom}$) is analysed to explore whether hydroclimatic extreme events in Yakutia became more frequent during current warming. Recent stable water isotope data of Lake Khamra allowed for a calculation of oxygen isotope fractionation between diatomaceous silica and lake water supporting the $\delta^{18}O_{diatom}$ measurements. Diatom assemblages from the same sample material help reconstructing changes in the lake's hydrochemistry, their timing and amplitude in relation to the $\delta^{18}O_{diatom}$ record. Biogeochemical analyses provide an insight into the changes in the lake system with regard to recent climate change and increasing human influence. An indication of industrial pollution can already be seen by the tripling of mercury levels throughout the record with a marked increase from the 1930s onwards. Meteorological data and other proxy climate records from the region are used to identify hydroclimate extreme events and find common driving mechanisms.

We present a new hydroclimate proxy record for an area with a great demand of paleohydrological data. The project will gain substantial knowledge for research on hydroclimate feedbacks to recent global warming to better assess potential risks for local water resources.

Holocene littoral molluscan assemblages from Uruguay: geochronology, paleoecology and paleoenvironmental reconstruction

***Dr. Alejandra Rojas* [1], *Dr. Sergio Martínez* [2], *Mr. Marcos Pringles* [1], *Ms. Melany Molina* [1]**

***1.** Departamento de Paleontología, Facultad de Ciencias, Universidad de la República. Iguá 4225, Montevideo, Uruguay., **2.** Paleontology Department, Facultad de Ciencias (UdelaR), Montevideo.*

Holocene marine fossiliferous beds from Uruguay allow the reconstruction of the biotic and paleoenvironmental conditions in mid latitudes of the southwestern Atlantic Ocean during the present interglacial. The deposits crop out in a thin strip along the coast which enables a paleoecological/paleoenvironmental comparison with the current conditions that develop in each geographic sector of the Río Uruguay-Río de la Plata-Atlantic Ocean west to east gradient. An ongoing project aims to expand the geochronologic and molluscan database to refine the paleoenvironmental reconstructions in different time slices. We incorporated about 30 AMS shell datings which mostly fall within the previously known age range for the Holocene marine molluscan assemblages, but we also obtained some new slightly older ages circa 7000 ^{14}C yrs BP. The oldest Northgrippian ages (from 7500 to 6000 cal yrs BP) correspond to dark clayey deposits with shells frequently preserved in life position. Assemblages are dominated by *Heleobia* spp., followed by *Ostrea stentina*, *Anomalocardia flexuosa* (marine euryhaline species). The youngest Northgrippian (6000 to 4200 cal yrs BP) are similar but include a better representation of the euryhaline *Mactra isabelleana*. This species and the estuarine *Erodona mactroides* predominate in the sandy deposits in the W and S-SE area of the Uruguayan coast. The oldest Meghalayan sandy deposits (4100 to 3000 cal yrs BP) from the W sector are dominated by *E. mactroides* with a scarce representation of *M. isabelleana*. The youngest Meghalayan assemblages (3000 to 1000 cal yrs BP) crop out mainly in the E sector. The sandy deposits are dominated by *M. isabelleana* or *Glycymeris longior*, and in the very fine grain lagoon deposits *H. australis* and *E. mactroides* predominate. The molluscan distribution pattern indicates higher salinity conditions in all the time slices analyzed towards the current fluvial and estuarine settings influenced by the Río Uruguay and inner Río de la Plata. Also, a higher temperature than present is supported by the record of warm extralimital species better represented in the oldest Holocene assemblages but still recorded in very young ones. This is a contribution to the research grant ANII FCE_1_2021_1_167109 and PEDECIBA Geociencias.

Holocene sedimentation in the southern Red Sea continental shelf controlled by monsoon dynamics and basin geometry

The shallow continental shelfs of the semi-enclosed Red Sea basin are regarded as excellent recorders of global sea-level and regional precession-driven climatic fluctuations. Sedimentation within the southern sector of the basin is strongly influenced by the winter and summer modes of the South Asian monsoon system, which impacts both terrestrial and marine processes. Moreover, the sedimentation of the submerged southern Red Sea shelf is influenced by a complex geomorphological configuration resulting from tectonic processes, such as salt diapirism, and the subsequent dissolution of evaporitic domes creating deep sinkholes along the shelf. To gain insight into the southern Red Sea Holocene monsoon dynamics and the effects of basin geometry on biotic and abiotic processes, we have generated a multi-proxy record from a deep sinkhole located within the inner shelf of the Farasan Archipelago. Our decadal- to centennial-scale resolution geochemical (X-ray fluorescence core scanning), mineralogical, sedimentological (grain sizes) and micropaleontological (planktic and benthic foraminifera) datasets are compared to a marine record from the outer continental shelf at a similar geographical latitude, in order to explore the controls of topography on sedimentation. Multivariate statistical analysis of our data provides a clear distinction between three chronostratigraphic intervals. Combined reconstructions of submerged paleoshorelines with both planktic and benthic foraminiferal assemblages suggest that early Holocene (9.8–8.7 ka BP) sedimentation is controlled by a restricted connection with the open sea and the development of suboxic conditions. The mid-Holocene (8.7–4.2 ka BP) reveals an increase in marine productivity, which we link to the strengthening of the south west monsoon (SWM). On the contrary an increase in fined grained aeolian inputs during the late Holocene (4.2 ka BP–recent) points to a strengthening of the north east monsoon (NEM). All in all, our record proves to be a sensitive recorder of South Asian monsoon changes on centennial timescales in the southern Red Sea. We conclude that the lag in the development of a fully marine state at our site can be attributed to the complicated topographical features of the inner shelf while the geometry of the sinkholes controls the boundary conditions for the local marine ecosystem.

Spatially diverse hydroclimatic response to the 4.2 ka event in the Asian monsoon region

The 4.2 ka event was a widespread abrupt cooling event in the Northern Hemisphere. However, there was a spatially inconsistent hydroclimatic response to the 4.2 ka event in the Asian monsoon region. To further characterize and to determine the origin of this phenomenon, we present a pollen record spanning the interval from 10.7 ka to the present from a subalpine lake in the Hengduan Mountains, southwestern China, which are climatically influenced by the Indian monsoon; and we then reconstruct the spatial pattern of the hydroclimatic response to the 4.2 ka event across the Asian monsoon region, based on a synthesis of our own and previously published data. The results reveal the following. (i) During the interval of 4.5–3.9 ka (spanning the 4.2 ka event) in the subtropical mountains there were abrupt decreases in evergreen broadleaved trees, including evergreen *Quercus*, *Castanopsis* and *Cyclobalanopsis*. (ii) The hydroclimatic response to the 4.2 ka event across the Asian monsoon region was characterized by a tripolar precipitation pattern, with decreased rainfall over India and southwestern and northern China, and increased rainfall over central China. Therefore, we conclude that the hydroclimatic response to the 4.2 ka event in the Asian monsoon region was spatially heterogenous, which we argue was related to the slowdown of the Atlantic Meridional Overturning Circulation (AMOC). During the interval of 4.5–3.9 ka, cooling at high latitudes of the Northern Hemisphere, caused by AMOC weakening, led to the southward movement of the Intertropical Convergence Zone (ITCZ), which resulted in decreased rainfall over most of the Asian monsoon region. The wet conditions in central China may have been modulated by the southward movement of the westerlies, which was also caused by the cooling at northern high latitudes. The southward displacement of the westerlies restricted the northward penetration of the monsoonal air flow, and thus the monsoon rainbelt stagnated over central China, where there was a corresponding increase in precipitation.

Holocene stages in the North-Western Europe: lake sediments archives

Dr. Tatyana Sapelko [1]

1. Institute of Limnology of the Russian Academy of Sciences – SPC RAS, St. Petersburg

We compared the formal subdivision of the Holocene into the Greenlandian, Northgrippian and Meghalayan stages/ages (Walker et al., 2012); subdivision of the Blytt–Sernander scheme; archaeological periods, the pollen inferred temperature curve and Baltic Sea stages for the North-Western Europe. The comparative analysis showed that the events 8.2 and 4.2 are not traced throughout the entire territory of the North-Western Europe. According to the Blitt-Sernander scheme subdivision of the Holocene are distinguished in the North-Western Europe everywhere. Good stratotypes in this case are sediments sequences of small lakes. At the same time, pollen data must necessarily be supported by the results of studies using the maximum set of other methods. We have original data of the transect from north to south for the North-West Russia. The lakes of the Kola Peninsula, Karelia, the Karelian Isthmus, the Valdai Upland and others regions were studied using a complex paleolimnological method with radiocarbon dating. The comparison of this data with those in the North-Western Europe lake sediments sequences and with existing regional schemes (Borzenkova et al., 2015; Hang et al., 2020; Wastegård, 2022) are make it possible to clarify the Holocene stages of over a large area of North-Western Europe. The region under study is united by the presence of lakes, which in their origin are associated with the last ice sheet. The stages of their development are similar to all synchronous changes in the natural environment. In the last time also we have obtained new results of the lacustrine sediments sequences from the North-West Russia with radiocarbon dating for the Pleistocene-Holocene boundary which allowed us to confirm the periods boundaries of warming and cooling: two Dryas Stadials and two Bølling and Allerød Interstadials.

Lakes history and environmental changes in the Lesser Caucasus: a case study of the lakes at the Aragats massif

Dr. Tatyana Sapelko [1]***, Prof. Vladimir Boynagryan*** [2]***, Dr. Ivan Gabrielyan*** [3]***, Prof. Dmitry Sevastyanov*** [4]***, Dr. Anna Ludikova*** [1]***, Dr. Denis Kuznetsov*** [1]***, Dr. Marianna Kulkova*** [5]***, Prof. Mikhail Naumenko*** [6]

1. *Institute of Limnology of the Russian Academy of Sciences – SPC RAS, St. Petersburg,* ***2.*** *Yerevan State University,* ***3.*** *Institute of Botany of NAS RA,* ***4.*** *Pushkin Leningrad State University,* ***5.*** *Herzen State Pedagogical University of Russia,* ***6.*** *Institute of Limnology of the Russian Academy of Sciences – SPC RAS*

The volcanic massif Aragats (4090.5 m a.s.l) is the most elevated part of Armenian plateau. Lots of small lakes are situated on Aragats, mostly between 2900 m and 3500 m a.s.l. We obtained new paleolimnological (lithology, radiocarbon dating, geochemistry, pollen, diatoms) and geomorphological survey data of the Aragats largest lakes, glacial (moraine-dammed) Lake Kari (3187 m a.s.l.; southern slope) and Lake Umroi (3050 m a.s.l.; eastern slope). The studied lakes formed during the Holocene. The first radiocarbon (AMS) dating of lake sediments in the Lesser Caucasus high-mountain lakes combined with pollen analysis could be taken as the most representative approach for indirect identification of the age of adjacent moraine deposits and for studying the rhythmic variability of environmental processes during the Holocene. The sediments of Lake Kari formed during the last 4000 years, and in Lake Umroi – for about 8000 years. The sedimentation rate in the Armenian high-mountain lakes is low; however it varied significantly in different periods of lakes history. According to paleolimnological data from Lake Kari and Lake Umroi, we recorded a period of warming and humidification of the climate around 3000-2000 cal. BP. This was a period of extensive development of forests and the shift of the forest boundary to its present elevation. Our results also indicate a reduction of mountain glaciers about 3000 years BP and subsequent cooling with the onset of new glaciation about 2000 years BP. We compare our results of the high mountain lakes with the available data on the mires (Cromartie et al., 2020) and archaeological sites of Aragats. At the foot of the massif Aragats in the steppe landscapes (about 2000 m a.s.l.) the archaeological investigations (Smith et al., 2009) recorded the archaeological sites dated from the Neolithic to the present day.

Mid and Late-Holocene palaeoenvironmental and land-use changes in NE Crimea based on a sediment record from Lake Chokrak

Dr. Yevhenii Rohozin [1], ***Dr. Karl Ljung*** [2]

1. *Taras Shevchenko National University of Kyiv,* ***2.*** *Department of Geology, Lund University*

In this study, a sediment core from Lake Chokrak, NE Crimea, was investigated to reconstruct the evolution history of Lake Chokrak and vegetation changes around the lake, as well as climate variations, recorded both in geochemical and palaeoecological proxies. The recovered deposits were subjected to bulk carbon and nitrogen, XRF, and palynological analyses. Between 7700 and 6900 cal yr BP a relatively shallow marine bay existed in the area of Lake Chokrak. During this period, steppe vegetation around the bay was dominated by mesic herbaceous communities, whereas in the Crimean mountains the expansion of broadleaved forests occurred. A transgressive stage is observed from 6900 to 6400 cal yr BP when the water level increased and finer sediments accumulated in the basin. Between 6400 and 6200 cal yr BP an aridity event led to a decrease in water level and precipitation of evaporites. Starting from 6200 cal yr BP, a renewed transgressive stage is observed with increased water level, accumulation of fine-grained sediments and precipitation of carbonates. Wetter conditions were revealed between 5400 and 5000 cal yr BP, when the terrigenous influx into the bay increased and meadow steppe spread around the site. After 5000 cal yr BP more arid conditions prevailed in the region with increased precipitation of evaporites and the expansion of grass steppe. The infilling of the basin and formation of the sandbar started around 3000 cal yr BP when clay sediments intermixed with sand layers and the steppe vegetation became more xeric. A transitional stage from semi-open to closed basin lasted from 1400 to 800 cal yr BP and is characterised by precipitation of evaporites and disappearance of molluscs. The current stage (from 800 cal yr BP to present) of the closed lake basin is marked by sediment lamination, intensive precipitation of salts, and complete absence of molluscs due to high salinity of the brine. Human impact on the vegetation was first recorded around 3500 cal yr BP by the emergence of agriculture in the region and further intensified after 700 BCE with the appearance of Greek settlements near the site.

Climate changes during the Lateglacial in South Europe: new insights based on pollen and brGDGTs of Lake Matese in Italy

The Lateglacial (14,700-11,700 cal BP) is a key climate period marked by rapid but contrasted changes in the Northern Hemisphere. Indeed, regional climate differences have been evidenced during the Lateglacial in Europe and the Northern Mediterranean areas. However, past climate patterns are still debated since temperature and precipitation changes are poorly investigated towards the lower European latitudes. Lake Matese in Southern Italy is a key site in the Central Mediterranean to investigate climate patterns during the Lateglacial. This study aims to reconstruct climate changes and their impacts at Matese using a multi-proxy approach including magnetic susceptibility, geochemistry (XRF core scanning), pollen data and molecular biomarkers like branched Glycerol Dialkyl Glycerol Tetraethers (brGDGTs). Palaeotemperatures and -precipitation patterns are quantitatively inferred from pollen assemblages (multi-method approach: Modern Analogue Technique, Weighted Averaging Partial Least Squares regression, Random Forest, and Boosted Regression Trees) and brGDGTs calibrations. The results are compared to a latitudinal selection of regional climate reconstructions in Italy to better understand climate processes in Europe and in the circum-Mediterranean region. A warm Bølling–Allerød and a marked cold Younger Dryas are revealed in all climate reconstructions inferred from various proxies (chironomids, ostracods, speleothems, pollen, brGDGTs), showing no latitudinal differences in terms of temperatures across Italy. During the Bølling–Allerød, no significant changes in terms of precipitation are recorded, however, a contrasted pattern is visible during the Younger Dryas. Slightly wetter conditions are recorded south of latitude 42°N whereas dry conditions are recorded north of latitude 42°N. During the Younger Dryas, cold conditions can be attributed to the southward position of North Atlantic sea-ice and of the Polar Frontal JetStream whereas the increase of precipitation is Southern Italy seems to be linked to relocation of Atlantic storm tracks into the Mediterranean, induced by the Fennoscandian ice sheet and the North European Plain. By contrast, during the Bølling–Allerød warm conditions can be linked to the northward position of North Atlantic sea-ice and of the Polar Frontal JetStream.

Palaeoenvironmental changes in the Iberian central system during the Late-glacial and Holocene as inferred from geochemical data: A case study of the Navamuño depression in western Spain

The Iberian Central System (ICS) is a clue region to reveal Mediterranean/Atlantic inferences over Iberia. We present a multidisciplinary study from western Spain conducted in the Navamuno depression (ND), covering the last 16.8 ka (cal BP). A reconstruction of the palaeotemperature from the resulting geochemical data highlights four cold and dry intervals, namely, the Oldest Dryas, Older Dryas, Intra-Allerød Cold Period (IACP), and the Younger Dryas, along with warmer intervals: the Bølling (14.7–14 ka) and the Allerød (12.9–12.6 ka); however, the Greenland Interstadial GI-1c (13.4–13.1 ka) is barely distinguishable in the ND. Despite the shortage of biomass to sustain fire, the earliest charcoals are from ~14.4–13.8 ka. Evidence of ash/dust events overprinting the geochemical background starts at ~13.8–12.8 ka. Significant fire activity in the Early Holocene at ~11.7–10.6 ka affected the ND, matching the westernmost ICS data. This period includes short oceanic spells inferred from Cl peaks at ~10.9–10.2 ka, and three cold intervals at 11.4, 9.3, and 8.2 ka disrupted the progressive temperature increase. The Mid-Holocene showed a continuously increasing trend towards an arid climate, peaking at 4.2 ka under a pervasive dust influx from North Africa, which has prevailed since almost ~7.9 ka. A prominent volcanic ash event at ~6.8–5.8 ka in Navamuño is identified from a heavy metal-rich layer, synchronous with the last known eruption of the Calatrava volcanic field (South-Central Spain; affecting even northern Spain (Rozañas). This volcanic eruption could affect many other regions half north of Iberia. The pervasive presence of oceanic aerosols in the last three millennia (2.8 ka ~) allowed the formation of a Cl-rich peat layer during the Ibero-Roman humid period ~2.1 ka, before a changing around ~0.4 ka toward colder and drier conditions at the Little Ice Age (LIA) period.

PAGES Human Traces Pb sediment records project: creating a community database of published Holocene Pb pollution records

Dr. John Boyle [1]

1. University of Liverpool

A mismatch between Greenland ice core data and European lake sediment records of millennial-scale atmospheric Pb deposition has prompted a fresh look at spatial variations in Pb pollution signals, with an emphasis on distinguishing global from regional synchronous events. The PAGES (PAst Global changES) Human Traces working group is leading the creation of a global community database of published Holocene Pb records in peat and lake sediments to address this and other unanswered research questions on global lead pollution. In this talk we introduce the database, explain the parameters for record inclusion, and present preliminary findings. We confirm that some episodes of Pb enrichment found in the Greenland Ice records, particularly those dated to late 9th century CE, are absent from European records indicating substantial transport of atmospheric Pb pollution from more distant sources in Asia with distinctly different histories of metal working. We also explore the extent to which Roman Pb pollution constitutes a global signal. The implications of this for our understanding of pollution pathways at local, regional, and global scales is discussed. This work is presented on behalf of the Human Traces Pb records sub-working group.

A molecular multiproxy record from Sumatra indicates continuous Holocene warming but a mid-Holocene rainfall maximum

Smittenberg*** [1]

1. *Bert Bolin Centre for Climate Research, Stockholm University, Stockholm. Department of Geological Sciences, Stockholm University, Stockholm,* ***2.*** *Department of Geological Sciences, Stockholm University, Sweden,* ***3.*** *Formerly at Nanyang Technological University, Singapore.,* ***4.*** *Universitas Negeri Padang, Padang,* ***5.*** *College of Life and Environmental Sciences, University of Exeter, Exeter, United Kingdom,* ***6.*** *Dept. of Physical Geography and Bolin Centre for Climate Research, Stockholm University, Stockholm, Sweden*

The maritime continent (MC) forms the central part of the Indo-Pacific Warm Pool (IPWP),. This tropical region is a critical component of the global climate system by providing large amounts of latent heat to the higher latitudes via deep atmospheric convection. Paleoclimate information remains relatively scarce from the MC despite its global importance, calling for additional records from the region. We generated a multisite-multiproxy record from Sumatra, with a main focus on the glycerol dialkyl glycerol tetraether (GDGT) distributions allowing the use of the MBT'5me as a paleothermometer proxy, and compared the results also with pure lake samples and a soil transect. We investigated one homogenous peat core and one paludified lake (now peat). The GDGT sources in the former remained constant, allowing a robust temperature reconstruction that shows gradual warming during the last 8 ka, including a plateau 3-5 kyr BP. Comparison of the GDGTs with other information like bulk density and mineral content of the paludified lake record led to the conclusion that these were mainly influenced by their provenance (soil, lake, peat) rendering this record unsuitable for temperature reconstruction, but allowing environmental reconstruction.

The finding of ongoing warming over the past 8 ka agrees with several climate model simulations for Sumatra and nearby marine SST reconstructions from the Indian Ocean (western IPWP). This trend is opposite to previous marine reconstructions in the eastern IPWP, which may be related to long-term changes in the Walker circulation. Of note is that there is little to no seasonal bias in our equatorial peatland site and bacterial lipid source, something that has been implicated as biasing temperature proxies.

Leaf wax hydrogen isotopes of both records, supported by bulk, chemical and other molecular proxies, indicate an increasingly humid Holocene with a maximum between 4-6 kyr BP, suggesting that export of heat and moisture from the IPWP to the rest of the globe was at its strongest in this period. We find a decline in precipitation strength that is coincident with the reorganization and general drying and cooling of global climate at the start of the Meghalayan age.

Midges through the ages - Chironomidae in Eemian and early Weichselian palaeolake sediments from Bispingen, northern Germany

Mr. Tomasz Polkowski [1], ***Ms. Agnieszka Mroczkowska*** [1], ***Dr. Stefan Lauterbach*** [1], ***Dr. Frank Neumann*** [2], ***Prof. Michal Slowinski*** [1], ***Prof. Achim Brauer*** [3]

1. *Polish Academy of Sciences, Stanislaw Leszczycki Institute of Geography and Spatial Organisation, Twarda 51/55, 00-818 Warsaw, Poland,* ***2.*** *North-West University, Faculty of Natural and Agricultural Science, School for Geo- and Spatial Science, Geology Group, Potchefstroom 2520, South Africa,* ***3.*** *GFZ German Research Centre for Geosciences, Section 4.3 – Climate Dynamics and Landscape Evolution, Telegrafenberg, 14473 Potsdam, Germany*

Investigating past climatic changes is crucial to understand the nature of present human impact on climate and environment. In this context, inferring past ecological conditions from the analysis of non-biting midges (Chironomidae) can bring us closer to the explanation of the nature of present climate change. The analysis of subfossil Chironomidae remains in lake sediments thereby offers the unique opportunity to reconstruct several important environmental parameters, including past trophic status and pH value of lakes as well as the average summer palaeotemperature. Nevertheless, not many high-resolution palaeoenvironmental reconstructions have been conducted on the basis of subfossil Chironomidae remains for the Eemian interglacial and early Weichselian glacial so far, periods that were characterized by distinct climatic changes but absent human impact. The present study is part of a larger project that applies a multi-proxy approach to the partially annually laminated sediments of the Eemian paleolake of Bispingen in northern Germany. The Eemian and Early Weichselian section of Bispingen core consists respectively of diatomitic, calcitic-diatomitic and clastic-organic material with either faint or fine lamination and was sampled with high resolution. This research layer is about 12 meters thick. Microscopic chironomid identification was carried out using identification keys, e.g. Brooks et al. (2007), Cranston (1982) and Vallenduuk (2007). Here we present first results of the analysis of subfossil Chironomidae remains, aiming at determining temperature changes during the Eemian and early Weichselian and the climatic gradient between northern and southern Europe. Supported by geochemical and palynological data, the main aim of the presented research was conducting palaeoecological analyses using subfossil Chironomidae remains and reconstructing past summer air temperature. In the final effect, some distinct phases were extracted, providing information about trophy and thermal conditions during the Eemian interglacial and early Weichselian glacial.

This project is funded by the Polish National Science Centre (No. 2019/34/E/ST10/00275).

Holocene Emiliania huxleyi and Braarudosphaera bigelowii blooms and abundance variations in Quaternary sediments of the Western Black Sea shelf

Dr. Eliza Anton [1]***, Dr. Mihaela Melinte-Dobrinescu*** [1]

1. National Institute for Research and Development on Marine Geology and Geo-ecology – GeoEcoMar

During the Holocene, the most important groups of primary marine plankton producers are the unicellular algae, especially the calcareous nannoplankton. In the NW Black Sea, the calcareous nannoplankton assemblages consists of *Emiliania huxleyi* and *Braarudosphaera bigelowii*. Nowadays, *Emiliania huxleyi* is found at the surface-waters of the Sea of Azov at approximately 11‰ salinity, but also in the Red Sea at salinity up to 41‰. The opportunistic *Braarudosphaera bigelowii* species is also present in the Red Sea, but not in the Sea of Azov. The minimum salinity where *Braarudosphaera bigelowii* is found is approximately 17‰, in the Black Sea.

Several cores have been collected from the NW Black Sea and have been detailed studied for the calcareous nannoplankton fluctuation. The abundance pattern of *Emiliania huxleyi* and *Braarudosphaera bigelowii*, the only two species present in the Holocene deposits of the NW Black Sea, mirrored the Late Pleistocene to Holocene paleoenvironmental changes, linked to the shift of the Black Sea from a giant lake, during its isolation in the LGM (Last Glacial Maximum) to a marine basin, after the reconnection with the Mediterranean.
As expected, our finding indicates that the Unit 3 (= the Lacustrine lutite) was deposited in a freshwater environment, overlapping the restricted water circulation interval („lake" phase) of the Black Sea. During the deposition of Unit 3, the salinity in the Black Sea was most probably lower than 11‰, which is also the minimum salinity tolerated by *Emiliania huxleyi*, so no *in situ* calcareous nannoplanton species occur. *Emiliania huxleyi* already occur in several cores at the top of Unit 3 (Lacustrine Lutite), while a persistent occurrence of both *Emiliania huxleyi* and *Braarudosphaera bigelowii* in the Unit 2 (Sapropel Mud) suggests a sharp water salinity increase above 17 ‰. In Unit 1 (Coccolith Mud), blooms of both *Emiliania huxleyi* and *Braarudosphaera bigelowii* have been recorded. Generally, the fluctuation pattern of *Braarudosphaera bigelowii* is negatively correlated with the *Emiliania huxleyi* one. In conclusion, a stable marine regime of the Black Sea basin during the depositional interval of Units 1 and 2 may be assumed.

Nature and humans in Serteya region - symbiosis or competition? A paleoecological perspective on 9000 years

The qualitative and quantitative analyses of subfossil invertebrates help to reconstruct the trends in changes of the past environment. Here we present palaeoecological studies of the human settlement and its environmental background in the Serteya region. It is an area located in the Vitebsk Lake District in the western part of the Russia. Since the late Palaeolithic times it has been attractive for human settlement, especially hunter-gatherers. Based on the results of palaeoenvironmental proxies, we can learn about the factors that could have been driving prehistoric settlers. During the ten-year study, eight biogenic sediment cores were studied: seven cores from the Serteya II archaeological site and one core from the nearby kettle hole. The study included the analysis of Chironomidae communities (cores ST IIa, STII M25, and STII L29), analyses of Chironomidae and Cladocera (KH, STP I and STP II) and Coleoptera (STII N24 and STII L22). The analyses were performed with high resolution (1 cm - 5 cm). The obtained results made it possible to reconstruct in detail the palaeoecological changes taking place in the Serteya region at the end of the last glaciation and throughout the Holocene. Reconstructions of climatic conditions were inferred with Chironomidae, Cladocera and Coleoptera subfossil communities. The obtained data were supplemented with the results of palaeobotanical analyses. The age-depth models of the cores are based on geochronometric and AMS radiocarbon dating. The performed palaeozoological and palaeobotanical analyses illustrated conditions of Neolithic communities settlement, their functioning and the way they impacted lake trophic state and its catchment landcape.
The project is funded by the Polish National Science Centre (2017/25/B/HS3/00274).

Multi-proxy analyses and synchronization of European palaeoclimate records from the Holsteinian interglacial (MIS 11c)

Abrupt climate oscillations are important features of natural climate variability. Nevertheless, given the substantial anthropogenic climate impact during the Holocene, disentangling between natural climate variability and superimposed human influences, especially with respect to the rates of climate change, still poses a major challenge. In this context, investigating natural climate variability and associated environmental changes during past warm periods can provide important information about the range and rates of natural climate fluctuations. This can in turn allow to assess the present level of anthropogenic interference in the context of progressive global warming. Among the most recent warm periods in Earth's history, the Holsteinian interglacial (~400,000 years ago; the terrestrial equivalent of Marine Isotope Stage (MIS) 11c in Central Europe) represents a particularly well-suited reference interval for studying natural climate variability under interglacial boundary conditions as it was characterized by a similar orbital configuration as the Holocene but lacked any notable anthropogenic climate impact. As known from previous studies, the Holsteinian interglacial was interrupted by two distinct centennial-scale cold periods, the so-called Older and Younger Holsteinian oscillations. However, the drivers and spatio-temporal patterns of these cold intervals have so far remained elusive. To improve the understanding of these rapid climate fluctuations, particularly with respect to (1) their characteristics, spatial extent and synchroneity across Europe and (2) the succession of associated environmental changes, two annually laminated (varved) palaeolake sequences from eastern Poland (Ossówka) and northwestern Germany (Dethlingen) will be analysed within the presented project by using a multi-proxy approach. Besides establishing robust internal chronologies through microscopic varve counting, parallelization of both sediment records will be facilitated by cosmogenic radionuclide (^{10}Be) measurements. In addition, high-resolution analyses of terrestrial and aquatic microfossils (pollen, diatoms, chironomids, cladocerans), geochemical parameters (X-ray fluorescence core scanning) and the stable isotope composition of terrestrial biomarkers will be carried out. These will allow to reconstruct the spatio-temporal characteristics of the environmental responses to the two rapid climatic fluctuations during the Holsteinian interglacial and ultimately yield a better understanding of the pace and range of natural interglacial climate variability.

This project is funded by the Polish National Science Centre (No. 2019/34/E/ST10/00275).

Environmental changes during the last millenniums in Barents Sea: multiproxy evidences

Dr. Gabriella Boretto [1]***, Dr. Tommaso Tesi*** [2]***, Prof. Giuliana Panieri*** [3]***, Dr. Lucilla Capotondi*** [2]

1. *Istituto di Scienze Polari, Consiglio Nazionale delle Ricerche ISP-CNR, Bologna, Italy,* ***2.*** *Istituto di Scienze Polari, Consiglio Nazionale delle Ricerche, ISP-CNR,* ***3.*** *Department of Geosciences, UiT The Arctic University of Norway, N-9037, Tromsø, Norway*

Atlantification is the increasing influence of the warmer and saltier Atlantic water in the Arctic Ocean. The Barents Sea is a key for the comprehension of the northern hemisphere oceanic circulation through its sensitive shallow water polar ecosystem, related to (1) the oscillating ice edge link to the Artic Water (ArW) and (2) the recent expansion of the warmer Atlantic Water (AW) into the region. Understanding the past variability of this "Atlantification" is thus crucial in providing a longer perspective on the current global change. In this sense, we reconstruct the paleoenvironmental and climate history from the core HH1141, located at 74.0155°N 21.0711°E collected at -285 m depth, during the late Holocene using benthic foraminiferal assemblages, stable isotopes analyses ($\delta^{13}C$ and $\delta^{18}O$), sedimentological studies and sea ice proxies (IP25). Based on radiocarbon analyses on carbonate tests, the sediment core encompasses ca. the last 3000 yrs BP. Preliminary results indicate that, at the base of the core, the relative dominance of *Islandiella sp*, *Cassidulina reniforme*, *Ephidium* sp. and *Cibicides lobatulus*, species associated with cold bottom water mass. Towards the top of the core, the foraminiferal content is characterised by the occurrence of *Nonionella labradorica, Trifarina angulosa, Stainforthia* sp., *Adercotryma glomeratum* and *Melonis barleanus,* taxa commonly related to the AW mass influence showing increasing temperatures. The sediment sequence is dominated by the fine fraction (i.e. silt) and clay, but sand content increases towards the top, and the presence of clasts (> 5 mm) is observed. We will couple data on foraminiferal assemblages with new data on $\delta^{18}O$ and $\delta^{13}C$ of foraminiferal tests and organic proxies to resolve the environmental changes associated with the late Holocene sea ice retreat, change in productivity and water mass properties. Finally, we will compare our results with other areas within the Barents Sea covering the same period to resolve the regional pattern and place the modern Atlantification into a larger context of natural climate variability.

Past changes in atmospheric circulation and precipitation source in eastern South Africa, based on combined pollen and sedimentary leaf-wax δD records

***Dr. Elin Norström* [1], *Ms. Anel Geer* [2], *Dr. Jemma M. Finch* [2], *Dr. Christos Katrantsiotis* [3], *Prof. Trevor Hill* [2], *Dr. Jennifer M. Fitchett* [4], *Mr. Gabriel Norén* [5], *Dr. Rienk H. Smittenberg* [5]**

***1.** Department of Physical Geography and Bolin Centre for Climate research, Stockholm University, **2.** School of Agricultural, Earth and Environmental Sciences, University of KwaZulu-Natal, **3.** Environmental Archaeology Laboratory, Department of Historical, Philosophical and Religious Studies, Umeå University, **4.** School of Geography, Archaeology and Environmental Studies, University of the Witwatersrand, Johannesburg, **5.** Department of Geological Sciences and Bolin Centre for Climate research, Stockholm University*

Proxy-based climate reconstructions from Southern Africa are still limited in both quality and quantity, and expanded data on regional hydroclimate is central for better assessments of climate change. South Africa is representing a key area in this respect, as its hydroclimate conditions are sensitive to latitudinal and longitudinal fluxes in circulation systems, e.g. the spatiotemporal interplay between the temperate westerlies and tropical easterlies. In this study we reconstruct hydroclimate and vegetation in eastern South Africa, by analyzing sediment cores from two ecologically stable but hydrologically sensitive wetlands (Braamhoek wetland, Dartmoor Vlei). The sediment cores span the last ca 15 000 and 24 000 cal yrs BP respectively. Both sites are located between 28 and 32°S, a latitudinal zone identified as sensitive to large scale atmospheric shifts between westerly and easterly air-masses. Applied proxies include hydrogen isotope composition (δD) in sedimentary fossil *n*-alkanes (leaf waxes) from both sites, and a new fossil pollen record from Dartmoor Vlei. The leaf wax δD co-varies between sites, suggesting an external, region-wide, probably climatic driver dictating the isotopic shifts. This is interpreted to reflect changes in moisture source area, indirectly also related to temperature and precipitation characteristics. Lower leaf wax dD between ca. 14 000 and 11 500 cal yrs B, as well as from 8 500 cal yrs BP onwards, reflect periods of cooler and drier conditions associated with D-depleted air masses from the Atlantic and Southern Ocean. High δD-values during the early Holocene (ca. 11000 - 8 500 cal yrs BP) indicate wetter and warmer conditions associated with isotopically enriched air masses from the Indian Ocean (easterlies). The Dartmoor pollen record generally support this pattern, when applying the variability of the Asteraceae to Poaceae pollen ratio which is considered a vegetation proxy for rainfall seasonality in this region. Overall, the long-term proxy evidences are in agreement with paleo-records from e.g. Antarctica and eastern equatorial Africa suggesting their variability is driven by periodic latitudinal expansions and retreat of the circumpolar circulation systems and Intertropical Convergence Zone as a response to orbital and oceanic forcing.

Summer climate variability in the Eastern Carpathians during the last millennium: a multiproxy approch

Dr. Carmen Andreea Badaluta [1]***, Dr. Aurel Persoiu*** [2]***, Dr. Monica Ionita-Scholz*** [3]***, Prof. Ionel Popa*** [4]

1. *Stefan cel Mare University of Suceava,* ***2.*** *Emil Racoviță Institute of Speleology, Cluj Napoca,* ***3.*** *Helmholtz Centre Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany,* ***4.*** *National Research and Development Institute for Silviculture "Marin Drăcea", Câmpulung Moldovenesc*

Eastern Europe lies at contact between continental and oceanic climatic influences, with hot and dry summers and is also influenced by northward expanding Mediterranean climate, being thus especially sensitive to forecasted changes in the strength and intensity of summer heat waves. Understanding the past dynamics of summer climate variability is thus of paramount importance in our quest to mitigate and/or adapt to ongoing climatic changes.

In this context, we present and discuss here droughts and temperature changes in the heart of Eastern Europe (Transylvanian Basin and Eastern Carpathian Mountains) during the last 1000 years, through the analysis of documentary and proxy-based data.

Our historical analysis show that summers over the last millennium were characterized by three dry periods (AD 1100-1150, 1400-1750, 1750-1900). Climate in Eastern Europe during the last millennium was complex, with wet and warm conditions during Early Medieval Warm Period (MWP, AD 850 - 1100) followed by dry condition during the Late MWP (AD 1100 - 1150). The transition between the MWP and LIA periods (AD 1250 – 1400) is characterized by rainy and less dry periods. The most changes occurring during the Little Ice Age (LIA, AD 1400 – 1850), when the temperature drops and the occurrence rate of summer droughts show an increasing trend of ~ 0.3/season over the Eastern Carpathians. At the same time, the multiproxy analysis indicates a stability of the summer temperature in the last millennium, the variability being observed only for short periods.

The mechanism of the variability of temperature anomalies can be explained by the variations of the Sea Surface Temperature (SST) in the North Atlantic, so the prolonged periods of positive temperature anomalies during the summer are due to the warming of the SST, while the negative anomalies are due to the cooling of the SST.

Acknowledgments.

Valle di Castiglione (Rome, central Italy) is an ancient volcanic lake, artificially dried out, belonging to the northern sector of Alban Hills. Valle di Castiglione is the oldest hydromagmatic crater of the Alban Hills, developed during the last stage of activity of the Tuscolano-Artemisio central edifice and characterized by pyroclastic flows and by final lava flows. The past lake is 1 km in diameter and occupies a phreatomagmatic explosion crater.
The lithostratigraphic sequence is characterized mostly by brownish black slightly calcareous muds, containing volcanic material, tuffities, gray calcareous muds with freshwater fauna. Today the area is characterized by a Mediterranean climate with rain mainly concentrated in autumn and winter and aridity during summer. The mean annual temperature is 15°C, the average annual rainfall is about 800 mm. The potential vegetation is Mediterranean, dominated by oaks, but the strong human presence in the area has deeply modified the natural vegetation The present study is linked to a larger project of INGV “AMusED” (https://progetti.ingv.it/it/amused) whose purpose is to investigate climate change with a multidisciplinary method in three sites in Italy, one of which is Valle di Castiglione (Roma). Here we present a new pollen diagram of the last interglacial (LI), the Eemian, corresponding to Marine Isotope Substage, MIS 5e, of marine stratigraphy.
A preliminary pollen diagram, with a time resolution of 500 years, was obtained from a composite core taken close to the lake depocenter. It depicted with continuity the vegetation history of LI near Rome, indicating that the environment was rather open (with mainly Poaceae, Cyperaceae, Amaranthaceae) and that mediterranean (mainly characterized by evergreen *Quercus*, Ericaceae and *Olea*) and mesophilous (mainly characterized by deciduous and semi-deciduous *Quercus*, *Carpinus betulus*, and Ulmaceae) forests alternated in dominating the vegetation.
We have to consider that Valle di Castiglione has a key role to understand the past in Central Italy, being an archive of information about past biodiversity, volcanic ash and tectonic activity.

The Holocene expression in humidity and sea surface temperatures in the western Mediterranean Sea

Mr. Albert Català [1]***, Dr. Leopoldo Pena*** [2]***, Dr. Ester García Solsona*** [2]***, Dr. Eduardo Paredes*** [2]***, Dr. Jaime Frigola*** [2]***, Dr. Anna Sànchez-Vidal*** [2]***, Dr. Antoni Calafat*** [2]***, Prof. Isabel Cacho*** [1]

1. *Universitat de Barcelona,* ***2.*** *GRC Geocencies Marines, Dept. de Dinamica de la Terra i de l'Ocea, Facultat de Ciencies de la Terra, Universitat de Barcelona*

The Mediterranean region is particularly sensitive to global climate variability that critically reflects on its hydrological conditions. A recently published high-resolution reconstruction of Holocene Sea Surface Temperature (SST) based on *Globigerina bulloides* Mg/Ca ratios set the basis to explore, within a warm climatic period, the impact of North Atlantic oceanographic conditions shaping the properties of the inflowing waters into the Mediterranean Sea. Going a step further in establishing the potential links between these oceanographical changes with the hydrological conditions on the southern Iberian Peninsula, we isotopically characterized (Sr, Nd and Pb) the present terrigenous sourcing and their transport processes on the Alboran Sea to use as an analogue to reconstruct the Holocene variations. The present-day isotopic characterization was performed of settling particles recovered by moored sediment traps under well-characterized meteorological conditions. This reveals that the main sources of the terrigenous particles arrive transported by the fluvial discharges around the Alboran Sea. Also, the observed isotopic changes during the recorded year were closely linked to rainfall patterns. Transferring this knowledge to the past time and compared with the SST, the results indicate that the most humid and warmer conditions were developed during the Early Holocene. Afterwards, a transition towards colder temperatures was linked with an aridification and enhancement of the torrential rainfalls, culminating with the coldest SST and higher torrential effect. During the Late Holocene, relative cold and drier conditions similar to the present were recorded.

Fluvio-estuarine sedimentation and estuarine evolution during the Late-Holocene in the upper Taw Estuary, England: unravelling the climate record of tidal river deposits.

Dr. Glenn Havelock [1], ***Prof. Antony Brown*** [2]

1. Kingston University, 2. University of Southampton

Present models of Holocene estuary evolution are driven largely by changes in relative sea-level (RSL) and other marine-realm boundary conditions, with less focus on long-term changes in fluvial regime and catchment climate. However, decadal-centennial scale climate change has been shown in fluvial studies to have a major control on Holocene river behaviour, with fluvial geomorphic records showing evidence for a high sensitivity in flood occurrence to changing climate and precipitation. It follows that the changes in river discharge associated with these climatic fluctuations should have an important bearing on inner estuarine hydrology and sedimentology. Indeed, some studies have shown that changes in freshwater inflow can be inferred by changes in estuarine palaeosalinity and that the timing of these events reflect changes in regional precipitation. Deposition in the transitional inner estuarine environment can therefore be seen to be controlled by both marine and fluvial influences, especially within tidal river environments. This gives the potential for tidal river deposits to provide both a record of catchment hydrology and regional precipitation, and a record of sea-level change.

The late-Holocene sedimentary record was investigated on both sides of the estuarine-fluvial boundary in the Taw Estuary, south-west England. The study aims to reconstruct regional climate based on changes in discharge-driven estuarine palaeosalinity. The diatom record of a comprehensive network of sediment cores enabled paleosalinity to be evaluated on both sides of the current tidal limit. The study also investigated the relative importance of changes in RSL and river discharge on estuarine sedimentation and centennial-scale geomorphic evolution. The fluvio-estuarine valley fill was split into a series of stratigraphic units, with a chronological framework derived using radiocarbon and OSL dating methods.

Geomorphic change in the inner estuarine zone is shown to be mainly influenced by phases of increased river discharge and catchment precipitation, with fluvial instability translating down river into the inner estuarine system. Changes in RSL during the late Holocene are also shown to influence inner estuarine sedimentation and geomorphic change, but to a lesser extent than centennial-scale climate-driven river discharge variability. A new late-Holocene multi-proxy climate record for the region is presented.

Tracking the Older Holsteinian Oscillation: a multi-proxy record from Eastern Poland

Mrs. Monika Czajkowska [1]

1. *University of Warsaw*

Based on similarities with regard to orbital climate forcing, Marine Isotope Stage (MIS) 11c represents one of the closest astronomical climate analogues for the Holocene. Hence, insights into the climate variability of this interglacial can contribute to a better understanding of the present climate evolution and the natural climate drivers as it would occur without human interference.

The aim of the present study is to better understand the environmental variability during the MIS 11c. Therefore, eastern Poland as the area where the transition from maritime to continental conditions can be observed is an excellent region for this kind of palaeoenvironmental studies.

Lake sediments exposed in Ortel Królewski II (Eastern Poland) are characterized by a remarkable abundance of molluscs and ostracods, in many cases constituting over 70% of the deposits. The reconstruction of the paleoenvironmental conditions was possible using a multi-proxy analysis on the lake sediments from the Ortel Królewski II site. The high-resolution analysis covered the uppermost part of the profile, representing the so called pre-optimal part of the interglacial, namely the *Taxus* and *Pinus-Larix* pollen zones. High-resolution faunal analyses (ostracods and molluscs) combined with pollen, stable isotope and lithological analyses enabled detailed reconstruction of the rapid climatic fluctuations during the Holsteinian interglacial

While during the *Taxus* zone the temperature was rather stable, the short cooling event was documented in the beginning of the *Pinus-Larix* zone. The higher numbers of some cold-loving ostracods (*Candona candida*, *Candona neglecta* and *Fabaeformiscandona protzi*) indicate some deterioration of thermal conditions, which was additionally confirmed by the mutual ostracod temperature range (MOTR) method and the isotope record of ostracod carapaces. Additionally, lake level drop and expansion of reed zones within the *Pinus-Larix* pollen zone are inferred from the increased abundance of shallow water ostracod and mollusc species as well as increased $\delta^{13}C$ values. The short cooling event documented early in the *Pinus-Larix* zone in the studied profile might be an equivalent to the mid-MIS 11c cooling, the so-called Older Holsteinian Oscillation. Thus, by comparing this data with other sites from area nearby will hopefully allow to determine the spatial range of this climatic oscillation.

Further challenges for Pleistocene palaeogeography of the Middle Dnieper basin recorded in loess-glacial sediments

Middle Dnieper loess-palaeosol sequences (up to 50 m thick) are considered as valuable long-term geoarchives of climate and environmental change during the Middle-Late Pleistocene. Their sedimentary record undoubtedly has a high correlative potential also due to the presence of the sub- or intra-loess till layer of the Dnieper (=Saalian) glaciation, which thus represents an important stratigraphic marker. The stratigraphy of these loesses is debatable due to different conceptions of the age of the Pryluki (pl) and Kaydaki (kd) palaeosols, separated by the Tyasmyn loess (ts), which lie over the Dnieper glaciogenic sediments and (sometimes) dn loess of the same period. Two schemes for correlating these units with marine isotope stages are currently in use: 1) till and/or loess dn are equivalent to MIS 8, palaeosol kd - MIS 7, loess ts - MIS 6, pedocomplex pl - MIS 5; 2) alternatively, unit dn (till, loess) are correlated with MIS 6, while units kd-ts-pl are combined with MIS 5. The post-recession loess-palaeosol sequences located on both sides of the Dnieper River (the Kremenchuk Reservoir) were selected for palaeogeographical and stratigraphic studies. These sequences are characterised by complex layering and variable lithology; palaeosols of the same age have different genetic profiles. A multidisciplinary study of these sites yielded lithological, geochemical, pedological, palaeontological, luminescence and AMS data. The results offer interesting reliable material for the reconstruction of the dynamics and directions of environmental changes as well as the evolution of loess landscapes after deglaciation of the Dnieper ice sheet in its marginal zone, the establishment of their enough precise chronological framework, and solid arguments for the stratigraphic distinctiveness of pl (S1; MIS 5) and kd (S2; MIS 7) palaeosols. They also contribute to a better understanding of the regional climatic context, as well as the link between similar sediments in continental scale.

Research carried out as part of the grant of National Science Centre, Poland (the project no. 2018/31/B/ST10/01507) entitled "Global, regional and local factors determining the palaeoclimatic and palaeoenvironmental record in the Ukrainian loess-soil sequences along the Dnieper River Valley - from the proximal areas to the distal periglacial zone".

The coldest summer temperature in Serbian loess-palaeosol sequence Stari Slankamen during the MIS 12 – malacological evidence

Ms. Milica Radaković [1]***, Mr. Rastko Marković*** [2]***, Dr. Tin Lukić*** [1]***, Dr. Milivoj Gavrilov*** [1]***, Prof. Slobodan Marković*** [1]

1. *Department of Geography, Tourism and Hotel Management, Faculty of Sciences, University of Novi Sad, Trg Dositeja Obradovića 3, 21000 Novi Sad, Serbia,* ***2.*** *Department of Geography, Faculty of Sciences, University of Niš, Višegradska 33, 18000 Niš, Serbia*

Stari Slankamen loess-palaeosol sequence (LPS) is located at the northern slope of Fruška gora mountain in the Carpathian basin, at the Tisza and Danube River confluence. It accumulated over nine glacial and interglacial cycles, thus being the oldest continuous terrestrial record of Pleistocene sediments in Serbia, and among the oldest studied LPSs in Europe. In this study, the malacological record of the Marine Isotope Stage (MIS) 12 is presented. The profile is sampled at 20 cm resolution for 4.8 m. The results from 15961 snail shells in total, from which 769 were too damaged to be identified, gave new insights into the glacial environment of the southern part of the Carpathian basin. Preliminary results show 27 mollusk species, more than half of which belong to mesophilous and highly tolerant species in terms of humidity and temperature, respectively. The MIS12 was shown to be more humid and cold compared to subsequent glacial cycles according to mollusks found in Serbian LPSs. Four results will be pointed out here:

- For the first time, the specie *Acanthinula aculeata* was found in Serbian loess.
- The *Orcula dolium* (today living in Alpine environment) was thriving, at some points making 20% population per the sample.
- The cold-resistant and frigophilous species comprised 14% of found snail population in entire MIS 12 which is not recorded in previous investigations of younger Serbian loess.
- July temperatures based on the malaco-thermometer method ranged from 14.4 °C to 19.7 °C.

The last result indicates that at some point the estimated July temperature was almost 8 °C lower compared to the modern. Still, the cold temperatures were not a restricting factor controlling the snail abundance, as there could be over 1500 shells per 10 kg of sediment. The warmer event indicated at the middle of loess unit L5 was also documented in equivalent chronostratigraphy at the Chinese loess plateau based on mollusk assemblage. The colder MIS 12 conditions over the Carpathian basin are in agreement with the pronounced glacier extent over its surrounding mountain systems and one of the strongest Pleistocene glacial environments in this part of Europe.

Unexpected light carbon isotope values from calcified root cells in a palaeosol (Chinese Loess): a result of contrasted seasons?

Loess deposits are widespread in China and are important archives of Quaternary climate and environmental changes over East Asia. The alternance between palaeosols and loess units from the Chinese loess plateau (Central China) revealed that glacial and interglacial cycles are dominated by East Asian monsoon variations. Here, we study a loess profile in the northwest part of Beijing, the Fanshan loess profile, with a focus on the MIS 5 palaeosol and the loess units above and below. We investigate a potential new paleoenvironmental proxy: the calcified root cells (CRC) which are typical of herbaceous vegetation of steppe environments. These calcifications form relatively quickly (a few weeks to a few months) during the dry phases of the vegetation growing season. CRC concentration variability show a good correlation with the pedostratigraphy and grain size with high concentrations within the palaeosol and few CRC in the loess units. The high CRC concentration during the formation of the palaeosol suggest that the environment was favourable to the development of the vegetation. To better understand the past environment and climate, we measured the carbon isotope composition of the mineral phase and of the organic matter preserved in the CRC. Although the $\delta^{13}C$ of CRC for the organic matter do not shift from C_3 values, the $\delta^{13}C$ of CRC of calcite has an average of ~ -19‰, 5 unit below the expected values based on the root respiration. This signature is probably due to contrast seasonal period and might provide evidence for freeze-thaw processes during MIS 5 paleosol formation in the peri-desert zone. During the formation of this palaeosol, warm and humid conditions were prevailing and were associated with the development of the vegetation and the high abundance of the CRC. However, our isotopic signature suggest that winter season was characterized by cold and dry conditions (longer and intense) producing enriched soil ^{12}C reservoirs which was then pumped by the roots. By combining the carbon isotopic signature from the mineral phase and the organic matter, we have essential data on the carbon cycle in palaeosols.

(Mis)interpretation of grain size data of loess-paleosol sequences

The proper interpretation of grain size data of aeolian dust deposits is of particular importance in environmental reconstructions. Today, modern methods for grain size determination and data processing are readily available to scientific researchers.

The uncertainties arising from the different chemical pretreatment of the samples and from the inadequate use of particle size determination methods are not addressed in this presentation.

Large number of research papers dealing with grain size data apply simple statistical descriptors and size-fraction ratios to draw conclusions on the stratigraphic, sedimentary and evolutionary meaning of granulometric data. This kind of approach which provide direct linkage among single statistical descriptors and wind speed, strength, distance from source area or aridity/extent of source areas is rather oversimplified as the grain size of sedimentary samples from aeolian dust deposits is influenced by an integrated effects of several concurrent processes and by several simultaneous environmental factors.

The simplified stratigraphic characteristics of the loess-paleosol sequence suggest that loess was formed from accumulated dust during the glacials, and the uppermost layers of loess were then pedogenised during the interglacials. The picture is also nuanced, to varying degrees in space and time, by glacial soil formation processes and interglacial dust accretion mechanisms. In this sense, the history of the development of an entire sedimentary series cannot be traced back to purely aeolian conditions.

Sedimentary subpopulations of (primarily) bimodal grain size distribution curves are decomposed by different mathematical methods (e.g., parametric curve fitting, end-member modeling). The loess sub-populations of parametric curve fitting are proposed to illustrate the background and the local-derived dust components for each sample. While the end-members of loess-paleosol samples can be regarded as representation of the average dust grain-size distribution of three temporal aeolian sediment clusters of seasonal or other short-term intervals.

Our aim is to discuss the main differences of frequently used statistical methods and to provide possible interpretations of the results by applying these various approaches on the high-resolution loess-paleosol record of Dunaszekcső, Hungary (Central Europe).

The research was funded by the NKFIH FK138692 project and National Multidisciplinary Laboratory for Climate Change, RRF-2.3.1-21-2021 project.

Forward step for using silicon isotope ratio in paleoenvironmental studies: Si isotope fractionation in Norway spruce

The importance of the plant-soil silica linkage is predicted by silicon making up a quarter of the mass of the earth's crust. The cycle of biogenic silica is faster than the dissolution of silica minerals from the earth's crust in the geochemical cycle. Thus, the composition of silicon isotopes in sedimentary diatoms, choanoflagellates, radiolarian tests, and sponge spicules seems to be a valuable indicator for dissolved silicic acid utilization and, therefore for paleoecological studies. Silicon isotope measurements in fossil remains of higher plants also provide a possibility to determine the rate of silicon usage. To understand the silicon isotope fractionation caused by the biochemical processes during the transport between silicon uptake and precipitation in a plant, silicon isotope fractionation in Picea abies [L.] H. Karst needles taken from different height-zones of a tree was measured by multi-collector inductively coupled plasma mass spectrometry (MC-ICP-MS). Our study demonstrates that we have to consider the intra-plant silicon fractionation, which was between -0.8 ‰ and 2.2 ‰ in spruce needles depending on the pathway length of the sap containing mono-silicic acid. The current study is the first report on silicon isotope fractionation in

Testing the potential of stable isotopic analysis of secondary carbonates from loess-palaeosol sequences in the southern Caucasus to understand hydroclimatic change and hominin population dynamics

Stable isotopic (δ^{18}O and δ^{13}C) analysis of secondary carbonates forming in loess-palaeosol sequences have been demonstrated to provide a reliable record of long-term hydroclimatic changes in many regions across Eurasia. When combined with independent chronologies, these records allow for inferences to be made regarding the timing and nature of temperature and precipitation change during the Pleistocene.

The southern Caucasus contains many loess-palaeosol sequences, but these have seen relatively limited study in comparison to other loess regions in Eurasia. This is despite the fact that the region: 1) lies at an important intersection between the northern temperate, and southern subtropical climatic zones, and 2) has a rich Palaeolithic archaeological record containing evidence for multiple episodes of hominin expansion, cultural and technological change during the Pleistocene. Understanding long-term hydroclimatic change in the region is therefore of considerable importance.

Here, we report new results from the first systematic stable isotopic study of secondary carbonates in five loess-palaeosol sequences in the Armenian Highlands. We first present a description and independent absolute chronologies for each sedimentary succession. The morphology and petrology of the main carbonate facies (rhizoconcretions, nodular carbonates, laminar calcrete) identified are then explained, followed by the results of bulk stable isotope analysis of these facies. The δ^{18}O and δ^{13}C signatures of these carbonates are interpreted to provide inferences with regard to local environmental change and regional hydroclimatic variability. Through the integration of the stable isotope records and site chronologies, we demonstrate how the data improve our understanding of the spatial and temporal variation in hydroclimate regimes in the southern Caucasus, and the impacts on hominin population dynamics.

18O analyses of bulk lipids as novel paleoclimate tool in loess research – a pilot study

The analysis of the stable oxygen isotopes ^{18}O and ^{16}O has revolutionized paleoclimate research since the middle of the last century. Particularly, δ^{18}O of ice cores from Greenland and Antarctica is used as a paleotemperature proxy and δ^{18}O of deep-sea sediments is used as a proxy for global ice volume. Important terrestrial archives to which δ^{18}O as a paleoclimate proxy is successfully applied are speleothems, lake sediments or tree rings. By contrast, δ^{18}O applications to loess-paleosol sequences (LPSs) are scarce. Here we present a first continuous δ^{18}O record (n=50) for the LPS Crvenka in Serbia, SE Europe, spanning the last glacial-interglacial cycle (~last 145 ka). From a methodological point of view, we took advantage of a recently proposed paleoclimate/-hydrological proxy based on bulk δ^{18}O analyses of plant-derived lipids. The Crvenka $\delta^{18}O_{\text{bulk lipid}}$ values range between -10.2 ‰ and +23.0 ‰ and are systematically more positive in the interglacial and interstadial (paleo-)soils corresponding to the marine oxygen-isotope stages (MIS) 1, 3 and 5, compared to the loess layers (MIS 2, 4 and 6). Our Crvenka $\delta^{18}O_{\text{bulk lipid}}$ record provides no evidence for the occurrence of interstadials and stadials comparable to the Dansgaard-Oeschger events known from the Greenland $\delta^{18}O_{\text{ice core}}$ records. Concerning the interpretation of our Crvenka $\delta^{18}O_{\text{bulk lipid}}$ record, plant-derived lipids such as fatty acids and alcohols are certainly strongly influenced by climatic factors such as temperature (via $\delta^{18}O_{\text{precipitation}}$) and relative air humidity (via ^{18}O enrichment of leaf water due to evapotranspiration). However, pool effects in the form of not water-correlated lipids such as sterols or input of root-derived lipids need to be considered, too. Similarly, the input of soil-microbial lipids and oxygen exchange reactions represent uncertainties challenging quantitative paleoclimate/-hydrologic reconstructions based on $\delta^{18}O_{\text{bulk lipid}}$ analyses from LPSs.

Pollen-based Holocene quantitative temperature reconstruction on the eastern Tibetan Plateau using a comprehensive method framework

1. *Key Laboratory of Land Surface Pattern and Simulation, Institute of Geographic Sciences and Natural Resources Research, Chinese Academy of Sciences,* ***2.*** *Institute of Geographic Sciences and Natural Resources Research, Chinese Academy of Sciences, Beijing, 100101, China,* ***3.*** *School of Earth Science and Geological Engineering, Sun Yat-sen University, Guangzhou, 510275, China,* ***4.*** *State Key Laboratory of Lake Science and Environment, Nanjing Institute of Geography and Limnology, Chinese Academy of Sciences, Nanjing, 210008, China,* ***5.*** *1. School of Geography and Ocean Science, Nanjing University, Nanjing 210023*

Quantitative climate reconstruction on long timescales can provide important insights for understanding the climate variability and providing valuable data for simulations. Unfortunately, the credibility of some attempts was hampered by incomplete reconstruction procedures. We here establish a comprehensive framework resting on high-quality Chinese modern pollen database, including modern pollen data screening, calibration set selection, major climate factor analysis, appropriate model selection, strict statistical assessment of results and ecological interpretation. The application of this framework to three high-resolution pollen records from the eastern Tibetan Plateau allows accurate quantitative inferences of Holocene temperature changes, which is the major control of regional vegetation. The results show that the mean warmest month temperature (MTwa) during the early Holocene was ca. 10.4°C and reached the highest value at 8.5–6 ka BP (ca. 11°C). The early and mid-Holocene (11–5 ka BP) warmth was followed by 1.2°C temperature decrease, culminating in the coolest temperatures of the Holocene during the Neoglacial cooling. Superimposing on the general cooling trend, MTwa reveals a significant 500-yr periodicity with varying intensities through time, showing that warm (cold) intervals are in phase with solar maxima (minima) periods. This spectral similarity indicates a possible connection of multi-century scale climate fluctuations with solar forcing.

Characterization and origin of the Clay-Rich Sediments from the Ases Cave (Mallorca, Spain)

Mrs. Ana Entrena [1], ***Dr. Joan J. Fornós*** [1], ***Dr. Luis F. Auque*** [2], ***Dr. Francesc Gràcia*** [1], ***Dr. Elisa Laita*** [2]

1. *University of Balearic Islands,* ***2.*** *Department of Earth Sciences, University of Zaragoza*

This work is the first study entirely focused on sedimentary deposits inside a cave in the Mallorca Island, specifically the sediments found in the Ases cave. A great number of coastal caves are located in Mallorca and are characterized by the magnificent presence of speleothems that have been studied for decades, especially those related to sea level variation. Nevertheless, the sedimentary deposits also present in these caves have not been studied in depth and that is the main objective of the work presented here. The analyses carried out on samples collected in the cave include the study of the grain size and the mineralogy of the deposits (X-rays and electron microscopy). Typically, the sediments are formed by calcite, quartz and clay minerals, with minor proportions of dolomite, albite, orthoclase, hematite, and goethite. The most important clay minerals are the illitic phases, kaolinite, smectite, and chlorite. The grain size and the electron microscopy studies have allowed to interpret the presence of different sedimentation processes: bedrock degradation, creep or saltation, and suspension; and different origins for the sediments: authigenic and detrital. Autochthonous deposits are located on the floor of chambers and corridors in subaqueous zones, indicating the stability over time of the mixing zone and, therefore, of the sea level. These deposits seem to be related principally to bedrock degradation. Allochthonous deposits are related to creep or saltation and suspension processes and appear filling voids on the walls and the ceiling in the terrestrial zone, evidencing the filling of the cavity in the presence of water (during a wet period). These results support the relevance of the study of these materials in paleoenvironmental studies in order to complete the understanding of the caves and their evolution.

Clarifying abrupt changes in the terrestrial environment on the Japanese archipelago from the aeolian sediments sequence between the end of the middle Pleistocene and the Holocene

Prof. Masashi Takada [1], ***Prof. Shin Toyoda*** [2], ***Ms. Ayane Tsuruta*** [3]

1. *Department of Geography, Nara Women's University,* ***2.*** *Institute of Paleontology and Geochronology, Okayama University of Science,* ***3.*** *Okayama University of Science*

The Quaternary is a period of intense climate change characterized by glacial-interglacial cycles. During the process of warming in the cycles, abrupt cooling such as the Younger Dryas event and the Dansgaard-Oeschger cycle occurred. These cooling events have been triggered by changes in oceanic environment in the North Atlantic to the east of Greenland, and many related phenomena have been identified in Europe. On the other hand, considering how these changes affected East Asia is important for understanding global climate change. For example, Nilson and Lehmkuhl (2001) indicate that in the case of interpreting temporal patterns in the late Quaternary dust flux from Asia to the North Pacific, simplified assumptions concerning the reasons for dust variability may lead to incomplete or even erroneous palaeoecological conclusions. However, in order to analyze which Quaternary climate change events reported from Europe around the North Atlantic are linked to climate change events in East Asia, more specific field data are needed.

In this study, we perform continuous sampling of latest middle Pleistocene to Holocene volcanic loess soil distributed in the Japanese archipelago. Then, based on the analysis of various paleoenvironmental indices such as (1) characteristics of stratigraphy, (2) grain size distribution, (3) phytolith sequence, (4) ESR E_1' center signal change and (5) crystallinity of clay minerals and plagioclase, we try to reveal abrupt terrestrial environment changes with a time scale of several hundred years order. In future, we will apply similar analyses to loess samples in the western part of the Eurasian continent. Finally, by comparing such analyses, we would like to discuss on the global and the local - regional changes related to the terrestrial environment during the period.

Harder, Better, Faster, Stronger - new insights on the frequency and hazard risks of extremely large volcanic eruptions (VEI≥7) from polar ice cores

Department of Chemistry "Ugo Schiff", University of Florence, Florence, 8. Max‐Planck Institut für Meteorologie, Hamburg

Large-magnitude volcanic eruptions, are considered the most severe natural global catastrophic risk, because they are able to eject large amounts of fine particles (e.g. sulfuric aerosols) into the stratosphere, where block incoming solar radiation. Our ability to predict the global hazards and risks to society of future volcanic sulfur injections is, however, compromised by the lack of a complete record of global volcanism with well-constrained evidence of timing and magnitudes of stratospheric sulfur aerosol injections. In order to mitigate and adapt to the climate effects of future large volcanic eruptions we need to better quantify the risk of these eruptions including (a) the probability of their occurrence and (b) their expected climatic impact.
Well-dated, high-time-resolution ice-core measurements provide, if not the only, certainly the most direct and detailed records of atmospheric aerosol concentrations before recent decades when instrumental and satellite measurements began. Sulfate and ash preserved in ice layers allow us to reconstruct the timing and associated stratospheric sulfate content of past volcanic events.
Here we use arrays of synchronized, accurately dated, high-resolution ice-core aerosol records from Greenland and Antarctica to reconstruct the timing, sulfur injections and likely source locations or latitudes of > 2000 volcanic eruptions occurring during the last Glacial (60-11.7 ka BP) and Holocene (the past 11,500 years) to answer the questions:
1) What is the likelihood of a stratospheric sulfur injection comparable in strength to that of Tambora in 1815 CE or of Toba in 74 ka BP to occur somewhere on the globe within the next 100 years?
2) How has subaerial volcanic activity changed in space and time throughout the last Glacial and Holocene?
We further demonstrate how state-of-the-art continuous-flow-analyses of ice cores combined with geochemical fingerprinting techniques performed on minute amounts of volcanic acids and cryptotephra shards present in polar ice can be used to detect and identify the source of past volcanic eruptions (including "supereruptions") sometimes even when these occurred more than 10,000 km away from the ice-sheets.

Signature of volcanic climatic impacts recorded in the Astronomical Diaries and Related Texts from Babylonia

Ms. Rhonda McGovern [1], ***Dr. Francis Ludlow*** [1], ***Dr. Conor Kostick*** [1]

1. *Trinity College Dublin*

The *Astronomical Diaries and Related Texts from Babylonia* represents a compilation of the oldest continuous written weather records in the ancient world. These diaries date from 652-61 BCE with a majority of the surviving data spanning from ~390-61 BCE. Following a process of coding and cataloguing these data into an analysable dataset, the researcher is currently reconstructing the climate for the region in this period, with some exciting results unfolding. During the timeframe represented by the diaries, there are approximately 30 notable explosive volcanic eruptions captured by polar ice-core sulphate deposition data. Some of these eruptions are likely to have impacted on Babylonian climate, and potentially also society, with evidence preserved within the *Astronomical Diaries*. The extent to which the *Diaries* will capture the impact of all such eruptions is however tempered by factors such the distribution of missing diaries and other biases through time. For example, the climatic impact of the major tropical eruption of 168 BCE is not captured in the diaries because of missing data. This paper will highlight the signature of volcanic climatic impacts as evident in the recorded observations. Signatures uncovered thus far include increased impacts on the levels of the Euphrates river, recording of severe cold, alongside terms such as “the disk of the sun looked like that of the moon”, and the “sun set (or rose) in a box (or black cloud)”. These will be discussed in parallel with the scale of omissions, an intriguing aspect of the *Diaries*.

Volcanic Eruptions and Civil War in Persia - 424 and 465 BCE

Dr. Conor Kostick [1], ***Dr. Francis Ludlow*** [1], ***Dr. Selga Medenieks*** [1]

1. *Trinity College Dublin*

In 465 BCE a coup against Xerxes I brought to an end his reign as ruler of the Persian empire. Records from the Persepolis Tablets show that there is a very distinct spike - a unique moment in the reign of Xerxes I - when silver was disbursed by the administration instead of grain. In the year 424 BCE civil war broke out in the Near East in the aftermath of the death of the Persian emperor Artaxerxes. The only legitimate son, Xerxes II, became ruler. He held power for just forty-five days, before a coup took place, plunging the empire into a crisis. Evidence from Murašû Archive indicates that it was also a year of exceptional economic crisis, when landowners failed to pay taxes in crops and sought to mortgage their land for silver. In both cases the outbreak of civil war co-incided with the aftermath of a major volcanic eruption, strongly suggesting that these events were triggered by the impact of the volcanoes on agriculture.

Tracing the Social and Environmental Dimensions of Volcanic-induced Climate Change in the 1st Millennium AD

Ms. khadijeh Alinezhad [1]***, Dr. Ingo Feeser*** [1]

1. *Institute of Prehistoric and Protohistoric Archaeology, Christian-Albrechts-Universität zu Kiel, Germany*

Volcanic eruptions are one of the natural disasters that have raised short-lived climate change, which has potentially affected the human-environment relationship in prehistoric and historic times. Many paleoclimatic records are consistent that the first half of the 1st millennium AD is a tumultuous time of environmental, societal, agricultural, and political turbulence. At least three large volcanic eruptions occurred during that period in AD 536, AD 540, and AD 547. Whether or not these volcanic eruptions triggered the Late Antique Little Ice Age and had profound effects on social disruption from AD536-660 in the Northern Hemisphere is a matter of debate. Lake sediments record paleoclimatic and paleoenvironmental dynamics as climate variability, vegetation, settlement history, and trace effects of volcanic eruptions. In this study, an annually laminated sequence from Lake Kleiner Tornowsee, Northeastern Germany, was selected and a multiproxy approach including palynology, tephra analysis, XRF-geochemistry, varve, 14C-AMS dating, and age-depth modeling was conducted for the time window AD 330-1320 to disentangle the potential effects of the volcanic eruptions on climate variability and societal and environmental changes. Our data depict that the 1st millennium AD was a time of climatic, demographic, and environmental changes in North-eastern Germany. The volcanic eruption (tephra in 381cm; AD 364) was followed by a decline of anthropogenic indicators (API) (e.g. *Secale*, and Cereal-type) reflecting the start of the so-called "migration period" in the region. A woodland re-expansion is visible in the time window AD430-580. A high level of environmental impact was experienced during the Slavonic occupation from AD580 to AD 770 and in AD1170-1330 where there is a high value of Anthropogenic indicators (API) is the onset of Germanic colonization.

Keywords: Pollen, Tephra, Annually Laminated Lake Sediment, Climate, Migration

A proxy-based semi-stochastic ensemble reconstruction of volcanic climate forcing for the last glacial cycle (130,000 – 50 BP)

Dr. Matthew Toohey [1], ***Dr. Julie Schindlbeck-Belo*** [2], ***Dr. Marion Jegen-Kulcsar*** [2], ***Dr. Steffen Kutterolf*** [2], ***Prof. Kira Rehfeld*** [3]

Perturbations in stratospheric aerosol due to explosive volcanic eruptions are a primary contributor to natural climate variability. Observations of stratospheric aerosol are available for the past decades, and information from ice cores has been used to derive estimates of stratospheric sulfur injections and aerosol optical depth over the Holocene (10,000 BP to present) and into the last glacial period, extending back to 60,000 BP. Tephra records of past volcanism, compared to ice cores, are less complete, but extend much further into the past. To support model studies of the potential impacts of explosive volcanism on climate variability over glacial timescales, we present here an ensemble reconstruction of volcanic stratospheric sulfur injection (VSSI) over the last 130,000 years that is based primarily on terrestrial and marine tephra records. VSSI values are computed as a simple function of eruption magnitude, based on VSSI estimates from ice cores and satellite observations for identified eruptions. To correct for the incompleteness of the tephra record, we include stochastically generated synthetic eruptions, assuming a constant background eruption frequency from the ice core Holocene record. While the reconstruction often differs from ice core estimates for specific eruptions due to uncertainties in the reconstruction method, it shows good agreement with an ice core based VSSI reconstruction in terms of millennial-scale cumulative VSSI variations over the Holocene.

Monitoring and hazard assessment of Kolumbo submarine volcano, Greece

The Santorini volcano in the South Aegean Sea (Greece) is one of the most important and famous volcanoes in the world, with numerous large-volume explosive eruptions and caldera-forming events over the last 600.000 years. It is widely famous for its 3600BP Minoan eruption which had a catastrophic impact on the Minoan civilization in the island of Crete in Eastern Mediterranean Sea. The Santorini volcano, however, is but one volcano in a tectonically controlled domain that trends SW-NE in the Southern Aegean Sea. Other volcanoes are submarine and only partially explored.

Off the north coast of Santorini lies the Kolumbo volcanic chain, which consists of 25 submarine cores and craters and extends NE along the floor of the Anhydros Basin. The largest of those is the Kolumbo crater, one of the most active Mediterranean submarine volcanoes. Kolumbo erupted explosively in 1650 AD and caused significant damage and 70 fatalities on Santorini Island. In 2006, the R/V Endeavor made a significant discovery of an active, pumice-hosted, diffuse-flow, high-temperature (> 260°C) hydrothermal vent field in Kolumbo's crater at 500 m depth, which hosts the only known, actively- forming, Au-Ag-Tl-Sb-Hg-As(± Bi,Te, Mo)-rich, CO_2-venting seafloor massive sulfide chimneys and mounds related to continental margin volcanism. Owing to its vicinity to highly populated areas such as Santorini, the submarine volcano and its hydrothermal vent field pose significant risks in the form of geohazards such as earthquakes, tsunami, and toxic metal(loid)s and gasses while our knowledge remains severely limited on the repercussions of this type of volcanic activity. To address such risks, long-term, continuous, and high-resolution monitoring is required.

The SANTORY (SANTORini's seafloor volcanic observatorY) Research Program aims to monitor the Kolumbo system and how the regional tectonics affect or control its activity. Additionally, by using state-of-the-art equipment, SANTORY investigates how the volcano, and its physicochemical hydrothermal processes impact the surrounding environment and the threats that imposes to the nearby communities that yearly attract thousands of tourists. To understand how the Kolumbo hydrothermal system affects not only the seafloor morphology, but also the citizens of the nearby islands, in situ observations of these structures are highly important.

Improved source attribution of 7th Century CE volcanism from evidence in Greenland ice

__Ms. Helen Innes__ [1], Dr. William Hutchison [2], Prof. Joe McConnell [3], Prof. Michael Sigl [4], Dr. Andrea Burke [1]

1. University of St. Andrews, 2. University of St Andrews, 3. Desert Research Institute, 4. Climate and Environmental Physics (CEP), Physics Institute & Oeschger Centre for Climate Change Research (OCCR) University of Bern

Polar ice core records reveal several volcanic events during the 7th Century of the Common Era (CE), preserved as large peaks in deposited sulfate aerosol. In particular, eruptions during 626 and 682 CE are among the 25 largest events of the last 2500 years recorded in ice. Negative tree-growth anomalies and historical records indicate these eruptions were climatically significant, due to cooling associated with sulfate aerosol injection to the stratosphere.

Previous studies using ice core evidence have assumed either a tropical or mid-high latitude source for these eruptions based on the deposition of volcanic aerosol in one or both Greenland and Antarctic ice cores. However, the possibility of simultaneous high latitude eruptions in each hemisphere makes this assumption problematic, potentially leading to incorrect sulfur injection and climate forcing estimations.

High-resolution sulfur isotope analysis of aerosol deposited in polar ice provides a method informing us if a volcanic plume reached above the ozone layer by the presence of a mass independent fractionation signature, while differences in tropical and extra-tropical isotopic signals indicates source latitude.

We apply this technique to eruptions recorded in Greenland ice core Tunu2013 to test previous tropical or mid-high latitude source attributions of 4 eruptions during the 7th Century: 626, 682, 686 and 698 CE. Measured isotopic signatures allow us to better interpret eruptive source latitude for each event, aiding calculation of stratospheric sulfate contribution and therefore climate forcing associated with volcanism during this time period. In addition, we use major oxide geochemical fingerprinting of cryptotephra associated with the aerosol deposits in polar ice to give further insights to the sources of 7th Century eruptions

Simulated climate variability at the end of the mid-Holocene

***Dr. Roberta D'Agostino* [1], *Mr. Koushikh Karunakar* [2]**

1. National Council of Research, Institute of Atmospheric Sciences and Climate, 2. University of Hamburg

The Holocene epoch witnessed some extreme climatic events. The 4.2 ka BP event is one of the most severe climatic events that caused cooling and droughts in some parts of the world. Archaeological evidences show that many ancient civilizations collapsed during this period and it was also a period of large human migrations. The 4.2 ka BP event is still not well understood with regard to its triggering mechanism, however, reconstructions show weaker and narrower monsoons, consistently with mutidecadal-to-centennial mega-drought regimes. Here, we have analysed the migration of Asian monsoon fringe in a new set climate model simulations of the last 8000 years with the Max Planck Institute Earth System Model (MPI-ESM1.2). We have used the standard "slow forcing" simulation, that includes temporal evolution of CO2 and orbital forcing, and the "full forcing" simulation that includes additionally clusters of volcanic eruptions throughout the Holocene. We have found signal of decreased precipitation in the Indus valley, although the influence of the internal climate variability is so large preventing to attribute the 4.2 ka BP Asian mega-drought to volcanic forcing.

Leaf wax dD and pollen from a lake in Southeastern Norway reflect Iron and Viking Age climate variability

***Mr. Eirik Ballo* [1], Prof. William D'Andrea [2], Dr. Manon Bajard [1], Mr. Helge Høeg [3], Prof. Kjetil Loftsgarden [4], Prof. Kirstin Krüger [1], Prof. Henrik Svensen [5], Prof. Jostein Bakke [6]**

Museum of Cultural History, University of Oslo, Oslo, 5. Center of Earth Evolution and Dynamics (CEED), Department of Geosciences, University of Oslo, Oslo, 6. Department of Geography, University of Bergen, Bergen

In Northwestern Europe, the first millennium CE was characterized by climatic anomalies and cultural shifts, with the mid-6th century being one of the coldest periods in the past 2000 years, initiated by volcanic eruptions in 536 CE and 540 CE. In Norway, lack of archaeological finds from the mid-6th century has long been linked to societal crisis, crop failure and famine. However, the extent and timing of both the volcanic induced cooling and societal changes remains disputed, partly due to the lack of high-resolution reconstructions from natural archives.

Here, we reconstruct precipitation and lake water isotope variability from the analysis of leaf wax hydrogen isotopes (dD values) through the first millennium CE from Lake Sagtjernet in Southeastern Norway. We further analyse sedimentary pollen to give insight to the environmental changes of the region during this period. Samples from the varved sediments are analyzed at a high resolution (10-year frequency) during the period 400-800 Common Era (CE).

In the period 400-800 CE, we find significant changes in the variability of dD values that we interpret as changes in precipitation. These data show an increase in moisture delivery starting at c. 500 CE, followed by a rapid decrease in c. 550 CE (15 ‰ drop across 25 years). The corresponding pollen data show a decrease in cultivated species and increase in trees during the same period, indicating a decrease in human activities in the area. Finally, we review the precision and accuracy of the age model and its effects on the interpretation of the data and discuss our results in light of the archeology of the region.

No evidence of winter warming within Eurasia following large, low latitude eruptions over the Last Millennium

Dr. Ernesto Tejedor [1], ***Dr. Jason Smerdon*** [2], ***Prof. Mathias Vuille*** [3], ***Prof. Lorenzo Polvani*** [4], ***Dr. Nathan Steiger*** [5]

1. *Nacional Museum of Natural Sciences-Csic,* ***2.*** *Lamont-Doherty Earth Observatory, Columbia University,* ***3.*** *Department of Atmospheric and Environmental Science, University at Albany,* ***4.*** *Department of Applied Physics and Applied Mathematics, Columbia University / Doherty Earth Observatory, Columbia University,* ***5.*** *Lamont-Doherty Earth Observatory, Columbia University / Institute of Earth Sciences, Hebrew University of Jerusalem*

We critically reexamine the question of whether volcanic eruptions cause surface warming over Eurasia in wintertime, in the light of recent modeling studies which have suggested that internal variability may overwhelm any forced volcanic response, even for the very largest eruptions during the Common Era. Focusing on the Common Era, we combine model output, instrumental observations, tree-ring records, and ice cores, and build a new temperature reconstruction that specifically targets the boreal winter season. Using the latest volcanic forcing reconstruction, we identify 20 eruptions over the Last Millennium withvolcanic stratospheric sulfur injections (VSSI) larger than the 1991 Pinatubo eruption.

We find that 13 of these 20 events are followed by cold surface temperature anomalies over Eurasia in the first post-eruption winter, as one might expect from volcanic aerosolsimpacts on surface solar radiation. We find no evidence that the North Atlantic Oscillation is correlated with VSSI in winter. We also find, however, that internal variability is very large: the greatest post-eruption winter cooling occurs in the winter of 1600-1601, following the Huaynaputina eruption, which is only the 7th largest eruption in terms of VSSI.

Furthermore, by carefully examining individual events, and comparing our new reconstruction with additional reconstructions, we are able to reconcile our findings with those of previous studies. Beyond the uncertainties in the reconstruction and volcanic dating, we demonstrate that earlier claims of post-eruption winter warming primarily originated from averaging small eruptions with larger ones, thus diluting with noise the small cooling signal from the volcanic aerosols.

Elemental contents in a 200-yr marine sediment core from Santa Barbara Basin measured by scanning XRF, acid-leach and aqua regia dissolution ICPOES approaches: Analytic method matters (e.g., Pb pollution)

Prof. Hong-Chun Li [1], ***Ms. Joelle Tanuputri*** [1], ***Prof. William Berelson*** [2], ***Prof. Ludvig Löwemark*** [1]

1. National Taiwan University, 2. University of Southern California

Elemental contents in SBB-8-2012 core measured by an iTRAX core scanner (scanning XRF), 0.5N HCl acid leach (AL) and aqua regia (AR) have been discussed. The variation patterns of Ca and Sr contents on long-term scales are similar in three approaches as well as in AL and AR concentrations because the two elements come mainly from authigenic phases. AL/AR Fe (%) is averaged 25.7±8.7%, and the ratio is strongly correlated with AL Fe concentration (R^2 = 0.92), indicating that although the authigenic Fe is only 25% of the total Fe, it dominates the Fe variation especially when marine productivity increases. The scanning XRF Fe variation does not follow the variation pattern of acid dissolved Fe concentrations, unless the authigenic Fe becomes dominant. AL/AR Ti (%) is averaged 4.8±1.3%, and the ratio is positively correlated with AL Ti (R^2 = 0.63) but negatively correlated with AR Ti (R^2 = 0.62), indicating both authigenic (AL) Ti and detrital (mainly AR) Ti influence the variation pattern of Ti. The scanning XRF Ti variation does not agree with neither AL Ti nor AR Ti variation patterns. However, the scanning XRF Ti may represent the relative variation of total Ti in all phases on the core surface sediments. The average AL/AR Pb is 65.7±14.8%, reflecting the authigenic Pb is majority. The AL and AR Pb average concentrations were 5.6±0.9 and 9.8±2.1, 8.0±0.6 and 9.4±1.3, 8.5±0.8 and 17.4±4.1, 12.5±1.5 and 16.6±2.3, and 10.3±1.4 and 16.8±4.5 during the periods of 1820-1880, 1880-1895, 1895-1907, 1908-1978 and 1979-2012, respectively. Before 1880, the Pb was the lowest and stable. Slightly increased in AL Pb from 1880 to 1895, showing human influence began. Sharp increase in AR Pb but not in AL Pb during 1895-1907 might be due to mining activity near the Basin. From 1910 to 1978, the AL Pb was the highest and reached the maximum at 1978, reflecting atmospheric input from leaded gasoline consumption. After the ban of leaded gasoline usage in 1976, the AL Pb dropped quickly. The scanning XRF Pb does not agree with both AL Pb and AR Pb patterns.

Investigating seawater-shell relationships using tank experiments with living Tridacna to inform palaeoenvironmental reconstructions

Mr. Bohao Dong [1]***, Dr. Amy Prendergast*** [2]***, Dr. Laura Otter*** [3]***, Prof. Russell Drysdale*** [4]***, Ms. Mahsa Alidoostsalimi*** [2]

1. *School of Geography, Earth and Atmospheric Science, University of Melbourne, Melbourne, Australia,* ***2.*** *School of Geography, Earth and Atmospheric Sciences, University of Melbourne, Victoria, Australia,* ***3.*** *Research School of Earth Science, Australian National University, Canberra, Australia,* ***4.*** *University of Melbourne*

High-resolution past climate reconstructions of marine shells provide crucial baselines for understanding global environmental changes, allowing better adaptations to current and future climate changes. Giant clam shells (*Tridacnidae spp.*) are novel and reliable paleoenvironmental archives with many available geochemical proxies from which paleoclimate records can be faithfully reconstructed. For example, sea-surface temperature (SST), sea-surface salinity (SSS), dissolved inorganic carbon (DIC), insolation, rainfall, river input, marine primary productivity and extreme weather events can be detected at ultra-high resolution using both stable isotopes and trace elements. However, the specific relationship between paleoenvironmental parameters and giant clam shell geochemical composition is still not clear. Most previous research has used instrumental records to compare the accuracy of giant clam paleoenvironment reconstructions, which can often only provide qualitative reconstructions as their geochemical signals may be affected by multiple environmental variables.

In this ongoing research, a tank experiment is being used to culture giant clams whilst varying environmental parameters, including SST, SSS, insolation and primary productivity. In this lab setting, we can minimize the complexities that arise in the natural environment and control for single environmental variables. We have defined 28 culture conditions to maximize replication and to avoid cross-impacting of variables. The clams will live in each set of conditions for two weeks to grow an estimated ~0.7 mm increments for further geochemical analysis.

This study will: (1) decipher the relationship between *Tridacna* shell calcification rates and environmental variations; (2) investigate the relationship between seawater parameters (SST, SSS, insolation and primary productivities) and giant clam shell geochemical compositions (Sr/Ca, Mg/Ca, Ba/Ca, Fe/Ca, $\delta^{13}C$, $\delta^{18}O$); and (3) build predictive equations to quantitatively reconstruct high-resolution paleoenvironmental conditions from *Tridacna* geochemistry.

A fast, non-destructive and low-cost dating approach of sediment cores over the last century

Ms. Andréa Julien [1]***, Dr. Charline Giguet-Covex*** [1]***, Dr. Erwan Messager*** [1]***, Dr. Laurent Marquer*** [2]***, Dr. Anne-Lise Develle*** [1]***, Dr. Fabien Arnaud*** [1]***, Dr. Pierre Sabatier*** [1]

1. *Laboratoire EDYTEM UMR CNRS 5204 Université Savoie Mont Blanc,* ***2.*** *Department of Botany, University of Innsbruck*

Sediments from lakes and peat bogs are good archives to study changes that have occurred in the Earth system over the last century and older. However, developing such studies requires accurately dating the sediment accumulations. The common techniques are short-lived radionuclides (^{210}Pb, ^{137}Cs, and ^{241}Am) for recent sediments and radiocarbon analyses for older sediments. However, these methods are relatively expensive and not fast to acquired. Consequently, they are not adapted when the aim is to work on a large set of sediment cores. This is particularly the case when the research objectives are to look at the representativity of a proxy based on a modern reference dataset. In palaeosciences, such modern references are frequently used for calibrations. These studies are often based on a collection of surface samples with the same thickness that may not cover the same time period depending on the sites due to various sedimentation rates. These temporal differences may lead to biases in the calibration studies.

Here, we propose a fast, non-destructive and relatively cheap approach to provide a chronology that can be used to develop a referential or to help the sampling strategy and/or to improve/validate age-depth models based on classical analyses.

Our protocol is based on known lead pollutions providing chronological markers for the last century and the Medieval and Roman periods. These lead pollutions can be observed by X-ray fluorescence core scanner analysis. Three markers can be identified for the last century: the lead peak before the oil crisis in 1973, the postWorld War 2 (1950) and end of Second Industrial Revolution in 1910 increases. Two older and less precisely dated peaks can be recorded, which correspond to the extraction and processing of ores during the Middle Ages and Roman period.

In this poster, we present our approach applied to 23 lakes and 14 peat bogs; it has been independently validated on 6 different sites by short-lived radionuclides and radiocarbon dates. Although this approach was successfully applied in most cases, the results should be taken with caution and combined with the other established methods or chronological markers from historical events (earthquakes, floods, avalanches…).

The role of large-scale climate oscillations on the annual deposition of varve couplets in Crawford Lake, Ontario, Canada

Dr. Carling Walsh [1], ***Ms. Krysten Lafond*** [1], ***Prof. Tim Patterson*** [1], ***Prof. Francine M.G. McCarthy*** [2]
1. Department of Earth Sciences, Carleton University, 2. Department of Earth Sciences, Brock University

Due to its approximately 500-year record of undisturbed annually deposited varve couplets, Crawford Lake, Ontario, Canada is under consideration for the Global Boundary Stratotype Section and Point (GSSP) of the Anthropocene. This new epoch is characterized by the influence of industrialization on the geologic record. Annual varve couplets are divisible into seasonal pairs: light-coloured, calcite-rich laminae deposited in the summer and dark-coloured, organic-rich laminae deposited in the winter.
The thicknesses of these laminae are influenced by environmental and climatic conditions at the site. Varve deposition during the industrial era, specifically between 1870 and 2000, is examined to assess the influence of large-scale natural climate oscillations on the Crawford Lake system during a time of anthropogenic influence. Using cross wavelet transforms (XWTs), the records of seasonal laminae are compared to a variety of climate oscillations to establish any relationships between the two cyclical events. The 11-year Schwabe Solar Cycle (SSC) and the Pacific Decadal Oscillation (PDO) are correlated particularly strongly with the quasi-decadal and interdecadal oscillations in laminae thickness, respectively. Furthermore, interactions between the SSC and PDO influence the phase of the relationship between the SSC and the light laminae. The El Nino Southern Oscillation (ENSO) and the Arctic Oscillation (AO) are also correlated, albeit less strongly, with some interannual to quasi-decadal oscillatory behaviour in the laminae records.

Using millimetre scale pollen analysis to resolve distal vegetation responses to the 25.5 ka Ōruanui supereruption, New Zealand

Mr. Stephen Piva [1]***, Prof. Rewi Newnham*** [1]***, Dr. Andrew Rees*** [1]***, Dr. Simon Barker*** [1]***, Prof. Colin Wilson*** [1]***, Prof. Lionel Carter*** [2]***, Dr. Nels Iverson*** [3]***, Dr. Benjamin Läuchli*** [4]***, Dr. Paul Augustinus*** [4]

1. *School of Geography, Environment and Earth Sciences, Victoria University of Wellington,* ***2.*** *Antarctic Research Centre, Victoria University of Wellington,* ***3.*** *New Mexico Bureau of Geology & Mineral Resources,* ***4.*** *School of Environment, University of Auckland*

The ~25.5 ka Ōruanui supereruption from Taupō volcano, New Zealand, is the youngest known supereruption globally, erupting >1,100 km^3 of pyroclastic material during the Last Glacial Maximum. Impacts of this event on climate and the New Zealand environment remain unresolved, particularly on ecological timescales, due to incomplete or low-resolution geological records. Using sediment cores from Onepoto maar palaeolake, Auckland (~240 km upwind from source), pollen assemblages were analysed at contiguous 1-mm intervals, directly above and below the intact 3-cm-thick Kawakawa-Ōruanui Tephra layer to assess post-eruptive vegetation responses. At the time of the eruption, the Auckland region was cooler, drier, and windier with a terrestrial landscape occupied by established closed canopy beech forest. Sediments immediately above the tephra record a decline in the relative abundance of pollen from the dominant canopy species of *Fuscospora*, and concurrent increase in the relative abundance of grasses, herbs, ferns, and shrubs. These changes reflect a temporary (<10 years), part-defoliation of trees in the forest canopy, which likely would have permitted more light to penetrate and to encourage sub-canopy vegetation growth. In addition, increased relative abundances of pollen from wetland/aquatic taxa lasted for ~60 years and are consistent with increased light availability, terrigenous sedimentation and nutrient flux in the catchment prompting a temporary expansion of wetland and littoral margins. Overall, the palynological record principally reflects the immediate and direct impact of ashfall on vegetation following the eruption. A short-lived volcanogenic cooling can be inferred from Antarctic ice core records and may have had a possible compounding, albeit minor effect at Onepoto, but this cannot be distinguished from the ecological impacts. These insights into rapid and enduring vegetation responses and landscape recovery to a supereruption are only possible due to the fine sampling resolution used. Our results demonstrate the value of millimetre-scale stratigraphic pollen analysis from non-varved lacustrine sediments as a tool for assessing ecological responses to past disturbance events, particularly explosive volcanic eruptions, on sub-decadal timescales.

Extracting seasonal climate signals from land-use events with updated Lake Nautajärvi (Finland) clastic-biogenic varve section

Ms. Emilia Kosonen [1]***, Prof. Antti Ojala*** [2]***, Mr. Ethan Silvester*** [3]***, Dr. Pierre Francus*** [4]***, Dr. Jukka Kuva*** [1]

1. *Geological Survey of Finland,* ***2.*** *University of Turku,* ***3.*** *Department of Geology, Lund University,* ***4.*** *Institut national de la recherche scientifique - Quebec*

Annually laminated (varved) lake sediments can provide high-resolution information on past environmental, climatic and human-induced changes. However, the comparison to short instrumental weather and hydrological records requires exceptional chronological accuracy in subannual level as well as detailed study on land-use history and understanding of the unique catchment area and lake basin dynamics. The well-studied Lake Nautajärvi is a small dimictic lake in southern central Finland with circa 10 000-year long clastic-biogenic varve record. Seasonal sedimentation processes and the formation of Lake Nautajärvi clastic-biogenic varves have been previously confirmed with monitored sediment trap study.

In this study, freeze cores taken in years 1999, 2011, 2021 enabled us to observe the recent varve formation and preservation processes, sediment compaction rate and connect the existing varve chronology from 1999 to present-day. In addition, the existing varve chronology was verified with high-resolution 137Cs dating and land-use marker horizons. In this study, we were able to collect high-resolution annual and seasonal subsamples to reconstruct the 1986-year 137Cs Chernobyl marker horizon on a seasonal level (spring-summer 1986).

Epoxy embedded samples from fresh cores taken in 1999, 2011 and 2021 were used to reveal recent short-term geochemical (ITRAX) and physical changes (grain size, computed tomography density) in seasonal and annual level. In addition, human-induced changes in catchment area were recorded from maps, aerial photographs and other archives. This study focused on connecting the extreme weather or hydrological events in the region with changes in geochemical and physical proxies. With updated chronology and land-use history study we were able to extract extreme land-use event related varves and to distinguish the changes in autumn and winter precipitation and discharge events, especially prolonged dry periods, in biogenic lamina properties.

Replicability of high-resolution sea surface temperature records in proximal Santa Barbara Basin sediment cores

Mr. Jannis Viola [1], ***Dr. Susanne Alfken*** [2], ***Ms. Janina Groninga*** [2], ***Dr. Lars Wörmer*** [2], ***Prof. Kai-Uwe Hinrichs*** [2], ***Prof. Thomas Laepple*** [1]

1. *Polar Terrestrial Environmental Systems Research Group, Alfred Wegener Institute Helmholtz Centre for Polar and MarineResearch, Potsdam, Germany,* ***2.*** *MARUM – Center for Marine Environmental Sciences, University of Bremen, Bremen, Germany*

Determining the magnitude of natural climate variability is necessary for predicting the plausible range of future climates and to test climate models. As the instrumental record is too short, the analysis of proxy records can provide crucial information about climate variability from sub-annual to centennial timescales or longer and across critical climate transitions. However, current marine paleoclimate records are often too coarse in temporal resolution, noisy and show low reproducibility - either pointing to low information content or to more pronounced local climate variability than predicted by climate models.
The sediments of the Santa Barbara Basin (SBB), California, offer an ideal setting to quantify the robustness and representativity of marine proxy records and to reconstruct past climate variability. Suboxic bottom waters and strong seasonal sedimentation create a varved record that has been well-studied and has precise age control over the last millennia. Mass spectrometry imaging (MSI) using laser-based desorption/ionization allows sub-mm scale mapping of molecular proxies and the creation of proxy records with up to monthly resolution. In particular, targeting alkenones of haptophyte algae and the derived proxy has been shown to accurately capture the interannual variations in sea surface temperature in modern samples from the anoxic center of SBB.
In this study, we compare two previous MSI records and records from four additional cores along a bathymetric and oxygenation gradient (~14 km) in terms of elemental composition (X-Ray Fluorescence) and MSI-based $U^{K'}_{37}$ records. This allows us to estimate the magnitude of local noise and the shared climatic signal. We further investigate how well the shared regional signal captures the sub-annual to decadal variability of the Californian current system as known from the local instrumental record.

Our results shed light on the spatial representativeness of sedimentary archives and on the robustness of the environmental proxy record. They further provide the basis to develop optimal sampling and measurement strategies to reconstruct the past temperature evolution with explicit uncertainty estimates. Such replicated ultra-high temporal resolution archives are needed to close our knowledge gaps on the societally relevant decadal to centennial natural climate variability.

Antarctic sea ice in a changing planet – insights from palaeoclimate archives.

Ms. Zelna Weich [1], ***Dr. Claire Allen*** [1], ***Dr. Liz Thomas*** [2], ***Dr. Jenny Pike*** [3]

1. *British Antarctic Survey,* ***2.*** *British Antarctic Survey (BAS), Natural Environmental Research Council (NERC), High Cross, Madingley Road, Cambridge CB3 0ET, UK.,* ***3.*** *School of Earth and Environmental Sciences, Cardiff University*

Sea ice is currently undergoing major changes. Observations of both Antarctic and Arctic sea ice conditions are limited to the satellite era (post 1970). Prior to the satellite era (post-1970) and historical records (post-1930s), the best method for reconstructing past sea ice conditions comes from palaeoclimate archives. Changes in Antarctic sea ice conditions have been reconstructed from the chemical or isotopic records measured in continental ice cores and from microfossil or geochemical tracers in marine sediment cores. Marine records typically assess changes in sea ice over millennial timescales, with only a few produced at sub-decadal resolution. Conversely, ice core records are available at annual resolution or higher but the longest coastal ice core records extend just a few hundred years, which is arguably too short a time period to investigate the full range of natural variability (Thomas et al., 2019). Amalgamating these archives offers the best potential to enhance our understanding of longer term variability and place the recent changes in an extended context.

Many of the existing marine cores with sea ice records have sufficiently high sedimentation rates (≥50 cm/ka) to permit higher resolution reconstructions. By increasing the resolution of marine records, particularly in areas where ice cores exist, we can combine the marine and ice core records to provide a continuous record of sea ice that overlaps with satellite and historical data at the highest resolution and extends back over the last millennia to resolve natural variability.

This project aims to enhance Antarctic sea ice records by combining existing marine and ice core archives. This will include targeting key areas where records can be considered in parallel, adapting the sampling scheme, increasing the resolution of existing marine records and analysing newly discovered chemical proxies in the ice, to improve alignment between the ice core and marine sediment records.

High-resolution paleomagnetic dating of a long maar lake sediment sequence from the Leizhou Peninsula, South China

Ms. Fan Yang [1]***, Prof. Huayu Lu*** [1]***, Dr. Liang Yi*** [2]***, Mr. Yao Wang*** [1]***, Ms. Kehan Shao*** [1]***, Prof. Shuangwen Yi*** [1]***, Ms. Xiaoyi Dong*** [3]***, Mr. Fuzhi Lu*** [3]

1. School of Geography and Ocean Science, Nanjing University, Nanjing, 2. State Key Laboratory of Marine Geology, Tongji University, 3. School of Geography and Ocean Science, Nanjing University

Understanding longer-term dynamics of the East Asian monsoon is important and has implications for the evolution of environments in Asia during the Quaternary. Continuous, reliable monsoon climate records from lake sediments of terrestrial South China that encompass several glacial-interglacial cycles are, however, lacking. Here, we apply palaeomagnetic methods to two newly drilled long (>220 m) parallel cores (TY1 and TY2) from the Tianyang (TY) maar lake, South China, which lies within the East Asian monsoon core region, to reconstruct variations in monsoon precipitation over an extended period of the upper Quaternary. The results of alternating field (A.F.) demagnetization show that the entire sediment sequence was deposited in the Brunhes normal chron, including eight possible magnetic alternations. Using anhysteretic remanent magnetization (ARM) to normalize natural remanent magnetization (NRM), we calculated the relative paleointensity (RPI) of the past magnetic field from the TY2 core sediments. The RPI record is consistent with global reference RPI stacks (Sint-800 and PISO-1500) and this enables us to obtain 17 age fitting points. Using these fitting points, a chronological framework for the TY maar lake sediment sequence is constructed and referenced against a published independently obtained chronology of the upper part (~38 m) of the core. The basal age of sediments is thus calculated 707.3 ka, indicating a mean sedimentation rate of 31.4 cm/kyr. Our continuous, high-resolution (2 cm interval) measurements of magnetic susceptibility yield a time series exhibiting pronounced lows and highs. Magnetic susceptibility of the sediments reflects monsoon precipitation variations, whereby high values indicate greater precipitation and low values less precipitation. The TY maar lake sediments reveal dominant precessional and semi-precessional cycles, evidencing low-latitude insolation forcing on tropical monsoon precipitation variations over the past 700,000 years. The record provides the first robust and independent chronology for a maar lake sediment sequence in the subtropical monsoon region of East Asia, and reveals variations in monsoon precipitation over the past seven glacial-interglacial cycles.

Keywords: Paleomagnetism; geomagnetic paleointensity; maar lake; glacial-interglacial cycles; East Asian monsoon

Considerations on the application of magnetic properties to estimate the provenance of marine sediments: use of a new methodology in a case study in the early Quaternary

Ms. Stephanie Leone [1], *Mr. Muhammad Bin Hassan* [1], *Prof. Luigi Jovane* [1]

1. Oceanographic Institute of the University of São Paulo

The provenance of marine sediments is usually defined through geochemical proxies. In general, these techniques are destructive, which require a large amount of sample, time, and have a high financial cost.
Magnetic parameters can be used to determine provenance through the ratio of physical to magnetic grain size (Mrs/Ms ratio) in different grain size fractions, using non-destructive, fast methods with require a small amount of sample.
Unusual magnetic techniques were used to determine the provenance of sediments during glacial and interglacial periods in the early Pleistocene in North Atlantic, with excellent results when compared to the geochemical data. The results showed that most of the particles came from Icelandic basalts with the magnetic grain size smaller and incompatible to the physical grain size, while in glacial cycles the amount of non-basaltic material increases, with the physical grain size comparable to the magnetic grain size.
Less than 0.2 g of sediment was used for each fraction, not exceeding 1.2 g of sediment to analyze 6 different grain size fractions. Good results depend on the difference between the magnetic grain size of the possible source areas as well as the separation of the grain size fractions. It was observed that there is no need for the separation of very coarse silt, coarse silt, and medium silt as they show very similar results. In this way we decrease the required analysis and preparation time. The separation of the fine and very fine silt is necessary to remedy the magnetic grain size overlap of the clay fraction, as these fractions have similar hydrodynamic behavior. Separation of the sand from the rest of the sample is vital, as it can provide opposite signals to the other fractions, with a higher IRD contribution. FORC diagrams of the sediment were made but did not show very enlightening results, exhibiting very less change in magnetic signals.
This study concluded that the application of magnetic properties to define the provenance of marine sediments has certain restrictions, but presents very promising results, with some modifications to optimize the time of analysis and decrease the amount of material used.

Refining the chronological framework of MIS 5c-d millennial climate variability using 40Ar/39Ar and proximal-distal correlations of Mediterranean tephra units erupted from Campi Flegrei, southern Italy

Precisely determining timing and chronology of millennial-scale climate variability is fundamental for understanding past climate dynamics. Paleoclimate studies frequently rely on chronologies underpinned by orbital tuning, which can lead to erroneous reconstructions. Absolute chronology based on radiometric dating allows instead assessing the timing of the climate variability independently of any uncertainty and a priori assumption inherent in orbital tuning process. In this framework, tephra layers preserved in sedimentary sequences and hosting K-rich minerals (e.g., sanidine, leucite) can be dated by means of single crystal $^{40}Ar/^{39}Ar$ laser fusion technique, providing the needed chronological constraints. Furthermore, these same tephra layers can be correlated over great distances to synchronize past climate events at regional scale. Tephra layers of supposedly Campanian origin (i.e., X-6, X-5, C-22) preserved in Mediterranean Marine Isotope Stage (MIS) 5 sedimentary records have long been used as tie points for correlation purposes. They have also been documented in numerous paleolithic successions of the Mediterranean and Europe areas, providing fundamental stratigraphic and chronological constrains for archaeological investigations in these regions. However, the specific volcanic source(s) of these tephra layers has never been determined and uncertainties still exist on their spatial distributions and ages. Here we present new geochemical (major, minor and trace elements, Sr-Nd isotope ratios) and geochronological ($^{40}Ar/^{39}Ar$ ages) data of 5 ash-fall units from the Campanian Plain. Our data allowed the identification of the medial equivalents of the MIS 5 tephra markers, including the widespread C-22, X-5, and X-6 tephra, and their assignment to a previously undocumented Campi Flegrei activity in the time span between 109 ka and 92 ka. In addition to substantially extending the Campi Flegrei explosive activity back in time, and thus providing the basis for a revaluation of its explosive history, our findings provide new precise radiometric dating to better constrain the chronology of the millennial scale climatic oscillations of the MIS 5c-d in the Mediterranean area and possibly on a larger scale. Finally, results from this study allowed a review of previous correlations proposed for these MIS 5 Campi Flegrei tephra in the central Mediterranean area.

The upper boundary of the Eemian Interglacial in Central Europe compared to the marine and ice cores

Prof. Mirosława Kupryjanowicz [1]

1. Department of Paleobiology, Faculty of Biology, University of Białystok, Poland

The Eemian Interglacial, detailed described in Central Europe, including Poland, on the basis of palynological data from many fossil lakes and bogs, is commonly correlated with the MIS-5e. Also the correlation of the Brørup *sensu lato*, the oldest European interstadial of the Last Glaciation, with MIS-5c is beyond any doubt. It is tripartite in Europe. Cooling in its middle part is correlated with the marine C-23 event and Greenland GS-24 stadial. It separates two warmer periods – the older one corresponds to the marine W-23 warming and ice GI-24 interstadial, while the younger one to the W-22 and GI-23. Only in Western Europe this cooling has the rank of a stadial (between the Amersfoort and Brørup *sensu stricto*). In European pollen records, Brørup *sensu lato* is separated from the Eemian by a stadial (Herning or Melisey I), which usually is correlated with the marine C-24 and Greenland GS-25 stadials. However, in both marine and ice cores there is one more stadial (C-25 or GS-26) and interstadial (GI-25 or W-24) between the Eemian and the Brørup *sensu lato*. Unfortunately, these events are not reflected in the stratigraphic patterns of Central Europe, including Poland. Meanwhile, in many pollen profiles from this region, a temporary cooling was noted in the final part of the Eemian followed by an improvement in climate at the very end of the interglacial, just before the transition to the Early Weichselian. This cooling, as shown by its palynological record, has a lower rank than cooling during the Herning stadial, and is recorded only in profiles developed with high stratigraphic resolution. In pollen profiles it is commonly included to the Eemian, and the Eemian/Weichselian boundary is set only above the subsequent warming. This cooling can be correlated with the C-25 and GS-26 stadials, while the warming terminating the terrestrial Eemian with the W-24 and GI-25 interstadials. On this basis, it can be hypothesized that the upper boundary of the Eemian in pollen diagrams of Central Europe is not synchronous with the upper limit of this interglacial in the marine and Greenland cores, and this shift is approximately 8,000 years.

Coastal progradation associated with sea-level oscillations in the later phase of the Last Interglacial period, central Japan

***Dr. Hiroko Okazaki* [1], *Prof. Masakazu Nara* [2], *Dr. Hiroomi Nakazato* [3], *Dr. Akira Furusawa* [4], *Dr. Kazumi Ito* [5], *Dr. Toru Tamura* [5]**

Stratigraphic records of minor sea-level highstands in Marine Oxygen Isotope Stage (MIS) 5c and 5a are valuable archives of late Pleistocene sea levels and paleoenvironments, but have been identified less commonly in siliciclastic coastal systems than the highstand of MIS 5e. In the Kanto Plain, central Japan, the Iioka terrace comprises the seaward margin of the uplifted Last Interglacial (MIS 5) marine terrace. Sedimentological characterization, post-infrared infrared stimulated luminescence (pIRIR) dating, and tephra and paleontological analyses of the Iioka terrace allow identification of a wave-dominated coastal sedimentary system that prograded onto the Pliocene-Pleistocene basement during MIS 5c and 5a. The pIRIR ages of the coastal deposits range from ca. 80 to 112 ka and define a seaward younging trend, which is corroborated by the seaward lowering of the terrace surfaces. In an outcrop in the seaward part, two pIRIR ages were obtained above and below the tephra layer On-Pm1 (95.7 ka), supporting the general validity of the pIRIR chronology. The elevation of beach facies in the landward part (ca. 53 m above the present sea level) abruptly lowers (to ca. 37 m) and is further truncated by fluvial incision in the seaward part. The pIRIR ages include uncertainties that prevent distinction between MIS 5c and 5a. However, the abrupt and large gap in the beach levels between the central and seaward parts suggests the presence of a minor unconformity between MIS 5c and 5a; contemporary uplift may account for the gap. The Iioka terrace is thus interpreted as representing the successive downdip accretion of depositional sequences controlled by relative sea-level changes in the later Last Interglacial period. The refined characterization of the Iioka terrace allows reevaluation of the tectonic uplift rate of this area as ca. 0.7 mm/yr, twice the rate assuming correlation of the deposits with MIS 5e. Such refinement is likely elsewhere if marginal marine terraces are characterized in detail, as carried out here.

A new Middle-Late Pleistocene succession from the southern Dardanelles (Turkey) sheds lights on the Mediterranean-Black Sea gateway evolution

Dr. Hülya Alçiçek [1], Prof. Yeşim Büyükmeriç [2], Prof. Wout Krijgsman [3], Prof. Chuan-Chou Shen [4], Dr. Tsai-Luen Yu [5], Dr. M. Cihat Alçiçek [6], Dr. Frank Wesselingh [7]

The Mediterranean-Black Sea gateway region consists of a complex set of basins (Aegean basins, Marmara Sea) and sills (Bosporus, Dardanelles, South Aegean threshold) that have a dynamic connection and isolation history impacting marine and terrestrial ecosystems in the Eurasian transition region during the Quaternary. Within the gateway region very few successions exist that enable the construction of a chronology of connection and isolation. Gateway configuration is impacted by both global sea level trajectories and regional tectonic modifications. Here we record a succession of marine and terrestrial deposits in the southern Dardanelles gateway region in western Turkey that constrain periods of connection and isolation during intermediate low stand- and high stand time intervals of the late Middle and Late Pleistocene (MIS9-MIS4). We describe five unconformity bounded stratigraphic units in three sections that form part of a coastal section north of Çanakkale (western Turkey). Twenty U-Th analyses provide age estimates for the units. Combined with facies and faunal analyses the presence of marine conditions during relative low stands of MIS6 and MIS5a-d time intervals is shown. The presence of marine intervals representing sea level low stands at or above today's sea level shows severe uplift rates in the Dardanelles threshold region in the latest Pleistocene enabling the rare exposure of these successions. Our findings also clearly indicate an important role of gateway tectonics in the connectivity history of the Black Sea-Mediterranean region in addition to eustatic sea level trajectories. The newly reported Dardanelles successions provide further age constraints of Black Sea – Mediterranean connectivity during the Late Quaternary. This study was sponsored by the Scientific and Technical Research Council of Turkey (TÜBİTAK research grants ÇAYDAG116Y541).

Disentangling the depositional systems and ecosystem evolution of the southern North Sea Basin during MIS5.

Nearshore marine stratigraphic records in shelf areas are subject to intense reworking resulting in very incomplete, mixed and biased understanding of the evolution of depositional systems and biota. The southern North Sea Basin (SNSB) is a shallow shelf sea located south of the glacial advances that during glacial low stands became emerged. Much of the successive marine and coastal records have been reworked during glacial low stands destroying most of the Quaternary successions. Marine-coastal deposits of the Last Interglacial maximum (MIS5e: Eemian) are widespread in the subsurface of the SNSB, but deposits for the entire MIS5a-d interval (Early Weichselian) are reworked hampering our understanding of landscape and ecosystem evolution in this transitional time interval. However, the presence of deep river valley and estuarine channel systems has provided local preservation traps that contain MIS5a-d successions, even though these records also experienced different grades of reworking and mixing. Here we investigate and disentangle mixed MIS5 successions within a MIS6-MIS5 fluvial to tidal inlet in the Netherlands and a drowned MIS6 River Valley System on the Belgian continental platform in order to understand the evolution of coastal and shallow marine depositional systems, ecosystems and landscapes in the SNSB. Within a seismic/sedimentary facies framework we distinguish different provenance of mixed faunas using preservation characteristics, and ecological and stratigraphic compatibility criteria. The unmixed faunas show a succession of warm temperate to subarctic conditions and different paleoenvironments with strong biotic turnover related to sea level trajectories and paleogeographic connectivity of the North Sea in the MIS5 time interval, a period for which very little is known so far. The approach to target preservation traps and disentangle mixed records based on fossilization and other criteria is novel and applicable to shelf areas worldwide in order to investigate low-intermediate high stand time intervals.

Constraining stratigraphic age and paleoenvironments in submarine sand extraction areas: context for the rich fossil findings from nourished Dutch beaches

***Dr. Freek Busschers** [1], **Dr. Frank Wesselingh** [2], **Prof. Jakob Wallinga** [3], **Mr. Bram Langeveld** [4], **Mr. Isaak Eijkelboom** [2], **Ms. Irene Waajen** [5], **Prof. Thijs van Kolfschoten** [6], **Dr. Sytze van-Heteren** [7]*

Major sand nourishments serving to enhance coastal safety and expand land surface area for port development in the western Netherlands are among the most important locations for late Quaternary fossil and artefact finds world-wide. The finds may provide insight into the mammoth steppe faunas, faunal-hominine interactions and Paleolithic and Mesolithic hominin behavior, but interpretation is cumbersome.
The sand used for the nourishments is extracted offshore in the North Sea from submarine extraction pits below ~20m water depth. These archives of late Quaternary associations, palaeoenvironments and hominine behavior are now exposed on accessible beaches, where a large community of collectors and citizen scientists help to gain important insights. However, linking this now ex-situ natural history archive to the geological context has been problematic due to poor knowledge of the late Quaternary stratigraphic successions in the offshore extraction area, the severe reworking and erosion of these successions during lowstand phases and problems with radiocarbon ghost ages (finite ages of 25 - 50 ka BP for material that is much older).
Here we present sedimentary facies and fossils from a series of continuous cores obtained from the flanks of an offshore extraction pit west of Rotterdam. We define stratigraphic units, allowing us to link fossils and artefacts found on the nourished beaches to specific stratigraphic units. A large set of luminescence age estimates provide age constraints for the units.
A succession of units covering MIS6 to MIS1 is shown, and major hiatuses are identified. The succession provides new insights into the critical MIS5d-MIS5a (Early Weichselian) time interval and includes a unit that contains an in-situ cold-boreal marine fauna. The new age-constrained stratigraphic successions provide important new insights into the origin of so-called walrus faunas and mammoth steppe faunas and their depositional context. These insights are imperative to improve our understanding of the origin and age of the very rich fossil fauna and artefacts from the nourished beaches and the late Quaternary landscape and ecosystem evolution of the southern North Sea Basin.

MAGY project: MAllorca hydroloGY over the last few centuries. Instrumental validation of speleothem archives.

Geochemical analyses of speleothems and cave monitoring offer a complete framework for cave systems concerning hydrological changes and climate variability at very different timescales. In this regard, one critical target becomes the period when paleoclimatic records overlap with the directly measured instrumental records of climate. In order to improve the interpretation of speleothems as paleoclimatic records and therefore elucidate past climate changes in the western Mediterranean region, the MAGY project intent is the comparison of a new collection of speleothem records from Mallorca Island, which spans the last centuries, with precipitation and temperature data acquired in the weathering station from the Mallorca airport. This information is particularly critical on this island which is likely to face high hydrological stress under the current conditions of climate change. The implementation of this study requires high-resolution trace element profiles obtained by LA-ICP-MS to detect even seasonality variability in the speleothems and parallel well-resolved age models. The combination of U/Th dating, the ^{14}C technique, and the confocal laser scanning microscopy technique, which allows annual layer counting, will provide solid chronologies. Preliminary results show that the Mg/Ca signal corresponds with the precipitation patterns recorded by regional instrumental records.

Poster - sessions 13, 15, 18, 147, 157, 208

Dansgaard-Oeschger climate oscillation during the early MIS3 in Europe: evidence from a multi proxy speleothem record in Han-sur-Lesse, Belgium

Speleothems are precious continental records in Europe and provide important climatic information at high resolution, such as during the Dansgaard-Oeschger (DO) events . However, the north central Europe is less studied because the MIS 3 is generally not recorded, due to the climatic conditions. Here, we present the first Belgium continuous speleothem (flowstone) record covering the early MIS 3 (from 60 to 40 ka) from the Verviétois Gallery that is part of the Han sur Lesse cave system (southern Belgium). High resolution bulk stable isotope and elemental combined with U-Th dating are used to define the Belgium climatic variability. Additionally, clumped isotope measurements have been performed to reconstruct temperature to better constrain climatic response during the DO 16-12.
The multiproxy approach used to investigate the speleothem record shows a regional response to the global climate conditions during MIS3. The $d^{13}C$ and $d^{18}O$ values as well as the elemental analyses (Mg, Ba and Sr as water availability proxies and P and Zn as soil development) mirror the DO 16 and 12 events indicating dry-wet and cold-warm changes. During interstadials events low values of $d^{18}O$ and $d^{13}C$ and Mg, Ba and Sr content suggest wet/warm conditions, while the increase of isotopic and elemental values during the stadials support a climate deterioration with cooling and drier conditions. The clumped-isotope temperatures, performed at high resolution on the DO 16 and 12, suggest warm interstadials ($12^{O}C$ +/- $2^{O}C$) and cold stadials ($7^{O}C$ +/- $2^{O}C$) climate. During the DO12, a delay in the climatic amelioration and the vegetation is observed. This delay, also noted in south-west France cave (Villars cave), seems to be linked to a delay between increase of temperature and water availability allowing the soil above the cave to growth. Also, a climatic deterioration occurred after the DO11, with an increase time lag from the north to the south of Europe, suggesting a progressive cooling to the south Europe. It is interesting to note that this gradual cooling in Europe coincides, withing dating error bars, with the potential progressive north-south decline of the Neanderthals in Europe.

Temperature response in East Central Europe to North Atlantic interstadial warming over the 26-31 ka period

Dr. Gábor Újvári [1], ***Prof. Stefano Bernasconi*** [2], ***Dr. Thomas Stevens*** [3], ***Dr. Sandor Kele*** [1], ***Dr. Barna Páll-Gergely*** [4], ***Dr. Gergely Surányi*** [5], ***Prof. Attila Demény*** [1]

MTA-ELTE Geological, Geophysical and Space Sciences Research Group

The last glacial period (115–11.7 ka) was characterized by extensive high to mid-latitude ice sheets, low carbon dioxide (CO_2) concentrations, sea levels and global mean surface temperatures, with the most pronounced global cooling of 4−5 °C occurring over the Last Glacial Maximum (26–19 ka). However, this generally cold glacial climate was perturbed by numerous rapid shifts to milder interstadial conditions, called Dansgaard–Oeschger (D–O) events or Greenland Interstadials (GI). In Greenland, air temperatures during D–O events rose by 5–16 °C within decades, followed by a less rapid temperature decline back to stadial conditions. Around Europe, interstadial warming of 2–6 °C in sea surface temperatures (SST), corresponding to last glacial D–O events, is recorded in marine sediments and the effects of D–O events also extended across much of continental Europe and western Asia, reflecting profound changes in ecosystems and glacial atmospheric circulation. A major impediment to resolving the cause and geographical propagation of D–O events, as well as to understanding their impact on continental climates and environments, is a lack of precisely dated continental records of quantitative paleotemperatures from this time period, especially in Eastern and East Central Europe. Here we present land snail shell carbonate clumped isotope-based active season paleotemperature estimates and $\delta^{13}C/\delta^{18}O$-based aridity reconstructions from Greenland Stadial/Interstadials (GS/GI) between 31 and 27 ka from the ^{14}C-dated Dunaszekcső loess section (Hungary). This reconstruction is complemented with a new ^{230}Th-dated flowstone stable isotope record covering 30−26 ka. Our snail shell clumped isotope (Δ_{47}) data indicate growing season temperatures of 16−18 and 7−14 °C for the investigated interstadials and stadials, respectively. Stable carbon and oxygen isotope compositions of shells and flowstone calcite reveal milder interstadials with drier summers and more available moisture over the winter season, and colder stadials with annually/seasonally (winter) drier conditions, promoting increased loess/dust deposition. We propose that large scale ocean-atmospheric variability may have imparted a major control on transmitting abrupt North Atlantic climate event signals into continental Europe during the last glacial.

Dansgaard-Oeschger physics controls the Younger-Dryas Preboreal transition

Mr. Jesse Velay-Vitow [1], *Dr. Deepak Chandan* [1], *Prof. Richard Peltier* [1]

1. *University of Toronto*

The Younger Dryas (YD) represented a rapid return to glacial conditions which occurred between 12.9 ka and 11.7ka. The rapid entrance into the YD has been conclusively demonstrated to have been caused by a release of meltwater from proglacial lakes into the Arctic Ocean through the Mackenzie River outlet. This freshwater was transported to sites of North Atlantic Deep Water (NADW) formation where it caused a pronounced slowdown of the Atlantic Meridional Overturning Circulation (AMOC). The recovery from the YD led to a series of climate variations known as the Preboreal Oscillation (PBO). This event was equally rapid but is as yet unexplained. Previous attempts to model the YD have all had inaccuracies, such as having been based upon incorrect boundary conditions, releasing volumes of freshwater that violate eustatic sea level (ESL) constraints, and failing to couple the ocean model to an appropriate atmospheric model. Using the University of Toronto version of CCSM4, we model the YD using appropriate boundary conditions, as well as a volume of freshwater forcing that is compatible with not only the ESL constraints but also the much more stringent constraints imposed by estimates of the volume of proglacial lakes. We find that the approximately 1000-year duration of the YD arises naturally. Equally important, we recover the rapid return to deglacial conditions as well as a pronounced overshoot of AMOC strength, which could potentially lead to further climate fluctuations that characterize the PBO. Equally important, is the observation that the recovery from the YD occurs in precisely the same way as it has been argued that the transition from stadial to interstadial conditions occurs during Dansgaard-Oeschger events: intense vertical mixing below the sea ice causes a massive polynya to open in the Irminger Sea. This allows for a dramatic exchange in heat between the ocean and the atmosphere, which rapidly warms the Northern Hemisphere.

Abrupt Ice Age Climate Variability: Deterministic or Random?

Dr. Guido Vettoretti [1], ***Prof. Peter Ditlevsen*** [1], ***Prof. Markus Jochum*** [1], ***Prof. Sune Rasmussen*** [1]

1. Physics of Ice, Climate and Earth, Niels Bohr Institute, University of Copenhagen

Complex coupled climate models that simulate ice age climate are now able to simulate millennial time-scale Dansgaard-Oeschger (D-O) oscillations that agree well with observed proxy climate records. Whether D-O events are random or part of an internal climate system oscillation, modelling studies suggest that they can be modulated under changes in internal and external forcing such as atmospheric carbon dioxide concentration and the Earth's orbitally controlled insolation. Regularity in the pacing of D-O events may be part of an oscillatory behaviour that can exhibit cyclicity when a control parameter (associated with internal or external forcing) passes through a critical point which results in an unstable oscillatory state. Nonlinear dynamical systems used to emulate D-O oscillations are very sensitive to noise, and transitions between warm and cold states may be caused by noise perturbations possibly associated with internal climate variability. Possible mechanisms associated with noise induced D-O transitions (such as volcanic forcing) will be discussed in an effort to shed light into the erratic signal observed in ice age climate records.

Early warning signals in model simulations of spontaneous Dansgaard-Oeschger type events.

Mr. John Slattery [1], ***Dr. Louise Sime*** [1], ***Dr. Francesco Muschitiello*** [2], ***Mr. Keno Riechers*** [3]

1. British Antarctic Survey, 2. University of Cambridge, 3. Potsdam Institute for Climate Impact Research

Much progress has been made recently in understanding the physical mechanisms underlying Dansgaard-Oeschger events, with a consensus developing around the centrality of changes to the Atlantic Meridional Overturning Circulation (AMOC). What triggers these changes, however, remains unclear, with sea ice coverage, atmospheric patterns, or freshwater forcing all considered potential causes. An interesting question here is whether DO events are induced by a bifurcation in the dynamical system or simply by noise. The answer to this question would reveal much about the potential range of physical causes of these events, providing a focus for future work. To probe this question, we can search for Early Warning Signals (EWS) prior to DO events in the form of increased variance and autocorrelation within the decadal frequency band associated with a critical slowdown. Such EWS, if found, would be compelling evidence that there is an underlying bifurcation. Previous research has shown some EWS in ice core derived temperature proxy records for Greenland, however this is not universally agreed. Here we perform such analysis on output data from climate models which show spontaneous oscillations in AMOC resembling DO events, allowing investigation of a wider range of physical variables and spatial locations than are recorded in proxy data. As well as providing insight into the dynamics of DO events as they occurred in the past, this also provides a useful test of how effectively these models capture the relevant physical mechanisms.

Control of ice sheet configuration, atmospheric CO2 and orbital forcing on millennial-scale climate variability in an Earth system model

Dr. Matteo Willeit [1], ***Dr. Andrey Ganopolski*** [1]

1. *Potsdam Institute for Climate Impact Research*

Dansgaard-Oeschger events are a ubiquitous feature of glacial climates involving abrupt and large changes in climate, particularly over the North Atlantic region. A number of climate models, under particular boundary conditions, have been able to reproduce various aspects of these rapid climate changes, suggesting that they could be the result of internal oscillations in the climate system.

Here we use the fast Earth system model CLIMBER-X to explore ice sheet configurations, atmospheric CO2 concentrations and orbital parameters that are favorable to the existence of self-sustained oscillations.

We find that for ice sheet configurations corresponding to intermediate glacial conditions and for a range of CO2 concentrations between 160 and 200 ppm, the model produces spontaneous millennial-scale oscillations that resemble observed Dansgaard-Oeschger events. The oscillations involve rapid changes in the location of deep water formation and strength of Atlantic meridional overturning circulation, with pronounced effects on climate in the North Atlantic region and beyond.

Millenial-scale oscillations of lower amplitude are simulated in the model also with present-day ice sheets with sufficiently low CO2 concentrations, while the large ice sheets of to Last Glacial Maximum act to largely suppress the spontaneous oscillations.

In our simulations, the orbital configuration has a relatively minor effect on simulated millennial climate variability.

Global footprints of Dansgaard-Oeschger oscillations in a GCM

Dr. Kenji Izumi [1] ***, Dr. Edward Armstrong*** [2] ***, Prof. Paul Valdes*** [1]

1. School of Geographical Sciences, University of Bristol, 2. Department of Geosciences and Geography of the University of Helsinki

We have identified Dansgaard-Oeschger (DO)-like millennial-scale climate variability in a glacial simulation based on the salt oscillator hypothesis with the HadCM3B coupled atmosphere-ocean-vegetation model. The simulated DO-like warming shows temperature changes of 7.1 ± 2.5°C in Greenland, comparable to DO9 or DO6, the smallest temperature changes of the observed DO events. This presentation focuses on the impacts of DO-like events on climate and vegetation beyond the North Atlantic. We find that the simulated warming in the Northern Hemisphere extratropics during Greenland interstadials largely agree with available proxy estimates. The simulated tropical hydroclimatic responses during the interstadials, such as northward propagation of the Intertropical Convergence Zone, strengthening of some Northern Hemisphere summer monsoons, and weakening of some Southern Hemisphere monsoons, are also roughly consistent with proxy estimates.

Moreover, simulated vegetation cover increases in the Northern Hemisphere during interstadial relative to stadials, while no large-scale dominant vegetation changes are consistent with observed biome changes associated with observed DO6. To further assess detailed vegetation responses and fire effects in DO-like cycles, we run the LPJ-LMfire dynamic global vegetation model (DGVM) and test differences with the TRIFFID DGVM.

Our simulation based on the salt oscillator hypothesis can account for many observed features of DO events. However, it cannot simulate several observed climate responses in the equatorial Indian and western Pacific Oceans, including the East Asian and South African monsoon. The causes of those mismatches need to be further explored, whether they are hypothesis-dependent or model-dependent.

Rapid atmospheric CO2 rise during Heinrich Stadials and Dansgaard-Oeschger Events

Dr. Kathleen Wendt [1], _Mr. Michael Kalk_ [1], _Ms. Sierra Smith_ [1], _Dr. Shaun Marcott_ [2], _Dr. Edward Brook_ [1], _Dr. Christo Buizert_ [3]

1. *College of Earth, Ocean, and Atmospheric Sciences, Oregon State University, Corvallis, OR, USA,* ***2.*** *University of Wisconsin Madison,* ***3.*** *College of Earth, Ocean and Atmospheric Sciences, Oregon State University (OSU), Corvallis, OR, USA*

The impact of Heinrich Stadial (HSs) and Dansgaard-Oeschger (D-O) events on global atmospheric CO_2 concentrations (pCO_2) was previously thought to be negligible. This traditional viewpoint was upended with the recent discovery of centennial-scale rises in pCO_2 during HSs and D-O events (Bauska et al. 2021). The newly resolved pCO_2 record sheds critical light on carbon-cycle variability during these rapid climate shifts, yet the exact rate and magnitude of pCO_2 remains a topic of debate. This study aims to examine pCO_2 variations at sub-centennial scale resolution in order to fully resolve pCO_2 variability during HSs 2-5 and D-O events 3-18. To do so, we sub-sampled the West Antarctic Ice Sheet Divide ice core (WDC) down to 5-year resolution along select depth intervals. Measurements were replicated to within an average standard deviation of 1ppm. Preliminary results show an average rise of ~10 ppm pCO2 that coincides with the mid-stadial rise in atmospheric methane associated with HSs 2-5 (Rhodes et al., 2015) following the onset of stadial conditions in the Northern Hemisphere. The largest increase in pCO_2 is associated with HS4, during which pCO_2 rose 17 ppm from 39.58 to 39.47 kyrs before present on the WD2014 chronology. Lower-magnitude rises of ~5 ppm occurred at the abrupt warming of most D-O events. The difference in magnitude between stadial versus interstadials point to separate mechanisms operating under distinct climate modes. Additional sampling is currently underway to further investigate rapid pCO_2 changes linked to abrupt shifts in North Atlantic climate.

Changing sea ice distribution in the northern Nordic Seas over GS-9 and GI-8

Mrs. Wanyee Wong [1], Dr. Bjørg Risebrobakken [1], Dr. Kirsten Fahl [2], Prof. Rüdiger Stein [2], Dr. Chuncheng Guo [1], Prof. Eystein Jansen [1]

1. NORCE Norwegian Research Centre, and Bjerknes Centre for Climate Research, 2. Helmholtz Centre Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany

The sediment core MD99-2304, retrieved from the eastern Fram Strait (1300 m water depth; 77°37'15.6"N, 9°56'54.0"E), is analyzed for biomarkers in high-resolution (ca. 20 years/sample) over stadial (GS-9) and interstadial (GI-8). The results document changes in sea ice dynamics between 40 and 37 b2k with unprecedented detail. The combined results of IP_{25}, HBI III (Z-isomer) and sterols suggest that a seasonal to long-lasting sea ice cover dominated the northern Nordic Seas during the stadial, with possible opening of polynyas. The existence of polynyas in the Fram Strait during stadial conditions is also found in a freshwater forced transient model run of the Norwegian Earth System Model (NorESM). The sea ice in this region started to retreat within GS-9, likely related to the accumulated ocean heat reservoir, and the sea ice extent decreased sharply at ca. 500 years before the end of the stadial, as defined from NGRIP. At the start of GI-8, the sea ice cover expanded rapidly and returned to similar sea ice condition as seen early in GS-9. The early decrease in the northern sea ice cover emphasizes the importance of sea ice dynamics for the abruptness of the Dansgaard-Oeschger events. The new results from the Fram Strait will be discussed in context of existing sea ice records from a transect of sediment cores along the eastern Nordic Seas. It is indicated that in the late phase of GS-9, polynyas may have already existed in the north when the open ocean associated with the recovery of the warm Atlantic Water started to erode the sea ice cover from the south, since the pelagic phytoplankton in the north bloomed ca. 300 years before fully open water conditions are documented in the south.

Multi-tracer(2H, 3H, 13C, 14C, 18O, 39Ar, 81Kr, Noble gases) study-Groundwater dating and paleoclimate reconstruction in Leizhou Peninsula, South China

Mr. Shaoheng Li [1]***, Prof. Jianyao Chen*** [1]***, Dr. Zuobing Liang*** [1]***, Mr. Qirui Wu*** [1]***, Mr. Di Tian*** [1]

1. *School of Geography and Planning, Sun Yat-Sen University*

Groundwater is a key water source for natural environments and human society, detailed knowledge about the groundwater system is necessary, especially under global change. Groundwater residence time, or so-called *groundwater age*, is a very important parameter, which can be used for the assessment of groundwater renewability and sustainable development. In addition, groundwater is a natural archive of paleoclimate information, which is valuable for the understanding of climate change. In this study, we applied multiple tracers, namely ^{2}H, ^{3}H, ^{13}C, ^{14}C, ^{18}O, ^{39}Ar, ^{81}Kr, and noble gases to estimate the groundwater age and reconstruct the signals of paleoclimate, mainly the history since the LGM (Last Glacial Maximum) in the Leizhou peninsula, South China. In total, 41 monitoring wells were chosen for groundwater sampling. The dating results of ^{3}H, ^{4}He, ^{14}C, ^{39}Ar, and ^{81}Kr can corroborate each other, though, for some samples, the processes of diffusion, dispersion, and groundwater mixing may make the interpretation trickier. Most of the samples are in the dating range of ^{14}C, less than 24,000 yrsBP. Some samples with ^{14}C less than 2 pMC cannot rely solely on ^{14}C and the results of ^{81}Kr indicate quite old age. Surprisingly, both $_{39}Ar$ and ^{81}Kr are found to be significantly higher than the modern atmosphere value in some samples, which may indicate potential underground sources of them and require further research. Regarding the paleoclimate reconstruction, noble gas temperatures derived from their concentrations show that the temperature difference between LGM and modern is at least 5.4 °C, which is comparable with other studies in the tropical area. ^{18}O and 2H are more correlated with the precipitation amount than with the temperature. Besides, the paleoclimate signals derived from the groundwater are compared with those from other local climate archives, such as the Maar lake sediment.

Palaeoenvironmental reconstruction of the LGM period in the Upper Dnieper basin (Ukraine) based on multi-proxy analysis of the youngest loesses

Prof. Przemysław Mroczek [1], ***Prof. Maria Łanczont*** [2], ***Prof. Maryna Komar*** [3], ***Prof. Jerzy Nawrocki*** [2], ***Mr. Karol Standzikowski*** [2], ***Prof. Oleksii Krokhmal*** [4], ***Prof. Kateryna Derevska*** [5], ***Dr. Sergii Prylypko*** [4]

1. *Maria Curie-Skłodowska University in Lublin,* **2.** *Maria Curie Skłodowska University, Institute of Earth and Environmental Sciences, Lublin,* **3.** *National Museum of Natural History, National Academy of Sciences of Ukraine, Kyiv,* **4.** *National Academy of Sciences of Ukraine, Institute of Geological Sciences, Kyiv,* **5.** *Taras Shevchenko National University of Kyiv*

The youngest loess cover of the Ukrainian part of the Upper Dnieper basin belongs to the northern fragment of the European loess belt developed both as a continuous cover and as isolated ‘islands’ located in the foreland zone of this belt. The litho- and pedological development, similar thickness (4-5 m), age (~28-15 ka) of the upper, near-surface part of these covers, i.e. the Bug loess (MIS 2), are its common features. The subject of the palaeoenvironmental studies are key loess sites in a meridional arrangement. These profiles were analysed based on the results of, inter alia, physico-chemical studies, spectrophotometric studies, magnetic susceptibility anisotropy and luminescence dating. In terms of litho- and pedological formation, the studied profiles have the character of loess-paleosol sequences, in which loess bg (=L1LL1), formed after the end of loess- and soil-forming processes during MIS 3.

The starting point for the environmental analyses were spectrophotometric and grain size measurements. The first reflect the colour parameters, while the second reflect the size of the elementary particles. In the light of the measurements, the litho- and pedological development shows a number of specific features related to the syn- and postdepositional evolution of the environment. The colour parameters correspond to the pigmentation occurring during the epigenetic stage, while the granulometric parameters mainly record the characteristics of the sedimentary environment. In the spectrophotometric images of the individual samples, as well as in the shapes of the lines of variation of the granulometric indices and in the heat maps, specific patterns of change corresponding to climate oscillations are noticeable. In the spectrophotometric images, as well as in the shapes of the lines of variation of the granulometric indices and in the heat maps, specific patterns of change are noticeable. These changes correspond to global climate oscillations and can also be very local.

Research carried out as part of the grant of National Science Centre, Poland (the project no. 2018/31/B/ST10/01507) entitled “Global, regional and local factors determining the palaeoclimatic and palaeoenvironmental record in the Ukrainian loess-soil sequences along the Dnieper River Valley - from the proximal areas to the distal periglacial zone”.

Deglacial history of the Kattegat-Baltic Sea using x-ray micro-computed tomography of benthic foraminifera

Mr. Jonas Donnenfield [1], Prof. Helena Filipsson [2], Dr. Constance Choquel [2], Dr. Behnaz Pirzamanbein [3], Dr. Dirk Müter [4], Dr. Sha Ni [2], Dr. Nadine Quintana Krupinski [2], Mr. Mario Scheel [5], Dr. Karen Luise Knudsen [6], Prof. Marit-Solveig Seidenkrantz [6]

***1.** Department of Geology, Lund University, Sweden/College of Earth, Ocean, and Atmospheric Sciences, Oregon State University, USA, **2.** Department of Geology, Lund University, **3.** Department of Statistics, Lund University, Sweden, **4.** FORCE Technology, Brøndby, **5.** Synchrotron SOLEIL, **6.** Paleoceanography and Paleoclimate Group, and iClimate Centre, Dept. of Geoscience, Aarhus University, Aarhus, Denmark*

The Baltic Sea is strongly affected by the combined stressors of deoxygenation, acidification, and eutrophication. These are primarily derived from 1) anthropogenic CO_2 emissions, which increase atmospheric temperatures, enhance surface water stratification, reduce oxygen solubility, and alter carbonate chemistry, and 2) nutrient pollution from the Baltic Sea's heavily populated coastline. Together, these rapid environmental changes are significantly impacting fragile coastal ecosystems and dependent economies, yet the combined effects of multiple stressors are still not well understood. Paleoceanographic reconstructions of the Baltic Sea from past periods of rapid warming can provide benchmarks for and help predict future synergistic effects of multiple stressors as well as regional oceanographic responses to changes in global climate.

Our research uses a continuous, high-resolution sediment record of the last deglaciation (~18-15 ka) from the Kattegat seaway between Sweden and Denmark (IODP Expedition 347 Site M0060). Existing results for M0060 from benthic foraminiferal stable oxygen and carbon isotopes, trace elements, species assemblages, and a recalibrated age model support evidence of an early deglacial, poorly ventilated setting that undergoes freshening until ~15.5 ka, concomitant with the retreat of the proximal Fennoscandian Ice Sheet (FIS), followed by a transition to better ventilated, more saline conditions. We use synchrotron-based x-ray micro-computed tomography of benthic foraminiferal species *Elphidium clavatum* at decadal- to centennial-scale resolution to generate three-dimensional shell morphology (e.g., shell thickness, density, porosity, surface area/volume ratio). These morphometrics are expected to reflect bottom water environmental changes, likely controlled by the combined influence of adjacent FIS dynamics, European continent glacial meltwater, and North Atlantic circulation. Quantifying morphometric variability across the deglaciation will further constrain end-Pleistocene changes in temperature, oxygen, salinity, carbonate chemistry, and productivity, as well as disentangling the relative controls of regional ice-sheet and climate dynamics on the Baltic Sea from larger North Atlantic climate.

Impact of Climate Change on Gas Hydrate Stability Zone due to Progression of Bottom Water Temperatures in the Krishna Godavari Basin.

Mrs. Jyothsna Palle [1], ***Mrs. Satyavani Nittala*** [1]

1. *CSIR-National Geophysical Research Institute*

Gas hydrate dissociation acts as a primer/trigger for many historical landslides due to changes in temperature, pressure, salinity, etc. Gas hydrates are more sensitive to Temperature change than to pressure. The 3D seismic data from a small region in the Krishna Godavari basin is examined in the present study to understand the dissociation mechanism of the gas hydrates. Seismic Interpretation reveals that the Bottom simulating reflector (BSR) is shoaling upwards and truncating near the seafloor creating slope failure. The reason for the shoaling of BSR is examined and found that the Bottom water temperature is a critical parameter for causing the shift in BSR Post-Glacial maximum. The hydrate stability zone during the Glacial time (seafloor temperature 4 °C) and the present day (seafloor temperature 6.5°C) is computed with varying geothermal gradients (GTG) of 45 + 3° C per km observed from well log data of NGHP-01-10A lying close to the study area. It is observed that the Base of the hydrate stability zone (BSR) shifted by 80 meters post-glacial at 1000 meters of water depth. Changing the GTG has caused only a ten-meter change in the shift but changing the seafloor temperature has caused 80 meters shift in the BHSZ.

Quaternary terrace deposits in the Apulia region (southern Italy): an archive for the reconstruction of palaeo SSTs and Meditterranean pressure pattern during the last interglacial.

Terraced deposits associated to palaeoshorelines in the Apulia region (southern Italy) proved to be a useful palaeoclimatic archive.

In the area of Gallipoli, the aeolian units AU1 and AU2 present within *Il Carmine-Li Foggi* paleo littoral ridge and the aeolian unit AU3 which outcrops in the *Il Campo* locality allowed us to reconstruct the paleo-directions of the winds and the atmospheric pressure patterns during MIS 5.5. AU1 is the first unit to settle and indicates a "first aeolian phase" of MIS 5.5, characterised by a NW-S bimodality of the winds, which involved fall-winter and spring-summer pressure patterns similar to the current ones, with a spring-summer not very effective for the aeolian transport and an autumn-winter characterised by an Atlantic footprint effective for the aeolian transport by the onset of winds from the S and NW which alternate following the transit of pressure lows from Atlantic across the Mediterranean.

AU2 and AU3 settled later than AU1, in a "second aeolian phase" of MIS 5.5, characterised by a prevailing NW wind regime. AU2 and AU3 settled under a pressure pattern similar to the current one in fall-winter, but characterised by a pressure gradient from west (high) to east (low), in the spring-summer, much stronger than the current one. This regime caused summer NW winds stronger than today and effective for wind transport. These strong NW winds in summer, coupled with the NW-S bimodality in fall-winter, caused the overall prevalence of NW winds during the "second aeolian phase". This summer pressure gradient on the Mediterranean greater than today was caused by a summer strengthening of the east Mediterranean low-pressure, in turn caused by the northward shift of the ITCZ, widely documented during the Sapropel S5 event, occurred during the MIS 5.5 after sea level had risen to the highstand.

On the other and, marine terrace deposits dating back to MIS 5.5 and MIS 7.3 near Lizzano, both containing *Cladocora caespitosa*, allowed us to reconstruct palaeo SSTs of these two stages thanks to several palaeo temperature proxies provided by this coral. Our reconstruction highlights a different warming of coastal waters during these two stages.

Late Pleistocene- Holocene boundary: A preliminary study of paleoceanographic conditions at the Santos Basin, São Paulo, Brazil

Ms. Ana M souza [1], ***Dr. Franklin Bispo-Santos*** [1], ***Ms. Rafaela Dantas*** [2], ***Ms. Stephanie Leone*** [1], ***Ms. Allana Queiroz de Azevedo*** [3], ***Dr. Jairo Savian*** [4], ***Mr. Manoel Damaceno*** [2], ***Ms. Milena Santos de Lara*** [1], ***Mr. Mateus Gama*** [1], ***Prof. Luigi Jovane*** [1]

1. Oceanographic Institute of the University of São Paulo, 2. University of Sao Paulo, 3. Federal University of Fluminense, 4. Federal University of Rio Grande do Sul

In April of 2022, a teaching and research expedition reunited young scientists and graduate students to gather data and study the geology and geophysics of the continental shelf and slope of the Santos Basin (24°S/44°W). Prolonged exposure to the continental platform during past glacial stages may have influenced paleoecology and sediment deposition. Therefore, this study aims to understand changes in this region's climate and oceanographic circulation since the Last Glacial Maximum (LGM). The gravity corer drilled five cores at least three meters long of continuous marine sediments. Lithological description followed the facies analysis. Mass normalized magnetic susceptibility was measured using the Kappabridge MFK1-FA (AGICO) in 2 frequencies: 976 Hz and 15616 Hz. Samples for micropaleontological analyses were wet-sieved in a >63 µm mesh and dried at 50°C. The assemblages of planktonic foraminifera were performed through a binocular microscope. The preliminary results show that the five studied cores are mainly composed of clay minerals with fine-grained sediments, detrital siliciclastic grains, and carbonate microfossils. The major species of planktonic foraminifera found were: *Globigerinoides ruber, Trilobatus trilobus, Globorotalia menardii, Neogloboquadrina dutertrei, and Globorotalia crassaformis*, which are characteristics of warm and transitional waters. Most core tops identified the biostratigraphic biozone X associated with interglacial climates. At the cores C1GC1, GC03, C3GC3, and C2GC3, the last glacial Biozone Y (the Last Glacial Maximum, LGM) was identified by the lack of subtropical and transitional climate foraminifera. At the bottom of the core GC03, the high abundance of *G. menardii* indicates the interglacial Biozone X. The magnetic susceptibility results mostly agree with the lithology and sea-level fluctuations, showing higher values in a sandy mud substrate, perhaps due to higher terrigenous input at transitioning (interglacial-glacial) climates. The Field dependent susceptibility has most of the values ranging from 2-10%, suggesting a mixture of Superparamagnetic (SP) and coarser non-SP grains. Thus, this consistent signal throughout the cores suggests that the differences seen in the lithology are closely related to sea-level fluctuations rather than differential input sources in the area.

Multi-sensor core logging (MSCL) data of Marine Cores from Santos Basin (São Paulo, Brazil): A Preliminary Analysis

Dr. Franklin Bispo-Santos [1], *Ms. Ana M souza* [2], *Mr. Mateus Gama* [1], *Prof. Luigi Jovane* [1]

1. Oceanographic Institute of the University of São Paulo, 2. University of Sao Paulo

The Pleistocene-Holocene paleoceanographic variability recorded in South Atlantic sediments is less well documented and understood compared to North Atlantic sediments. Therefore, in April 2022, an oceanographic expedition at the Santos Basin recovered marine sediments from the Pleistocene-Holocene boundary. The Santos Basin is located on the Brazilian southeast-south continental margin between 23ºS and 28ºS, its lithology is characterized by fine sand and silt in the middle and outer portions of the shelf. This study aims to reconstruct the paleoenvironment from the physical properties of 4 cores drilled near the Santos slope. The cores working halves passed through a Geotek MSCL (Multi-Sensor Core Logger) automated instrument for measuring the physical properties of the sediment (gamma ray attenuation, gamma natural, P-wave velocity, magnetic susceptibility, density), with a spatial resolution of 0.5 cm. The data were further processed to attenuate the spiky profiles resulting from the instrumental acquisition that was set up with a relatively low counting time (1 s). A slight data smoothing was achieved by a 3-point running average after removing all existing anomalously low/high values. The MSCL data provided the following characteristics for the analyzed marine cores: a relatively high density; low porosity; low-to-mean natural gamma count; high susceptibility; and low-to-mean resistivity. The density changes abruptly following the magnetic susceptibility. These changes in density may be indicating changes in material composition as variations in clay content. The high magnetic susceptibility may be an indication of a clay matrix that has magnetic elements such as iron present within the clay or other elements such as pyrite. Resistivity measurements are low suggesting the clay-rich sediments. MSCL data show us a very low natural gamma profile indicates sediments with lower clay content. We observes an increase in natural gamma, density, and magnetic susceptibility resulting from an increase in grain size in some intervals. For better correlation, we intend to perform geological and lithological descriptions of the marine cores facies to identify with precision the lithological boundaries.

Keywords: Pleistocene-Holocene, Santos Basin, MSCL, Magnetic Susceptibility

Late Glacial to Holocene transition: the story told by subfossil Cladocera remains (Żabieniec Mire, Poland)

Ms. Marta Rudna [1]***, Dr. Marta Wojewódka-Przybył*** [2]***, Prof. Jacek Forysiak*** [3]

1. *University of Lodz, Doctoral School of Exact and Natural Sciences,* ***2.*** *Institut of Geological Sciences PAS, Twarda 51/55 PL00818 Warsaw, Poland,* ***3.*** *University of Lodz, Faculty of Geographical Sciences, Department of Geology and Geomorphology*

One of the most discussed research topic in Earth sciences at present is contemporary climate change. Paleogeographic study allow to recognize and reproduce changes in environmental conditions over past geological eras. In a time period from the Late Vistulian (the youngest part of the last glaciation) to the Early Holocene (the beginning of interglacial), there were periods of rapid changes in climatic conditions (coolings - stadials and warmings - interstadials). The aim of the conducted studies was to trace in detail the periods of rapid changes during Late Glacial based on subfossil Cladocera analysis. The Żabieniec site is located on the moraine plateau of the Łódź Hills in Central Poland. Biogenic sediments of more than 12 m thick have been identified with continuous accumulation since the beginning of the Late Vistulian to modern times. Sampling was performed with high resolution (1 cm), which corresponds to time intervals of about 10 to 20 years. Such approach allowed to set up borders between stadials and interstadials of Late Glacial.

The fluvial influx and upwelling changes off Saurashtra coast during the Late Quaternary.

Ms. Sruthy Rose Baby [1], Dr. Mohan Kuppusamy [1], Dr. Ravi Mishra [2]

1. Vellore Institute of Technology(VIT), 2. National Centre for Polar and Ocean Research (NCPOR)

The climate of the Indian subcontinent is mainly determined by the Arabian Sea and the Bay of Bengal. The sediments of the Arabian Sea are widely used for the reconstruction of past variability in Indian Summer Monsoon (ISM) and coastal upwelling. For the present study, we used 4.30 m core samples SK240/473 from off the Saurashtra coast with a water depth of 121 m. This study aims to understand the weathering response of the Himalayas to climate forcing during the late Quaternary by using relative abundances of Planktonic foraminifera *Globigerina bulloides* and the Ratio of *G.bulloides/G.ruber*. *G.bulloides* is the asymbiotic species commonly seen in transitional to polar, but it is also characterized in nutrient-rich upwelling areas. The relative abundance of *G.bulloides* varies between 35 % to 4% and the ratio changes between 0.1 to 2.5. The *G.bulloides/ G.ruber* ratio and *G. bulloides* abundance show a positive correlation, where its abundance indicates high productivity in the area. The high value of *G.bulloides/ G.ruber* in two depths (302 cm and 316 cm) indicates a period of intense upwelling, which coincides with high benthic percent. In section, I, a period of low *G.bulloides/G.ruber* ratios would indicate lower production and the influence of warm, oligotrophic water. The depth range of 140 cm to 430 cm (II section) denotes periods of strong productivity, as well as the influence of cold, nutrient-rich water. As a result of the data, we can deduce that this site has a period of low production up to 140 cm, after which the rate of terrestrial input and upwelling doubles. Also, past weathering regimes are important for a better understanding of the influence of climate on weathering in the study area.

A novel East Asian Summer Monsoon index reconstructed from a mixed approach and the multidecadal variability revealed in the1400-1900s

Prof. Elaine KH Lin [1], ***Prof. Wan-Ling Tseng*** [2], ***Ms. Jen-Ing Lee*** [1], ***Mr. Chen-Wei Lin*** [3], ***Prof. Huang-Hsiung Hsu*** [4], ***Prof. Pao K. Wang*** [3]

1. National Taiwan Normal University, 2. National Taiwan University, 3. Academia Sinica, 4. Acadmia Sinica

The East Asian summer monsoon (EASM) is a distinctive component of the Asian climate system due to orographic forcing. Unlike Indian summer monsoon which occurs within the South Asian monsoon trough and presents a uniformity of rainfall distribution allowing for an All Indian Rainfall index to measure its variability, the definition of the EASM intensity has been much more complicated. One of the main reasons is the extensive domain of the EASM encompassing tropics, subtropics and midlatitudes and thus the complex space and time structures making it difficult to quantify the EASM variability. Despite the challenges, studying the evolution of EASM over hundreds or thousands of years is essential to build a comprehensive understanding on the monsoon behaviors and their associations with the general circulations. Hence, many previous studies have used geochemical proxy records from oceanic sedimentary or continental archives to build paleo-EASM indices by depending on mostly rainfall information retrieved from the records at some sites. The sort of the methods inevitably faces the issue of spatial coverage and limited explanatory power for the overall EASM.

In this study, we present a novel approach to reconstruct a paleo-EASM index. First, the current observational Western North Pacific monsoon index (Wang et al. 2008, in Journal of the Climate) approach was used to calculate the wind fields (zonal and meridional winds at 850hPA) from 1950 to 2020 using ERA5 data and rainfall data from NOAA Precipitation Reconstruction over Land to construct the modern EASM index and to examine the relationships between the rainfall and circulation anomalies. Then, the EASM rainfall pattern was projected to the gridded REACHES (Reconstructing East Asian Climate Historical Encoded Series) (Wang et al., in Scientific Data) historical climate index data between 1400 and 1900s. Thus, the reconstructed REACHES EASM index considers both temporal and spatial variability. In addition, the REACHES EASM index was further examined by overlaying the data with extreme events such as flood and drought from social archives. Therefore, the indication of the dominate large-circulation is able to be investigated at the multidecadal to centennial scale at the historical time.

Abrupt global change and the East Asian Monsoon: the impact of Heinrich Event 4 and Greenland Interstadial 8 inferred from the sediments of Lake Suigetsu, Japan

Mr. Alexander Francke [1], ***Dr. Jonathan Tyler*** [1], ***Ms. Vanessa Nowinski*** [1], ***Mr. John Tibby*** [1], ***Dr. Jack Lacey*** [2], ***Prof. Melanie Leng*** [2], ***Ms. Charlie Rex*** [3], ***Dr. Richard Staff*** [4], ***Prof. Takeshi Nakagawa*** [5]

The climatic drivers controlling the Asian Summer Monsoon (ASM), which directly affects water resources and water-borne geohazards for over half of the Earth's population, are still highly debated. The long-proposed alignment between SM and high latitude climate forcing suggested by the similarities between Greenland ice core records and speleothem archives from China is increasingly challenged by terrestrial and marine sedimentary records. But there are only a handful of palaeorecords with sufficiently accurate chronological constraints to provide insights into the lead and lag of ASM variability compared to global benchmarks, such as ice core records.

The annually layered sediments of Lake Suigetsu (Japan) provide a unique opportunity to study ASM variability during periods of rapid climate change at unprecedented precision. The chronologic framework for Lake Suigetsu is an integral component of the IntCal20 radiocarbon calibration, and sampling and chronological work follows strict protocols. Lake Suigetsu's location at the western coastline of Japan's main island, Honshu, makes it sensitive to climatic influences from the north-westerly winter monsoon, and summer to autumn south-western and Pacific monsoonal influences. Here, we aim to use the Lake Suigetsu sediments to untangle rapid ASM variability during the last glacial cycle, with an initial focus on the time interval between 40 and 34 cal ka BP sampled at a temporal resolution of on average < 60 years and covering Heinrich event 4 and Greenland Interstadial 8.

Hydrologic change is reconstructed by stable isotope analysis (oxygen, carbon) of non-traditional lake sediment material, namely biogenic silica (diatoms) and early diagenetic siderite ($FeCO_3$); supported by FTIR (Fourier-Transform Infrared Spectrometry) estimates of sedimentary (mineral) composition. These analyses in concert with previously collected X-ray fluorescence and pollen data provide detailed insights into hydrologic response in Japan during an episode of abrupt global change. This includes a potential temporal mismatch with warming in Greenland in the Suigetsu record while simultaneously highlighting stronger correlations with Pacific and Antarctic climate records.

East Asian monsoon variability recorded in lacustrine sediments from the Jingpo Lake, NE China

Prof. JI SHEN [1]

1. *School of Geography and Ocean Science, Nanjing University*

Abstract: The Northeastern China involves complex interactions between the East Asian monsoon (EAM) circulation and the polar climate system, and plays a significant role as the bridge communicating low and high latitude climatic processes. High-resolution pollen, grain size, magnetic susceptibility, TOC/TN mass accumulation rate (MAR), C/N ratio, and carbon isotope of organic matter data from a 11.54 m lacustrine sediment core recovered from Jingpo Lake in northeastern China provides a detailed history of East Asian monsoon (EAM) variability and vegetation changes during the Mid- to Late Holocene. The 13 AMS ^{14}C ages (nine from terrestrial plant leaves and four from bulk organic matter samples) used for the robust chronological sequence indicate that the lacustrine sediment core has been accumulated since ~5100 cal. yr BP. From ~5100 to 3600 cal. yr BP, is characterized by the highest pollen percentages of *Quercus*, *Ulmus*, *Juglans* and *Corylopsis*, low Md (median diameter) and high $\delta^{13}C_{org}$ values reflecting relatively warm and humid period. Between ~3600 and 2100 cal. yr BP, high Md and low $\delta^{13}C_{org}$ values, and the rapidly increase in herbs pollen percentages, indicating cool and dry climatic conditions. From ~2100 to 100 cal. yr BP, a gradual increase in $\delta^{13}C_{org}$ values and low Md values, and the rapidly increase in *Carpinus*, *Juglans* and *Corylopsis* pollen percentages denoting climate changed towards warmer and wetter conditions. After ~100 cal. yr BP, the highest values of TOC-MAR, TN-MAR and χ_{lf} suggesting that the Jingpo Lake region is severely affected by human activities. The EAM variability over the northeastern China during the Mid- to Late Holocene have similar trends to EAM records in China. Furthermore, our findings indicate that variability of the EAM during the Mid- to Late Holocene on multi-decadal to centennial scale are forced by changes in both solar output and oceanic–atmospheric circulations.

A 1250-year long monsoon-driven drought record from Ea Tyn Lake (Vietnam)

Prof. Ingmar Unkel [1]***, Prof. Dương Nguyễn-Thùy*** [2]***, Prof. Hướng Nguyễn-Văn*** [2]***, Prof. Antti Ojala*** [3]***, Dr. Arndt Schimmelmann*** [4]***, Dr. Thái Nguyễn-Đình*** [2]

1. *Institute of Geography, Heidelberg University, Heidelberg / Institute for Ecosystem Research, Kiel University, Kiel,* ***2.*** *Faculty of Geology, VNU University of Science, Vietnam National University, Hanoi,* ***3.*** *University of Turku,* ***4.*** *Indiana University, Department of Earth and Atmospheric Sciences, Bloomington, Indiana*

The South-East Asian tropics remain severely under-represented in paleoenvironmental and paleoclimatic reconstructions, although a few recent paleoclimate studies evaluated the variability, position and strength of the main Asian monsoon systems at different timescales from modern records to the last 45,000 years. Comparable data from Vietnam, however, are scarce although Vietnam and its Central Highlands are critically located at the intersection of the East Asian Summer Monsoon and the Indian Summer Monsoon with highly important socio-ecological consequences from changes in the climate system. We here present a high-resolution sedimentary climate record from Ea Tyn Lake in the Vietnam's Central Highlands covering the last 1,250 years. Using geochemical and sedimentological proxies and principal component analysis, we reconstructed at least 12 drought events, some of which appear to be of supraregional significance as they coincide with historically documented droughts in India, China, and Cambodia. Especially the summarizing XRF-based PC2 values are in very good agreement with the Palmer Drought Severity Index (PDSI) of the region so far based on tree rings. Beyond tracking short-term climate events, the Rb/Sr elemental ratio along our lake sediment sequence reflects long-term monsoon variability throughout the last millennium, which was previously only reconstructed via δ^{18}O speleothem records from China and India. Our record shows that the East Asian Summer Monsoon was relatively strong between ~1000 and 1350 cal CE and weaker between 1350 and 1850 cal CE, followed by renewed intensification after ~1850 cal CE. Future work can extend the Ea Tyn Lake record further back in time, and studies on changes in land-cover and land-use in the Central Highlands of Vietnam may yield a clearer picture of the impact of monsoonal variability on regional vegetation.

Deciphering the influence of SST on monsoon rainfall: A combined proxy data – modeling approach

Dr. Martina Hollstein [1], ***Dr. Mahyar Mohtadi*** [1], ***Dr. Matthias Prange*** [1], ***Dr. Lukas Jonkers*** [2]

1. *MARUM-Center for Marine Environmental Sciences, University of Bremen,* ***2.*** *MARUM, University of Bremen, Germany*

The Australasian monsoon systems constitute central elements of the global hydrological cycle and influence the living conditions of billions of people. With respect to global future warming, it is thus an enduring issue to gain a comprehensive understanding of the regional monsoon dynamics, particularly under warm climate conditions.

Paleoclimatic data provide evidence that monsoon rainfall is influenced by varying sea surface temperatures (SST) and SST gradients, for instance in response to changing astronomical forcing. However, this connection has yet to be studied in a systematic approach. Climate model simulations provide ideal means to address the coupling between SST and monsoon rainfall and underlying mechanisms. However, the uncertainty in monsoonal rainfall simulations is still high and temperature simulation is one of the main sources of error.

To tackle this issue, we combine a network of proxy-based reconstructions of SST and rainfall amount from the Australasian monsoon realms with numerical model simulations. More specifically, we compile proxy-based SST reconstructions from the Australasian monsoon realms. We intend to analyze the spatial-temporal variability of SST (and rainfall) during the Holocene and previous interglacial periods, such as MIS5 and MIS11, from proxy-based reconstructions, and use the results as a testbed for model simulations of monsoon rainfall.

Dust impacts on paleomonsoons from CESM simulations

Dr. Samuel Albani [1], ***Dr. Natalie Mahowald*** [2]

1. *University of Milano-Bicocca,* ***2.*** *Cornell University*

Mineral dust acts both as a tracer and a forcing agent of climate change. Past dust variability, imprinted in paleodust records from natural archives, offers the unique opportunity to reconstruct the global dust cycle within a range of possibilities that plausibly encompass future variations in response to climate change and land-cover and land-use changes. Dust itself has direct and indirect feedbacks on the climate system, through impacts on the atmosphere radiative budget and the carbon cycle. Starting from well-constrained re- constructions of the present and past dust cycle, we focus on quantifying dust direct impacts on the atmospheric radiation. We discuss the intrinsic effects of dust onto climate, and how changes in the global dust budget and surface conditions modulate the effective impacts on surface temperatures and precipitation. Most notably, the presence of dust tends to enhance the West African monsoon and warm the Arctic. We also highlight how different choices in terms of dust optical properties and size distributions may yield opposite results, and what are the observational constraints we can use to make an informed choice of model parameters.

Insolation and CO2 impacts on the spatial differences of the MIS-9 and MIS-11 climate between monsoonal China and central Asia

Dr. Hao Lu [1]

1. key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences,

Marine oxygen isotope records and ice cores in Antarctica suggest that Marine Isotope Stage (MIS) 9, an interglacial occurring about 300 ka ago, is a strong interglacial and has the highest greenhouse gases (GHG) concentrations during the past 800 ka. Model results also show that MIS-9 is the warmest interglacial among the last nine ones as a result of both its high CO_2 concentration and its high summer insolation in the northern Hemisphere (NH). However, the China loess records show that the paleosol S3 that corresponds to MIS-9 is not necessarily strong as compared to some other paleosol units such as the S4 soil that was formed during MIS-11, suggesting relatively drier climate condition during MIS-9. By contrast, in Tajikistan of southern central Asia, the paleosol S3 is the most developed soil over the past 800 ka, indicating a relatively warm and humid climate conditions. The difference in the paleosol formation and the MIS-9 climate between monsoonal China and central Asia is intriguing. In this study, we combine loess records from monsoonal China and central Asia as well as climate simulation results to understand the spatial difference of the MIS-9 climate in particular in comparison with the climate of MIS-11. The individual and combined contributions of insolation and greenhouse gases are quantified through simulations with the LOVECLIM model and using the factor separation technique. Our results show that the simulated effective moisture conditions between northern China and southern central Asia are consistent with the loess records and field observation. Insolation leads to much more annual mean precipitation than GHG during MIS-9 in southern central Asia, explaining a much wetter MIS-9 there. By contrast, both insolation and GHG lead to more annual mean precipitation and evaporation during MIS-9 in northern China, leading to only a slight difference in the effective moisture between MIS-9 and MIS-11. In addition, compared to MIS-11, the higher insolation and GHG concentration during MIS-9 lead to an anomalous atmospheric circulation pattern similar to negative phase of North Atlantic Oscillation (NAO), favoring precipitation increase in southern central Asia and therefore explain strong soil development in Tajikistan.

Warming-induced northwestward migration of the Asian summer monsoon in the geological past: Evidence from climate simulations and geological reconstructions

Dr. Xiaofang Huang [1], Prof. Shiling Yang [1], Prof. Alan Haywood [2], Prof. Dabang Jiang [3], Dr. Yongda Wang [1], Ms. Minmin Sun [1], Dr. Zihua Tang [1], Prof. Zhongli Ding [1]

The cold and warm intervals during the Plio-Pleistocene provide an opportunity to assess the response of the Asian summer monsoon (ASM) to different levels of global warming. In this study, the northern edge of the ASM, a sensitive indicator of the advance and retreat of the ASM rain belt, was analyzed using climate outputs from PMIP3 and PlioMIP1, for the Last Glacial Maximum (LGM, □21,000 yr BP), the preindustrial, the mid-Holocene (□6,000 yr BP), and the mid-Pliocene (□3.3–3.0 Ma), among which the global temperature increased sequentially. The results show that the northern edge of the ASM migrated northwestward by □200 km, □50 km, and □50 km with global warming from the LGM to preindustrial, from the preindustrial to mid-Holocene, and from the mid-Holocene to mid-Pliocene, respectively. These results are generally consistent with geological records. The simulations show that the western Pacific subtropical high (WPSH) intensified and expanded geographically, and the intertropical convergence zone (ITCZ) migrated northward over the Indian Ocean and was shifted southward over the western Pacific. This led to a northwestward shift of the Asian monsoonal rain belt, and consequently to wetter conditions in India and northern China. During the mid-Pliocene, pronounced warming substantially intensified the WPSH, leading to the suppression of moisture transport from the Indian Ocean to southern China and the Indo-China Peninsula. Our results suggest that if the planet returns to a Pliocene warm world, precipitation will increase in northern China, while southern China and the Indo-China Peninsula will experience more frequent droughts.

Vegetation and hydroclimate changes in the Ganges–Brahmaputra basin since the Last Glacial Maximum

The Bengal Fan, the largest submarine active fan in the world, is fed by the Ganges and Brahmaputra (G-B) rivers, and corresponds to the final sink for the huge erosional system draining most of the Himalayan range. Although tectonic processes mainly control long-term changes in riverine sediment flux, and associated erosional carbon burial, the intensity of Himalayan weathering on the Glacial-Interglacial timescale may be modulated by changes in climate and vegetation cover in the G-B basin. However, detailed changes in vegetation composition of the G-B hydrological basins in response to the Indian Summer Monsoon variations is cruelly lacking and remain to be documented.

Our study is based on an original approach that consists of pollen analysis of marine sediments collected in northern Bay of Bengal (16°N). Hence, pollen assemblages from the cores SO-93 represent an integrated image of the regional vegetation, and therefore climate, in the G-B hydrological basin during the last 18 kyrs.

We present herein the preliminary results of our palynological investigations. Pollen assemblages indicate the dominance of an open savannah prior to 11 ka, as evidenced by the highest percentages of arid herbs and lowest percentages of tropical and temperate trees. The Holocene vegetation is characterized by the expansion of forest with a precipitation maximum recorded between 11 and 8 ka by the highest development of moist tropical deciduous and evergreen trees. In addition, pollen data will be compared with others records of the studied cores, including geochemical vegetation record consisting in the $d^{13}C_{\text{orga bulk.}}$, as well as monsoon indicators estimated on the calculated $dD_{\text{precipitation}}$ based on C28 Fatty Acid and $\delta^{18}O$ of planktonic foraminifers. Therefore, we attempt to better constrain the relationship between vegetation changes, tropical precipitation and weathering in the G-B basin since the last glacial maximum.

Reconstruction of the Indian Summer Monsoon variability and the impacts of Toba super-eruption

__1.__ CR2P-UMR 7207, CNRS, MNHN, Sorbonne Universités, __2.__ LOCEAN, Sorbonne Universités (UPMC, Univ Paris 06) -CNRS-IRD-MNHN, Paris, France, __3.__ LSCE, __4.__ Université Paris Cité, Institut de Physique du Globe de Paris, CNRS, Paris, 75005, France, __5.__ Institut des Sciences de la Terre de Paris ISTeP UMR 7193, Sorbonne Université, __6.__ MNHN

The Toba volcano super-eruption occurred about 74,000 years ago on the island of Sumatra, during the transition between interglacial Marine Isotope Stage (MIS) 5 and glacial MIS 4. This eruption, is currently described as the largest volcanic eruption of the Quaternary. However, its impact on climate is widely debated and its effects on the ocean remain poorly understood. This eruption occurred in an area of the world where important climatic phenomena like the Indian Summer Monsoon (ISM) occur.

The aim of this work is first to reconstruct the variability of the ISM for the last 100 ka. To do so, we reconstructed ocean surface temperature using Mg/Ca of surface-dwelling planktonic foraminifera *Globigerinoides ruber* picked from core BAR94-25 located in the Andaman Sea. We also measured $\delta^{18}O$ on the same samples. By coupling the temperature reconstructed from Mg/Ca and the $\delta^{18}O$, we derived the $\delta^{18}O$ of the sea water ($\delta^{18}O_{sw}$), a proxy of ocean salinity. Andaman Sea salinity is mainly driven by the freshwater discharge of the Irrawaddy River during the ISM. Therefore, $\delta^{18}O_{sw}$ changes in core BAR94-25 are directly related to changes in the strength of ISM since the last interglacial.

After reconstructing the variability over the last 100 ka, we zoomed in on the Toba interval, to decipher the potential impact of the Toba eruption on the ISM. This eruption is characterized in core BAR9425 by several tephra and cryptotephra layers which were interpreted as distinct eruptive events. The results show an increase of sea surface salinity during the Toba eruptive activity, which may be linked to a decrease of fresh water inflow to the Andaman Sea during the ISM. This could reflect the Toba eruption may have disrupted the ocean-atmosphere dynamics and therefore, the ISM.

East Asian winter monsoon variability over the last 700 ka: grain-size evidence from the sediments in the East Sea (Japan Sea)

Mr. Junho Jang [1], *Prof. Jang Jun Bahk* [1]

1. Chungnam National University

This study reconstructed East Asian winter monsoon variability over the last 700 ka based on grain- size distributions of detrital components of the IODP Site U1430 core sediments in the East/Japan Sea. End-member analysis of the grain-size distributions revealed two end-member size distributions, relatively fine-grained EM1 (median size 2.86 mm) and coarse-grained EM2 (median size 9.00 mm), which were interpreted to represent dusts transported by high-level westerlies and East Asian winter monsoon surface winds from the Asian interior, respectively. The relative contributions of EM2 over EM1 in the total size distributions tend to increase in the glacial periods, which are consistent with the grain-size changes in the Chinese Loess Plateau, which tend to be coarse-grained during the glacial periods and fine-grained during the interglacial periods. The changes in the contributions of EM2 suggest that the strengthening of East Asian winter monsoon during the glacial periods has persisted since 700 ka. In addition to the orbital scale glacial-interglacial changes, the contributions of EM2 show sub-orbital millennial-scale fluctuations which tend to be increasing in the relatively bright-colored sediments and decreasing in the dark-colored sediments. The association of EM2 contributions with the sediment brightness change is interpreted to represent the millennial-scale strengthening of East Asian winter monsoon which would have increased the flux of detrital quartz and feldspar and simultaneous facilitated the deep ocean circulation by winter cooling in the East/Japan Sea. Spectral analysis of the millennial-scale cycle indicates that the dominant period is about 6.2 kyrs.

Late Miocene–Pleistocene tectonic and climatic evolution of the Dali Basin, southeastern margin of the Tibetan Plateau: Constraints from the terrestrial sedimentological record

Dr. Chunxia Zhang [1]***, Dr. Xiuli Zhao*** [2]***, Dr. Wenchao Zhang*** [3]***, Dr. Shihu Li*** [4]***, Prof. Haibin Wu*** [1]***, Dr. Chenglong Deng*** [5]

1. *Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences,* ***2.*** *College of Earth Science and Engineering, Shandong University of Science and Technology, Qingdao 266000, China,* ***3.*** *Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing 100029, China,* ***4.*** *State Key Laboratory of Lithospheric Evolution, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing 100029, China,* ***5.*** *State Key Laboratory of Lithospheric Evolution, Institute of Geology and Geophysics, Chinese Academy of Sciences*

The southeastern margin of the Tibetan Plateau is a key area for determining whether the late Miocene–Pleistocene environmental changes in the South Asian monsoon region were induced mainly by tectonic activity, climate change, or both. Here we present clay mineralogical, geochemical, and palynological proxies from the terrestrial Dasongping section (7.6–1.8 Ma) in the Dali Basin, which is located in the northeastern Diancang Shan (DCS), SE Tibetan Plateau. Diachronous climatic changes are found in the multiple proxies, with the most pronounced changes occurring at ~4.2 Ma for geochemical and mineralogical indices and at ~2.6 Ma for palynological record. The dominant vegetation changed from subtropical broadleaf evergreen forest to cool-temperate mixed forest or cold evergreen conifer forest. These changes indicate that the climatic conditions of the Dali Basin were warm and humid at ~7.6–4.2 Ma, cooler and humid at ~4.2–2.7 Ma, and cold and humid at ~2.7–1.8 Ma. Various proxies imply that the DCS underwent multiple phases of rapid exhumation during the late Cenozoic. The DCS attained a paleo-elevation of >3500 m above sea level (asl) at ~7.6 Ma, maintained a constant elevation between ~7.6 and 4.2 Ma, underwent multiple phases of surface uplift at ~4.2–1.8 Ma, and reached a paleo-elevation of at least ~4000 m asl during the early Pleistocene. A comprehensive comparison between marine and continental records demonstrates that the climatic conditions of the Dali Basin were controlled mainly by global climatic changes at ~7.6–4.2 Ma and mainly by surface uplift of the DCS at ~4.2–2.7 Ma. Changes in vegetation during the Pliocene were caused predominantly by the increasing paleo-elevation of the DCS, whereas ongoing global cooling with the development of northern hemisphere glaciation played a key role in maintaining cold and humid climatic conditions in the Dali Basin after ~2.7 Ma. Our study discriminates the relative contributions of global climate and regional tectonics on the late Cenozoic environmental changes in the Dali Basin.

Monsoon-driven vegetation changes during glacial MIS 16 in the core monsoon zone of India

The Indian Summer Monsoon (ISM) is responsible for 80-90% of the annual precipitation in Central India yet understanding the ISM natural variability during past glacial periods remains a challenge in paleoclimate research. The ISM dynamics during the Last Glacial Maximum (LGM) are fairly well-documented but the fundamental drivers of India's hydroclimate are still highly debatable. While boreal summer insolation and the North Atlantic circulation have been commonly considered as the primary forcings at orbital and millennial timescales, respectively, other studies point to the influence of mechanisms related to ice sheet volume, atmospheric CO_2 concentrations and the export of latent heat from the Southern Hemisphere. Paleorecords from glacials prior to the LGM are, therefore, needed to disentangle the forcings driving ISM changes and to evaluate the responses of fragile ecosystems dependent on monsoon rainfall, such as the forests and savannas of India. Here, we focus on the glacial MIS 16 (676-621 ka) which represents one of the most severe glacial periods of the Quaternary, occurring right after the end of the middle Pleistocene transition. Moreover, it is known to be marked by the first instabilities of the Laurentide ice sheet that resulted in the development of Heinrich layers in the northern North Atlantic. We present the first MIS 16 vegetation reconstruction from India's Core Monsoon Zone (CMZ) based on pollen analysis from IODP Site U1446 strategically recovered at the exit of the Mahanadi River to capture a robust signal of the ISM rainfall. Our pollen analysis results will be compared with records from the same site and other proxy and modelling data to unravel the drivers of the ISM dynamics during the cold MIS 16 in the CMZ of India.

Anomalous widespread arid events in Asia over the past 550,000 years

***Mr. Igor Gustavo da Fonseca Carrasqueira* [1], *Prof. Luigi Jovane* [2], *Prof. André W. Droxler* [3], *Dr. Carlos A. Alvarez Zarikian* [4], *Dr. Luca Lanci* [5], *Dr. Montserrat Alonso-Garcia* [6], *Dr. Juan Carlos Laya* [7], *Prof. Dick Kroon* [8]**

Records of element ratios obtained from the Maldives Inner Sea sediments provide a detailed view on how the Indian Monsoon System has varied at high-resolution time scales. Here, we present new records from IODP Site U1471 based on a refined chronology through the past 550,000 years. The record's high resolution and a proper approach to set the chronology allowed us to reconstruct changes in the Indian Monsoon System on a scale of anomalies and to verify their relationships with established records from the East Asian Monsoon System. On the basis of Fe/sum and Fe/Si records, it can be demonstrated that the Asia continental aridity tracks sea-level changes, while the intensity of winter monsoon winds responds to changes in Northern hemisphere summer insolation. Furthermore, the anomalies of continental aridity and intensity of winter monsoon winds at millennial-scale events exhibits power in the precession band, nearly in anti-phase with Northern hemisphere summer insolation. These observations indicate that the insolation drove the anomalies in the Indian Summer Monsoon. The good correspondence between our record and the East Asian monsoon anomaly records suggests the occurrence of anomalous widespread arid events in Asia.

Late Pliocene-Early Pleistocene monsoonal climate dynamics recorded in lacustrine-fluvial deposits in Datong Basin, Northern China

Ms. Huandi Zhang [1]***, Prof. Qingzhen Hao*** [2]

1. *Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, Beijing, 100029, China,* ***2.*** *Institute of Geology and Geophysics, Chinese Academy of Sciences, Key Laboratory of Cenozoic Geology and Environment*

The East Asian summer monsoon (EASM) has responded to the profound global changes with the Northern Hemisphere Glaciation (NHG) since the late Pliocene. The Chinese loess provided generous evidence of the EASM evolution history on tectonic and orbital timescales, while the evidence from lacustrine-fluvial deposits, sensitive to hydrological changes, has remained rare. Here we provide a sedimentary record of lacustrine-fluvial deposits through late Pliocene to the early Pleistocene from the Datong Basin in the northern EAM region, providing independent evidence of the EASM revolution.

The depocenter site experienced through an offshore lake during 3.6-2.7 Ma, alternative lacustrine and alluvial plain during 2.7-1.8 Ma to alluvial plain after 1.8 Ma, mainly reflecting hydrological variations in the basin. Grain size analysis were conducted with the End-Member decomposition. The (EM1+EM2)% (mode size of 4.2 and 10.8μm) was employed as the indicator of low-energy suspended load during the offshore stage and a background hydrology originate from intervals between unsteady upper flow regimes during the alluvial stage, and thus reverse to the hydrological energy. Considering its general negative correlation with color reflectance a* and κfd on orbital time scale during the alluvial stage, the finer fraction (EM1+EM2)% could thus be used as a proxy of EASM precipitation variations.

On orbital time scale, spectral analysis and ensemble empirical mode decomposition (EEMD) of the (EM1+EM2)% reveal the highest variance of obliquity component during the late Pliocene with subordinate precession and eccentricity-like components. During the early Pleistocene, the eccentricity-like component significantly increased compared with that in late Pliocene. This features are identical to records from the Chinese Loess Plateau, while distinct to enhanced and dominant obliquity cycle in global ice volume recorded in LR04. We propose EASM variations on the glacial-interglacial cycles enhanced significantly responded to the NHG across ~2.7 Ma, which disturbed potential meridional insolation gradient forcing of ~40 ka in the late Pliocene. In addition, the enhanced eccentricity-like cyclicity during 2.7-1.8 Ma compared with 3.6-2.7 Ma and even 1.8-1.2 Ma demonstrated that the ice volume explanation of ~100 ka periodicity during mid Pleistocene could not be directly extended to early Pleistocene and before.

Simulated Air-Ocean interaction in the western North Pacific since the Last Glacial Maximum

1. Chungnam National University, 2. Korea Institute of Ocean Science and Technology

1. The Kuroshio Current affects the modern sea level and brings warm and salty water to the marginal seas of the midlatitude East Asia. Since the Last Glacial Maximum (LGM), while the proxy data suggest the subarctic control in the Kuroshio Extension (KE) region during cold intervals, it is not yet clear what specific role played by air-ocean interaction in the vicinity of the western boundary current most efficiently caused such distinction from the present condition.
2. Here, we examine the simulated air-ocean coupled variability in the Kuroshio and the Extension region during the LGM and the mid-Holocene using Paleo Model Inter-comparison Project 4 data archives.
3. Especially, the variability in the meridional location and axis orientation of the north hemispheric Westerly jet associated with the paleo-Arctic Oscillation under such contrasting mean states across the multi model simulations. In addition, for selected models with high enough temporal resolution outputs, storm track activity is analyzed for the two different climate periods in comparison with the present.
4. Finally, the mean and the variability of the simulated Kuroshio with different models are assessed for the contrast under both the LGM and the mid-Holocene climates.

Drivers of Indian vegetation and summer monsoon dynamics during MIS 11

Dr. Dulce Oliveira [1]***, Prof. Philippe Martinez*** [2]***, Dr. Qiuzhen Yin*** [3]***, Dr. Anupama Krishnamurthy*** [4]***, Mr. Srinivasan Prasad*** [4]***, Prof. Ralph Schneider*** [5]***, Dr. Coralie Zorzi*** [2]***, Ms. Charlotte Clément*** [2]***, Mr. Ankur Deb*** [1]***, Dr. Stéphanie Desprat*** [2]

Asian monsoon variations dramatically affect nearly half of the world's population as the ecosystems, agriculture and economy in Asia are intrinsically linked to monsoon rainfall. The Indian Summer Monsoon (ISM) is the dominant Asian summer monsoon subsystem concerning energy flux, being considered as one of the strongest hydrological regimes on Earth. It brings up to 90% of the annual rainfall into the Indian Core Monsoon Zone (CMZ), where the ISM has its most representative expression. Alarmingly, the uncertainty in ISM precipitation projections is still high due to the complexity of simulating its various interconnections. High-fidelity ISM proxy records of past interglacials, warm periods of reduced ice volume as the Holocene, are thus critical to address important questions regarding the role of the primary forcings (insolation, ice volume and CO_2) in driving ISM natural variability.

Based on pollen analysis at IODP Site U1446 strategically retrieved from the CMZ, this study focuses on the Indian monsoon-induced vegetation changes during MIS 11 (425-374 ka), a key analogue of the current interglacial owing to its similar astronomical configurations, higher than present-day sea-level and greenhouse gas-driven climate warming. On orbital timescales, our results show a first major forest phase during the peak of MIS 11 (MIS 11c) followed by two forest phases separated by open vegetation periods (MIS 11b-a) indicating a shift to drier conditions due to reduced ISM. The forest maximum development occurs during the highest insolation level of MIS 11c which reveals the dominant influence of this forcing on the ISM hydroclimate under interglacial conditions, i.e., relatively high sea-level and atmospheric CO_2 concentrations. However, the forest declines during MIS 11b-a while insolation remains high suggest that the insolation forcing is overshadowed by the influence of increasingly large ice caps and lower atmospheric CO_2 concentrations, as well as the interaction of orbital and millennial scale variability. Our results highlight, therefore, the complex interplay between the forcings in driving hydroclimate and vegetation change under the distinct boundary conditions of MIS 11.

Mass contributions to the early onset of post-industrial sea-level rise from ice sheets and glaciers using sea-level constraints and fingerprinting

Dr. Sophie Williams [1], ***Dr. Fiona Hibbert*** [2], ***Dr. Sönke Dangendorf*** [3], ***Dr. Ed Garrett*** [2], ***Dr. Andrew Sole*** [4], ***Prof. Roland Gehrels*** [2]

1. *Durham University,* ***2.*** *University of York,* ***3.*** *Tulane University,* ***4.*** *University of Sheffield*

Quantifying historical contributions to sea level from glaciers and ice sheets can elucidate potential impacts of ice dynamics and ice loss in a warming world. This is vital for assessing the (in)stability of ice sheets and glaciers. However, observational estimates of mass loss from Greenland and Antarctica are scarce before the satellite era (*i.e.* prior to the 1990s), and glacier length records before the early 20th century are also sparse. As an alternative to direct observational methods, we can estimate historical ice-mass changes using numerical modelling by calculating past melt and accumulation rates from ice cores, or by undertaking analysis known as sea-level fingerprinting. Sea-level fingerprinting is based on the principle that when an ice mass melts, the contribution to sea level is not uniform around the globe; rather, a spatial gradient in sea-level change can be identified. To use sea-level fingerprinting over historical timescales, tide-gauge data can be employed. However, little long-term data are available for the Southern Hemisphere prior to ~1900. Therefore, tide-gauge data can be supplemented with high-resolution proxy reconstructions (which use microfossils preserved within sediment cores or coral microatolls as sea-level indicators). To assess the source of significant ice-loss contributions over the 20th century, we first select long-term tide gauge and proxy data (*i.e.*, 100 years+). We then isolate the barystatic component in the records by correcting for sterodynamics and the inverse barometer effect. We use an empirically-constrained optimisation model to identify the combination of sea-level fingerprints that best match the observational data. We find a significant contribution from the Greenland ice sheet over the 20th century, as well as from glaciers in Alaska, the Russian Arctic, North America and Asia. Furthermore, our results also suggest a significant contribution from the Antarctic ice sheet.

Regional sea-level highstand triggered Holocene ice sheet thinning across coastal Dronning Maud Land, East Antarctica

Dr. Yusuke suganuma [1], ***Dr. Heitaro Kaneda*** [2], ***Mr. Martim Mas e Braga*** [3], ***Dr. Takeshige Ishiwa*** [1], ***Dr. Takushi Koyama*** [4], ***Ms. Jennifer Newall*** [3], ***Dr. Jun'ichi Okuno*** [1], ***Dr. Takashi Obase*** [5], ***Dr. Fuyuki Saito*** [6], ***Dr. Irina Rogozhina*** [7], ***Dr. Jane Lund Andersen*** [8], ***Dr. Moto Kawamata*** [9], ***Dr. Motohiro Hirabayashi*** [1], ***Dr. Nathaniel Lifton*** [10], ***Dr. Ola Fredin*** [7], ***Prof. Jonathan Harbor*** [11], ***Prof. Arjen P Stroeven*** [3], ***Prof. Ayako Abe-Ouchi*** [5]

The East Antarctic Ice Sheet stores a vast amount of fresh water, which makes it the single largest potential contributor to future sea-level rise. However, the lack of well-constrained geological records of past ice sheet changes impedes model validation, hampers mass balance estimates, and inhibits examination of ice loss mechanisms. Here we identify rapid ice-sheet thinning in coastal Dronning Maud Land from Early to Middle Holocene (9,000-5,000 years ago) using a deglacial chronology based on in situ cosmogenic nuclide surface exposure dates from central Dronning Maud Land, in concert with numerical simulations of regional and continental ice-sheet evolution. Regional sea-level changes reproduced from our refined ice-load history show a highstand at 9,000-8,000 years ago. We propose that sea-level rise and a concomitant influx of warmer Circumpolar Deep Water triggered ice shelf breakup via the marine ice sheet instability mechanism, which led to rapid thinning of upstream coastal ice sheet sectors.

Discussion on early Holocene relative sea-level changes on the central east coast of the Yellow Sea

Dr. Dong-Yoon Yang [1]***, Dr. Min Han*** [2]***, Dr. Hyun Ho Yoon*** [2]***, Dr. Ara Cho*** [1]***, Dr. Jin Cheul Kim*** [2]***, Prof. Eunseo Choi*** [3]***, Prof. Kaoru Kashima*** [4]

1. *Korea Institute of Geoscience and Mineral Resources,* ***2.*** *Korea Institute of Geoscience and Mineral Resources (KIGAM),* ***3.*** *the University of Memphis,* ***4.*** *Kyushu University*

Paleo-relative sea level (paleo-RSL) records are lacking in far-filed of the Pacific coast, particularly the Yellow Sea in Northeast Asia. So far, there have been few research data indicating the beginning of the early Holocene transgression using basal peat on the east coast of the Yellow Sea. The early Holocene transgression data based on basal peat excavated from the study area will be of great significance in that it compares the beginning of transgression between the study site and other areas. We compared the early Holocene RSL history on the central east coast of the Yellow Sea with those of Bohai Bay, the northernmost point, and Gunsan Bay, south of the study area. A multi-proxy approach, including lithostratigraphy, biostratigraphy, combined with radiocarbon and OSL dating, facilitated the generation of 28 sea level index points (SLIPs) using 11 borehole samples. Excavation of basal peat of the 10.3 ka in the study area established that the observed RSL of the transgression in the early Holocene was − 14.88 m, which was much shallower than − 27.9 m in Gunsan Bay at 9.8 ka and was similar to − 17.3 m in Bohai Bay at 9.7 ka. The differences between the observed RSL of the study area and other two areas should be discussed in the viewpoints of a combination of global (glacio-eustatic) sea-level changes and regional land movement. Therefore, we attempt to compare the observed and the predicted in the site's GIA model, discuss the differences between the site and the other two, and estimate the causes.

Holocene regional subsidence and relative sea-level rise in the Netherlands, based on interpolated coastal plain water table rise

Ms. Kim de Wit [1], ***Prof. Roderik van de Wal*** [1], ***Dr. Kim M. Cohen*** [1]

1. Dept. of Physical Geography, Faculty of Geosciences, Utrecht University

In the Netherlands land subsidence is a major societal problem, caused by both shallow soft soil subsidence (alteration of Holocene strata) and deeper natural subsidence. Isolating the different deeper subsidence components, such as glacio-isostatic adjustment (GIA) and tectono-sedimentary basin loading and sinking, in the total subsidence signal is difficult since these processes act on similar spatial scales and cause similar subsidence rates in the Netherlands. Different methods are used to study the contributions of GIA and tectonic basin loading separately. However, the Holocene rates, the patterns and especially the relative importance of the two processes in the coastal plain are poorly known.

Our aim is to use a data-based approach to reconstruct the contribution of GIA and tectono-sedimentary basin loading and sinking to regional subsidence in the Netherlands during the Holocene using coastal plain water level indicators. We apply a 3D KT-kriging interpolation method (Kriging residuals after applying a Trend function) to our dataset of geological paleo-water level index points (e.g. basal peats) in the Dutch coastal plain (576 observations of X,Y,T and Z), inventoried from many sea-level and inland water table reconstruction studies. The interpolation predicts GW-table elevations on a spatio-temporal grid for given locations X,Y (block averaged at 1x1km) for many moments in time, T (200 yr steps from 10 ka to 1 ka). We use observation-filtering techniques and the outcomes of the trend-fitting part of the interpolation to identify subsidence trends in the RSLR observations. We use kriging of the residuals to resolve further sub-regional patterns (tides, hinterland seepage). The main result of the current research is the ability to produce a data-driven break down of subsidence across the full coastal plain. Additionally, the spatial and Holocene-temporal variance are quantified. Results show that in the Middle Holocene (8-4 ka) a southward reducing GIA subsidence pattern is evident. This reduces in the Late Holocene (2-4 ka), where the remnant GIA signal becomes of equal magnitude as the basin subsidence in the northwest of the Dutch coastal plain. Overall the highest subsidence rates are found in the north east of the country.

Production of postglacial sea-level databases in near, intermediate and far field regions. What are the current limitations?

Prof. Matteo Vacchi [1]

1. *DST, Department for Earth Sciences, University of Pisa (Italy).*

In recent years, efforts were made to create Relative Sea Level (RSL) databases in order to a better framework to understand the primary mechanisms of RSL change since the Last Glacial Maximum (LGM). These databases, assembled following a standardized methodology, were used to investigate the different sources of meltwater influx, to reconstruct the deglacial history of the major ice sheets and to calibrate the glacio-hydro isostatic models.

I report here the results some recent RSL databases compiled in very different geographic and climatic regions: The Ross Sea in Antarctica, the Western Mediterranean Sea and the Atlantic coast of Africa.

I will outline some of the inherent difficulties, and potential solutions to analyse sea-level data in such different depositional environments. In particular, I will discuss problems related with the definition of standardized indicative meaning and the considerable lack of modern analogs for sea-level indicators such as beach deposits of fixed biological indicators. I will further address complexities related to different the material used to radiocarbon date the sea-level proxies. I will then discuss how the application new statistical approach on these newly compiled sea level datasets allowed to: i) improving our understanding of the deglacial history in west Antarctica, ii) define the millennial variability in the sea-level rising rates along the Mediterranean coast; i) constrain both the timing and the magnitude of the isostatic highstand along the western marging of the African continent.

Finally, I will discuss the implications of these results for the patterns of glacio-isostatic adjustment in these regions with a particular focus on the possible explanations of the misfits observed between GIA models and RSL data.

Relative sea level over the past 4000 years in the western Mediterranean Sea

Earth's dynamic response to changes in grounded ice loads drove global scale, geographically variable sea-level fluctuations between glacial and interglacial times. This variability is relatively subtle in the Late Holocene, but an accurate record of pre-industrial sea-level is necessary to place the modern rise in global mean sea level (GMSL) in context relative to natural variability. New results from accurately dated phreatic overgrowths on speleothems that form at sea level in the coastal caves of Mallorca preserve a detailed history of Late Holocene sea level that mirrors GMSL. Our data indicate that sea level stabilized at 0.25 ± 0.11 m (95% confidence) below pre-industrial level at ~3.89 ka. After ~700 years of near-stable conditions, a relatively rapid rise (0.54 mm/year; 95% confidence interval between 0.30 and 0.91 mm/year) to pre-industrial level occurred between 3.26 and 2.84 ka; from 2.84 to 0.07 ka, sea level once again remained stable (within ±0.08 m; 95% confidence) at these sites. Given the tectonic stability of the region, the brief sea-level rise at ~3 ka is best explained by an episode of rapid ice mass flux. As an example, the observed rise can be reconciled by melting of the West Antarctic Ice Sheet equivalent to a GMSL increase of 0.22 m. The observed sea-level history since 3.89 ka is reproduced with a 1D model of glacial isostatic adjustment characterized by a relatively weak upper mantle viscosity of ~10^{20} Pa s with negligible change in ice volumes with the exception of the ~3 ka event. The stability of sea level throughout the Late Holocene, during which there was significant natural climate variability, indicates that the observed GMSL rise of ~3 mm/year over the last few decades cannot be explained by natural climate drivers.

Middle-Late Holocene environmental changes from Malawanna, a coastal wetland in Southwestern Sri Lanka

***Dr. Rathnasiri Premathilake* [1], *Mrs. Nuvanprabha kapugeekiyana* [1], *Dr. Anupama Krishnamurthy* [2], *Mr. Srinivasan Prasad* [2]**

***1.** Postgraduate Institute of Archaeology, University of Kelaniya, **2.** French Institute of Pondicherry*

Radiocarbon dated core at Malawanna was studied through sediment and palynological analysis to reconstruct palaeoenvironment of the coastal wetlands in the Southern Sri Lanka. The palaeoenvironmental changes in coastal wetlands of the study region were caused by changes in sea-level, climate, vegetation, coastal erosion, sedimentation, seawater intrusion and anthropogenic activities during the Mid-Late Holocene. Pollen core data indicate the Early Holocene rapid sea level rise decelerated around 7,600 cal yrs BP developing a brackish water estuarine mangrove forest in the study region. Sea level transgression and regression at six stages occurred between 7,380-1,000 cal yrs BP whereas the period of existence of sea level high stands was longer than that of sea level low stands. The sea level reached its present level at 1,000 cal yrs BP. Typical lowland rainforest pollen proxy indicates the intensifying summer monsoon trend between 7,600-4,500 cal yrs BP, interrupted by the abrupt dry episodes at 7,300 and 5,500 cal yrs BP. The Mid Holocene monsoon weakened until 3,000 cal yrs BP, whereas the most severe dry (arid) climatic condition prevailed between 4,200-3,900 cal yrs BP. The Late Holocene monsoon rains significantly fluctuated, whereas severe monsoon failures occurred between 2,250-1,900; 1,500-1,200 and 500-400 cal yrs BP. Forest cutting, clearance, biomass burning and soil erosion on the coastal plains were associated with cultured lowland rainforest environment between 6,000-4,000 cal yrs BP. Responding to climatic amelioration and sea level low stands, management of the cereal-type plant, e.g., rice cultivation and crops (*Areca* sp. and *Durio* sp.) commenced between 5,600-5,500 cal yrs BP. A climatic shift from humid to severe arid vanished the plant management until 3,600 cal yrs BP. The fluctuation of the Late Holocene monsoon supported the re-establishment of rice cultivation with the appearance of *Cocos* sp. (cf. *nucifera*) in the Southern coastal plains. The rice cultivation was more likely to have increased between 2,250-1,900 and 1,500-1,200 cal yrs BP, whereas the monsoon downturn prevailed.

Holocene relative sea-level database of the mid-Pacific

Ms. Fangyi Tan [1], ***Dr. Nicole Khan*** [2], ***Dr. Tanghua Li*** [3], ***Prof. Aron J. Meltzner*** [4], ***Dr. Jędrzej Majewski*** [1], ***Dr. Niamh Cahill*** [5], ***Mr. Nicholas Chan*** [6], ***Prof. Matteo Vacchi*** [7], ***Prof. Benjamin Horton*** [1]

Holocene relative sea-level (RSL) records from the mid Pacific are useful for inferring ice-equivalent sea-level changes and for constraining glacial isostatic adjustment (GIA) models. However, reconstructions of RSL from the mid-Pacific are hindered by differences in study methods and by the reworking and/or post-depositional lowering of dated material. Here, we present a standardised, quality-controlled database of published RSL data from five island groups in the mid-Pacific: Cook Islands, Tuamotu Islands, Christmas (Kiritimati) Island, Gilbert Islands and Fiji. We critically assessed the RSL data derived from various sea-level indicators (e.g., peat, beachrock, corals) and developed criteria to classify high and low quality RSL data.

We rejected 152 of the 614 data points and reinterpreted 178 sea-level index points (SLIPs) as limiting data. Of the remaining 59 SLIPs, 240 marine limiting and 163 terrestrial limiting data points, ~90% are < 6 ka and ~70% are high-quality. We show that the early- to mid-Holocene evolution of RSL in the mid-Pacific is not as well understood as previously thought and that there is currently no unique solution for a global ice-melting history due to poor constraints of data. For example, while the Fiji data were formerly used to justify the ice-melting histories of GIA models that predict a highstand at ~4 ka, our database cannot preclude alternative highstand timings between ~2.8 ka and ~6.1 ka. We also illustrate how data-quality consideration can influence the choice of best-fitting GIA models by assigning different weights to low-quality data. This study emphasises the need to standardise and critically evaluate the RSL data that are used for GIA model validation.

Common Era relative sea-level changes in Southeast Asia: A new reconstruction from the Matang Mangrove Reserve, Malaysia

Dr. Timothy Shaw [1], ***Prof. Behara Satyanarayana*** [2], ***Dr. Wenshu Yap*** [1], ***Dr. Tanghua Li*** [3], ***Dr. Jędrzej Majewski*** [1], ***Dr. Jennifer Walker*** [4], ***Ms. Yun Fann Toh*** [1], ***Dr. Abang Nugraha*** [1], ***Prof. Mohd Fadzil bin Mohd Akhir*** [2], ***Prof. Benjamin Horton*** [1]

Reconstructions of past relative sea level (RSL) during the Common Era (last 2000 years) have shown a response to natural climate warming and cooling phases such as the Medieval Climate Anomaly and Little Ice Age. Coupled with long-term instrumental measurements from tide gauges, they also showed a timing of emergence in RSL rate centered around the mid-19th century, with a 20th century rise that is extremely likely ($P \geq 0.999$) faster than the proceeding 3000 years. These conclusions, however, are derived from RSL reconstructions and tide-gauge records that currently excludes Southeast Asia and hinders the interpretation of sea-level change and the validation of models that predict future changes and their spatial variability.

Here, we present a new RSL reconstruction using mangrove sediments from the Matang Mangrove Forest Reserve, western Peninsula Malaysia to constrain RSL change during the Common Era. Stratigraphic investigations of the site revealed uniform sedimentary sequences comprising subtidal and intertidal silty clay muds overlain by organic mangrove peats to depths of ~2.5 m. From this we extracted a type core based on quality of preservation of mangrove peat that was surveyed relative to Malaysian geodetic benchmarks. We constrained temporal uncertainties using accelerator mass spectrometry radiocarbon dating of in-situ plant macrofossils and bulk sediment fine-fractions coupled with short-lived radionuclide chronohorizons within a Bayesian age-depth framework. We constrained vertical uncertainties using a modern training set of biological markers from foraminiferal tests in combination with new approaches to confirm their presence or absence in fossil sediments through environmental DNA analyses.

We applied a spatiotemporal empirical hierarchical model to quantify the magnitude and rate of RSL change. We compared the new reconstruction with a compilation of published RSL data from southern Peninsula Malaysia and Singapore that suggested RSL fell ~1m below present between 2 ka and 0.5 ka years before present. Furthermore, we evaluated glacial isostatic adjustment model predictions with the new reconstruction to assess the influence of driving processes of RSL change.

Salt Marsh Microfossil Sea-Level Reconstruction along the South African Coastline using Bayesian Transfer Functions

Dr. Lauren Pretorius [1], ***Dr. Niamh Cahill*** [2], ***Dr. Jemma M. Finch*** [3], ***Prof. Trevor Hill*** [4], ***Dr. Robert Barnett*** [5], ***Dr. Kate Strachan*** [6], ***Mr. Craig Cordier*** [4]

1. Durham University, 2. Maynooth University, 3. School of Agricultural, Earth and Environmental Sciences, University of KwaZulu-Natal, Private Bag X01, Scottsville, 3209, 4. University of KwaZulu-Natal, 5. University of Exeter, 6. ICLEI Africa

To predict future sea-level rise, recent trends need to be examined to provide context regarding short and long-term variability. Sea-level records in South Africa have been generated by a range of proxies spanning from ~ 250 000 yr BP, however these records are discontinuous and lack the resolution needed to disentangle natural variability from anthropogenic climate forcing. SA's far-field location eliminates isostatic effects associated with recent deglaciation, reflecting eustatic sea-level behaviour, thus making it an ideal location for Late Holocene reconstruction. The performance if regional and site-specific Bayesian transfer functions based on modern microfossil data from multiple estuaries are compared for sea-level reconstruction along the southern coastline of SA. Sediment cores are chronologically constrained using Bayesian age-depth models based on AMS radiocarbon and Pb-210 dating. The results of the sea-level reconstructions show higher than present sea level occurring between ~1100 and ~500 Cal yr BP, falling to ~0.6 m lower than present sea level at ~ 500 cal yr BP, followed by a rise to present sea level. Model performance shows similar coverage for both the regional and site-specific models, with the site-specific scoring the lowest root mean squared error. The regional transfer function observed vs predicted values display more noise associated with variability between sites when compared with the site-specific approach. We explore state of art methods in high-resolution sea-level reconstruction to shed light on the optimum balance in precision and prediction power.

Strategy and problems to set up a global relational database for sea-level data

Dr. Volker Klemann [1]***, Mr. Henri Dümpelmann*** [2]***, Mr. Roman Sulzbach*** [3]***, Prof. Frank Lehmkuhl*** [4]

1. *Helmholtz Centre Potsdam, German Research Centre for Geosciences GFZ,* ***2.*** *RWTH Aachen University, FB Geography, Phillips-Universität Marburg,* ***3.*** *Institute for Meteorology, Freie Universität Berlin,* ***4.*** *RWTH Aachen University*

The information provided by sea level index points can be classified to be diverse by means of character and accuracy. Recent standardized compilation strategies for sea level datasets (e.g., HOLSEA or WALIS) result in an increasing number of regional dataset publications.

Glacial isostatic adjustment or paleo-climate modelling demands a global access to such data. Accordingly, datasets have to be combined and unified. Focusing on the HOLSEA compilation, the filling of the respective spread sheets by different groups remains inconsistent beside its detailed documentation (https://www.holsea.org). In most cases, the meaning of specific fields is interpreted differently. One has to keep in mind, the HOLSEA format contains about 80 fields. This impedes to string together the respective datasets directly in order to form a global dataset. Furthermore, research evolves and, so, the number of fields will rise, interpretation of specific information will change and values of specific fields have to be updated regularly.

The HOLSEA compilation covering the last 20,000 years contains already about 6,000 data points, demanding an automatized access as well as update of the data. In order to evaluate this compilation, we have setup a server-based relational database RSL2, in which we first store all datasets in their original form separately and then adapt or combine deviating formats by implementing specific rules or functions. This strategy keeps the process transparently and also allows to update the data routinely, when additional information is provided or the interpretation of specific fields has to be adjusted. Furthermore, we have defined interfaces for recalibration of radiocarbon ages with the most recent IntCal20 calibration curve and for uniform tidal corrections applying the global (palaeo-)tidal model TiME.

In sketching the respective compilation steps, this presentation can be seen as a lessons-learned tour, while setting up this database structure. But most important, the SQL-format allows direct access by analysis and visualization tools, provided that suitable interfaces are programmed. As an example, we could identify a potential late-glacial lake stage of the White Sea, while analyzing indicative ranges due to variations in tidal levels over time.

Reconstructing recent relative sea-level variations using saltmarsh foraminifera in the North Atlantic

Mr. Fermin Alvarez [1]***, Dr. Robin Edwards*** [1]***, Dr. Zoe Roseby*** [1]***, Dr. Gerard McCarthy*** [2]***, Dr. Niamh Cahill*** [2]***, Ms. Maeve Upton*** [2]***, Dr. Andrew Kemp*** [3]

1. *Trinity College Dublin,* ***2.*** *Maynooth University,* ***3.*** *Tufts University*

Sea level rise (SLR) varies in time and space in response to a suite of different controlling mechanisms. Modern-day instrumental measurements of sea level are too short to reliably establish secular rates of SLR and unravel the relative contributions of the processes driving sea level change. The reliable reconstruction of past relative sea-level (RSL), using foraminifera buried in high-saltmarsh sediments, allows us to extend the historic sea level record. This methodology, known as the ‘geological tide gauge technique’ (GTG), allows the development of near continuous high-resolution records of RSL change and a better understanding of the processes driving RSL variations, both in time and space. Due to the spatial bias of recent RSL reconstructions, there remains considerable uncertainty regarding the contribution from regional and local scale processes to spatial and temporal RSL variability, outside of the western Atlantic margin (Kemp et al., 2018). In this study, we apply the saltmarsh based GTG approach in Ireland and Canada, with the aim of reducing the spatial and temporal gap in recent RSL reconstructions. We present new regional training sets of contemporary saltmarsh foraminifera, to quantify the relationship between elevation and foraminiferal assemblage and produce a predictive transfer function for each study area. Individual high resolution RSL reconstructions have been developed for Ireland and Canada by the application of the GTG technique. We finally compare the RSL reconstructions to assess the spatio-temporal evolution of RSL in the North Atlantic and test the relative importance of local, regional and global processes for determining spatial trends.

Historic Relative Sea-Level Rise in South Carolina, USA: How to Get a Grip on Local Subsidence and the Implications for Future Flood Risk

Ms. Madison Fink [1], ***Dr. Till Hanebuth*** [2]

1. Department of Marine Science, Coastal Carolina University, 2. Coastal Carolina University

Along the east coast of the United states, rates of relative sea-level rise vary greatly due to differences in ocean dynamics and local to regional subsidence. Within the southeastern region, there is a gap in accurate and modern data points related to relative sea-level rise between southern North Carolina and Charleston, South Carolina. In this region, lies Myrtle Beach, South Carolina, one of the fastest growing cities in the country and a hot-spot of tourism. The modern rate of relative sea-level rise in this area is significantly faster over the last century (4.6 ± 0.6 mm/yr) compared to Charleston (3.3 mm/yr; 100 km to the south) and Wilmington (2.5 mm/yr; 185 km to the north) due to a current undifferentiated subsidence effect of 2.9 mm/yr in the Winyah region (the region's major estuary). Nuisance and compound flooding have become a common occurrence in the area over the past years. Myrtle Beach experienced 72 hours of nuisance flooding per year in 2001-2015 with a projection of 1,368 hours per year by 2045 (Dahl et al., 2017); Data collected from Georgetown, a low-lying historic city on Winyah Bay, indicated 436 hours of flooding in 2021 with a projection of a majority of the year having daily flooding events by 2040.

The demand is urgent for qualitatively and quantitatively understanding the natural and anthropogenic mechanisms that lead to rising coastal water levels. The three goals of this study are to a) Resolve historic sea-level changes (recent centuries) at inter-decadal resolution; b) Quantify local short-term (decades) and long-term (millennia) subsidence rates (land sinking) by distinguishing the various participating natural and anthropogenic processes; c) Informing and assisting local communities in assessing their current and future flood risk. The study will be conducted using a combination of geodetic, historic, geological, and on-site monitoring approaches. These data will be integrated into a regional framework to examine temporal and spatial variations.

High-Resolution Late Holocene Relative Sea-Level Reconstruction in the Northeastern Gulf of Mexico and Implications to Regional Variability

Mr. Zachary Czoer [1], ***Dr. Zhixiong Shen*** [1], ***Prof. Mead Allison*** [2], ***Prof. Barbara Mauz*** [3]

1. *Coastal Carolina University,* ***2.*** *Tulane University,* ***3.*** *University of Liverpool*

High-resolution stratigraphic studies are important for exploring the spatial and temporal variability of relative sea level (RSL) at centennial to millennial timescales. These studies are rare in the northern Gulf of Mexico (NGOM), where the relative effects of glacial isostatic adjustment (GIA) and sediment isostatic adjustment (SIA) in the Mississippi Delta, and climate change have been debated. This study adds a 3000 yr basal-peat-based RSL reconstruction at St. Vincent Island (SVI), a barrier island in the northeastern GOM where we found around 1.5 m of salt-marsh peat overlaying barrier sand. The above-modern sea-level beach ridges in SVI were used to argue for Holocene RSL high stand in the region. The bases of the peat deposits were surveyed for elevation control through differential leveling and DGPS measurements and dated using ^{14}C and optically stimulated luminescence to create sea-level index points. The new RSL data was also analyzed along with data from published NGOM studies using a spatial-temporal empirical hierarchical model. Preliminary results show that the RSL in our study area increased by around 1.5 m over approximately 3000 yr at an average rate of 0.5 mm/yr. The rate agrees with other regional studies, including those from the Mississippi Delta, confirming that the late Holocene RSL rise in the NGOM is dominated by GIA and that the effect of SIA in the Mississippi Delta is small. Our results also confirm that the beach ridges of SVI and similar high beach ridges in other NGOM sites are not accurate sea-level indicators. Initial results from the hierarchical model show that the regional component of RSL fell from -1000 to 1000 CE, coincident with the southward shift of the ITCZ, suggesting a likely climatic forcing of the RSL signal. Additional data and statistical analysis will be presented in the meeting.

Late-glacial to Holocene relative shore-level data covering the Baltic Sea

The glacial history of the Baltic region is of interest for paleo-climate reconstructions and the sea-level change of this region and its surrounding. One major aspect is the repeated opening and closing of the Baltic Sea since the last glacial maximum. During the different lake stages (Baltic Ice Lake and Ancylus Lake) following the last glacial maximum, the Baltic basin filled up with meltwater of the retreating Fennoscandian ice sheet and so deviated significantly from the global ocean's sea level. Furthermore, variations in relative shore-level height around the respective lake's stage were controlled by the glacial isostatic adjustment of Fennoscandia. The water itself has been transported away continuously through channels or was rapidly drained during catastrophic events, releasing large amounts of freshwater into the oceans. Baltic Ice Lake drained a large amount of fresh water at least twice, lowering the water levels in the Baltic Sea Basin by up to 20 m and 25 m, around 12.9 cal ka BP and 11.7 cal ka BP, respectively. The magnitude of Ancylus Lake up-damming around 10.8-10.0 cal ka BP varies from 20 to 10 m depending on the intensity of the uplift. Submerged rooted pine stumps from Hanö Bay in the southern Baltic at different elevations suggest a rapid lake level rise of ~40 mm/year of the Ancylus Lake. The reconstruction of the lake levels and their dynamics have to be based on RSL indicators for which a respective database has to be built up. Accordingly, we will extend our recently published database of Holocene data covering the Baltic Sea, which already contains a larger amount of shore-level data covering the Ancylus Lake phase. Also, for this compilation, we follow our preferred strategy and store the already published data in an SQL database system in the format given in the original publication. Homogenization, formatting, and additional information will be given by specific rules and will end up in a HOLSEA-consistent format. The results of this compilation will contribute to the PALSEA efforts on sea-level data as well as to the German paleo-climate modeling initiative PalMod.

Dynamics and drivers of fen-bog transitions in northern peatlands

During their development, peatlands commonly transition from wet, nutrient-rich, biodiverse, methane-emitting fens; to drier, nutrient-poor, carbon dioxide-emitting bogs. These changes in wetness and trophic status reflect decreasing hydrological connection between a peatland and local sources of mineral-rich surface-water and shallow groundwater. Such hydro-chemical changes also cause pronounced shifts in plant assemblage along a semi-predictable successional gradient, and are thus identifiable in plant macrofossil records from peat cores. The drivers of fen-bog transitions (FBTs) remain a subject of ongoing research. Spatial patterns in the contemporary distribution of northern fens and bogs have been taken to suggest that climate plays a role in driving FBTs, but other factors such as landscape age and topographic wetness may also be important. We present a two-part analysis that seeks to establish spatiotemporal patterns of FBTs in northern peatlands since the Last Glacial Maximum, and to elucidate the drivers of these trophic changes. Firstly, a reanalysis of more than 100 published plant macrofossil records indicates that the most rapid phase of FBTs in northern peatlands occurred during the late Holocene, between approximately 5 and 2 ka BP. Long-term apparent rates of peat accumulation vary greatly between study sites, but are remarkably consistent between fen and bog phases within sites. We take this to indicate the important role of site-specific hydrotopographic setting in controlling peat accumulation and FBT timing. Secondly, a geospatial analysis reveals that the contemporary distribution of fens and bogs in Canada is related to time since deglaciation and/or drainage of postglacial waters. Bogs are more common in older landscapes in which peat has had longer to accumulate, lifting the growing surface above external hydrological influences, whereas fens are more common in younger landscapes, particularly along the shores of the Hudson and James Bays. Topographic wetness is also important, with fens being more prevalent in poorly drained, down-flow locations. Peatland trophic status is less clearly related to climate, meaning that fen and bog distributions may resist a poleward shift despite ongoing warming.

The long-term development of peatlands in western Amazonian

Ms. Yuwan Wang [1]***, Prof. Angela Gallego-Sala*** [1]***, Prof. Ted Feldpausch*** [1]***, Prof. Patrick Moss*** [2]***, Prof. Hamish McGowan*** [2]***, Dr. Juan Carlos Benavides*** [3]

Most of the currently known intact peatlands for the Amazon Basin are in the western Amazonian region, an area that receives the largest annual precipitation in the basin. These peatlands sequester large amounts of carbon and therefore play an important role in the global carbon cycle. This significant carbon sink region may switch to a major source of greenhouse gas emissions through land-use changes and more frequent drought events associated with anthropogenic climate change. Therefore, improving understanding of the mechanism of peatland development in western Amazonia is becoming increasingly important. The purpose of this project is to use multiple sediment cores from Colombia and Peru to better understand the long-term development of peatlands in western Amazonia during the Holocene, as well as examine how key ecosystem functions such as carbon accumulation have changed over this period. Peatlands are important archives of past environmental change, with ongoing analysis of organic carbon content, palynomorphs, and pyrogenic carbon providing insight into Holocene carbon accumulation rates and vegetation dynamics for this region, as well as the impacts of fire and how peatland development varied spatially within the western Amazonian region. Preliminary results showed that peatlands disconnected from the river channel exhibited smaller variations over time in carbon content and bulk density compared with those under the influence of fluvial activities. Further results are expected to contribute knowledge about current ecosystem resilience and peatland dynamics that will assist with the development of future management of the western Amazonian peatlands

Holocene hydroclimatic and fire dynamics on the southern Cape coast of South Africa - A 7.2 ka multi-biomarker record from the peatland Vankervelsvlei

Mr. Paul Strobel [1], ***Ms. Theresa Henning*** [1], ***Dr. Marcel Bliedtner*** [1], ***Dr. Kelly Kirsten*** [2], ***Ms. Stella Mosher*** [3], ***Ms. Humay Rahimova*** [4], ***Prof. Torsten Haberzettl*** [5], ***Prof. Eva Lehndorff*** [4], ***Dr. Mitchell J. Heisenberg Chair of Physical Geography with Focus on Paleoenvironmental Research, Institute of Geography, Technische Universität Dresden

Fire is a natural phenomenon along South Africa's southern Cape coast during the Holocene, but identifying its climatic drivers has been subject of considerable debate. In this study we investigate hydroclimatic and fire dynamics on a 9.6 m long sediment core from Vankervelsvlei covering the past 7.2 ka. The fen is located near the southern Cape coast at an elevation of 152 m above mean sea level within the year□round rainfall zone of South Africa. For reconstructing hydroclimatic dynamics, we analysed oxygen isotopes from hemicellulose-derived sugars and hydrogen isotopes from leaf wax-derived *n*-alkanes. Coupling both isotopes enables to robustly reconstruct the atmospheric source and seasonality of precipitation as well as local relative humidity. Past trends in fire activity are inferred from macro-charcoal and innovative polycyclic aromatic hydrocarbon (PAH) analyses, the latter serving as fire biomarkers in our study.

Results indicate high fire activity at Vankervelsvlei accompanied by generally moist conditions and a year-round rainfall regime due to contributions of both Westerly-derived winter precipitation and Easterly- and locally-derived summer precipitation from 7.2 to 4.0 ka cal BP. From 4.0 to 2.0 ka cal BP, low fire activity is accompanied by rather dry conditions due to the presence of Westerly-derived winter precipitation but a decrease of Easterly- and locally-derived summer precipitation leading to a shift to a winter rainfall regime. From 2.0 ka cal BP until present day, macro-charcoal and PAH concentrations show diverging patterns, possibly due to the impact of anthropogenic activity, e.g., wildfire control and man-made fires for food production. This period shows variable climatic conditions but moisture is generally increasing due to increasing contributions of both Westerly-derived winter precipitation and Easterly- and locally-derived summer precipitation leading to the presence of a year-round rainfall regime along the southern Cape coast.

Our study highlights that the frequency of El Niño Southern Oscillation is a potential driver of short-term hydroclimatic dynamics, which drives fuel availability and fire activity at Vankervelsvlei during the Holocene. Results from Vankervelsvlei are in line with regional records providing a coherent hydroclimatic and fire picture along South Africa's southern Cape coast.

Recent carbon sink capacity of subtropical peatlands in China

Atmospheric CO_2 concentration has increased substantially and rapidly since the industrial revolution, resulting in global warming. Mitigating global warming and achieving carbon neutrality is therefore a topical issue for many communities. Peatlands are globally important carbon stocks, and have the great potential of either cooling or warming the climate. However, compared to high-latitude peatlands, the low-latitude peatlands have received little attention and are currently poorly understood. In this study, we investigated and sampled different subtropical peatlands along an 1800 km transect in southern China. We found very diverse conditions of subtropical peatlands, e.g., newly appearance of *Sphagnum* patches at one site and increasing bamboo dominance due to drying at another site. We are currently studying the recent changes in peat carbon accumulation over the past *ca.* 300 years using multiple dating approaches and peat property analysis. We will also measure modern carbon fluxes in these peatlands. Together, our results will provide valuable insights into the recent and also future peatland carbon sink capacity in the subtropics.

Palaeoecological reconstruction of 2000 year-long history of Sphagnum peatland development in the context of the transition from a mixed forest to a pine plantation

Mr. Mariusz Bak [1], ***Prof. Mariusz Lamentowicz*** [2], ***Prof. Piotr Kołaczek*** [2], ***Ms. Daria Wochal*** [1], ***Mr. Patryk Fiutek*** [2], ***Dr. Michał Jakubowicz*** [3], ***Prof. Katarzyna Marcisz*** [2]

The *Sphagnum*-dominated peatlands are very sensitive not only to global climate change but also to local human activities. Therefore, they are suitable for palaeoecological reconstructions. A particular case of anthropogenic changes that influence peatland functioning is a change in the forest composition related to planned forest management, for example, from mixed forests or open areas to plantations/monocultures. Based on multi-proxy analyses, it is possible to trace the history of the development of peatlands and their nearest surroundings, both locally and extra-locally. In this study, we analyzed a peat core from the Miały peatland, surrounded by a pine (*Pinus sylvestris*) plantation – the Noteć Forest (NE Poland). The main objective is to trace the local history of the peatland's development over the past 2,000 years, with particular emphasis on the period associated with the transition from mixed forests to pine monoculture, focusing on how forest management impacted the vegetation and hydrological conditions of the peatland. In addition, we investigate the response of the peatland to extreme events, including fires and insect outbreaks. Our reconstruction is based on a high-resolution multi-proxy approach, including pollen, plant macrofossils, charcoal and testate amoebae. We also use neodymium isotopes to reconstruct possible inputs of mineral matter associated with human activity in the area. Our results show that the introduction of planned forestry and pine monoculture planting led to substantial changes in the composition of peatland vegetation in favor of mosses. That dramatic change caused significant fluctuations in the depth of the water table in the peatland. We are testing the hypothesis that pine afforestation affects peatland acidity, trophic state and hydrology. The results of the study are essential for forest ecology and forest management in the temperate climate of Central and Eastern Europe. Furthermore, we want to underline the significance and importance of ecosystem services of wetlands for forest ecosystems and sustainable forestry.

Study financed by the National Science Centre, Poland, grant no. 2020/39/D/ST10/00641.

Signature and ecological consequences of abrupt climate change in northeastern China: A multiproxy-based investigation of the Younger Dryas

Dr. Nannan Li [1]***, Prof. Dongmei Jie*** [2]

1. Xiamen University, 2. Northeast Normal University

During the rapid deglaciation period, temperatures in the Northern Hemisphere suddenly returned to near-glacial conditions (average temperature decrease of about 3°C). This near-glacial period is called the Younger Dryas (12,900 to 11,600 cal. yr BP). Plenty of geological evidence exist around the Atlantic region that recorded this abrupt climate shift. However, the timing and amplitude of the YD and its potential impacts on terrestrial ecosystems are still in great dispute, particularly in East Asia. Current results even point to contrasting 'wet vs. dry' conditions. Information about the hydroclimatic conditions in East Asia during the YD and its impacts on terrestrial ecosystems will improve our understanding of abrupt climate shifts in particular their global impact. Such information, however, is still lacking. This knowledge gap results from the absence of suitable proxies that can reconstruct past hydroclimate parameters quantitatively, and the absence of absolutely dated vegetation records. In this study, we focused on a peatland located in northeastern China and used cutting-edge compound-specific hydrogen isotope analyses to quantitatively reconstruct the hydroclimate conditions during the YD. The reconstructed hydroclimate sequence was compared to the pollen-inferred vegetation history, to evaluate the response of regional vegetation to abrupt climate shifts. In addition, the multiple proxy dataset obtained from the investigated peatland, such as TOC content, $\delta^{13}C$ of bulk organic matters, metal element concentration, and biomarkers, will help generate the influence of abrupt climate change on terrestrial ecosystems. These detailed palaeoenvironmental and palaeovegetation reconstructions at geographically spread study sites combined with reliable correlations between them would be used to shed light on the challenging problems concerning the hydroclimate conditions during the YD and its influences on vegetation succession, and inform models that will be used to predict the response of vegetation dynamics to future climate anomaly in monsoonal Asia.

Centennial-scale habitat change in European high-latitude peatland vegetation towards Sphagnum dominance

High-latitude peatland vegetation and consequent carbon dynamics are under a change as Arctic areas are warming at least double the rate of the global average. Permafrost thawing is an ongoing process in high-latitude peatlands and changes in peatland hydrology are expected due to both thawing permafrost and increased evapotranspiration. Hydrological conditions are a key for the prevalence and compositions of peatland vegetation that drives carbon dynamics. Both of these are expected to change, leading to uncertainty in future peatland carbon budgets.

We have compiled a comprehensive set of 33 peat records from 16 high-latitude peatlands in Fennoscandia and European Russia and reconstructed the changes in vegetation compositions over time. Our data covers the past two millennia and a special focus is on the recent centuries. Records collected from permafrost mounds (6 records) showed a vegetation change from sedges to dry vegetation reflecting permafrost aggradation. We show a habitat change pattern where intermediate microhabitats of permafrost (17 records) and non-permafrost (4 records) peatlands have undergone a change from wet indicating sedge dominated vegetation to the current Sphagnum moss dominated drier conditions. Sphagnum mosses are connected to higher peat and carbon accumulation rates and thus this habitat change may have a significant effect on carbon sink capacity of high-latitude peatlands, if this process is amplified by climate change.

Postglacial climate and wetness changes in the Linje mire, Poland (Central Europe)

***Ms. Eliise Kara* [1], Dr. Leeli Amon [1], Mr. Patryk Fiutek [2], Dr. Karolina Leszczyńska [3], Prof. Katarzyna Marcisz [3], Prof. Piotr Kołaczek [3], Dr. Monika Karpińska-Kołaczek [3], Prof. Michał Słowiński [4], Prof. Siim Veski [5], Prof. Friederike Wagner-Cremer [6], Dr. Dmitri Mauquoy [7], Prof. Mariusz Lamentowicz [3]**

Palaeoecological methods are a practical approach to understand past climate change impacts on the environment and biota. Peatland archives represent excellent resources for high-resolution paleoclimate studies due to their ombrotrophic nature. Plants and testate amoebae are two proxies of the biota that differ in their response speed to water-table changes. A multi-proxy analysis of vegetation and testate amoebae assemblage dynamics gives a broader understanding of past climate-driven mire surface wetness changes.

Linje mire is a protected peatland located in northern Poland, near the city of Bydgoszcz. The vegetation on Linje mire indicates a poor fen, but areas of ombrotrophic vegetation are present in the centre of the site, from where a 12 m length peat core was extracted. In addition to hosting several experimental research projects, the site is the only remaining *Betula nana* habitat in the Polish lowlands.

The 12 m core recovered from Linje mire has an extensive ^{14}C and tephra chronology, thus providing a palaeoecological record from the Late Glacial until the present. To date, Linje mire is the only site in Poland, where the existence of a stable peat bog is confirmed for such a long time. Testate amoebae analysis has already been performed at 5 cm resolution and has been used to reconstruct palaeohydrological conditions at the site. These results will complement plant macrofossil, pollen, non-pollen palynomorphs, charcoal and microphenological analyses of subfossil dwarf birch leaves. This multi-proxy approach will be used to reconstruct past vegetation and mire surface wetness changes at a local scale and track climate change as well as human impacts on the peatland ecosystem. Moreover, microphenological analysis of subfossil *Betula nana* leaves will provide insight into the spring seasonality changes of the Holocene period.

Expanding boreal peatlands – case studies from Finland

Dr. Minna Väliranta [1]***, Mr. Teemu Juselius-Rajamäki*** [1]***, Prof. Atte Korhola*** [1]***, Dr. Sanna Piilo*** [1]

1. *Environmental Change Research Unit (ECRU), Ecosystems, Environment Research Programme, University of Helsinki, Finland*

Under the present climate crisis, it is crucial that all factors contributing to the global carbon cycle are profoundly understood. In this cycle, peatlands play a major role, but their current spatial dynamics – especially regarding the expansion of peatland margins and development of new peat patches – have been overlooked. We studied the lateral expansion of Finnish peatlands over the last decades and centuries by means of radiometric dating of the basal peat of the peatland margins. In addition, mineral substrate and landscape features, including terrain topography and slope, were studied using sedimentological and remote sensing techniques to analyse possible causes and constrains for the lateral expansion.

Our results show that lateral expansion is still occurring all around in Finland. However, the spatiotemporal patterns vary even within the same peatland. Five out of six studied peatlands indicate substantial areal expansion during the last 150 years. On these sites, the peatland margins have expanded from the center of the peatland towards the edges in chronological order. In two other cases, the lateral expansion data were more complex.

In short, our new finds reveal that under current climate conditions new long-term carbon sinks and pools are emerging. Our results further show that the long-held view, according to which all the topographically suitable areas for lateral expansion are already covered by peat, is not valid. The lateral expansion is still an on-going process that is, in addition to carbon cycling, affecting the boreal landscapes and ecology in multiple ways.

Climatic and hydrological controls on peatland accumulation rates

Prof. Graeme Swindles [1]

1. *Geography, School of Natural and Built Environment, Queen's University Belfast, Belfast, UK*

Peat accumulates when there is a positive mass balance between plant productivity inputs and litter/peat decomposition losses. Here we examine the peat accumulation rates from 28 well-dated European peatlands. Peat accumulation rates range between 0.005 and 0.448 cm yr^{-1} (mean = 0.118 cm yr^{-1}). Our work provides important context for the commonplace assertion (of unknown origin) that peatlands grow vertically at ~1mm yr^{-1}. We find that summer temperature is the strongest control on the site average and highest recorded accumulation rates across our European sites. Peatland accumulation rates tend to also be higher when water-table (reconstructed from testate amoeba subfossils) is within the 5-10 cm range. When a Gaussian response curve is fitted to the data, the optimal water-table depth for greatest peat accumulation is ~10 cm. Peat accumulation rates appear to be generally lower when water table depths are <0 cm (standing water) or >25 cm, which may relate to a decrease in plant productivity and increased decomposition losses, respectively. These findings corroborate previous experimental studies which examined the relationship between peatland water-table depth, or the thickness of the aerobic surface layer (the 'acrotelm'), and the rate of peat formation. Our work suggests that an average water-table depth of around 10 cm is optimal to enable rapid peat growth and therefore carbon sequestration in the long term, which supports current experimental studies and informs targets set in peatland restoration and rewetting projects, as awareness of the peatland carbon stock's vulnerability to climate change continues to grow.

Quantitative analyses of testate amoebae as a potential bioindicator of chromium contamination in peatlands

Ms. Anne Nguyen [1], ***Dr. Josué Jautzy*** [2], ***Dr. Joëlle Marion*** [2], ***Dr. Eleanor Berryman*** [3], ***Dr. Nicole Sanderson*** [4], ***Dr. William Shotyk*** [5], ***Prof. Tim Patterson*** [6], ***Dr. Jennifer M. Galloway*** [2]

1. *Ottawa-Carleton Geoscience Centre and Department of Earth Sciences,,* ***2.*** *Geological Survey of Canada, Natural Resources Canada,* ***3.*** *CanmetMINING, Natural Resources Canada,* ***4.*** *Département de Géographie, Université du Québec à Montréal,* ***5.*** *Department of Renewable Resources, University of Alberta,* ***6.*** *Department of Earth Sciences, Carleton University*

The largest peatland complex of Canada and the second largest contiguous wetland in the world, the Hudson Bay Lowlands (HBL), spans the northern regions of Manitoba, Ontario and Québec. Large chromite deposits are situated in this highly sensitive environment, which are targeted for mining of critical metals, i.e., chromium. Chromium (Cr) is a common environmental contaminant, predominantly found in aquatic ecosystems as Cr(III) and Cr(VI). Cr(III) is more abundant and is largely immobile precipitated or adsorbed onto mineral, although it can be mobilized by forming complexes with dissolved organic carbon. Conversely, the genotoxic carcinogenic Cr(VI) is mobile in natural waters where reducing materials are limited and can occur as a result of erosion/weathering of chromium deposits or, more commonly, from industrial pollution. The potential fate and impact of Cr in the HBL is currently unknown.

Using pre-mining site in northern Quebec, Ménarik Lake, this study aims to assess natural Cr background and its fate in a typical northern boreal environment. The mobility of Cr due to natural weathering, changes to water table depth, changes in lake sediment redox transition zone, and forest fires will be evaluated using peat natural archives. In particular, testate amoebae, a biological indicator sensitive to climatic and ecological change, will be investigated alongside a comparison of metalloid profiles. Testate amoebae have been extensively used to reconstruct water table depth and have also been shown to be a viable bioindicator for certain metalloid contamination.

The main objectives of this study are to: 1) quantify testate amoebae assemblages in the pre-mining site, 2) develop a transfer function to reconstruct water table depth, 3) determine if testate amoebae can be used as a bioindicator for Cr contamination through multivariate and ordination techniques in conjunction with metalloid concentration data. This will improve our understanding of how the mobility of metals and metalloids are affected in wetlands as they respond to changes in climate and anthropogenic stresses.

Long-term changes in Carbon accumulation in mountain peatbogs in the South-West of Norway

Mr. Christian Hans Quintana Zagaceta [1], *Prof. Anne Bjune* [2], *Dr. Alistair Seddon* [2], *Prof. Hanna Lee* [3]

1. Department of Biological Sciences, University of Bergen and Bjerknes Centre for Climate Research, Bergen, Norway, 2. University of Bergen, 3. Norwegian University of Science and Technology

There is relevant research on temporal carbon accumulation changes, mostly in arctic permafrost peatlands in Norway, but little is known about the differences and comparisons with more oceanic and lower latitude peatlands in the region, where rainfall is one of the main climatic drivers. Climate projections in Norway for 2031-2060 and 2071-2100 show a rise in mean temperature and an increase of annual rainfall with more intense seasonal events in western, eastern, and northern parts. Under this rationale, this study hypothesizes that temporal variability of temperature and precipitation during the Holocene led to weaker and stronger evapotranspiration and moisture signals affecting local and regional vegetation in peatland ecosystems, water-table changes, and carbon accumulation capacity. This study will contribute to the generation of evidence of the roles and interactions of hydrology, temperature, vegetation, and land use changes on peatbogs carbon accumulation capacity during the Holocene. It will help to disentangle the responses of the carbon budget at different time scales. Methods involve the use of a set of proxies such as pollen, testate amoeba, LOI and bulk density to reconstruct the peat composition rate, organic matter, water table, and local (and regional) vegetation. A generation of an age-depth model and further multivariate analysis will allow to investigate the relationship between the proxies and carbon accumulation rate over the Holocene to further understand the temperature/precipitation correlation and the effects of a changing climate on the carbon budget.

Keeping above the waves? The response of coastal freshwater peatlands to sea-level rise

Ms. Madeleine Timmins [1], ***Dr. Tom Roland*** [1], ***Prof. Dan Charman*** [1], ***Dr. Matthew Palmer*** [2], ***Dr. Natasha Barlow*** [3], ***Dr. Alice Milner*** [4], ***Prof. Andy Baird*** [5]

***1.** Geography, Faculty of Environment, Science and Economy, University of Exeter, UK,* ***2.** Met Office Hadley Centre, Exeter, UK,* ***3.** School of Earth and Environment, University of Leeds,* ***4.** Department of Geography, Royal Holloway University of London, London, United Kingdom,* ***5.** School of Geography, University of Leeds, Leeds, UK*

Global mean sea-level rise is occurring at an increasing rate, and is projected to continue under all future emissions scenarios. With high emissions, we cannot rule out a rise of 15 m at 2300 (IPCC AR6, 2021). Understanding coastal responses to sea-level rise is a priority for policymakers and land managers, especially as the influence of coastal processes is likely to extend further inland with rising seas. Much previous work has addressed the impacts of sea-level rise on saltwater wetland ecosystems, such as saltmarshes and mangroves, but less attention has been given to freshwater systems such as peatlands which occupy equally vulnerable spaces.

Peatlands are significant ecosystem service providers: they store at least twice as much carbon as forests, attenuate floods, improve water quality, and enhance biodiversity (Loisel *et al.*, 2020). Will rising seas threaten the survival of these systems? Or will they adapt to or keep pace with this environmental change?

This PhD project takes a past-present-future approach, combining peatland palaeoecology, contemporary ecohydrological monitoring and future-facing sea-level projection modelling approaches. Here I present Holocene-age multi-proxy palaeoecological reconstructions (testate amoebae, diatoms, LOI) used to investigate what past sea-level rise has meant for peatland function at two key UK sites: Cors Fochno, a raised bog on the Welsh coast, and Wheatfen, a floodplain fen in Norfolk.

Depressions occurring in landslides initially tend to fill up with water, and subsequently with organic deposits, transforming in that way into landslide fens. The delivery of allochthonous material to these fens during intense rainfalls (generated slopewash processes) causes the peat to be intercalated with horizons of mineral sediments. Multiproxy analyzes of landslide fen deposits based on lithological, palynological and non-pollen palynomorphs (NPPs) analyzes, as well as Cladocera, diatoms, geochemical, and dendrochronological studies of subfossil wood, allow for the reconstruction of palaeoenvironmental changes in the Carpathians during the Late Glacial and Holocene. In the Polish Carpathians, several dozen of landslide fens have been analyzed in detail. The horizons of mineral sediments in peat sequences indicate a particularly strong increase in climate humidity in the Bølling and Allerød interphases of the Late Glacial, at the beginning of Preboreal, at the end of the Boreal Phase and the beginning of the Atlantic Phase, at the transition Atlantic/Subboreal phases, in the middle Subboreal, at the beginning of the Subatlantic phase and during the Little Ice Age.

In the upper parts of these fens, mineral covers (0.5-2.0 m thick) have formed. The beginning of their formation was related to the climate moistening during Subboreal and Subatlantic phases. In several fens, sedimentation of mineral covers is continued today, when short-term flooding of peatlands with water during intense rainfall occurs. In two landslide fens, the fluctuation of the water table are monitored instrumentally. The increase in thickness of mineral sediments deposited during single events causing flooding of the fen is highly variable and ranges from a fraction of a half millimeter to 4 cm.

The dendrochronological analysis of a dozen subfossil trunks of fir (*Abies alba*) exhumed from the sediments of the Kaletowa landslide fen in the Beskid Makowski Mts. allowed for the development of a short floating chronology of fir. These results emphasize the high research potential of fens that are sensitive indicators of palaeoenvironmental changes in the Late Glacial and Holocene in the Carpathians.

This study was supported with funds from the National Science Centre (NCN), Poland, grants No. 2017/25/B/ST10/02439 (2018–2022), and 2020/39/O/ST10/03504 (2021-2025).

Multi-Proxy Investigation of the Relationship between a Drying Climate, Peatlands and Human Activity

Mr. James Dill-Russell [1], Dr. Gill Plunkett [1], Prof. Graeme Swindles [2], Prof. Jo Smith [3], Dr. Jonathan Holland [4]

1. Archaeology & Palaeoecology, School of Natural and Built Environment, Queen's University Belfast, 2. Geography, School of Natural and Built Environment, Queen's University Belfast, Belfast, UK, 3. School of Biological Sciences, University of Aberdeen, 4. Agri-Food and Biosciences Institute

As atmospheric CO_2 concentrations continue to increase and contribute to global warming, peatlands are increasingly susceptible to drier conditions. Ombrotrophic peatlands are especially vulnerable to climatic changes, as moisture deficits may limit their ability to form peat and sequester carbon, and increase their vulnerability to fire. With peatlands currently acting as a substantial carbon sink, it is important to understand how peatlands responded to drier climates in the past.

Previous studies have identified a warmer and/or drier climate in Britain and Ireland ca. 6000-5000 BP, providing potential information for future mechanisms of peatland response to climate. This timeframe contains both the Hypsithermal/Neoglacial transition and the Mesolithic-Neolithic transition, which saw a relatively rapid expansion of farming and the first significant woodland clearance in both islands in the earlier part of the millennium. Climate change (cooling) at this time was driven at least in part by a reduction in Northern Hemisphere insolation, but increases in sub-fossilised timbers in Ireland suggest a drier climate from 5400 BP. Paired with the varying impact of land-use change, this period provides information for current trends influenced by anthropogenic change.

There remains, however, a level of uncertainty relating to the climate oscillations and resultant environmental change 6000-5000 BP. Here we present a multi-proxy palaeoenvironmental investigation of peat-cores from Northern Ireland. Core chronology is established through radiocarbon dating and tephrochronology, whilst testate amoebae, pollen influx and stable isotopes (carbon, nitrogen and oxygen) are used as palaeo-hydrology and -climate proxies. Bog system responses to observed changes and carbon capture are examined through plant macrofossil, bulk density, loss-on-ignition and carbon-nitrogen ratio analyses. Palynology is used to infer the importance of anthropogenic influences on vegetation cover in the surrounding catchment, including potential impact on the local water-table, as well as the relationship between changing land-use and climate. Thus, we consider 1) the timing and direction of environmental shifts within Northern Ireland peatland records in the mid-Holocene, 2) the response of the peatlands to climate changes in terms of hydrology, vegetation and carbon accumulation, and 3) how humans contributed or responded to the observed changes through land-use practices.

Impacts of a national road construction on peatland carbon dynamics in the Côte-Nord region, Eastern Canada

Ms. Chloé Giraud [1], ***Prof. Michelle Garneau*** [2]

1. Université du Québec à Montréal, 2. Geotop-Université du Québec à Montréal, Montréal, Canada

The impact of tracks, winter roads or seismic trails on peatlands has been well-documented. Few studies, however, have focused on the impact of permanent and paved roads on peatlands, particularly as northern remote regions are being increasingly connected to road networks.

In this regard, sections of the national road (*Route 138*) in the Côte-Nord region (Québec) have been built since 1959, and the road will be expanded eastward over the next two decades to connect every village along the coast of the Gulf of St-Lawrence to the Labrador border. More than 400 kilometers will be constructed through territory that, in some sections, is densely covered by peatlands.

We aim to document the response of road construction on carbon dynamics in the threatened peatlands using a chronosequence approach. Along 120 kilometers of road, we examine vegetation and hydrological changes, as well as dust inputs and carbon accumulation in peatlands along four segments of different ages (1991, 2005, 2011 and yet to be constructed). During summer 2022, peat monoliths (50 cm, n = 24) were extracted 5, 25 and 100 m from the road along two perpendicular transects in each road segment. An additional 100 cm core was collected at each road segment for comparison with undisturbed conditions (n = 4). Surface vegetation, water table depth, pH and microtopography were documented at each station, and a water level logger was installed to record continuous water table depth variability on either side of the road. Preliminary results show that the hydrology of the peatlands is more impacted on the downstream sections. Loss-on-ignition results from the 24 short cores show important dust peaks at all 5 m plots, particularly downstream, which decrease with increasing distance from the road. At 100 meters, dust is mostly absent within the peat stratigraphy. Further analyses will investigate whether dust inputs have modified peat chemistry, and chronological control (radiocarbon, ^{14}C and radiometric lead-210 dating, ^{210}Pb) will allow for recent peat accumulation reconstructions along with vegetation succession and water table variations using respectively plant macrofossil and testate amoebae analyses.

Peatland records of recent (last ca. 250 years) climate change in the North of Ireland

Prof. Helen Roe [1] ***, Dr. Heidi Rea*** [2] ***, Prof. Graeme Swindles*** [1]

1. *Geography, School of Natural and Built Environment, Queen's University Belfast, Belfast, UK,* ***2.*** *Queen's University Belfast*

The North of Ireland holds great potential for the development of peatland-derived palaeoclimate records, reflecting: (i) the significant cover of ombrotrophic peatlands (>25,000 ha), which are responsive to hydro-climate fluctuations; (ii) the sensitivity of the region to changes in westerly airflow and frontal systems in the North Atlantic region; and (iii) the availability of instrumental records of climate change (>200 yr), which provide a basis for calibration of proxy records. We present hydrological reconstructions from nine ombotrophic peatlands spanning the last ca. 250 years based on testate amoebae, plant macrofossil remains and other proxies. These are chronologically constrained via AMS ^{14}C dating and the presence of a series of well developed tephra layers. The records show a high degree of similarity, especially in the last ca. 100 years, with synchronous changes occurring at all sites. Allogenic controls, notably climate forcing, rather than local internal disturbances, are suggested to be the dominant driver of the inferred hydrological changes. A phase of cool and/or wet conditions predominates from ca. AD 1750 until the late 1800s/early 1900s, probably reflecting the end of the Little Ice Age. Rapid drying is then recorded, and whilst the timing of the onset varies locally, this is prominent at all sites from AD 1940. The testate amoeba-derived hydrological fluctuations are validated through statistical comparisons with instrumental climate datasets. Strong correlations are observed between the hydrological records and summer temperatures, and to a lesser extent summer precipitation, indicating that the interaction of summer seasonal temperature and precipitation have a major influence on peatland-hydrological change in the region. Comparisons with climate proxy-records from elsewhere in NW Europe suggest that the recent drying observed in the region's peatlands is part of a climatic shift with wide spatial extent, although the exact timing shows minor variations.

Mid- to late Holocene mineral deposition and peat decomposition in the Faroe Islands using geochemical proxies: disentangling storm signals from volcanic eruptions

Mr. Andreas Nylund [1], ***Dr. Jenny Sjöström*** [1], ***Prof. Antonio Martínez Cortizas*** [2], ***Dr. Daniel Ellerton*** [3], ***Mrs. Lis E. Mortensen*** [4], ***Prof. Richard Bindler*** [5], ***Dr. Malin Kylander*** [3]

1. *Department of Geological Sciences, Stockholm University, 10691 Stockholm, Sweden,* ***2.*** *University of Santiago de Compostela,* ***3.*** *Stockholm University,* ***4.*** *Faroese Geological Survey (Jarðfeingi),* ***5.*** *Department of Ecology and Environmental Sciences, Umeå University, Umeå, Sweden*

Climate projections the North Atlantic region remains uncertain, as the forcing mechanisms of large-scale climate patterns like the Atlantic Meridional Overturning Circulation (AMOC) and the North Atlantic Oscillation (NAO) on longer time-scales remain to be fully understood. Paleoclimatic studies can decrease this knowledge gap and constrain model projections. An ideal location for such studies are the Faroe Islands, where temperature, precipitation and storminess variation are determined by the AMOC and NAO. With the earliest human settlement set around 6th century CE, the Faroe Islands offer a unique opportunity to reconstruct past climate changes with minimal anthropogenic disturbances. Despite this, terrestrial paleoclimatic reconstructions from the Faroe Islands are few and those that exist are mostly focused on biological proxies. Based on this, there is a need to improve the spatiotemporal coverage and the range of proxies studied at this climatically strategic location. Here, we investigate inorganic climate proxies in a peat core representing the last ~8000 years from the Faroese mire complex of Mýrarnar. Focusing on past variation in peat decomposition and mineral deposition, we analysed for elemental geochemistry (WD-XRF), mineralogy (XRD, SEM-EDS and ATR-FTIR), loss on ignition and bulk density. The degree of peat decomposition, here based on halogen contents and bulk density, generally increases with time. This indicates that the Holocene climate of the Faroe Islands became gradually drier. Eight mineral deposition events are identified by increased lithogenic element and mineral input, with peaks dated to 7790, 5740, 4440, 4130, 3740, 2800, 1960 and 820 cal. yr BP. At least three of these are dominated by tephra deposition and can be linked to known tephra horizons in the Faroe Islands. Whether the remaining events represent volcanic or climatic signals is currently unresolved, with a possibility that tephra dominates the geochemical proxy data. This calls for continued characterization of the mineral deposition events, possibly aided by statistical analysis, that can allow extracting climatic information in areas dominated by volcanic activity.

Developing a new testate amoeba-based hydrological transfer function for permafrost peatlands of Western Siberia

Ms. Agnieszka Halaś [1], ***Prof. Mariusz Lamentowicz*** [2], ***Dr. Dominika Łuców*** [1], ***Prof. Michał Słowiński*** [1]

1. *Department of Past Landscape Dynamics Laboratory, Institute of Geography and Spatial Organization, Polish Academy of Sciences, Warsaw, Poland,* ***2.*** *Climate Change Ecology Research Unit, Faculty of Geographical and Geological Sciences, Adam Mickiewicz University*

Large areas of permafrost peatlands in Western Siberia store a significant amount of carbon on a global scale that is now under threat due to anthropogenic global warming. About 20-60% of frozen soil in Western Siberia is exposed to rapid thawing, which contributes to the destruction of characteristic palsa landscape and the expansion of thermokarst lakes or fens. Permafrost responds variously to environmental changes due to the complex climate-ecosystem interactions driving its formation and degradation. Information about past environmental transitions in Western Siberia is crucial to understand current changes, but knowledge about it still needs to be extended. Therefore, in this study, we aimed to build a hydrological testate amoebae (TA) transfer function (TF) from the Khanymei area to reconstruct past hydrological conditions in permafrost peatlands. Additionally, we wanted to integrate information about TA communities dwelling in lichens with the calibration data set and test their influence on TF performance. In the summer of 2019, 75 surface samples of *Sphagnum*, vascular plants, and lichens (genus *Cladonia* sp.) from the above active layer or permafrost were collected. Moreover, one peat core was extracted from the same area to perform the quantitative depth to the water table (DWT) reconstruction. The transfer function was developed on two datasets: all samples (n=75) and only bryophytes samples (*Sphagnum* and brown mosses) with *Cladonia* sp. excluded (n=55). We were able to confirm that the presence of *Cladonia* sp. lichens on the surface of the peatland affects the typical transition of TA community structure along the microtopographic (wet-dry) gradient. Both developed TFs showed satisfactory results. Even though the TF constructed on all samples performed better, it nevertheless provided a more accurate representation of the current vegetation conditions on the Khanymei peatlands. Lichens (e.g.: *Cladonia* sp.) predominate as a vegetation type and are an essential indicator of the permafrost state. We conclude that TF containing local environment features may be better adapted for the quantitative reconstruction, especially in the newly explored permafrost area of Western Siberia.

Climate-driven ecosystem changes – comparison of boreal peatlands response from Eastern Canada and Western Siberia

Ms. Agnieszka Halaś [1]***, Prof. Michał Słowiński*** [1]***, Dr. Dominika Łuców*** [1]***, Prof. Mariusz Lamentowicz*** [2]***, Prof. Michelle Garneau*** [3]

1. *Department of Past Landscape Dynamics Laboratory, Institute of Geography and Spatial Organization, Polish Academy of Sciences, Warsaw, Poland,* ***2.*** *Climate Change Ecology Research Unit, Faculty of Geographical and Geological Sciences, Adam Mickiewicz University,* ***3.*** *Geotop-Université du Québec à Montréal, Montréal, Canada*

Northern hemisphere peatlands occupy only 2,5% of the land surface but store about 415 +/- 150 Pg C (~21% of global soil C), with the majority accumulated in boreal and subarctic biomes of Canada and Western Siberia. Present-day global warming threatens these huge C stocks, which have been shifting from the current sink to a source for the atmospheric C content. We hypothesize that the magnitude and direction of changes in peatlands differ between regions due to the modifying local and regional hydroclimate conditions. A recent comparative study indicates that the hydrological response pattern of permafrost peatlands to climate warming could be divergent. This study's objective is to compare the response of peatlands located in the discontinuous permafrost zone of Western Siberian (Khanymei region) to peatlands located in the isolated permafrost zone of Eastern Canada (north shore of the Gulf of St. Lawrence). These regions are characterized by different hydroclimatic conditions influencing former permafrost aggradation and current degradation. Processes related to permafrost degradation significantly affect Western Siberian peatlands, which were exposed to the most substantial warming worldwide in the last decade. Along the north shore of the Gulf of St. Lawrence, peatlands are affected by changes in precipitation, seasonal surface freezing, the influence of the Labrador Current, and intense wind exposure. All factors mentioned above are being transformed due to anthropogenic global warming causing widespread changes in these ecosystems and their related C sink capacity. Our study aims to validate our hypothesis that the response of boreal peatlands to ongoing climate change may vary due to regional hydroclimatic conditions.

This research is part of the project founded by the National Science Center of Poland (no. 2019/35/O/ST10/02903) and an internship by the Polish National Agency for Academic Exchange.

Monitoring peatland changes at the Roman site of Magna, Northumberland, UK

Dr. Gillian Taylor [1], ***Dr. Caroline Orr*** [1], ***Dr. Stanislav Selitskiy*** [2], ***Dr. Vladan velisavljevic*** [2], ***Dr. Vitaly Schetinin*** [2]

1. *Teesside University,* ***2.*** *University of Bedfordshire*

The Roman fort of Magna is one of the most well-preserved sites along the Roman frontier in Northumberland. The fort holds a commanding position as the junction between three Roman roads – the Stanegate, Military Way, and Maiden Way – and surveys have indicated that activity there stretched from c.AD 80/85 until the end of the official Roman occupation of Britain c.AD 410.

Magna has an extremely damage peat area, visual changes over the last 20 years have shown the peat is drying and stone work is emerging from the peat. In 2021 a programme of monitoring was initiated at the site, this includes underground sensors being used to collect data such as ground water levels, conductivity, oxidation-reduction potential, pH and soil moisture. Above ground an extensive weather monitoring station was also installed to collected data every 15 minutes. The importance of monitoring and creating prediction models for these conditions especially changes in soil conditions, can impact upon preservation and ultimate degradation of artefacts, losing them to future study.

Assessing the Timing of Shifts in Recent Carbon Accumulation Rates in Eastern Canadian Peatlands

Recent and rapid changes in climate and permafrost thaw are affecting carbon dynamics in high-latitude peatlands. There is growing interest in evaluating the C sink potential of peatlands for conservation as nature-based climate solutions. However, rapid decadal-to centennial-scale changes are poorly understood, in part due to poor dating resolution in surface peat. Here, we evaluate the timing of vegetation shifts and rates of carbon accumulation for the past ~200 years peatlands for 64 cores from boreal and subarctic regions in Québec and Labrador (Eastern Canada). We used classical (Constant Rate of Supply - CRS) and Bayesian (Plum) approaches to model age-depth relationships from lead-210 (^{210}Pb) and radiocarbon (^{14}C) dates. Results highlight the important role of permafrost thaw in altering local peatland hydrological conditions, favouring new peat addition and especially *Sphagnum* growth in subarctic regions. While both models provide similar ages for the last century in complete cores, the CRS model tends to overestimate peat ages compared to Plum prior to ~1900CE. When applying either model, it is important to provide an estimate for the supported ^{210}Pb or the influx, which may be complicated by disturbance. While ^{210}Pb activity profiles are a clear indicator of disturbance in the peat column from permafrost thaw, the addition of independent dating markers (e.g., postbomb ^{14}C dates) is especially important to validate age-depth models. Finally, using Bayesian models also allows for posterior distribution analyses such as proxy data changepoints. The choice of age-depth model and user decisions can have important knock-on effects for interpreting timings of environmental shifts, as well as estimating the order of magnitude of C stocks for policy and conservation purposes.

Sphagnum spore and charcoal co-profiling reveals hydrological conditions and fire activities during the past 2000 years in Daxing'an Mountains, northeast China

Dr. Yiyin Li [1]

1. Peking University

The Daxing'an Mountains are located at the northernmost tip of China. Here, at the end of the East Asian monsoon, scattered a vast expanse of peatland. As an important timber base and a high incidence area of fire in China, however, there is limited research in long-term change of hydrological conditions and fire occurrence in the region. The change of hydrological conditions and fire activities here over the past 2000 years reflects the process of climate change and human activities affecting natural ecosystems, thus will have great significance to predict future ecosystem changes under global warming climate. Using sediment records of *Sphagnum* spore and charcoal from three peatland profiles (PG, TQ, MG), we reconstructed hydrological conditions and fire history in the region during the past 2000 years. Results show that charcoal peak is negatively correlated with *Sphagnum* spore, confirming that drier hydrological conditions help produce frequent fires; in addition, charcoal peak is positively correlated with drought-tolerant pioneer taxa, such as *Pinus*, *Betula* and *Quercus*. Our results also revealed the occurrence of the Medieval Warm Period (MWP, AD 680-1300) and the Little Ice Age (LIA, AD 1300-1900) in the region. Three periods of greater frequency of fire with different hydrological conditions were detected over the past 2000 year: MWP (warm and dry), early LIA (AD 1300-1500) and late LIA (AD 1700-1900) (cold and dry). These more intensive fire activities coincide with the phases of drier hydrological conditions. Fewer fires have been identified in the middle LIA (AD 1500-1700) due to the cold and wet hydrological conditions. Fire frequency has been changed by intensive human activities over the past century.

PEATFLAMES: Identifying tipping points for ecosystem functioning of northern peatlands during the climate crisis

Dr. Luke Andrews [1] ***, Prof. Michał Słowiński*** [2] ***, Mr. Harry Roberts*** [2] ***, Prof. Katarzyna Marcisz*** [3] ***, Prof. Piotr Kołaczek*** [3] ***, Ms. Agnieszka Halaś*** [2] ***, Dr. Dominika Łuców*** [2] ***, Prof. Mariusz Lamentowicz*** [3]

1. *Climate Change Ecology Research Unit, Adam Mickiewicz University,* ***2.*** *Past Landscape Dynamics Laboratory, Institute of Geography and Spatial Organization, Polish Academy of Sciences, Warsaw, Poland,* ***3.*** *Climate Change Ecology Research Unit, Faculty of Geographical and Geological Sciences, Adam Mickiewicz University*

Peatlands currently act as carbon sinks and stores. Still, warmer climate and changing weather patterns due to anthropogenic climate change could cause them to become carbon sources in some regions, exerting a positive feedback upon global climate. Warmer, drier conditions also make peatlands more vulnerable to wildfire, which have increased in frequency and intensity across many peatland-covered areas in the Northern Hemisphere, including permafrost regions. Such events may release vast quantities of formerly stable, ancient carbon over a very short period of time.

How northern peatlands will respond to climate change remains uncertain. This uncertainty has prevented peatlands from being included in many Earth System Models, despite their significance in the global carbon cycle. Understanding how past climate changes and anthropogenic activity have affected peatland ecosystem functioning in the past will allow us to better understand how peatlands may respond to future changes, reducing this uncertainty.

Our project aims to assess how warming, drought and wildfire have impacted the resilience of peatlands and permafrost in the Northern Hemisphere over the past c. 2000 years. Multiple cores taken across a latitudinal gradient spanning several countries across Europe (Poland, the Baltic states and Scandinavia) will be analysed using multiple palaeoecological proxies at high resolution to reconstruct past fire activity, hydrological dynamics and vegetation change. This will allow us to define baselines and threshold values for ecosystem shifts relevant to future projected changes in climate.

Coastal peat records: an exploration of potentials and problems

Using the information contained in the organic matrix as well as the archived mineral content in parallel, we can acquire a continuous picture of past paleoenvironmental changes using peat sequences. Peat sequences from coastal ombrotrophic bogs are increasingly used for reconstructing *storminess* (a term encompassing both frequency and intensity) on centennial to millennial timescales, where greater quantities of coarser grained beach sand are deposited by strong winds during storm events. To date, grain size, ash content, elemental and spectral approaches have all been applied as proxies of increased wind intensities in peat sequences. Coastal environments are however, heterogenous and isolating climate signals in peat deposits can be complicated by e.g., past changes in sea level, dune development as well as landscape morphology and geometry.

To explore the potential impact this has on coastal paleoclimate records we turn to Islay, a small island located on the Scottish west coast. Islay is a perfect natural laboratory for paleoclimate and in particular, paleostorm studies, in that it has abundant coastal dunes and beaches with relatively thick peat deposits located closely downwind (<3 km). We also have the previously published Laphroaig peat paleostorm record, covering the last ~6 ka, available for comparison. We introduce the RSPB (~8 ka) and the Duich (~5 ka) records which have both been analysed for basic peat properties, elemental concentration, grain size and mineralogy as measured using a new mid-infrared spectrometry protocol. We test the coherence of the multi-proxy climate signals both within a single sequence and across the island as a whole by applying changepoint modelling to all three records; this identifies the depth/age of changes in proxies through Bayesian modelling approaches. We attempt to link any observed differences to the individual site settings and tease out controlling factors. We hypothesize that random, analytical and site-specific noise is best dealt with by applying the changepoint modelling. This can in turn be compared with available pollen and dune activity data from the island for a more wholistic paleoclimate reconstruction.

Improved chronology and palaeoecological interpretation derived from peat horizons interbedding the Late Glacial mineral sequence of the Klaklowo landslide fen (the Outer Western Carpathians, Poland)

Mrs. Jolanta Pilch [1], Prof. Włodzimierz Margielewski [1], Prof. Renata Stachowicz-Rybka [2], Mr. Krzysztof Buczek [1], Dr. Katarzyna Korzeń [3], Prof. Valentina Zernitskaya [4]

1. Institute of Nature Conservation, Polish Academy of Sciences , Adama Mickiewicza Ave 33, 31-120 Kraków, Poland, 2. W.Szafer Institute of Botany, Polish Academy of Sciences, Lubicz 46, 31-512 Kraków, Poland, 3. Kazimierza Wielkiego Str. 110/2-3, 30-074 Kraków, 4. Institute of Natural Management, National Academy of Sciences of Belarus, F. Skorynu Str. 10, 20114 Minsk

Klaklowo landslide fen developed within the subscarp depression of the Klaklowo landslide in the Beskid Makowski Mts. (the Outer Western Carpathians, Poland) at the earliest stage of the landslide formation. As a consequence, it possesses the Late Glacial sedimentary sequence of rarely occurring thickness reaching up 2.5 m, which bottom parts allows for dating the onset of landslide formation as well as for reconstructing palaeoenvironmental changes during Bølling and Older Drays climatic oscillations. Improved chronology based on the current AMS radiocarbon dates enabled us to clarify the age of the lowermost organic horizon (decomposed peat) occurring within the mineral sequence at 14,896-14,277 cal BP, which time span corresponds to Bølling climatic oscillation and is in agreement with the pollen data obtained from Klaklowo site.

As inferred from the results of plant macrofossil analysis, the identified zones of different plant taxa fit very well to climatically-conditioned changes in lithology of the sedimentary sequence. During Bølling Interstadial, when a thick interval of clayey silt was deposited, the local conditions were aquatic and poor in vegetation, what is confirmed by occasionally occurring macrofossils of Characeae, *Batrachium* sp. and *Zanichellia palustris*. Enrichment in different, mostly boggy, plant taxa at the depths of both organic horizons intercalating the mineral sequence reflects the process of water reservoir shallowing and vegetation encroachment. The lower peat horizon contains mostly seeds of *Juncus* sp., whereas the upper one, beside the predominating occurrence of *Carex rostrata* along with *Eleocharis palustris* and *Phragmites australis*, documents a slight transition in trophy, as suggested by the presence of oligotrophic *Eriophorum vaginatum* followed by the eutrophic *Urtica dioica* and *Thelypteris palustris*. Second organic horizon is overlaid by the 0.5 m thick Older Dryas mineral sequence, which is abundant in macrofossils of aquatic plants, e.g. Characeae and *Potamogeton* sp., confirming the existence of a permanent waterbody. The gradual overgrowing with sedges, brown mosses and birch, as well as the appearance of *Pinus sylvestris* in the uppermost part of the studied interval signalizes the onset of the Allerød warming.

This study was supported with funds from the National Science Centre, Poland, grant No. 2020/39/O/ST10/03504 (2021–2025).

Quantitative reconstruction of surface wetness between 13.8 and 8.2 cal kyr BP in Hani peatland in the Changbai Mountains, Northeast China

Prof. Hongyan Zhao [1]***, Ms. Jingjing Sun*** [1]***, Prof. Hong-Chun Li*** [2]***, Mr. Guangyuan Xu*** [1]***, Prof. Hongkai Li*** [1]***, Prof. Zhaojun Bu*** [1]***, Prof. Shengzhong Wang*** [1]

1. *Key Laboratory of Geographical Processes and Ecological Security in Changbai Mountains, Ministry of Education, School of Geographical Science, Northeast Normal University, Changchun, Jilin, 130024, China,* ***2.*** *National Taiwan University*

Peatlands are valuable ecosystems owing to their various functions such as storage of carbon, regulation of catchment hydrology, and in particular archives of environmental change. Peatlands began to develop widely since the last deglaciation, when have significant relevance to present climate changes. Quantitative reconstruction of peatland surface wetness changes, which is dominantly controlled by effective precipitation and thus closely associated with climate, has been a priority in Quaternary Science. In this study, we presented a high-resolution (20 years/cm) record of plant macrofossils from Hani peatland in the Changbai Mountains, Northeast China, where climate is mainly controlled by East Asian monsoon. The surface wetness of the peat sequence between 13.8 and 8.2 ka BP was quantitively reconstructed through a plant-based transfer function developed for this region. The reconstructed surface wetness described by depth to water table (DWT) reveal wet phase (DWT ≈ 10 cm) at Allerød period (from ~13.8 to ~12.3 ka BP), dry phase (DWT ≈ 13.2 cm) at YD stage (from ~12.3 to ~11.9 ka BP), a general wetting trend (DWT ranged from 10.3 to 8.0 cm) from ~11.9 to ~0.98 ka BP with a major dry shift (DWT ≈ 15.4 cm) at the stage from ~11.23 to ~11.15 ka BP, followed by an increased dry phase (DWT ≈ 14.1 cm) from ~0.98 to ~0.95 ka BP, and a general wetting trend (DWT ranged from 10.2 to 7.0 cm) from ~0.95 to ~0.82 ka BP. Compared with the climate changes revealed by pollen and stable carbon and oxygen isotopes from the same peatland, the surface wetness of Hani peatland responds well to regional climate change. Reconstructed peatland surface wetness provides an important basis for reconstructing past climate changes in this region, and also gives a reference for predicting mire surface wetness under global climate warming in the future.

A 13.5 ka record of environmental changes derived from Wawerner Bruch fen (Saar valley, SW-Germany)

Mrs. Katrin Geiger [1]***, Dr. Karsten Schittek*** [1]***, Prof. Frank Schaebitz*** [1]

1. *University of Cologne, Institute of Geography Education, Cologne, Germany*

Wawerner Bruch fen (Saar valley, Rhineland-Palatinate, SW-Germany) has formed in an abandoned meander bow of Saar River. Peat cores were retrieved from the central part of the extended peatland and analysed by applying a multi-proxy approach (micro-/macrofossil analyses, XRF, total carbon and total nitrogen measurements).

The beginning of fen peat accumulation is evidenced at ca. 13,400-13,490 cal. BP, during the Older Dryas/ Allerød interstadial. The study focuses on the vegetation and settlement dynamics of the lower Saar valley, an area of exceptional Celtic and Roman history.

During Allerød and Younger Dryas, the fen was dominated by an open vegetation with dominating sedges, replaced by *Salix* towards the end of the Allerød. Local forest vegetation was dominated by cold-tolerant tree species like *Pinus sylvestris*, *Betula* (partly *Betula nana*) and *Salix*. Open landscapes with steppe vegetation were the prevailing vegetation type of this period. Between the Preboreal and the Boreal, the vegetation shifted from boreal Birch-oak-forests to an open woodland with high abundances of hazel. During the Atlantic period, a wetter phase led to the reestablishment of a *Salix* forest-mire within the peatland. From 5000 cal. BP on, alder has begun to show increasing percentages in the pollen record, and the last 4000 years show a stepwise establishment of a prevailing *Alnus* fen. The Romans supposedly cleared the alder forest, but it re-established during the migration period. Until 1000 cal. BP, the pollen data show highly fluctuating percentages in zonal forest vegetation with conspicuous correlations within typical tree species: *Fagus sylvatica*, *Carpinus betulus* and *Corylus avellana*, or *Betula* and *Quercus*. During the Middle Ages, the decline of nearly all tree species, especially *Fagus* is evident, in favour of open-land cultivation. During the Little Ice Age, the agricultural land was continuously used as grassland. In the near past, the construction works of the Saar channelization led to severe drop of the peatlands´ water level. Currently, fallow lands with monotone *Filipendula ulmaria* stands and *Salix* bushland are among maintained sedge reeds, which characterize today the landscape of the Wawerner Bruch.

Two millennia of fire activity: influence of climate and people in a peat-bog from Western Romanian Carpathians

Fire is an episodic phenomenon driven by the interplay between climate, terrain, vegetation (fuel moisture, availability, composition, structure) and human activities. This fine-scale process is a key component in natural ecosystems and has been essential in human evolution and an important tool for anthropogenic land cover. More recently, in the face of current climatic changes, with the increasing fire-promoting conditions combined with increasing human activities (e.g., rural land abandonment, flammable trees), areas such as central and eastern Europe where historically, fires were rare are expected to experience an increase in fire events. Paleofire data allow us to study the trend in fire frequency at different timescales and are necessary to understand better the connection with climate variability and human activities and assess the role of fire in shaping the landscape. The main aim of this study is to assess the past relationship between changes in fire, human activities (mining, pasturing, forest clearance), and climatic variability over the past 2600 years in the mid-elevation landscape of Western Romania. Here, we focus on the Mluha peat sequence located at 1240 m in the Apuseni mountains. We applied a combined approach based on macro- and micro-charcoal counting, pollen analysis, 14C dating, high-resolution geochemistry, archaeological information and climatic (temperature, precipitation) modelled data. Our multi-proxy results show three periods of fire activity, with the first interval between 2600 to 2000 cal yr BP characterised by moderate fire activity. The major fire event registered in our record around 2100 cal yrs BP might have been driven by Dacian populations; likely, they used fire for forest clearance and pastureland management. However, more favourable climatic conditions for fire activity can't be ruled out. During Roman Antiquity-Migration Period, fire activity was relatively low, but the fire events corresponded with a major vegetation reorganisation suggesting that human activities were responsible for setting fires. The Medieval times are outstanding, the intense fire activity is paralleled by the establishment of mountain pastures and large-scale landscape openings, as shown by pollen data, and intensified mining activities, as shown by geochemical records. Our reconstructions provide greater insights into the long- and short-term climate-human-fire relationships.

Antarctic Peninsula peatbank oxygen isotope values during the warmest summer and in the oldest continental profile

Dr. David Beilman [1], ***Dr. Dulcinea Groff*** [2]

1. Department of Geography and Environment, University of Hawaii Manoa, Honolulu, USA, 2. Department of Geology and Geophysics, University of Wyoming

The Antarctic Peninsula region is warming and ice-free areas are expanding, resulting in the re-exposure of dead plants and overall greening with new vegetation. During austral summer 2020, during record-setting warm conditions, we collected snow, water, plant, and peat samples from 15 sites from 62 to 65°S with support from the RV Laurence M Gould. Values of δ^2H and δ^{18}O in late-lying snow and surface waters were similar to local meteoric-water-line values. Plant water, however, showed substantial evaporative enrichment in δ^{18}O, regardless of species. We measured peatbank stratigraphic cellulose δ^{18}O extracted from subfossil leaf tissue of a single plant species at two sites. In the deepest (2m) and oldest (4 ka BP) peatbank south of 61°S, δ^{18}O values varied across a range of 6‰, suggesting previous warm summers with high evaporation, particularly around 2.3 ka. This record extends the peatbank history of terrestrial hydroclimate in the central Antarctic Peninsula region by ~2000 years.

Acoustic and physical properties of the Nakdong River valley and delta sediments

Dr. Gil Young Kim [1], *Dr. Kiju Park* [1], *Dr. Seok-Hwi Hong* [1], *Dr. Gwang-Soo Lee* [1], *Dr. Dong-Geun Yoo* [1], *Mr. Shin Yu* [1]

1. *Korea Institute of Geoscience and Mineral Resoiurces*

The core samples collected from the Nakdong River valley and delta areas were used to characterize acoustic and physical properties in relation to depositional and lithological units. The acoustic and physical properties data were readily classified in good agreement with the depositional units: Units I, II, III, and IV in ascending order. In other words, the variations in the physical properties reflected well the relative characteristics of the depositional units. Overall, Unit I was characterized by high values of the data such as compressional wave velocity (1683 m/s on average), wet bulk density (2.17 g/cm^3 on average), and shear strength (41.2 kPa on average), whereas the porosity of Unit I was the lowest (approximately 35%). Moreover, the physical properties other than grain density reflected well the characteristics of each unit, characterized by gradual change from Unit I to Unit IV. Nevertheless, based on the acoustic and physical property data, the lithology, rather than compaction with burial depth, likely played an important role in the variation of acoustic and physical properties of each unit. These results suggest that the acoustic and physical properties were mainly controlled by depositional processes at the time of deposition. The velocity anisotropies were mostly negative without a significant effect of compaction with burial depth. Nevertheless, the cracks occurring along bedding planes after coring were responsible for low horizontal velocities and negative anisotropies.

First results from two research drill-cores in the former Salzach and Isar-Loisach foreland glacier areas (Bavaria, Southern Germany).

The multinational pan-alpine research project ICDP - DOVE (International Continental Scientific Drilling Program - Drilling Overdeepened Alpine Valleys) currently investigates overdeepened structures in the Northern Alpine Foreland (NAF). This presentation focuses on two depositional structures in the central part of the NAF. The first investigated overdeepened basin presented here is located west of Freilassing and was formed by the former lobe of the Salzach foreland glacier. A 136 m long core (ICDP-5068_4), drilled near Neusillersdorf consists of 117 m of Quaternary sediments on top of 19 m of Flysch bedrock. The Quaternary sediments can be further divided into a base diamicton (117-115 m) overlain by fine-sand/silt sized laminated sediments (115-27 m) that are covered by sandy-gravel/diamicton sediments (27-0 m). The second overdeepened structure discussed here is situated south of Munich and was eroded by the Isar-Loisach foreland glacier. Near the town of Schäftlarn a drill-core (ICDP-5068_3) consisting of 199 m of Quaternary sediments was retrieved. In this case the Molasse bedrock was not reached. The drill-core can be divided into diamicton remnants (198.8-198.5 m) at the base, overlain by silty sand with dropstone presence (198.5-184 m), again overlain by partly laminated silt (184-170 m), fine sand interlayered with silt and dropstones (170-158 m) and partly laminated silt with decreased presence of dropstones (158-115.5 m). The sequence is topped by sandy-silty gravel (115.5-6 m) and a clast supported diamicton (6-0 m) below the surface. We present current results and progress of the multi method analysis of the two drill-cores, including but not limited to, sedimentological and sediment-petrographic analyses, geophysical logging and geochronology based on single grain luminescence dating of potassium-rich feldspar using a pIRIR225 (post infrared, infrared stimulated luminescence @ 225°C) single aliquot regenerative (SAR) dose protocol. The investigated research drill-cores were kindly provided by the Bavarian Environment Agency (LfU).

Are sediments of the glacially overdeepened Tannwald Basin seismically anisotropic?

***Ms. Sarah Beraus** [1]**, Dr. Thomas Burschil** [2]**, Dr. Hermann Buness** [1]**, Dr. Daniel Köhn** [3]**, Mr. Bennet Schuster** [4]**, Dr. David C. Tanner** [1]**, Prof. Thomas Bohlen** [5]**, Prof. Gerald Gabriel** [6]*

Leibniz Institute for Applied Geophysics, Hannover, Germany

Glacially overdeepened valleys / basins were excavated by glaciers below their fluvial base level and filled up by sediments. One such basin in the northern foreland of the European Alps is the Tannwald Basin (ICDP site 5068_1), where three boreholes were drilled that reached the Quaternary base at 153 to 158 m depth. In this environment, fine layering, a preferred depositional direction or the alignment of clasts as well as glaciotectonic shearing and the overdeepening itself through an alignment by load can cause seismic anisotropy, i.e. a directional dependency of wave propagation. Vice versa, seismic anisotropy can be interpreted in terms of sedimentation processes. To investigate the sediments regarding this effect, the boreholes were arranged in an isosceles triangle with N-S and W-E orientation of the two short edges (ca. 30 m length). This setup allows us to study not only polar but also azimuthal anisotropy through a crosshole experiment and an inverse walk-around VSP (vertical seismic profiling).
We investigate the hypothesized anisotropy by means of polarization analysis looking for a phenomenon called shear-wave splitting. For this purpose, we rotate the three-component data into a radial, a transverse and a vertical component using energy maximization. Afterwards, the direction of particle-motion, i.e., polarization, can be depicted by hodograms that indicate anisotropy. For noisier parts of the dataset, we apply more sophisticated methods, like eigenvalue or singular value decomposition. Furthermore, we give an outlook on how the type of anisotropy is determined and its degree quantified by the results of polarization analysis as well as simulation and inversion of the seismic wavefield. As one of the three boreholes was completely cored, the results can be interpreted in terms of the known lithostratigraphy.

ICDP Project DOVE (Drilling Overdeepened Alpine Valleys): The Basadingen Borehole (ICDP 5068_2)

Mr. Sebastian Schaller [1]***, Mr. Bennet Schuster*** [2]***, Ms. Sarah Beraus*** [3]***, Dr. Marius W. Buechi*** [4]***, Mr. Gustav Firla*** [5]***, Mr. Clemens Schmalfuss*** [5]***, Prof. Flavio Anselmetti*** [6]***, Mr. DOVE scientific team*** [1]

1. *University of Bern, Faculty of Science, Institute of Geological Sciences,* ***2.*** *University of Freiburg, Faculty of Environment and Natural Resources, Institute of Earth and Environmental Science,* ***3.*** *Leibniz Institute for Applied Geophysics,* ***4.*** *Institute of Geological Sciences, University of Bern,* ***5.*** *University of Natural Resources and Life Sciences, Vienna, Department of Civil Engineering and Natural Hazards, Institute of Applied Geology,* ***6.*** *Univ. of Bern*

The panalpine project "DOVE" (Drilling Overdeepened Alpine Valleys), co-funded by the International Continental Scientific Drilling Program (ICDP), comprises a series of drill holes into overdeepened glacial troughs around the Alps that were formed by subglacial erosion during past glaciations. The sedimentary fill of these troughs, consisting of multiple stacked and nested glacial sequences, provides promising archives for deciphering when glaciers reached certain parts of the Alpine forelands. The combined data from all DOVE sites comprising synchronous or asynchronous ice advances and ice extents in the different regions, will provide a crucial database for improved understanding of the patterns in glacial-interglacial paleoclimates and landscape evolution during the Mid-Pleistocene.

The overdeepened Basadingen Trough in Northern Switzerland is one of the DOVE targets (5068_2). The area of the overdeepening was glaciated by a western lobe of the Rhine Glacier during several Middle to Late Pleistocene Glacials. The trough is a narrow, ca. 250-300 m deep, SSE-NNW trending structure, forming a so-far poorly understood, old overdeepened valley system that connected the present-day Thur Valley with the Rhine Valley – a connection that does not exist in the present surface morphology and that was probably active only during the Middle Pleistocene. The drill core supports the interpretation of the high-resolution 2-D seismic, which indicates that the valley fill consists of deposits from multiple glaciations, thus, verifying the Basadingen Trough an ideal target for DOVE. Based on the correlation and integration of the various existing data (e.g. 2D seismics, sedimentological description, core-to-seismic correlation, geophysical logs of the borehole and drill core, geotechnical properties, chronological data …), we aim to establish a model for the glaciations that affected the Basadingen Trough and the Northern Alpine foreland in general.

The panalpine project “DOVE” (Drilling Overdeepened Alpine Valleys), co-funded by the International Continental Scientific Drilling Program (ICDP), comprises a series of drill holes into overdeepened and filled glacial troughs proximal to the Alps that were formed by subglacial erosion during past glaciations. The sedimentary fill of these troughs, consisting of multiple stacked and nested glacial sequences, provide promising archives to decipher when glaciers reached certain parts of the Alpine foreland. The combined data from all DOVE sites, comprising synchronous or asynchronous ice advances and ice extents in the various regions, will eventually provide a critical database to evaluate patterns in glacial-interglacial paleoclimates and landscape evolution back to the Mid-Pleistocene.

The Tannwald Basin is an overdeepened bedrock trough in the distal part of the Rhine Glacier landscape north of Lake Constance. Previous drilling and a seismic survey suggest that the Tannwald basin has a maximum depth of 240 m below the actual surface and hosts two generations of glacial infill. For DOVE, one core and two flush drillings on the western flank of the basin have been carried out from April to November 2021 (5068_1A, B, C). All drillings reached bedrock, i.e. Tertiary Molasse, and the core drilling also recovered 10 m of Molasse down to a final depth of 166 m. The cores in the Tannwald basin recovered sediments that show basal diamicts and sands overlain by a 110 m-thick succession of fine deposits with dropstones. These are overlain by 39 m of sands, gravels and coarse grained diamicts. Soft sediment deformation is also observed, which may represent glaciotectonic activity or mass movements. We will present a detailed sedimentological description of the core, which will be combined with 2D seismics, borehole and core geophysics, geotechnical properties, pollen analysis, OSL dating, cosmogenic nuclides dating, and noble gas dating of pore water to constrain the glacial history of the basin.

Drilling in the Baza Paleolake (SE Spain): Understanding Early Human Dispersal in the Western Mediterranean

Long, continuous sedimentary sequences are essential to contextualize hominin fossils and early Paleolithic sites. Both, building a solid chronological framework and exploring the role of environmental forcing in shaping human evolution are fundamental questions that demand such continuous sedimentary records. The eastern part of the Guadix-Baza Basin hosts the largest, southernmost paleolake in Europe and holds an invaluable sedimentary archive for the Plio-Pleistocene period. The paleolake's rich and extensive depositional sequence holds the key to understanding the former gateway between the Atlantic Ocean and Mediterranean Sea (the Betic Corridor) before the early-Pliocene connection at Gibraltar, providing an unprecedented paleoclimatic and paleogeographic record of the region throughout the Cenozoic. Lastly, is the only basin in Western Europe that holds human presence near a continuous fluvio-lacustrine environment. The Baza Formation includes lacustrine–palustrine carbonates and alluvial sediments, and it is known for hosting numerous Plio-Pleistocene paleontological sites, including lithic artifacts. In 2022 we launched a new drilling program for obtaining continuous sedimentary records from this basin, since its deposits are otherwise partially exposed along degraded outcrops. Two complementary boreholes were drilled at the archeo-paleontological site of Barranco León (Orce). The locality is known for containing a significant Oldowan lithic assemblage and a human tooth, in association with a rich and diversified faunal assemblage made of large and small mammal remains. Dated to around 1.4 Ma old, the site documents some of the earliest evidence of human presence in Europe. The drilling resulted in the recovery of ca. 80 meters of continental sediments, including limestones and siltstones belonging to the lacustrine Baza Fm. Core sections are initially passed through a Geotek Multi-Sensor Core Logger that provides a suite of geophysical measurements, including bulk magnetic susceptibility and natural gamma. Cores are then either split or sliced to obtain samples for paleomagnetism, XRF, meteoric ^{10}Be and other analyses (e.g., grain size, carbonate contents, δ^{18}O, pollen, stable isotopes analyses, etc.) in order to characterize the sedimentary record. Our initial results, mostly based on magnetic reversal stratigraphy, provide new constraints to the chronology of the lake sediments and hence to the archaeological site of Barranco León.

Late Pliocene North Atlantic Current temperature records highlight millennial-scale climate variability prior to the Quaternary

Dr. Xiaolei Pang [1], *Dr. Antje Voelker* [2], *Prof. Liping Zhou* [1], *Prof. Xuan Ding* [3]

1. Peking University, 2. Instituto Português do Mar e da Atmosfera, 3. China University of Geosciences (Beijing)

The late Pliocene marks the initiation of the Northern Hemisphere Glaciation (NHG) and major transition from a relatively stable warm climate to more pronounced glacial-interglacial climate variations. The warm, salty water carried poleward by the Gulf Stream and subsequently the North Atlantic Current (NAC) plays a key role in controlling or modulating North Atlantic climate change. Its Pliocene changes are considered to precondition the initiation of the NHG. To evaluate the climatic effects of the NAC changes at the beginning of the late Pliocene, we produced millennial-scale planktonic foraminifers Mg/Ca-derived surface and subsurface water temperature (Mg/Ca-T) records at IODP Site U1313 (41°N, 33°W, 3412m), an ideal location to monitor past NAC changes, for the interval from 3372 to 3654 ka. The Mg/Ca-T of mixed layer species *Globigerinoides ruber*, interpreted as reflecting summer surface water conditions, varies within the narrow range of 20.5–24 ℃ without clear glacial-interglacial cycles. Subsurface water dwelling *Globototalia hirsuta*
exhibits Mg/Ca-T in the 16–19.5 ℃ range, following a pattern similar to *G. ruber*. The temperature difference between these two species is relatively constant with an average of 4.5 ℃. Surprisingly, the Mg/Ca-T record of mixed layer species *G. bulloides*, interpreted as representing spring conditions due to its comparability with the $U^{k'}_{37}$ temperatures, shows large abrupt variations within a wide range between 15℃ and 23 ℃, but also a general trend similar to those of *G.ruber* and *G.hirsuta*. We interpret the intervals where *G.bulloides* Mg/Ca-T shows values similar to *G.ruber* Mg/Ca-T as reflecting reduced seasonality and consistent strong NAC presence at Site U1313. By contrast, intervals of *G.bulloides* Mg/Ca-T reaching values like subsurface species *G. hirsuta* indicate strengthened seasonality and a deepened spring mixed layer. We conclude that the NAC shows prominent oscillations at the beginning of the late Pliocene and the repeatedly weakened NAC periods may have contributed to the fast growth of northern hemisphere ice sheets.

Cyclostratigraphy applied to ICDP downhole logging data: potential and methodological considerations

Dr. Christian Zeeden [1], ***Dr. Arne Ulfers*** [2], ***Dr. Mehrdad Sardar Abadi*** [3], ***Mr. Mathias Vinnepand*** [1], ***Dr. Simona Pierdominici*** [4], ***Dr. Thomas Wonik*** [1]

LIAG, Leibniz Institute for Applied Geophysics, Stilleweg 2, 30655 Hannover, Germany, 4. Helmholtz-Zentrum Potsdam, Deutsches GeoForschungsZentrum GFZ, Potsdam, Germany

Extensive borehole logging datasets have been collected for commercial and scientific purposes, but studies exploring their full potential considering time series analysis are scarce. Even in some ICDP projects, borehole logging data has the potential to contribute relatively fast available proxy data and first age-model constraints. Here, we briefly summarize the key properties of borehole logging data and pitfalls in the context of time series analysis and cyclostratigraphy. We demonstrate its applicability in several case studies. Further, we discuss various methodological/statistical approaches, and provide arguments for analysis beyond cyclical components via Fourier Transform. Especially assessing hierarchical cycle patterns in logging data, and relating these to insolation properties provides strong stratigraphical constraints in some cases.

Evidence for Last Interglacial hydroclimate and vegetation changes in subtropical Southeast Africa from plant leaf wax stable isotope analyses on IODP Site U1477 sediments

Dr. Stefan Lauterbach [1]***, Dr. Nils Andersen*** [1]***, Dr. Thomas Blanz*** [2]***, Dr. Jeroen van der Lubbe*** [3]***, Prof. Ralph Schneider*** [4]

1. *Leibniz Laboratory for Radiometric Dating and Stable Isotope Research, Kiel University, Kiel, Germany,* ***2.*** *Institute of Geosciences, Kiel University, Kiel,* ***3.*** *Cluster Geochemistry & Geology, Department of Earth Sciences, VU University Amsterdam, Amsterdam, The Netherlands,* ***4.*** *Institute of Geosciences, Kiel University, Kiel, Germany*

Future global warming is commonly considered to significantly affect hydroclimate conditions in subtropical Southeast Africa, but the extent of this impact is still debated. Investigating regional hydroclimate variability during warmer-than-present periods in the past such as the Last Interglacial might therefore provide important information about the hydroclimatic response to future warming. In addition, improved knowledge of the region's Last Interglacial hydroclimate can also enhance our understanding of possible controls of the cultural evolution and migration of the first anatomically modern humans. To reconstruct Last Interglacial hydroclimate and vegetation changes in subtropical Southeast Africa, we analysed the stable hydrogen (δ^2H) and carbon isotope composition (δ^{13}C) of long-chain *n*-alkanes preserved in deep-sea sediments recovered at IODP Site U1477, located ~85 km off the Zambezi River delta in the Mozambique Channel. As the δ^2H of the long-chain *n*-alkanes, which are major components of the epicuticular waxes of higher terrestrial plants, primarily reflects amount-controlled changes in the δ^2H of precipitation, it can be used to reconstruct hydroclimate variability in the Zambezi River catchment through time. In addition, the *n*-alkane δ^{13}C allows to trace past hydroclimate-driven vegetation changes, i.e. variations in the relative abundance of C_3 (e.g. trees) and C_4 plants (e.g. savanna grasses). Already during the terminal phase of the Penultimate Glacial we observe a decrease in *n*-alkane δ^2H, indicating increasing humidity in subtropical Southeast Africa. Fairly humid conditions prevailed thereafter, interrupted by two distinct episodes of relatively high δ^2H values at about 125–119 and 105–112 ka BP, most likely reflecting intervals of pronounced dryness. This is in good agreement with parallel reductions of the *n*-alkane concentration in the sediments, indicating reduced supply of terrestrial organic matter by the Zambezi River. After ~105 ka BP, *n*-alkane δ^2H values further decreased, likely reflecting progressively increasing humidity during the transition into the Last Glacial. To conclude, our results document a considerable hydroclimate variability in Southeast Africa across the Last Interglacial with two pronounced dry episodes. These might have been contemporaneous with wet intervals in Northeast Africa, together fostering the episodic northward migration of early modern humans.

New insights into marine ecosystem changes during the early to middle Pleistocene at IODP Site U1387, southern Portuguese margin

Dr. Antje Voelker [1]***, Ms. Aline Mega*** [1]***, Ms. Giulia Molina*** [1]***, Ms. Monica Duque Castaño*** [1]***, Ms. Erin O'Neill*** [2]***, Dr. Samanta Trotta*** [3]***, Prof. Maria Marino*** [3]***, Prof. Patrizia Maiorano*** [3]***, Dr. Emilia Salgueiro*** [1]***, Dr. Teresa Rodrigues*** [4]

Centennial-scale planktonic and benthic foraminifera stable isotope and alkenone sea-surface temperature (SST) records from IODP Site U1387 (36°48´N 7°43´W; 559 m water depth), drilled into the Faro Drift on the southern Portuguese margin, record paleoclimatic changes in this transitional zone between the subtropical North Atlantic and the Mediterranean Sea. With the paleoclimatic framework established for Marine Isotope Stage (MIS) 16 to MIS 52, we are now able to evaluate how the marine ecosystem responded to the paleoenvironmental changes prior to and during the Early to Mid-Pleistocene transition (EMPT). For that we are studying the planktonic and benthic foraminifera fauna as well as the nannofossil flora during selected time periods.

Early Pleistocene interglacial periods prior to the EMPT exhibit warmer SST with the planktonic foraminifera fauna indicating a strong influence of subtropical waters. The common occurrence of tropical species even hints to a persistent contribution of tropical waters and thus the northward expansion of the subtropical gyre. This is supported by higher contributions of warm water taxa to the nannofossil flora. Subtropical gyre influence persisted during the EMPT, but at a reduced level, pointing to a contracted subtropical gyre. Extreme cooling events marking most of the abrupt glacial/interglacial transitions (e.g., MIS 22/21, MIS 26/25, MIS 48/47) were associated with a significant influx of cold-water species *N. pachyderma* and *C. pelagicus ssp. pelagicus*, respectively, and thus a southward advance of subpolar waters. The benthic foraminifera fauna, on the other hand, responded mostly to changes in food flux sources and thus productivity changes in the prevailing surface waters, although short-term response to bottom current velocity increases, e.g. Mediterranean Outflow Water presence, were also recorded.

Deep Dust: Exploiting Dust and Loess Archives in Deep Time to Probe Permian Continental Climate

Quaternary lake and loess deposits are amongst the highest-fidelity archives of continental paleoclimate, and form an excellent target for coring. Analogously, these sediment types should archive high-fidelity records in deep time, albeit less recognized. Here, we present a plan for continuous coring of the thickest suspected loess accumulation in Earth history, spanning the 50 My encompassing both Earth's last icehouse collapse, and largest extinction known.

The climatic, biotic, and tectonic events of the Permian are amongst the most profound in Earth history. Global orogeny leading to Pangaean assembly culminated by middle Permian time, and included multiple orogenic belts in the equatorial Central Pangaean Mountains, from the Variscan-Hercynian system (east) to the Appalachian and Ancestral Rocky Mountains (west). Earth's penultimate global icehouse peaked in the early Permian and largely collapsed soon thereafter, transitioning to full greenhouse conditions by later Permian time, thus archiving the only example of icehouse collapse on a fully vegetated Earth. The Late Paleozoic Icehouse was the longest and most intense glaciation of the Phanerozoic, with hypothesized low-elevation glaciation posited for both eastern and western tropical Pangaea during early Permian time. Reconstructions of atmospheric composition record the lowest CO_2 and highest O_2 levels of the Phanerozoic, with average CO_2 levels comparable to the Quaternary, rapidly warming climate. A global megamonsoon developed and the tropics aridified. Extreme environments are well documented in the form of voluminous dust deposits, acid-saline lakes and groundwaters, extreme continental temperatures and aridity, and major extinctions/extirpations, ultimately culminating at the Permo-Triassic boundary with the largest extinction of Earth history.

We seek to elucidate paleoclimatic conditions and forcings through the Permian at temporal scales ranging from millennial to Milankovitch and beyond by acquiring continuous core in continental lowlands known to harbor complete records dominated by loess and lacustrine strata. Our initial site is in the midcontinental U.S.— the Anadarko Basin (Oklahoma), which harbors a complete continental Permian section from western equatorial Pangaea. We will also address the nature and character of the modern and fossil microbial biosphere, Mars-analog conditions, and exhumation histories of source regions.

Timing and progression of Dansgaard-Oeschger events in Central Europe based on three precisely dated speleothems from Bleßberg Cave, Germany

Ms. Jennifer Klose [1], ***Prof. Denis Scholz*** [1], ***Dr. Michael Weber*** [2], ***Dr. Hubert Vonhof*** [3], ***Dr. Birgit Plessen*** [4], ***Dr. Sebastian Breitenbach*** [5], ***Dr. Norbert Marwan*** [6]

1. *Johannes Gutenberg University Mainz, Institute for Geosciences, Mainz, Germany,* **2.** *Institute for Geosciences, Johannes Gutenberg-University Mainz,* **3.** *Climate Geochemistry, Max Planck Institute for Chemistry, Mainz,* **4.** *GFZ - German Research Centre for Geosciences, Climate Dynamics and Landscape Evolution, Potsdam, Germany,* **5.** *Geography and Environmental Sciences, Northumbria University, Newcastle, UK,* **6.** *Potsdam Institute for Climate Research (PIK)*

Speleothems can be dated with unprecedented precision using U-series disequilibrium methods and provide numerous climate proxies, such as stable oxygen ($\delta^{18}O$) and carbon isotopes ($\delta^{13}C$) or trace elements, resulting in long, sometimes continuous climate proxy records. Therefore, speleothems have great potential for reconstruction of past climate variability during Marine Isotope Stage (MIS) 3 and precise determination of the timing and duration of Dansgaard-Oeschger (D/O) events. While first discovered in Greenland ice cores, various speleothem records around the globe provided clear evidence for the supra-regional character of the D/O events. However, MIS 3 speleothem records from Central Europe are very limited. Here we present three spleothem (flowstone) MIS 3 records from Bleßberg Cave, Germany.

All flowstones show episodic growth with distinctive, partially very thin (<2 mm) growth phases, interrupted by visible hiatuses consisting of detrital material. Precise and accurate $^{230}Th/U$ dating of the individual growth phases is challenging due to potential detrital contamination from these layers. Combining different sampling and analytical techniques, we were able to date even the thinnest growth layers with very high precision, i.e., 2σ-age uncertainties of at most a few hundred years.

The timing of the growth phases aligns with several D/O events, which have not been recorded in other Central European speleothems yet. The $\delta^{18}O$ and $\delta^{13}C$ records of all three flowstones are highly correlated which suggests a dominant process influencing both isotope systems. Comparison with the Sr and Mg records provides evidence for a strong influence of Prior Calcite Precipitation (PCP) in the aquifer above and inside the cave on the stable isotope and trace element signals. In addition, all proxy records are interpreted as evidence for past changes in precipitation and vegetation density and document a clear trend from more humid climate during early MIS 3 (ca. 57 – 50 ka) to less humid conditions during mid and late MIS 3 (ca. 45 – 30 ka).

Our multi-proxy approach thus allows us not only to precisely determine the timing, duration, and progression of several D/O events, but also to deepen our general understanding of climate variability during MIS 3 in Central Europe.

Modelling alluvial peatland development at Holocene timescales

Dr. Ward Swinnen [1], Mr. Alexander James [1], Prof. Gert Verstraeten [1]

1. KU Leuven, Department of Earth and Environmental Sciences, Division of Geography and Tourism

It is well known that accumulation rates in peatlands are higher for short-term measurements, compared to long-term rates based on peat stratigraphy. When looking for effective management practices, insight in peatland dynamics at longer timescales is imperative. Various models have been developed to simulate the long-term dynamics of peatlands and applying such models can be a useful tool to evaluate the interactions between peat growth and environmental changes or management practices. While many of these models assume peat to develop in a geomorphically stable setting, this assumption is not valid for floodplains. For example, many river valleys in Europe have known phases of peat growth throughout the Holocene, influenced by the geomorphic behaviour of the local river channel(s) and associated sediment dynamics. As the effects of the river geomorphology is currently lacking in peatland models, a proper assessment of the relationship between peatland development and river dynamics remains difficult.

Here, we constructed a new peatland model, developed specifically for floodplains, by coupling a modified version of an existing peatland model (Digibog 1D) with a water balance model (STREAM). By combining this new tool with pollen-based land cover and climate reconstructions and reconstructions of the Holocene stratigraphy, detailed simulations of the peatland dynamics were made for several case-studies. This modelling framework allows to study the effect of changes in river network properties on peat growth and the associated carbon dynamics. The model was applied to contrasting case-studies, located in the European loess belt (Dijle river) and sand belt (Grote Nete and Zwarte Beek rivers). The results indicate that river discharge variations as a result of climatic and land cover changes have a limited effect on alluvial peat growth as discharge differences mostly impact the magnitude of peak events. In contrast, the configuration of the local river network (the number of channels and their position relative to the peat surface) have a strong impact on the peat thickness. These results indicate that management focussing on the river network configuration such as reducing the number of channels or raising the river bed can be effective strategies to promote long-term alluvial peat growth.

Arctic peatland carbon dynamics and extent with climate change

The Arctic is warming at more than double the rate of lower latitudes, leading to rapid and widespread ecological change. Arctic peatlands are carbon-rich ecosystems where the net carbon (C) uptake by plants has exceeded losses to microbial decomposition over decades, centuries, or millennia. Permafrost thaw associated with warming exposes previously frozen peat to greater and faster decomposition. However, increasing temperatures will also lead to greater plant productivity and a lengthening of the growing season that may result in greater C accumulation overall and/or an expansion in peatland extent. The potential for increased high-latitude peatland C accumulation is untested and unknown. Quantifying the relationship between recent past climate change and carbon accumulation is crucial to inform models that aim at capturing the response of the Arctic peatland C pool to future climate change. We aim to establish the relationship that climate change has with peatland i) net carbon balance (NCB) and ii) lateral expansion in the Arctic, with focus on two latitudinal transects in Northeastern Canada and the European Arctic. We will fit an ecosystem model to data from peat cores to estimate long-term NCB across multiple sites on our transects. In modelling NCB, we aim to tackle the well-established issue of incomplete decomposition towards the peatland surface associated with using apparent carbon accumulation rate (ACAR) as a metric for recent carbon accumulation history. To assess rates of lateral expansion, we will date peat initiation along transects perpendicular to the margins of existing peatlands. The topography of these transects will be informed by high-resolution contemporary drone data. This work is complemented with a remote sensing study focussing on the same regional transects.

Anthropocene ecological environment changes in high-latitude wetlands of Amur River Basin wetlands

Dr. Wei Xing [1], ***Prof. Kunshan Bao*** [2]

***1.** National Park Research Centre, Sanming University,* ***2.** School of Geopraphy Sciences, South CHina Normal University*

The high-latitude wetlands are quite sensitive to the projected global warming and increased anthropogenic impacts, and are gradually subjected to the hydrological ecological functions' degradation. Therefore, three peat cores were collected from three high-latitude wetlands that they are Tuqiang, Youhao and Honghe wetlands located in the upper, middle and lower streams of Amur River Basin (ARB) in northeast China. These peat cores were dated by 210Pb and 137Cs method. Multi-proxy analysis (Testate amoebae, black carbon and element contents) was used to reconstruct the water level and environmental changes in Amur River Basin wetlands during Anthropocene. The response of Amur River Basin to anthropogenic and climatic disturbances, and the possible affecting factors were also discussed. The results showed that: in the early Anthropocene (approximately AD1915), the wetland habitat was relatively humid and the Testate amoebae were dominant with the "humid" species. After that the variations of wetland water levels showed significant difference in the upper, middle and lower streams, while the regional climate remains the dominant factor. Since 1990, there was an increasing anthropogenic impact on the water table change throughout the Amur River Basin wetlands. The depth to water table gradually decreased throughout the Amur River Basin wetlands, and the dominant species of the Testate amoebae were *Phryganella acrospodia, Assulina muscorum* and *Assulina seminulum*. Thas was mainly due to the increasing anthropogenic, such as agricultural excess irrigation. Therefore, the water table change in Amur River Basin wetlands was controlled by regional climate change and the human being's activities, and suggested a significant spatial difference in the upper, middle and lowers streams in the past century.

Paleoenvironmental histories over the past 81,000 years on the Jeju Strait shelf, off southwestern Korea, inferred from palynological records

Dr. Sangheon Yi [1], *Dr. Seok-Hwi Hong* [1], *Dr. Jin Cheul Kim* [1], *Dr. Dong-Geun Yoo* [1], *Dr. Gwang-Soo Lee* [1]

1. *Korea Institute of Geoscience and Mineral Resoiurces*

Palynological records from H-series cores (H-C05, 07, 11, 18, 26 and 27) has revealed changes in the depositional environment, vegetation, and climate of the southwestern Korean Peninsula since marine isotope stage (MIS) 5a. During MIS 5a (ca. 74–81 ka), the Jeju Strait shelf was an inner shelf with deposition influenced by the Jeju Warm Current (JWC), surrounded by land covered by mixed conifer and deciduous broadleaf forests under warm temperate conditions. The paleoenvironment during MIS 4 (57–71 ka) remains unknown due to a lack of palynomorphs from this stage. During mid–late MIS 3 (ca. 29–50 ka), the Jeju Strait shelf was an inner shelf influenced by cold-water masses from the Korean Coastal Current combined with weaker influences by the JWC, and the surrounding land was covered by mixed conifer and deciduous broadleaf forests that were less dense than in MIS 5a under warm and relatively dry conditions. A cold, slightly wet climate during MIS 2 (ca. 12–29 ka) led to the extension of predominantly cold-tolerant conifer forests due to lowstand sea levels, although inland East Asia remained cold and dry. During MIS 1 (ca. 0–12 ka), cold-tolerant conifer forests persisted into the early Holocene, and were subsequently replaced by mixed conifer and deciduous broadleaf forests as a warm climate was restored in the mid–late Holocene, when the depositional environment became an outer shelf due to highstand sea levels, as it remains today.

Indian monsoon variability in the Mahanadi Basin (IODP Exp. 353 Site U1445) during the last 200 ka

***Dr. Jongmin Lee* [1], *Dr. Sunghan Kim* [2], *Prof. Minoru Ikehara* [3], *Prof. Keiji Horikawa* [4], *Prof. Yoshihiro Asahara* [5], *Dr. Chan Min Yoo* [1], *Prof. Boo-Keun Khim* [6]**

The orbital-scale variability of the Indian summer monsoon (ISM) has been influenced by multiple factors, such as atmospheric CO_2 concentration, global ice volume, and insolation. Proxies for weathering activity and paleoproductivity provide potential insights into the driving forces of its variability. We documented multi-proxy data at IODP Site U1445, located in the Mahanadi Basin of the northwestern Bay of Bengal, to find out ISM variability over the last 200 ka. The proxy records, such as Nd/Sr isotopes of detrital particles, clay mineral compositions of the fine-grained sediments, biogenic opal and $CaCO_3$, organic carbon contents, and carbon isotopes of organic matter, represent that sediment sources, weathering patterns, and paleoproductivity were related to the ISM variability. Detrital Nd/Sr isotope data and clay mineral compositions suggest that the sediments at Site U1445 originated mainly from the Ganges, Brahmaputra, and Meghna rivers without dramatic provenance change between the glacial and interglacial periods. The weathering activity inferred from clay mineral compositions and the paleoproductivity shift reconstructed by biogenic opal and $CaCO_3$ contents suggest that the land-sea interactions were closely linked to the ISM precipitation between the glacial and interglacial periods. High precipitation by the strong ISM resulted in intense chemical weathering and dominant biogenic opal deposition during the interglacial periods. In contrast, low precipitation by the weak ISM led to reduced chemical weathering and predominant $CaCO_3$ deposition during the glacial periods. Further, the ISM variability driving the land-sea interactions in the Mahanadi Basin was modulated by the Indonesian throughflow.

Molecular and isotopic indicators of fire history, population, vegetation and climate change in the Maya lowlands

Dr. Benjamin Keenan [1], *Dr. Andy Breckenridge* [2], *Dr. Kevin Johnston* [3], *Dr. Peter Douglas* [4]

1. McGill University. Department of Surface Waters, Swiss Federal Institute of Aquatic Science and Technology, 2. University of Wisconsin-Superior, 3. Independent Scholar, 4. McGill University

Understanding past societal responses to climate change requires proxy indicators of human population, climate and land-use change. We apply a range of proxies to a lake sediment core from Laguna Itzan, a cenote adjacent to the ancient Maya population centre of Itzan, in order to examine the response of the lowland Maya to climatic and environmental change, which remains poorly understood. By combining molecular proxies for population (faecal stanols) and biomass burning (polycyclic aromatic hydrocarbons or PAHs) with isotopic analyses of plant wax n-alkanes as proxies for vegetation change (δ13C) and palaeohydrology (δ2H), we show the complex interplay of environmental and societal changes over 3300 years.

Faecal stanols suggest at least three periods of significant population decline associated with precipitation change, including between 3300 and 2900 cal yr BP and 1860-1670 cal yr BP, as well as the widely documented Terminal Classic drought (1220-1050 cal yr BP). The use of PAHs provides a record of fire history from both hearths as well as from vegetation burning associated with hypothesised slash and burn land clearance, or swidden, agriculture. Fire history can be linked with records of vegetation change inferred by δ13C of n-alkanes, which fluctuate between more negative values associated with forest (C3) vegetation and more positive values associated with maize (C4) agriculture. Our data indicate that human population dynamics and patterns of land clearance for agriculture varied substantially throughout the sediment core record, and that palaeoclimatic change may have largely driven these patterns.

Climate history and vegetation changes in southwest Morocco

***Mrs. Sokaina Tadoumant* [1]*, Dr. Ilham Bouimetarhan* [2]*, Dr. Yassine Ait Brahim* [3]*, Dr. Martin Koelling* [4]*, Dr. Mohammed Hssaisoune* [5]*, Dr. lhoussaine Bouchaou* [1]**

__1.__ Laboratory of Applied Geology and Geo-Environment, Ibn Zohr University, __2.__ University Ibn Zohr of Agadir, __3.__ International Water Research Institute (IWRI), Mohammed VI Polytechnic University (UM6P), Ben Guerir 43150, Morocco, __4.__ MARUM-Center for Marine Environmental Sciences, University of Bremen, __5.__ Laboratory of Applied Geology and Geo-Environment, Ibn Zohr University, Agadir 80035, Morocco

Southern Morocco is presently subject to severe droughts, desertification and land degradation, because of the development of socio-economic activity and climate variability, which has provoked severe changes in the main natural forest ecosystems. In this study, we used palynological data from two high-resolution marine sediments cores collected off offshore Agadir in southwest Morocco in combination with published high-resolution stable isotopes ($\delta^{18}O$ and $\delta^{13}C$) from speleothem records, in order to evaluate the impact of past climate changes on the vegetation in southern Morocco. The results show that the rapid increase of population in southern Morocco caused land and vegetation degradation due to the expansion of pastoralism and agriculture with the good presentation of *Argania spinosa*, Cichorioideae and Asteroideae pollen, especially at the beginning of the Arab invasion of North Africa (700 CE), with the modest representation of deciduous oak. Increasingly arid conditions in Morocco after 619 to 940 CE are possibly related to NAO+ conditions. A long period of dry conditions in Medieval Climate Anomaly (MCA), with the short humid period, showed by the still quite high percentages of non-arboreal pollen with a significant expansion of Asteroideae, Cichorioideae and CCA. The Little Ice Age (LIA) was characterized by a recovery to wetter conditions, remarked by the decrease of Argania spinosa, Asteroideae and Cichorioideae pollen and an increase of *Cedrus atlantica*, *Juniperus* and *Pinus*. Therefore, the hydroclimate conditions in Morocco continued to be more humid until 1970 CE.

East Asian winter monsoon variability during middle to Late Holocene on Jeju Island, South Korea

***Dr. Ara Cho* [1], Dr. Jaesoo Lim [1]**

1. *Korea Institute of Geoscience and Mineral Resources*

Understanding the East Asian monsoon is necessary because society, culture, and the environment have been affected by climate change. To date, the change in the East Asian winter monsoon (EAWM) and its controlling factors is still unclear in downwind areas that experience the Siberian High, mostly due to the lack of a high-resolution EAWM index. Based on the correlation between diatom variations in a volcanic cone of Jeju Island, South Korea, with past regional climate changes such as temperature, dust, sea ice, and solar activity, in this study, we evaluated the changes in the climate from the sum of acidophilous species (SAS), known to be mainly controlled by the pH of the prevalent water pool, and inferred that the SAS increased during the cold and dry periods (e.g., Little Ice Age and Dark Age Cold Period). In addition, millennial-timescale fluctuation in the detrended SAS during the past 8000 years, with peaks at ~500, 1500, 3000, 5600, 6600, and 7600 cal yr B·P., corresponded to the ice-rafted events reported from studies conducted on subpolar ocean sediments and solar activity. In this study, we suggest that, historically, high-latitude climate change driven by solar activity has controlled the EAWM; additionally, we present the application of the SAS in Jeju Island as a high-resolution EAWM index.

Anomalous pollen evidence at the mouth of Ría de Vigo reveals new details about the Holocene marine transgression in NW Iberia

Xeociencias Mariñas, Universidade de Vigo, Facultade de Ciencias s/n E-36210, Vigo, Spain Vigo, Spain*

A high-resolution pollen record from the upper 155 cm of the MVR-3 vibracore (recovered at 30 m bsl in the outer sector of Ría de Vigo, NW Iberia) reveals noticeable sedimentation changes during the last 12,000 cal yr BP. A reliable age model was built using part of the 14 AMS radiocarbon dates available, namely 3 marine shells and 11 pollen residue samples extracted from muddy sediment. Deciduous *Quercus* pollen expanded during c. 9700-8500 cal yr BP at the beginning of the RSL rise. Subsequently, two *Pinus* pollen peaks (40-60%) are recorded between 138-115 and 98-73 cm depth separated by a *Quercus* maximum dated between 7800-6000 cal yr BP. The total accumulation rates of palynomorphs decline during both *Pinus* peaks, while *Lingulodinium machaerophorum* (characteristic of well-stratified estuarine waters) notably decays and other dinoflagellates (*Bitectatodinium tepikiense* and *Spiniferites* spp.) increase revealing enhanced mixing of coastal waters. Moreover, in spite of the suitable radiocarbon ages obtained from pollen extracts at the stage dominated by *Quercus* and also after the beginning of the regional deforestation, the ages obtained from the anomalous *Pinus* peaks seem inverted and notably aged. These apparently jumbled data may be a coherent high-resolution record describing the main sedimentary processes that occurred during the marine transgression, and it allows to improve the interpretation of the seismic evidence (units, unconformities) previously described. In Ría de Vigo, the transgressive system tract (TST) includes deposits accumulated from the onset of coastal transgression (<12 kyr BP) until the time of maximum transgression (i.e. the *Quercus* maximum dated between 7.8-6.0 kyr BP, which corresponds to the Holocene *Climatic Optimum*). The basal boundary of the Holocene sequence corresponding to the first *Pinus* peak is an erosional surface associated with marine transgression, i.e. a ravinement surface, with coarse sand or bioclastic gravel facies typical of high-energy environments. The Holocene unit below it is therefore interpreted as the first transgressive system tract (TST1) during the pulse of relative sea-level rise after the YD. The second Holocene unit, also with an erosional basal surface, i.e. the second *Pinus* peak, would correspond to a second phase of RSL rise (TST2).

Pollen sedimentation in fluvio-marine systems: a comparison between modern pollen evidence in sea-floor, coastal lagoons and upland ponds from Ría de Vigo, NW Iberia

***Mr. Alberto Castro Parada* [1], *Prof. Castor Muñoz Sobrino* [2], *Dr. Javier Ferreiro da Costa* [3], *Dr. Victor Cartelle* [4], *Dr. Natalia Martínez-Carreño* [5], *Prof. Soledad García-Gil* [6]**

Bioloxía Vexetal e Ciencias do Solo, Universidade de Vigo, Facultade de Ciencias s/n E-36210, Vigo, Spain, **3.** GI1934TB, Laboratorio de Botánica e Bioxeografía, IBADER, Universidade de Santiago de Compostela, Campus Terra s/n, 27002, Lugo, Spain, **4.** Flanders Marine Institute (VLIZ), InnovOcean Campus, Jacobsenstraat 1, 8400 Oostende, België, **5.** Spanish Institute of Oceanography (IEO-CSIC), 28002 Madrid, Spain, **6.** Centro de Investigación Mariña, Universidad de Vigo, Vigo, Spain, Dept. Xeociencias Mariñas, Universidade de Vigo, Facultade de Ciencias s/n E-36210, Vigo, Spain Vigo, Spain*

To determine whether modern pollen content from 1) marine, 2) coastal lagoon, and 3) upland lake sediments reflects the factual regional and extra-local vegetation composition, we analysed modern samples at the same main fluvio-marine basin (Ría de Vigo, NW Iberia). Aspects such as basin size and morphology, relative position in the catchment, local vegetation, canopy configuration and seasonality of the water table were considered. Our results suggest that the average pollen percentages of all upland pond sediment samples studied allows a fairly good reconstruction of the main vegetation units in the area. Still, major differences between the average samples obtained in each sedimentary system and also between some samples taken from the same system are found. The main factors explaining those differences are the size of the pond, its tree canopy and the seasonality of the water table, which strongly determines the Ericaceae and *Pinus* percentages. Anomalous *Pinus* pollen peaks occur in dry periods when the water table remains low, and sediment can also be depleted of some high-buoyancy pollen types (tetrads and saccate) when the water level is high and effluents are active. Samples taken in the semi-closed coastal lagoon-beach complex at the Cíes Islands suggest that *Pinus* pollen abundance increases in the intertidal flats samples with respect to those taken in the subtidal zone of the lagoon. Besides, the *Pinus* pollen concentrations in both the intertidal and subtidal samples at the lagoon are significantly lower than *Pinus* pollen concentrations found in other full-marine subtidal sediments recovered along the main axis of the ria. On the other hand, there is currently no local heathland on the islands, nor was there throughout the 20th century, and the closest heaths in the continent are more than 5 km distant. Nevertheless, we have found *Erica* pollen evidence inside the lagoon of Cíes Islands. Its spatial distribution seems to be preferentially related to the western connection between the lagoon and the ocean that allows water exchange throughout the tidal cycle. Thus, the new pollen data can confirm the preferential ability of tetrads to be long-distant transported by sea-water currents.

Holocene alpine vegetation, fire, and climatic dynamics of central Taiwan

Prof. Liang-Chi Wang [1]

1. *National Chung Cheng University*

Due to the frequent tectonic activity and high erosion rate, a lake or pond with sediments covering whole Holocene records is rare in Taiwan. Tien Pond (TP) of the Xueshan Range is a small pond at 2620 m in central Taiwan. A 250-cm length sediment core (DXS-TP) was taken in the TP in 2017. Based on the results of 14 radiocarbon dates, it covered the records during the last 8400 cal BP. The continuous data of pollen and macro-charcoal from a sediment core from TP to reconstruct the changes in Holocene vegetation, fire frequency, and climate under multidecadal resolution. The deposition hiatus during 6400-3600 cal BP may correlate to the 4.2 ka event or the change in local hydrological condition. The reconstruction of biome types in TP was simulated by using the biome model BIOME. The results of biome reconstruction reveal the consistent temperate forest during the Holocene in western alpine Taiwan. The paleo-temperature was inferred by the ratio of upper montane forest and montane forest pollen (UMF/MF) and principle component analysis axis two (PC2) and indicated two cool periods during the early Holocene and the Little Ice Age. The paleo-precipitating inferred by Cyperaceae pollen and macro-charcoal concentration showed relatively dry periods during the early Holocene and 3600-2000 cal BP. The study area's climatic condition was similar to the East Asian Monsoon pattern during the Holocene in Taiwan.

Holocene climate variability recorded in central Mexican lacustrine archives

Central Mexico represents a highly sensitive area for the study of Holocene climate variability as it lies beyond the northern limit of the Intertropical Convergence Zone and in the southern part of the North American monsoon domain. The HolMeCl project combines the acquisition and analysis of short and long sedimentary sequences retrieved from seven crater lakes spanning the Trans Mexican Volcanic Belt (TMVB). The TMVB represents widespread closed-system crater lakes whose sedimentary sequences are unique archives of past climate variability. Age-depth models will be constrained by a combination of geochronology (^{137}Cs, ^{210}Pb, and ^{14}C), tephrostratigraphy and varve counting (when present). To explore past hydrological and environmental changes, the sediments will be subjected to detailed multiproxy analyses using a spectrum of mineralogical, geochemical (δ^{13}C and δD signatures of *n*-alkanes leaf-wax and elemental compositions) and paleobiological (diatoms and pollen) indices. The youngest sections of the sedimentary sequences will be precisely dated to estimate the temporal resolution of sedimentation rates, allowing us to validate the signals that individual proxy data represent through comparing them with the local meteorological data. Using the validated proxies, the long sedimentary sequences will be interpreted in terms of past climate reorganizations particularly paleo-ENSO variability. Comparison of these new precisely-dated long sequences with the existing paleo-ENSO records for the tropics would bring a more global picture of ENSO variability over the Holocene at decadal or sub-decadal resolution, if the sedimentary records are annually laminated.

Human impact leads to unexpected late Holocene reoligotrophication of a Swiss mountain lake

Dr. Oliver Heiri [1], ***Ms. Nina Perret-dit-Gentil*** [2], ***Dr. Fabian Rey*** [3], ***Dr. Erika Gobet*** [4], ***Prof. Willy Tinner*** [4]

1. University of Basel, 2. Palaeoecology, Institute of Plant Sciences, University of Bern, 3. Geoecology, Department of Environmental Sciences, University of Basel, 4. Institute of Plant Sciences & Oeschger Centre for Climate Change Research, University of Bern

Early human impact on lakes has in many cases been reported to lead to nutrient release, increased algal productivity and eutrophication, as well as depleted deepwater oxygen concentrations. For Central Europe, and particularly the Alpine region, many records are now available that document early, human-induced eutrophication influencing lake ecosystems as early as the Neolithic, Bronze age, Roman and Medieval periods. Here we report the unexpected and contrasting finding of a pronounced oligotrophication trend in a Swiss mountain lake due to human activities during the Medieval times. A sediment core from Lac de Champex (1,466 m asl in the Valais, Switzerland) was analysed for fossil chironomid and other aquatic invertebrate remains. Chironomid assemblages in most of the record show pronounced changes that agree with the known climatic development during the early and mid-Holocene and a progressively stronger influence of peat development around the lake, resulting in an assemblage with low chironomid accumulations dominated by *Procladius* with high concentrations of *Chaoborus* around 2,000-3,000 cal. BP. In the latest part of the record, at around 1000 cal. BP, a pronounced and abrupt increase in sediment accumulation rates and chironomid influx was observed during a period with clear evidence for local human activities (e.g. pollen of pasturing-indicating taxa and cereals, dung spores). Some changes in chironomid and invertebrate abundances were also apparent at this depth followed by a major transition in the chironomid and invertebrate assemblage around 500 cal. BP, with the disappearance of *Chaoborus*, a decrease in *Procladius*, and the increase or new appearance of a range of chironomids including several stream inhabiting taxa. Numerical and palaeoecological analysis of the results confirmed that these changes were towards assemblages characteristic for more oligotrophic, oxygen-rich conditions. We conclude that late Holocene human impact on Lac de Champex and its surroundings resulted in a pronounced re-oligotrophication of the lake, possibly promoted by increased erosion from the Medieval period onwards but from 500 cal. BP very likely due to the building of an irrigation canal (bisse), leading to the inflow of clear, cool water and changing the hydrological characteristics of the lake.

Vegetation and climate dynamics in central Mexico during the past millennium recorded in a sediment core from Lake Teremendo

Dr. Reza Safaierad [1], ***Prof. Gabriela Domínguez-Vázquez*** [2], ***Prof. Isabel Israde-Alcántara*** [3], ***Dr. Marttiina Rantala*** [1], ***Prof. Nadine Mattielli*** [4], ***Prof. Nathalie Fagel*** [1]

1. *Clay, Geochemistry and Sedimentary Environments (AGEs), Department of Geology, Faculty of Science, University of Liège, B-4000, Liège, Belgium,* ***2.*** *Facultad de Biología, Universidad Michoacana de San Nicolás de Hidalgo. Central Mexico is influenced by multiple atmospheric circulation systems including the Intertropical Convergence Zone (ITCZ), the North American monsoon, and polar fronts, making it highly sensitive to climate change. Variations in the position and strength of these atmospheric systems result in significant changes in the terrestrial and aquatic ecosystems of central Mexico. The past millennium, characterized by warm and cold climate perturbations, namely, the Medieval Warm Period (MWP) and the Little Ice Age (LIA), provides a unique time interval to explore environmental responses to the anomalously warm and cold periods. Here, we present a multiproxy record including pollen, elemental geochemistry, loss on ignition, grain size, and magnetic susceptibility (MS) of sediment cores retrieved from Teremendo, a crater lake in central Mexico, spanning the last millennium. The dominance of temperate vegetation, particularly pine forests, at the expense of tropical plants around the fourteenth to nineteenth centuries suggests a decline in temperature and summer rainfall. The laminated sediments of this interval, which display the greatest variations in elemental abundances and MS in the record, hint at unstable climatic conditions with amplified seasonality during the LIA. Around AD 1910, the pollen and sediment indices suggest a transition from the LIA to the recent warm period, where a decline in pine forests coincides with an increase in tropical vegetation, and the weakly laminated sediments show smaller variations in elemental abundances and MS. Such observation suggests a rise in temperature and summer rainfall and more stable climatic conditions since AD 1910. Land use change related to the Mexican Revolution in the early 20th century may have contributed to the vegetation changes, however, evidence from other central Mexican records supports climate-driven vegetation dynamics. Thus, our results suggest that a southward displacement of the mean position of the ITCZ during the LIA was accompanied by reduced summer rainfall and increased polar front incursions over central Mexico in the winter. Given the great potential of the Teremendo lacustrine archive, we will extend our time interval beyond the last millennium by investigating an already retrieved long sediment core from the lake covering the entire Holocene epoch.

Towards a better understanding of lake ecosystem response to natural climate variability – a study of Lake Bright, New Zealand

Mr. Julian Eschenroeder [1], ***Dr. Christopher Moy*** [1], ***Dr. Sebastian Naeher*** [2], ***Dr. Marcus Vandergoes*** [2], ***Dr. Jamie Howarth*** [3], ***Dr. Christina Riesselman*** [1], ***Dr. Claire Shepherd*** [2]

The impacts of environmental and climate change on freshwater ecosystems are typically a combination of natural processes and human alteration (e.g. land-use changes). The arrival of humans to New Zealand about 750 years ago is known to have impacted landscapes and makes it difficult to study natural conditions that are undisturbed by human activities over timescales that are relevant for paleoclimatic reconstructions. However, remote, alpine lakes are thought to record environmental and climate changes independent of human impact in the Southwest Pacific.

For this study, we investigate sediment cores obtained from a remote alpine lake in Fiordland National Park on New Zealand's South Island. A 1.6 m long sediment core was recovered from the center of Lake Bright at a depth of 19.5 m in September 2019. In our multiproxy approach, we used bulk organic C and N stable isotopes, lipid biomarker concentrations and high-resolution X-ray fluorescence and hyperspectral imaging to study lake productivity, sources and provenance of clastic and organic matter, as well as changes in water quality and vegetation composition.

The Lake Bright pollen stratigraphy does not show any evidence of recent human-induced landscape change in the surrounding catchment. A largely stable vegetation community composed of forest and grassland pollen spans the last 4 kyrs of the record with a very low abundance of microscopic charcoal and exotic plant pollen in the uppermost part of the stratigraphy, which is likely sourced from lowland locations. Initial biomarker data confirms that the greatest proportion of organic matter is derived from vascular plants from the lake catchment and low contributions of aquatic organic matter sources. Non-destructive XRF and hyperspectral scans of the core indicate variations in algal productivity, while a trend to more reducing conditions is observed in the uppermost portion of the record. We will discuss these findings, along with results from a stable C and N isotope stratigraphy, biogenic silica concentrations, and organic geochemical reconstructions of air temperature and precipitation, to deconvolve changes in organic matter provenance and to better understand how climate changes affect remote alpine lake ecosystems, independent of human impact.

Summer temperatures during the Holocene inferred from a chironomid record from Sierra Nevada, southern Spain

Jiménez-Espejo*** [5]***, Dr. Charo López Blanco*** [1]***, Dr. Laura Jiménez*** [1]***, Dr. Carmen Pérez-Martínez*** [1]***, Dr. Marta Rodrigo Gamiz*** [1]***, Mr. Alejandro López Avilés*** [6]***, Dr. Jon Camuera*** [5]

1. *Universidad de Granada,* ***2.*** *University of Basel,* ***3.*** *Department of Stratigraphy and Paleontology, University of Granada,* ***4.*** *Northern Arizona University,* ***5.*** *Instituto Andaluz de Ciencias de la Tierra (IACT), CISC-UGR,* ***6.*** *University of Granada*

Accurate and continuous quantitative paleotemperature records from the past are rare in southern Iberia, mostly due to the scarcity of continuous sedimentary sequences in terrestrial environments from that area. In this study we show the first Holocene mean July air temperature reconstruction based on fossil chironomids from a sedimentary sequence obtained from Laguna de Río Seco, an alpine lake in Sierra Nevada, southern Spain. Reconstructed summer temperatures agree with changes in summer insolation and other palaeotemperature records from alpine environments from southern Europe and show the Holocene thermal maximum between 10 to 8.0 ka (1 ka = 1000 cal yr BP). Rapid cooling occurred after the warmest maximum and between ~8.0-7.0 ka and temperatures stabilized between ~6.5 and 3.0 ka. A further cooling trend started ~3.0 ka, and coldest summer conditions were reached at 1.4 ka (~550 CE) and ~0.2 ka (~1750 CE), coinciding with the Dark Ages and Little Ice Age, respectively. This record also shows relatively warmer summer temperature conditions during the Iberian-Roman Humid Period ~2.0 ka and during the Medieval Climate Anomaly at ~0.9 ka. Summer climate warming of more than two degree Celsius is observed in the last decades showing that recent warming is amplified in high alpine environments.

Distribution of long-chain diols in the Baltic Sea and its application in paleoenvironmental reconstruction

Dr. Bingjie Yang [1]***, Prof. Helena Filipsson*** [2]***, Dr. Karl Ljung*** [2]***, Prof. Stefan Schouten*** [3]

***1.** NIOZ, Royal Netherlands Institute for Sea Research, Department of Marine Microbiology and Biogeochemistry (MMB),* ***2.** Department of Geology, Lund University,* ***3.** NIOZ, Royal Netherlands Institute for Sea Research, Department of Marine Microbiology and Biogeochemistry (MMB); Utrecht University, Faculty of Geosciences, Department of Earth Sciences*

Long-chain diols (LCDs) are lipids produced by microalgae and occur widely in lakes, rivers and marine environments. A series of proxies based on the distribution of LCDs in the sea has been widely used to reconstruct the paleoenvironment. However, the LCDs' distribution and its related environmental proxies in brackish water environments are not well studied. In this study, we investigated the occurrence and distribution of LCDs in surface sediments and one sediment core from the Baltic Sea, and explore the relationship between their distributions and environmental factors including salinity, nutrient concentrations and sea surface temperature.

The surface sediments from the Gulf of Bothnia, the Gulf of Finland and the Baltic proper are dominated by the C_{32} 1,15-diol with a relative abundance between 38% and 75%, and it decreases towards the North Sea. Additionally, the relative abundance of C_{30} 1,15-diol which the Diol index, a salinity proxy, is based on does not correlate with salinity in the Baltic Sea. However, the relative abundances of C_{28} 1,13-, C_{30} 1,13- and C_{32} 1,15-diol correlate with salinity. Based on this, we propose a new salinity index that expresses the abundance of C_{28} 1,13-diol relative to C_{28} 1,13-, C_{30} 1,13-and C_{32} 1,15-diol. The new salinity index shows a strong positive correlation with the sea surface salinity (r^2=0.7594, p<0.001).

In the sediment core from a fjord-like inlet to the Baltic Sea located on the southeast coast of Sweden, the salinity index proposed in this study indicates decreasing salinity over the last 5500 years, which is in concert with the relative sea level decreasing due to isostatic rebound. Considering that freshwater from river runoff can be a major driver at the location near the river mouth, the salinity index could potentially reflect changes in riverine organic matter input after the coast stabilized. However, both the BIT index, a proxy for soil organic matter, and the C/N ratio suggest an increase in the terrestrial organic matter input responding to farmland expansion over the last 600 years, but no change is observed in the riverine input indicated by our new proxy.

Seasonal hydroclimate in the North Sea-Baltic Sea region during the Last Interglacial

Dr. Sha Ni [1]***, Dr. Zhengyao Lu*** [2]***, Prof. Qiong Zhang*** [3]***, Dr. Jeroen Groeneveld*** [4]***, Dr. Karen Luise Knudsen*** [5]***, Prof. Marit-Solveig Seidenkrantz*** [5]***, Prof. Helena Filipsson*** [6]

1. *(1) Institute for Geology, University of Hamburg, 20146 Hamburg, Germany,* ***2.*** *Dept. of Physical Geography and Ecosystem Science, Lund University, Lund, Sweden,* ***3.*** *Dept. of Physical Geography and Bolin Centre for Climate Research, Stockholm University, Stockholm, Sweden,* ***4.*** *Institute of Oceanography, National Taiwan University, Taipei City, Taiwan,* ***5.*** *Paleoceanography and Paleoclimate Group, and iClimate Centre, Dept. of Geoscience, Aarhus University, Aarhus, Denmark,* ***6.*** *Department of Geology, Lund University*

The Last Interglacial (LIG) experienced substantial changes in seasonal insolation compared to the present day. The higher-than-present seasonality in insolation could have led to changes in hydrography and water mass exchange in the North Sea and Baltic Sea region. Here we investigate the influence of solar radiation and greenhouse gas (GHG) forcing on the regional climate, using both model simulations of LIG (127 ka BP) and the present day (PD, 1990 CE) and the reconstructions of seasonal water conditions based on benthic foraminifera and geochemistry data. The differences between the anomalies of LIG-PD and LIG-pre-industrial (PI, 1850 CE, control experiment) reflect the effect of greenhouse gas concentration. The simulated LIG conditions in the Baltic Sea region (including the Kattegat and the Danish Straits) show more saline and colder bottom waters than those in PD, which agrees with the reconstruction data from the investigated sites. The LIG sea surface temperature (SST) is lower in spring and higher in summer than those for PD conditions. The thermocline is stronger during the summer months in LIG due to the higher SST and lower bottom water temperature (BWT) compared to PD. Together it indicates that the Baltic LIG SST is highly influenced by the insolation factor whereas the PD BWT of the Baltic Sea is affected by North Sea input of warmer seawater into the southern Baltic, cause by increased GHG-forcing.. The simulated LIG surface water salinity suggests that during the winter months, the western Baltic is to a large degree affected by the North Atlantic Oscillation (NAO) and an associated larger influx of more saline North Atlantic water. Further, the temperature anomalies (LIG-PD) show significant inverse correlations with the precipitation-minus-evaporation (P-E) in the Baltic Sea entrance. However, the P-E balance may have minor effect in changing the salinity in the North Sea-Baltic Sea and the open sea area. Our study investigates the interaction and correlations of regional seawater temperature and salinity with internal variability (P-E and NAO) under different external forcing.

Postglacial landscape dynamics and fire regimes from Central Patagonia, Chile (44°S, 72°W): Evidence from Lago Las Mellizas.

Dr. Valentina Álvarez-Barra [1], ***Dr. Antonio Maldonado*** [2], ***Dr. César Méndez*** [1], ***Dr. Amalia Nuevo Delaunay*** [1], ***Dr. María Eugenia de Porras*** [2]

1. Centro de Investigación en Ecosistemas de la Patagonia (CIEP), 2. Centro de Estudios Avanzados en Zonas Áridas (CEAZA)

In central Patagonia (~44°S) palynological records from the eastern forest-steppe ecotone indicate substantive changes in vegetation cover after the LGM, coupled with high fire activity during the Early Holocene and at c. ~3000 cal. yr BP, the latter likely associated with prehistorical human occupation. However, there has been a lack of paleoenvironmental evidence for vegetation changes and fire activity within the rainforest in this area. Here, we present the reconstruction of past vegetation and fire activity for the last 13,700 cal yr BP at the wetter western margin of the forest-steppe transition obtained from a lacustrine sediment core from Lago Las Mellizas (LLM). (44°S, 72°W) located at the margin of the Cisnes River in the Aysén region, Chilean Patagonia. This area has also been the focus of an archaeological study. The LLM record indicates low fire activity (2 fires 1000 $yr^{-1)}$ between 12,500 and 10,500 cal yr BP; negligible fires during the Middle Holocene, and a maximum peak in fire magnitude at ~300 cal yr BP, likely associated with the beginning of the Chilean occupation and settlement in the region. After 12,200 cal. yr BP pollen concentrations increased substantially, likely reflecting a lowering in the Cisnes River elevation and isolation of LLM. After c. 10,000 cal yr BP the development of evergreen forest is most notable with the presence of the evergreen species *Podocarpus nubigenus* and Cupressaceae, probably *Pilgerodendrum uviferum*. A more open forest developed during the Middle Holocene, as indicated by the increase of Poaceae percentages from 5,300 cal yr BP. Vegetation changes associated with human activity are not identified and multivariate analyses indicate no association between fire parameters and vegetation changes. Therefore, we conclude that changes in landscape dynamic at the western margin of the Aysén region are directly controlled by climate, associated with latitudinal shifts of the Southern Westerlies Winds throughout the Holocene.

Changes in sediment distribution on the eastern continental margin of Korea since the LGM

Dr. In Kwon Um [1]

1. *Korea Institute of Geoscience and Mineral Resoiurces*

We analyzed surface sediments collected from the southeastern continental shelf of the Korean Peninsula below a water depth of 500 m for grain size, organic carbon, and geochemical elements. The surface sediments divided into four groups based on the chemical compositions: outer continental shelf, inner continental shelf, Korea Strait Shelf Mud (KSSM), Hupo Basin. Outer continental shelf sediments were composed mostly of coarse-grained sediments that seemed to have been deposited during the glacial age and remained in place due to morphological features since the LGM. Whereas, KSSM and Hupo Basin sediments were composed mostly of fine-grained sediments and developed along the coastline on the inner shelf area. KSSM sediments were deposited with mixed sediment from Chinese and Korean rivers since the LGM. Sediments in the Hupo Basin have geochemical characteristics indicating different sources from those of KSSM sediments. Considering with the seismic results and morphology comprehensively, the fine-grained sediments on the Hupo Basin supplied from nearby rivers beside on the Hupo Basin

Hydroclimatic fluctuations over the Holocene in southern Iberia (Sierra Nevada, Spain) disentangled by fossil cladocerans

Dr. Charo López Blanco [1]***, Dr. Antonio Garcia-Alix*** [2]***, Dr. Gonzalo Jiménez-Moreno*** [1]***, Prof. R. Scott Anderson*** [3]

1. Universidad de Granada, 2. Department of Stratigraphy and Paleontology, University of Granada, 3. Northern Arizona University

Laguna de Río Seco is a pristine alpine lake situated in the massif of Sierra Nevada, which is the most important mountain range in southwestern Europe and a region of extraordinary sensitivity to climate change. Here we analysed cladoceran subfossils in the Laguna de Río Seco sedimentary record covering the Holocene to investigate the faunal responses to environmental variables and to obtain new insight into past climate variability in the study region. In addition, we applied mean body size and abundance of fossil ephippia as supplementary proxies for paleoclimatic interpretations. Multivariate techniques showed that the main drivers controlling the biological assemblages were factors related to hydroclimatic parameters, deduced by the abundance of aquatic vegetation and the C/N ratio. Two different biological assemblages were described depending on the millennial-scale variations of lake level. A higher lake-level assemblage was composed of *C.sphaericus* and *A.rustica* and a low lake-level assemblage was characterised by *C.elegans*. The Early and Middle Holocene (ca. 10500 to 5500 cal yr BP) was relatively humid, with two different periods separated by a small decline in precipitation ca. 8000 cal yr BP. At ca. 5500 cal BP, there was a clear shift towards lower lake levels and thus, drier conditions. This is inferred by the increase of species that thrives well in shallow ecosystems, such as *C.elegans*. The Late Holocene is characterised by continuous changes in lake level within a trend towards hydrological aridification, which is interrupted by a positive peak in precipitation around the Iberian-Roman Humid period.

Late Holocene paleoenvironmental changes in north-eastern Germany derived from a high-resolution lacustrine record from Schweriner See

Ms. Marie-Luise Adolph [1], _Dr. Sambor Czerwiński_ [2], _Dr. Mirko Dreßler_ [2], _Dr. Sebastian Lorenz_ [2], _Dr. Maxime Debret_ [3], _Prof. Torsten Haberzettl_ [2]

***1.** Physical Geography, Institute for Geography and Geology, University of Greifswald, Germany, **2.** Physical Geography, Institute for Geography and Geology, University of Greifswald, **3.** Laboratoire de Morphodynamique Continentale et Côtière, UMR CNRS 6143, Université de Rouen*

Lacustrine deposits provide excellent archives to investigate past environmental variability. Schweriner See (See = lake) is the fourth largest lake in Germany (61.54 km²), and the second largest in NE-Germany. Because of its location, it constitutes great value for paleoenvironmental reconstructions, since in such a large system natural supraregional paleoenvironmental signals are not overprinted by single events. The lake was formed after the Last Glacial Maximum and is located ca. 20 km away from the Baltic Sea within the transitional zone from maritime to subcontinental climate hence making it very susceptible to environmental variations occurring within NE-Germany.

Schweriner See is a carbonate-rich, lowland lake (38 m a.s.l.) characterized by a complex bathymetry with several deep spots, channel structures and an extended littoral shallow water area. Due to this morphology, we coupled investigations on surface sediment samples to better understand internal lake dynamics, short gravity sediment cores (max. 1 m length) and an 18 m parallel cored sediment records from the deepest spot (52 m water depth). All samples were analysed using a multi-proxy approach of (hyper-)spectral, sedimentological (e.g., grain size distribution) and geochemical (e.g., CNS, XRF core scanning) methods. To record the general transitions within the lake and catchment, we additionally used a diatom-based trophic and a pollen-based vegetation reconstruction. The chronology of the long sequence is based on a multi-dating approach including radiocarbon (only terrestrial macro-remains) and $^{210}Pb/^{137}Cs$ ages. Currently, only the upper part of the 18 m long sediment record possesses robust chronology, that is 12 ^{14}C dates per 10 m with a maximum age of $3300^{+130}/_{-130}$ cal. BP. This section reveals a high sedimentation rate of ca. 0.3 cm a^{-1} for the Late Holocene highling its suitability to infer natural past environmental changes in high-resolution. Anthropogenic impact is visible in all gravity cores recovered from Schweriner See indicated by an increase in eutrophication and heavy metal contamination since the Industrial Revolution around 1850 and peaks shortly before the German reunification in AD 1989.

Dynamics of planktonic foraminifera population in the Arabian Sea during the last climatic cycle.

Mrs. Linda Rossignol [1], ***Dr. Thibaut Caley*** [1], ***Dr. Sebastien Zaragosi*** [1], ***Dr. Frederique Eynaud*** [1], ***Dr. Hugues Blanchet*** [1], ***Dr. Franck Bassinot*** [2], ***Dr. Bruno Malaizé*** [1]

1. University of Bordeaux, 2. LSCE

Planktonic foraminifera are calcite shell organisms, which are widely used in paleoceanographical studies to reconstruct climate variables (for example ocean temperatures). For that purpose, the composition of planktonic foraminifera assemblages is determined in samples from marine sedimentary cores from various oceanic provinces in order to reconstruct species related distributions both along time and space. Based on nearly one century of acquisitions of this kind of data, some species have been identified as good tools to determine hydrographical parameters like productivity or as relevant to stratigraphy. However, these data are rarely used to quantify the intraspecific dynamics of the population, particularly during extreme time periods as glacial/interglacial flips. The purpose of this on-going work is to study the dynamics of each species as well as one relative to another.

In this study, we propose to use descriptive statistics on various assemblages from the Arabian Sea to reconstruct the population structure and its variation during the last climatic cycle in an area under the influence of monsoon and characterized by the seasonal development of large upwelling systems. Multivariable analyses allow us to connect some species abundances and to observe how their similarity or dissimilarity evolved during contrasted climatic periods. These results coupled with ecological knowledges provide a way to improve the reconstruction of paleoenvironmental signals.

Paleolimnological changes in an alpine lake during the Holocene inferred from a diatom record from Laguna de Río Seco, Sierra Nevada (Southern Spain)

Mrs. Joana Llodrà-Llabrés [1]***, Dr. Carmen Pérez-Martínez*** [2]***, Dr. Antonio Garcia-Alix*** [3]***, Dr. Anderson Scott*** [4]***, Dr. Gonzalo Jiménez-Moreno*** [2]

1. *University of Granada,* ***2.*** *Universidad de Granada,* ***3.*** *Department of Stratigraphy and Paleontology, University of Granada,* ***4.*** *Northern Arizona University*

High-mountain ecosystems of the southern Iberian Peninsula are among the most vulnerable and the first to respond to modern climate change in southwestern Europe. Our main aim is to identify the changes in the diatom communities in the last ~12500 years to assess the ecosystem responses to climate change over time. A composite sedimentary record consisting of a long (LdRS,150 cm) and a short sediment core (SdRS, 16 cm) were retrieved at the deepest part of Río Seco Lake, an alpine lake at 3020 m a.s.l. in the Sierra Nevada National Park. A chronology for the past ~12500 years for LdRSand ~200 years for SdRS was stablished. Both cores were analyzed with a high temporal resolution (intervals of 0.25 and 1 cm) and a minimum of 300 diatom valves were counted for each sample. Diatom assemblage was dominated by small benthic fragilarioid taxa like *Staurosira venter* and tichoplanktonic species like *Aulacoseira alpigena*. The greatest compositional changes occurred at approximately 7200, 5000 and 2800 cal yr BP. Relatively low abundance of epiphytic, tichoplanktonic and other planktonic species indicates aridity, drying of catchment meadows and reduced water level and turbulence, linked to warm and dry climate between 10000 to 7200 cal yr BP. This warm period with low lake water levels, was followed by a long cooling trend between 7200 and 2800 yr BP in which tichoplanktonic species as *A. alpigena* are dominant, as our results highlight. Two steps were observed in this cool period: period between 7200-5000 yr BP, with small compositional changes, and the period between 5000 and 2800 yr BP with a noteworthy increase in the abundance of *A. alpigena* indicating high lake water level, and fragilaroid taxa such as *Fragilaria gracilis*. In the period between 2800 and 300 yr BP tichoplanktonic species decreased and small fragilariacean and alkaliphilous species increased but with several peaks of reverting conditions. SdRS core suggests a more pronounced tendency to alkalinization, catchment aridity and low water level, probably related to present climate warming.

Holocene climatic and environmental changes in the Yangtze River Delta

Dr. Xiaomei Nian [1]***, Prof. Weiguo Zhang*** [1]***, Prof. Yunping Xu*** [2]***, Dr. Wenjie Xiao*** [3]***, Mr. Fengyue Qiu*** [1]

1. *East China Normal University,* ***2.*** *Shanghai Ocean University,* ***3.*** *Southern University of Science and Technology*

The delta is located at the land-ocean interface and an ideal location to study climate and environmental changes. However, complex sedimentary environment hinders the establishment of a reliable chronostratigraphy for the area, which in turn impact the research process of environmental evolution on geologic time scales. In this study, optically stimulated luminescence (OSL) dating technique and geochemistry are used to study Holocene climatic and environmental changes in the Yangtze River Delta region.

One sediment core was drilled from Hengsha Island of the Yangtze River Delta to depth of 40 m. A total of 16 OSL samples were collected from the cores. Single-aliquot and single-grain quartz were used to determine the sediment ages. The results showed that there are two sedimentary hiatuses at ~15 m and ~34 m core depth, and the core is divided into three sections: (i) the upper 15 m of the sediment was deposited about 0.4 ka years ago; (ii) deposition is continuous from 1.5 to 5 ka in thickness from 15 to 34 m; (iii) the deposition time at the depth of 34–40 m is ~10–11 ka. On the basis of chronology, sampling at 2–20 cm intervals was used for geochemistry analysis, which is currently underway. Finally, we will discuss the similarities and differences of the Holocene Asian monsoon reflected by the estuarine records, stalagmite and lake records in the Yangtze catchment.

Climate oscillations during the transition MIS 6-5e against MIS 2-1, based on data from Central Europe

Dr. Aleksandra Majecka [1], *Mr. Dmitry Tsvirko* [2], *Prof. Leszek Marks* [3], *Mr. Dariusz Wieczorek* [4]

1. Faculty of Geology, University of Warsaw, Poland, 2. University of Lodz, Doctoral School of Exact and Natural Sciences, 3. Polish Geological Institute - National Research Institute, Warsaw, 4. Polish Geological Institute – National Research Institute, Holy Cross Branch of Jan Czarnocki, Kielce

Hundreds of the Eemian Interglacial sites are documented in Central Europe, therefore the Eemian pollen succession is quite easily recognizable and its regional characteristics are widely identified. By contrast, records of the Late Saalian, including a continuous transition to the Eemian Interglacial, are relatively rare and mostly short. Nevertheless, decline of the Late Saalian is recorded as the stadial-interstadial oscillations at many sites in the northern continental Europe. The Late Glacial sites that comprise a transition to the Holocene (MIS 2-1) are also numerous in this area. However, only a few of them possess a full record of the vegetation development throughout this period and most of the succession contains gaps or local disturbances. Most data that document these periods come from shallow lakes of different origin and the most complete sequences are usually derived from annually laminated sediments. Based on numerous data from the terrestrial sites in Poland, Ukraine, Belarus and Western Europe, similarities and differences of climate fluctuations during the Late Saalian/Eemian and the Late Glacial/Holocene were identified. The general climatic improvement during the Late Saalian, expressed in the pollen record, reflects two oscillations that were reported in Western Europe – the older cooler stadial and the younger warmer oscillation Zeifen-Kattegat. In some aspects, these oscillations can be compared to the decline of the Late Glacial during the Weichselian. The general trend of the vegetation transformation is clearly similar: from open communities in a cold period to boreal plant communities in a warmer one. The example of the Late Saalian “Parchliny 2016” section in Central Poland shows that the pollen succession of the Late Saalian is similar to the pollen record of the Late Weichselian. In addition, results of the analysis of the terrestrial data are found to be reflected in oxygen isotope curves from the North Atlantic deep-sea cores.
This is a contribution to the research project no. 2017/27/B/ST10/00165 funded by the National Science Centre in Poland.

Lipid biomarkers of marine phytoplankton variability in modern snow and marine sediments from the southwestern Ross Sea, Antarctica

Ms. Emma de Jong [1], *Dr. V Holly L Winton* [2], *Dr. Sebastian Naeher* [3], *Dr. Bella Duncan* [2]

1. *Victoria University of Wellington,* **2.** *Antarctic Research Centre, Victoria University of Wellington,* **3.** *GNS Science*

Phytoplankton play an essential role in ocean-atmosphere systems by forming the base of the marine food web and are crucial to the global carbon cycle, acting as a significant carbon sink. The Ross Sea, Antarctica has high primary production rates influencing atmospheric carbon dioxide drawdown into the ocean. However, our understanding of how phytoplankton in the Ross Sea may respond to future climate change is limited by short observational records.

Molecular fossils (lipid biomarkers) of phytoplankton can extend observational records of primary production. Biomarkers are found in snow and marine sediment samples providing a unique opportunity to compare across archives. Here we present new results of lipid biomarkers in Ross Sea paleoclimate archives: a spatial array of snow/ice samples and marine core tops from McMurdo Sound to Terra Nova Bay, as well as filtered Ross Sea ocean water. We have investigated the spatial variability of phytoplankton biomarker concentration and composition across the different archives. Results from all three archives demonstrate the presence of phytoplankton biomarkers in the southwestern Ross Sea. The multi-archive comparison will provide new information relating to the spatial distribution and community composition of primary production in the Ross Sea and how concentrations of biomarkers relate to primary production rates. Overall, it will help validate biomarkers as a proxy to interpret longer palaeobiology records in Antarctica and help inform the impact climate change might have on biodiversity and the global climate system.

Geochemical evidence for an increased primary productivity during the Bölling-Alleröd Interstadial period than the Holocene along the south-western continental margin of India

Prof. Busnur Manjunatha [1]

1. *Department of Marine Geology, Mangalore University*

The south-western continental margin of India (SWCMI) is one of high primary productivity (PP) regions in the Northern Indian Ocean (NIO) owing to the dominance south-west monsoon winds (S-W MW) during the summer monsoon, followed by north-east winds during the winter monsoon. The decreased PP during the glacial conditions attributed to the weakened S-W MW, however, this study shows that the S-W MW seems to have been increased during the interstadial conditions, particularly during the Bølling–Allerød (B-A) period than the Holocene. Geochemistry of a radiocarbon dated sediment core from SWCMI at 1400 m depth around 13^{o} N latitude indicates that the PP indicator elements, such as Zn and Ni show contrasting behaviour from late-Glacial to the Holocene period. The Al-normalized Zn and Ni data of the core studied show an inverse trend particularly during the B-A period and to some extend during the mid –Holocene. Further, Al-normalized Zn ratios to Al-normalized Ni ratios are nearly two-fold higher during the B-A, than the entire core, particularly the Holocene section. This suggests that the diatom productivity was much higher during the B-A period relative to the Holocene time span. This finding is in agreement with the increased rainfall inferred from speleothems over the terrestrial regions of the Indian sub-continent, and decreased salinity, enhanced PP and increased denitrification rate noticed in the continental marine realm surrounding the India during the B-A period. Although many trace elements required for primary productivity, the biochemical/metabolic reactions of a cell and uptake of carbon by the phytoplankton, the most preferred trace element is Zn rather than Ni. Henceforth, Zn and Ni in marine sediments, particularly in the pristine continental margin can be used as proxies to delineate paleo-primary productivity variations. The utility of the trace elements suggested here is in agreement with the similar trace elemental isotopic investigation made by the GEOTRACES group in the productive upwelling regions.

Interplay between climate, ecosystem development, and evolution of biodiversity in Lake Victoria, East Africa

Analysis of long-term climatic variability is critical for examining the intrinsic dependency of natural ecosystems and biodiversity on climate. The transition from the last glacial episodes of the Late Pleistocene to the dawn of the Holocene epoch led to major changes in climatic conditions that have had profound impacts on the landscape. Within East Africa, Lake Victoria is located across the boundary of two major climate zones: the precipitation-rich central African upland and the semi-arid east African plateau. Due to its shallow depth in relation to surface area (~68,800 km2), Lake Victoria is particularly sensitive to changing climatic conditions, and since its inception ~400ka, the lake has undergone multiple episodes of drying and filling coinciding with the glacial-interglacial cycles. Previous paleolimnological research shows the most recent refilling of Lake Victoria following the Last Glacial Maximum, occurred after desiccation events reported between ~18 and ~15 ka BP. Within this relatively short geologic history, the endemic adaptive radiation of >500 species of cichlid fish has occurred in record time, making Lake Victoria one of the most widely cited model systems in evolutionary biology. To reconstruct the dynamic state of the Lake Victoria ecosystem and its biodiversity from the late Pleistocene to the present, we analysed multiple biotic and geochemical proxies (pollen, biogeochemistry, invertebrates, and fish fossils) from a transect of four sediment cores that trace the development of the highly productive littoral zone and the less productive pelagic/profundal zones through time. We present a comprehensive analysis of past vegetation and ecological changes throughout the modern lake's history to assess how the long-term dynamics of the ecosystem interact with the evolution of its biota. Pollen data reveals the manifestation of climatic fluctuations, which suggests major transitions between rainforest and savannah grasslands. Additionally, other proxy datasets also indicate a dynamic history of lake filling that likely occurred over a longer timescale than previously reported. The integration of past ecological and limnological changes recorded in the chronostratigraphic sequences of Lake Victoria provides valuable insights into the interactions between climatic shifts, the development of an ecosystem, and the evolution of species diversity.

Diatom-bound nitrogen isotopes as a paleo-proxy in lacustrine environments: a preliminary report

Mr. Jules Millet [1], *Dr. Johan Rydberg* [2], *Dr. Christian Bigler* [2], *Prof. Nathalie Dubois* [3], *Prof. Moritz Lehmann* [1], *Dr. Anja Studer* [1]

1. Department of Environmental Sciences, University of Basel, Bernoullistrasse 30, 4056 Basel, Switzerland, 2. Department of Ecology and Environmental Science, Umeå University, Linneus väg 6, 901 87 Umeå, Sweden, 3. EAWAG

Diatom frustules are well preserved in marine and lacustrine sediments over hundreds or even thousands of years. They contain minute amounts of intra-crystalline organic matter that is thought to be protected by the silica against diagenetic alteration. Previous applications have shown that the $^{15}N/^{14}N$ ratio of the organic nitrogen contained in these frustules (the diatom-bound $\delta^{15}N$, or $\delta^{15}N_{DB}$) can be used as a proxy for nutrient cycling in the polar oceans, and that it is not affected by diagenetic effects. However, the applicability of this paleo-proxy to lacustrine sediments has never been tested.

One goal of this study is to validate whether the organic nitrogen contained in diatom frustules is indeed protected against diagenetic alteration. For this purpose, we will analyse and compare the $\delta^{15}N_{DB}$ and N_{DB} content of sediment trap, surface sediment and downcore sediment material from a time-series study of varved sediment cores from Nylandssjön, a lake in northern Sweden. We will also measure the $\delta^{15}N_{DB}$ and N_{DB} content from degradation experiments of diatom cultures, in order to assess diagenetic aspects on timescales from days to decades.

Another goal of this study is to explore the use of $\delta^{15}N_{DB}$ to reconstruct the history of nitrogen dynamics in Swiss lakes. Provided that the $\delta^{15}N_{DB}$ record is unaffected by diagenesis, it should record past changes in the N input/output processes and/or internal N cycling processes within a given lake. We chose to investigate the sedimentary record of the well-studied Lake Baldegg in Switzerland, a eutrophic lake with varved sediments between 1885 and 1995, which is being artificially ventilated since 1982. We will present the $\delta^{15}N_{DB}$ down-core record of Lake Baldegg sediments and compare it to other sedimentary proxies (e.g., bulk isotopic composition, elemental composition and chlorophyll *a*), as well as hydrochemical datasets from the lakes' monitoring program (e.g., nutrient concentrations), allowing us to constrain the environmental context of sedimentation, and to disentangle the multiple controls on the $\delta^{15}N_{DB}$ in Lake Baldegg in the recent past.

Novel techniques for reconstructing relative changes in past UV-B flux

Mr. Bert Verleijsdonk [1]***, Dr. Katherine Holt*** [1]***, Prof. Barry Lomax*** [2]***, Dr. Phillip Jardine*** [3]***, Dr. Marcus Vandergoes*** [4]***, Mr. Timothy Anane*** [1]

1. Massey University, 2. School of Bioscience, University of Nottingham, Sutton Bonington Campus, Loughborough, United Kingdom, 3. Westfälische Wilhelms-Universität Münster, Institut für Geologie und Paläontologie, Münster, Germany, 4. GNS Science

Many climate and environmental parameters can now be reconstructed over geological timeframes via biological, geochemical, biogeochemical and sedimentological proxies. However, reconstructions of past variations in UV-B radiation are comparatively limited, due to a lack of suitable proxies. Given the threat that UV-B radiation poses to both human and ecosystem health, there is a need to better understand past UV-B flux to appreciate the challenges that elevated surface UV-B levels could pose in the long-term.

Sporomorphs (pollen and spores) contain UV-B absorbing compounds (UACs) in the sporopollenin biomacromolecule which forms their outer walls. UACs function as a natural ‘sunscreen’, protecting the gametes within the sporomorph from damage caused by exposure to UV-B radiation. Empirical and experimental studies have determined that UACs are ubiquitous in sporopollenin, and that the quantity increases with increased exposure of the parent plant to UV-B. Because sporopollenin is highly resistant to decay, sporomorphs are abundant in the fossil record, and their UAC content stays stable over time. Sporomorphs therefore offer an avenue for the reconstruction of surface UV-B flux through time.

We present preliminary results from our project in which we are using Fourier Transform infrared (FTIR) microspectroscopy to measure UACs within sporomorphs from Lake Ohau (44°16.782’S, 169°55.480’E, New Zealand) sediment records. One of our project aims is to produce the first sporomorph-based UAC record from the Southern Hemisphere. To deliver this, we will target at least two taxa native to New Zealand within the Ohau record, to produce a high-resolution (biennial) record for the Maunder Minimum, and a low-resolution record for the entire Holocene. The data will be used to study key atmospheric research issues, including if Maxima and Minima respond the same way to forcing, if Schwabe cycles can be detected in high resolution sporomorph UAC records, and if variations in surface UV-B derived from the Ohau record can be linked to longer-term processes related to orbital forcing. Data from this study will be compared to a complimentary dataset using a similar sampling strategy from Nar Gölü, (Türkiye) in order to undertake the first interhemispheric comparison of UAC records of UV-B variation through time.

Constraining Black Sea nitrogen cycling during the Holocene using lipid biomarkers

Dr. Anna Cutmore [1] ***, Dr. Nicole Bale*** [1] ***, Dr. Rick Hennekam*** [1] ***, Prof. Gert-Jan Reichart*** [1] ***, Prof. Stefan Schouten*** [2]

1. *NIOZ Royal Netherlands Institute for Sea Research,* ***2.*** *NIOZ, Royal Netherlands Institute for Sea Research, Department of Marine Microbiology and Biogeochemistry (MMB); Utrecht University, Faculty of Geosciences, Department of Earth Sciences*

The study of marine basins under anoxic conditions can provide perspective on the current deoxygenation of the modern global ocean under anthropogenic warming and associated feedbacks with the marine nitrogen cycle. At present, a thorough understanding of the nitrogen cycle on timescales exceeding the observational record, particularly in anoxic environments, remains elusive. Today the Black Sea is the world's largest permanently stratified anoxic basin; it is a hyposaline (18-22 psu), vertically-stratified sea, with limited connection to the global ocean through the Bosporus Strait. However, the basin has only been anoxic below 200 m water depth (Arthur & Dean, 1998) since ~7.5 ka when post-glacial sea-level rise caused spillage of seawater over the Bosporus sill. Before this time it was a more oxygenated, fresh-water lake. Records from the Black Sea over the Holocene can therefore provide insight into the nitrogen cycle dynamics under drastic environmental changes.

Using a sediment record from the Black Sea spanning the Holocene (0 – 15 ka), this study aims to better constrain the marine nitrogen cycle in an anoxic environment using organic geochemical approaches. These approaches include the use of high-resolution accurate mass spectrometry (MS) to identify and semi-quantify a range of lipid biomarkers. The target biomarker in this study include (1) heterocyste glycolipids (HGs), associated with N_2 fixing cyanobacteria (Bauersachs et al., 2010; Bale et al., 2019); (2) isoprenoidal glycerol dialkyl glycerol tetraethers (GDGTs), including those associated exclusively with ammonia oxidising archaea (Sinninghe Damsté et al., 2002); and (3) bacteriohopanetetrols (BHPs), including bacteriohopanetetrol (BHT-x), which is y associated with marine anaerobic ammonium oxidizing (anammox) bacteria (Schwartz-Narbonne et al., 2020). Combining these records with total organic carbon, total organic nitrogen and redox-sensitive trace element data, we aim to better understand the marine nitrogen cycle under changing anoxic conditions, and its potential links to broader global climate dynamics.

Coastal vegetated ecosystems are important carbon storage for half of the carbon in marine sediments and soils. Seagrass meadows have exceptionally high carbon storage capacity which contributed to their recognition as significant Blue Carbon sinks. Their protection and restoration are included in climate change adaptation strategies. One of the seagrass species that notably modifies its growing substrate is the endemic *Posidonia oceanica* (L.) Delile from the Mediterranean Sea that occupies coastal areas of up to 40 metres of water depth. In addition to its carbon sequestration power, *Posidonia oceanica* contributes significantly to seawater oxygenation and sediment stabilisation. Studies of the interaction of *Posidonia oceanica* with sediments along the eastern Adriatic coast are scarce. The aim of this study was to provide a conclusive palynological, mineralogical, geochemical, and microbial overview of the *P. oceanica* substratum in the Vrulje bay of the Kornati islands. A detailed palynological analysis was conducted on a 269 cm long core in order to obtain paleovegetational background. Furthermore, the core was analysed for mineralogical composition and grain-size. The geochemical investigation included XRF core scanning, organic and inorganic carbon, and total nitrogen measurement, whereas ^{14}C dating results offered a chronological framework. The high-resolution seismic survey of the Kornati channel was also performed in order to gain insight into the subsurface of the coring area. Archaea and bacterial communities were investigated by environmental DNA metabarcoding. Our study provided the Holocene paleorecord of the formation and growth of the *P. oceanica* matte in the investigated area. We made new estimates on the seagrass carbon storage and organic carbon accumulation rates in the sediments during the last 8140 years B.P. The analysed sediment core further offered exhaustive evidence of the paleoenvironmental changes that occurred due to the Holocene climate and sea level variability. The obtained data are important for understanding the storage of carbon in sediments accumulated directly below the *P. oceanica* meadow.

The CLIMCOST Project: Recurrence of extreme weather events in Western Europe from a Holocene perspective and its implication for the management of coastal ecosystems in Galicia

Dr. Armand Hernandez [1]***, Prof. Roberto Bao*** [1]***, Dr. Rita González-Villanueva*** [2]***, Ms. Uxía Fernández*** [1]***, Dr. Blanca Moncunill-Solé*** [3]

__1.__ Universidade da Coruña, GRICA group, Centro de Investigacións Científicas Avanzadas (CICA), Spain, __2.__ Centro de Investigación Mariña, Universidade de Vigo, XM-1, España, __3.__ Universidade da Coruña, Departamento de Física e Ciencias da Terra, Spain

Climate predictions of precipitation and atmospheric circulation at decadal timescales are not entirely reliable due to the lack of quantitative reconstructions for long time periods. CLIMCOST project aims to evaluate climate variability during the late Holocene and identify recurrent patterns of extreme climate events and their impact on the coastal systems of Galicia (Northwest Iberia, Spain). To this end, quantitative reconstructions of decadal-scale precipitation in Western Europe are being carried out beyond the current instrumental record, to identify the interactions between the modes of climate variability in the North Atlantic, their relationship with the latitudinal position of the jet stream and the storm tracks. This will allow: 1) a much more complete understanding of the regional atmospheric circulation; 2) its direct relationship with extreme hydroclimatic events; and 3) the impact on coastal systems. To this end, we are using sedimentary archives and applying new approaches in geochronology, proxy calibration, advanced statistical modelling, and biogeochemical techniques.
CLIMCOST looks for forming a triple helix, integrating research, management, and society to provide key information on the relationship between jet stream migrations and their impact on coastal systems. The Holocene perspective of the project is crucial to analyse the resilience of ecosystems, generate an early warning system for risks and threats, improve predictive capacity in the short, medium, and long term and ensure the sustainability of aquatic ecosystems. All of this in a region where economic activities along the coast have always been the driving force of its economy and as is being demonstrated, is highly sensitive to rainfall variability in the context of current climate change.

A Late Holocene δ18O paleoclimate record from the afro-alpine Lake Garba Guracha, Bale Mountains Ethiopia: implications for human occupation/abandonment

Mr. SAMUEL, GETACHEW CHERNET [1]***, Mr. Lucas Bittner*** [2]***, Dr. Graciela Gil-Romera*** [3]***, Prof. Michael Zech*** [2]

1. *Heisenberg Chair of Physical Geography with focus on paleoenvironmental research, Institute of Geography, Technische Universität Dresden, 01069 Dresden,* ***2.*** *Heisenberg Chair of Physical Geography with Focus on Paleoenvironmental Research, Institute of Geography, Technische Universität Dresden,* ***3.*** *ARAID Researcher - Pyrenean Institute of Ecology - CSIC*

The Late Holocene, being a period when human footprint in paleoenvironmental archives became increasingly apparent, records important information about how early humans adapted to ever changing climatic conditions. Lake Garba Guracha is an afro-alpine cirque lake located in the Bale Mountains National Park in the Southeastern highlands of Ethiopia. The reconstructed age depth model of 10 years/cm makes it one of the best climate archives in the highlands of Eastern Africa. A total of 15.5 meter core recording 16 ka of sedimentation was retrieved from the lake. Previous works done on the archive include: (i) establishing the age-depth model and determination of sedimentation rates using bulk sedimentary organic matter, bulk *n*-alkane and charcoal ^{14}C ages; (ii) multi-proxy paleoenvironment reconstruction using charcoal, diatoms, biomarkers, and stable isotopes. Results from these works show a strong variability recorded in late Holocene that represents the termination of the African Humid Period (AHP) and increased fire intensity. This study focuses on the topmost sedimentary succession of the core representing the late Holocene (~5 ka to present) and implements $\delta^{18}O_{sugar}$ extracted from organic matter derived natural sugars in high resolution (every 4 cm). Variability in $\delta^{18}O_{sugar}$ record can be used as a proxy for lake evaporation history· Combing with other important proxies such as n-alkane and charcoals and archaeological studies will shade light on a possible synergy of climate and humans in this high alpine ecosystem.

Climate and land-use effects in southwestern Morocco during the last three millennia

The southwest of Morocco is considered to be an area of refuge within the Mediterranean region, hosting the endemic tropical Argan tree. This region is presently subject to severe droughts, desertification, and land degradation, and likely facing increased climate variability and socio-economic stress in the future. Here, we use the stable hydrogen and carbon isotope composition (δD and δ13C) of plant-waxes in a high-resolution marine sediment core (GeoB8601-3) collected off Cape Ghir in southwestern Morocco, in combination with published data on pollen and XRF element ratios from the same archive. We aim to reconstruct the hydroclimate and vegetation history during the last 3000 years. Stable carbon isotope compositions of leaf waxes (δ13Cwax) show that natural vegetation in southwestern Morocco consists of C3 plants. Minor variations in δ13Cwax were positively correlated to changes in stable hydrogen isotope compositions of leaf waxes (δDwax) before 700 CE. Changes in rainfall amounts and water use efficiency indicate a clear vegetation response to precipitation changes and thus to climate forcing. After 700 CE, δDwax and δ13Cwax became de-coupled suggesting that the plant wax discharge and their isotope signals were no longer solely controlled by climate; the waxes likely mainly originate from the lowlands and carry an enriched (dry) δD signal but a depleted 13C signature. The depletion of δ13Cwax correlates with the increased Argan pollen concentration in the record. The period between ~700 and 900 CE coincides with the Arabization of Morocco which had an impact on the demographic composition of the country leading to new agricultural habits and, as a result, on the land-use triggering a higher erosion of lowland material by the Souss River.

Sixty years scientific deep drilling in land, ice and sea floor: the north Andean guide to the Quaternary

Prof. Henry Hooghiemstra [1]***, Dr. Vladimir Torres*** [2]***, Prof. Lucas Lourens*** [3]***, Dr. Vivian Astrup Felde*** [4]***, Dr. Gustavo Sarmiento*** [5]***, Dr. Juan-Carlos Berrio*** [6]***, Dr. Suzette Flantua*** [4]

1. *Institute for Biodiversity and Ecosystem Dynamics,* ***2.*** *Exxon Mobil,* ***3.*** *Utrecht University,* ***4.*** *University of Bergen,* ***5.*** *Universidad Nacional de Colombia, Bogotá,* ***6.*** *University of Leicester*

We sketch the initial history of collecting deep cores in terrestrial basins, marine sediments on the ocean floor, and arctic ice cores to study the environmental and climate change. Subsequently, we focus on the development of long records from the Northern Andes. In the Bogotá basin, the 540 m long pollen record Funza09 from ancient Lake Bogotá reflects the last 2.25 Ma with 1200yr resolution. The grain size record continues up to the bedrock at 586 m depth possibly reflecting the complete Quaternary. Developing a robust age model has been challenging. We used orbital tuning and curve matching between the marine ∂18O record and the peaks in abundance of *Alnus* for the last 1 Ma, when extensive *Alnus* swamp forest surrounded the lake during interglacial conditions. Ancient Lake Bogotá was born 1.4 Ma and lost its water body at 27 ka. Before 1.4 Ma a drainage system with swamps and lakes covered the surface of the slowly subsiding basin floor while forest occurred on higher grounds. In the Fúquene basin, the 58 m long composite record from Lake Fúquene covers the 284-27 ka interval with 60 yr resolution. The last 27 ka were covered by record Fúquene-2 though at lower resolution. Absence of a seismic reflectance profile across the basin prevented identification of the optimal drilling location. In the basin of Lake La Cocha the last 14 ka were analysed at ~25 yr resolution bringing geological and human dimensions of climate change together. We show the relevance of high-resolution pollen analysis.

Feeding a Digital Elevation Model of the Northern Andes with Funza09 upper forest line positions of the last 1 Ma allowed the spatial reconstruction of the hyper-diverse high-elevation alpine ecosystems, the páramos. The operating Flickering Connectivity System drove speciation to high levels. In contrast, the montane forest experienced a continuous connectivity driving latitudinal migration of pre-adapted forest taxa. We show the relevance of high-resolution pollen analysis in deep continental records, and address the various challenges and limitations of working with deep cores based on our 50 years of experience in continental core drilling.

Character and behaviour of Qaanaaq (Piulip Nunaa) glaciers in north-west Greenland (Kalaallit Nunaat) since the Little Ice Age

Prof. Jonathan Carrivick [1]***, Dr. Jenna Sutherland*** [2]***, Dr. Mark Smith*** [1]***, Mr. Michael Grimes*** [1]

1. *University of Leeds,* ***2.*** *Leeds Beckett University*

The centennial and decadal timescale response of land-terminating glaciers is important for projecting future changes to Arctic sub-polar glaciers and hence meltwater and sediment fluxes. This study analyses prominent moraines, the proglacial areas and contemporary glacier character on the Qaanaaq peninsula (Piulip Nunaa) in NW Greenland to determine geometric changes of glaciers since the neoglacial maximum (Little Ice Age) and to interpret glacier behaviour then and now. Specifically, we made ice surface reconstructions and ice thickness datasets to determine geometric changes and likely thermal regime during the LIA, and a suite of field observations and measurements at five of the outlet glaciers of high-resolution topography, geomorphology and sedimentology, and glaciology. LIA moraines and proglacial outwash surfaces are predominantly composed of subglacially-mobilised boulders and thus related to areas of former temperate basal ice. In contrast, ice-cored lateral moraine ridges of sub-angular boulders are related to ice-marginal areas of (former) cold-based ice. Other ridges or mounds of englacial and supraglacial debris, and geometric and sinuous ridge networks are also associated with ice-marginal cold-based ice. Contemporary ice-margins and ice surfaces exhibit many features to suggest cold-based ice, including convex surface gradients, no crevasses, few but large supraglacial streams usually associated with medial moraine and sediment drapes and ridges emanating from thrust planes, for example. Overall, it is apparent that since the LIA these glaciers have retreated, thinned and evolved from more temperate to more cold-based conditions and behaviour.

Modelled palaeoclimate and ice dynamics in the low latitude Peruvian highlands

***Mr. Ethan Lee* [1], Dr. Stewart Jamieson [2], Dr. Neil Ross [1], Prof. Andrew Henderson [1], Prof. Andrew Russell [1], Dr. Derek Fabel [3]**

1. Newcastle University, 2. Durham University, 3. Scottish Universities Environmental Research Centre

The dynamics and response of tropical glaciers to past global climate changes are poorly understood. This is despite tropical glaciers being highly sensitive to climate and important indicators of recent climate change. We use the Parallel Ice Sheet Model (PISM), a hybrid, three-dimensional, numerical, finite-difference, shallow ice sheet model to model palaeo-glaciation within the northern Peruvian highlands.

Lagunas de las Huaringas is a low-latitude location that was previously glaciated at a relatively low elevations (3,900-2,600 m a.s.l.), presumably during the Last Glacial Maximum (LGM), but which is now completely deglaciated. Previous work has reconstructed a series of valley glaciers, from which an LGM temperature reduction of 6.5-8.8℃ has been inferred from the geomorphology.

Here we used PISM to reconstruct glaciation in this location, using the model to develop our knowledge of the climate conditions required for glaciation of this low-latitude low-elevation site. We implemented a range of palaeoclimate scenarios, using stepped temperature cooling and precipitation fractions, and allowed the model to run to steady state conditions. All model outputs were compared to reconstructed glacial extents from mapped glacial geomorphology, in order to determine the ‘best-fit’ climate conditions for the glacial geomorphic evidence. Model runs provided three-dimensional glacier geometries from which ice mass parameters such as palaeo-equilibrium line altitudes, surface mass balances, area, volume, ice thicknesses, velocities could be determined. Our model results provide insights into the sensitivity of these former tropical glaciers to different climates and model parameters, providing an understanding of the former climate envelope which these ice masses could form.

First analysis of neoglacial geomorphology in the Nevados de Chillán volcanic complex (36,8°s – 71,4°w), Central-South Chile

Ms. Sofia Navas [1]***, Dr. Alfonso Fernández*** [2]***, Dr. Edilia Jaque*** [2]***, Dr. Lewis Owen*** [3]***, Dr. Nathan Stansell*** [4]

1. *Universidad de Concepción, Facultad de Ciencias Químicas, Departamento de Ciencias de la Tierra, Concepcion, Chile,* ***2.*** *Universidad de Concepción, Facultad de Arquitectura, Urbanismo y Geografía, Departamento de Geografía, Chile,* ***3.*** *North Carolina State University,* ***4.*** *Northern Illinois University, Department of Earth, Atmosphere and Environment, USA*

The Nevados de Chillan volcanic complex (NCVC) is a set of stratovolcanoes aligned with NW-SE orientation and with an area of about 86 km^2. Located in the Southern Volcanic Zone of the Andes, the complex consists of two main volcanic edifices that reach a little above 3100 m above sea level (asl), surpassing the regional average summits elevation by almost 1000 m asl. The complex also lies near what is considered the northern rim of the largest extension of the Pleistocene Patagonian Icesheet during the global last glacial maximum (LGM), which likely resulted from a persistent northern shift of the Southern Hemisphere westerlies. The NCVC began its activity during the Middle Pleistocene (~640 ka) and is still active today, with many glacial-interglacial periods coeval with eruptive cycles. There are almost no glaciological studies, except for a recent mass-balance monitoring of the largest glacier of the complex, but there is an absence of research reconstructing the glacial history of the NCVC. The relief formed during the LGM is characterized by large U-shaped valleys and glacial cirques that were covered by vegetation throughout the Holocene. However, there are also "fresh" glacial landforms above 2000 m asl. resulting from more recent glacier advances. The oldest historical records date from 1862 (end of the Little Ice Age), suggesting the existence of larger glaciers on these volcanoes. We characterize these landforms to develop a glacier chronology and study the climatic factors leading to glacier fluctuations. Particularly, we focus on the analysis of neoglaciations, using field mapping, satellite, and aerial imagery, and morphometric analysis of glacial deposits and landforms such as moraines, streamlined landforms, and glacially polished surfaces that are present around the whole complex. These landforms have different degrees of preservation, different distribution, and variable heights, which enable detailed reconstruction of glaciers in the recent past. The best-preserved moraines are in the western flank of the complex and their lower elevations vary between 1933 and 2350 m asl, indicating an equilibrium-line altitude (ELA) of ~2619 m asl, equating to an ELA depression of ~220 m relative to present.

Depositional record of the Lower Aare Valley region, northern Switzerland

Dr. Daniela Mueller [1]**, *Dr. Lukas Gegg*** [1]**, *Mr. Alexander Fülling*** [1]**, *Dr. Marius W. Buechi*** [2]**, *Dr. Gaudenz Deplazes*** [3]**, *Prof. Frank Preusser*** [1]

The foreland of Northern Switzerland has been exposed to repeated advances of Alpine glaciers during the Mid- and Late-Pleistocene. While those glacial advances had a lasting impression onto the landscape evolution, constrains of timing, quantity and extent remain sparse. To further the understanding of Quaternary environmental change, a promising archive was found in the infill of the overdeepened Gebenstorf-Stilli Trough and the glaciofluvial palaeochannel system of the Lower Aare Valley. In an extensive scientific campaign, ca. 350 m of drill cores as well as outcrop samples were recovered. Sedimentological and petrographic results in combination with a new luminescence chronology reveal multiple phases of glacial and glaciofluvial activity. This provides insights into regional ice-margin positions and refines our understanding of glacial sediment yields.

Unravelling the maximum extent of Middle Pleistocene Glaciation in the Ybbstal Alps, Austria

Mr. Christoph Kettler [1]***, Dr. Jürgen Reitner*** [1]
1. *Geological Survey of Austria*

Unlike deposits from the LGM in Austria (Würm Pleniglacial; MIS 2) the glacial records from the Middle Pleistocene glaciations like Riss Glaciation (MIS 6) and older are usually fragmentary, concealed and significantly overprinted by postz-depositional processes (e.g. erosion, weathering and …) of the Late Pleistocene landscape evolution. This specifically applies to terminal positions of the ice tongues.
Contrary to parts in Western Austria, where extent, terminal positions and size compared to the LGM extent from the Mindel- and Riss glaciations are well constrained, our study area shows gaps in this regard.
The Ybbstal Alps, with peaks of 1800 m and valleys of around 500 m in elevation, a unique sedimentological archive is preserved that allows the reconstruction of glacier dynamics at the terminal positions of the Enns and Ybbs glaciers. Our reconstructions are based on sedimentological data and mapping results of several gravel pits and additional sediments from valley flanks. Deposits generally show at least four major facies assemblages, starting with fluvial to distal glaciofluvial deposits (1) from the phase before the Riss climax. Followed by glacial diamictons (2) which are overlain by rhythmites (3) that are associated with a glaciolacustrine environment. Finally, the successions generally end with several metres of deltaic conglomerates (4) indicating a rapid and quick aggradation due to high sediment influx associated with glacial retreat. The record from the pre-Riss includes glaciogenic and deltaic sediments that point to a much larger glaciation. Our preliminary results indicate a much larger glaciation during the Middle Pleistocene in the Eastern Alps than previously thought.

The last glacial termination in the Atlantic Iberian mountains: insights from lake sediments in Serra da Estrela (Portugal)

Understanding the climate evolution of the last glacial termination for sensitive and transitional climatic zones such as the Atlantic Iberian mountains is crucial to estimate potential changes in regions affected by current glacial melting. We present an 8.5-m-long record including detailed sediment analysis from Lake Peixão, a pro-glacial lake in the Serra da Estrela Mountain (Central Portugal). The age-depth model relies on a Bayesian approach that includes 16 AMS ^{14}C dates and ^{210}Pb-^{137}CS measurements, and robustly dates the lake formation at 14.7±0.32 cal. ka BP. The sediment sequence is composed of 5 lithological units: U1) sandy and unsorted fluvioglacial lacustrine deposits; U2) massive fluvioglacial silty lacustrine deposits (863-790 cm below surface (bsf); 14.7-13.8 cal. ka BP); U3) water current fluvioglacial lacustrine silty deposits (790-766 cm bsf; 13.8-12.9 cal. ka BP); U4) laminated/banded silt/clay lacustrine deposits characterised by sediments from ice-covered lake periods and episodic events of ice and snow melting (766-752 cm bsf; 12.9-11.7 cal. ka BP); and U5) massive muddy lacustrine deposits (752-0 cm bsf; 11.7cal. ka BP-present). The occurrence of U2 to U4 deposits matches the transition from glacial cold (U1) to net warm postglacial conditions (U5). These changes in the sedimentary facies reflect the different phases of the deglaciation, including episodes of very low sedimentation rates related to the Intra-Allerød Cold Period and the coldest phase of the Younger Dryas. The robust chronology of Lake Peixão shows the potential of Iberian pro-glacial lakes for dating deglaciation processes in the westernmost glaciated region of the Iberia Peninsula and will lead to unprecedented decadal-to-centennial timescale Holocene climate reconstructions in this key region between the Atlantic and Mediterranean climate impacts.

The role of topography in ice-marginal landform development at Fingerbreen, Østre Svartisen, Norway

Dr. Clare Boston [1], ***Dr. Benjamin Chandler*** [2], ***Dr. Harold Lovell*** [1], ***Dr. Paul Weber*** [3], ***Dr. Bethan Davies*** [4]

1. University of Portsmouth, 2. University of Nottingham, 3. Geological Survey of Norway, 4. Newcastle University

Mountain glaciers are sensitive indicators of climate change and many records demonstrate that their rate of recession has accelerated significantly in recent decades. Loss of ice in mountain regions has critical implications for water resource management, catchment-scale sediment budgets and ecosystem response. The wealth of geomorphological and sedimentological data left behind during glacier retreat can be used to help understand the complex response of glaciers to changes in climatic and topographic conditions. Improving understanding of these controls is imperative for both refining modelled predictions of glacier recession rates and for modelling climatic change from the glacial geological record.

We present the results of investigations at Østre Svartisen, Norway (66 °N), focussing on the temperate plateau icefield outlet glacier Fingerbreen. The research examines the geomorphological and sedimentological evidence deposited during overall retreat from the Little Ice Age maximum (~ 1750 AD) to present day. Section logging of moraines and flutes provides a detailed insight into changes in sediment delivery to the ice margin as glacier recession progressed. We show that the topography of the foreland strongly influences the shape of the ice margin and guides meltwater flow, causing variability in moraine-forming processes and preservation potential. This research demonstrates the complex relationship between the sedimentary record and glaciological, topographic, climatic conditions.

Last Glacial Maximum and early deglaciation in the Stura Valley, southwestern European Alps

Prof. Matteo Spagnolo [1]***, Prof. Adriano Ribolini*** [2]***, Dr. Andrew Cyr*** [3]

***1.** School of Geosciences, University of Aberdeen, Aberdeen, UK, **2.** Department of Earth Science, University of Pisa, Italy, **3.** USGS*

We combined data from geomorphologic surveys, glacial modelling, and ^{10}Be exposure ages of boulders on moraines, to investigate the Last Glacial Maximum (LGM) and the early retreat glacial phases in the Stura Valley of the Maritime Alps. We used the exposure ages to reconstruct the timing of the LGM and that of a standstill or readvance that interrupted the post-LGM withdrawal. We mapped and dated a LGM frontal moraine to ~22 ka and a post-LGM moraine, some ~ 7 km from the maximum external limit of the LGM, to ~19 ka (Bühl stadial). This morpho-chronologic succession is congruent with that obtained in the adjacent Gesso Valley and, combined with the similarity of Equilibrium Line Altitude values, demonstrates a consistent glacial response in the Maritime Alps to climatic forcing.

Our data are chronologically consistent with those of the southern flank of the European Alps, stressing not only a general synchroneity of the LGM across the various sectors, but also that of a LGM recessional standstill or readvance at ~22 ka. The short distance between the LGM moraines and the recessionary phase moraines indicates a modest variation in the mass balance of the Maritime Alps glaciers during this time interval. A similar modest variation between LGM and the first recessional phase glacier mass balance is also found throughout the western sector of the Southern Alps but is considerably more pronounced for the glaciers of the central-eastern sectors. The heterogeneous response to these same climatic events across the Alps can be explained by the interplay between the moisture supplied by southern currents sourced in the Western Mediterranean and that advected by the westerlies sourced in the North Atlantic, which likely affected the various sectors of the Southern Alps differently.

Understanding rapid deglaciation at Mittelbergferner through a sediment-landform association lens

Ms. Paulina Mejías Osorio [1]***, Prof. Daniel Le Heron*** [1]***, Mr. Christoph Kettler*** [2]***, Dr. Bethan Davies*** [3]***, Prof. Bernhard Grasemann*** [1]

Glaciers in the Ötztal Alps (Austria) have been undergoing retreat since the "Little Ice Age" in 1850, leaving a complex geomorphic record of subglacial features, glacial and fluvial deposits, and slope-derived talus. By systematically describing and studying these features in modern alpine glacial environments, we can obtain clues as to what is driving these changes and how they are responding to the current climate conditions the Earth is facing. Mittelbergferner is one of the largest glaciers in the Ötztal Alps, and also a tourist destination in the Pitztal area, where there is an extensive suite of hitherto unstudied supra- and subglacial morphotypes that require documentation and interpretation. Here, a high resolution geological-geomorphological map is presented for the East and West lobes of Mittelbergferner based on photogrammetric data, which will be the main tool for studying sediment-landform assemblages in the area. Some of the observed features include the glacio-structural framework, drainage networks, flutes, small moraines and talus slopes. There are also signs of imminent detachments from the main glacier at the West lobe, as well as exposed bedrock within the ice and associated trails of diamicton, which are indicators of decrease in accumulation and consequent retreat. Other questions arise regarding supraglacial debris, sediment distribution and the precise role that dead ice plays on sedimentary architecture during the retreat process. The analysis of the landforms associated with ice recession at Mittelbergferner will contribute to understanding the sediment dynamics operating at rapidly retreating glaciers, offer additional perspectives on processes that are occurring in comparable glaciated areas of the Austrian Alps, and possibly give insight into ice margin stability.

Glacial Geomorphology of the Brooks Range, Alaska, U.S.A.

Mr. Jack Mason [1]***, Dr. Robert McNabb*** [1]***, Prof. Paul Dunlop*** [1]***, Dr. Bethan Davies*** [2]

***1.** Ulster University, **2.** Newcastle University*

Global and regional estimates of glacier mass and area change are poorly constrained prior to 2000 due to a lack of data, particularly in high latitude areas. This impedes our ability to comprehend and contextualise observed glacier mass loss, particularly when investigating changing rates of mass loss. This can be resolved by extending the glacial record back in time, to improve understanding of how glaciers have changed in this region under a longer-term time series of climatic change. The geomorphological reconstruction presented here will form part of a larger project, incorporating geomorphology, photogrammetry and modelling techniques to accurately constrain and project Brooks Range glacial change.

This study aims to investigate the glacial geomorphology of the Brooks Range, Alaska, and to reconstruct glacier behaviour since the “Little Ice Age” (LIA), by reconstructing the LIA glacial maximum and comparing it to various temporal points between then and 2022 AD. We use mapped glacial features to infer LIA glacier outlines and calculate their approximate area. In some areas, glacier outlines digitised from topographic maps are available and were used as timestamps to correlate glacial features with their approximate age, as well as to evaluate changing rates of glacier wastage between LIA inferred outlines and 2022 AD outlines. We derive 2022 AD glacier outlines from Sentinel-2 imagery, using a band ratio method to automatically identify glaciers followed by vectorisation and manual editing to produce a Brooks Range glacier database. Generation of these outlines enables quantification of glacier area change from the LIA to 2022 AD, as well as higher accuracy in the modelling phase of the larger project.

Our new geomorphic maps will allow us to derive glacier area change across the Brooks Range, and constrain rates of change to analyse how Brooks Range glaciers are responding to changing climatic forcings in the region. This will enable insights into the style and manner of the neoglaciation and deglaciation in the Brooks Range. Further, the results of this investigation will be used to inform the methods used as part of the larger project.

Geometry and reconstruction of former glacial formations in the El Cervunal obturated depression (Sierra de Gredos, Iberian Central System)

Dr. Rosa M. Carrasco [1], ***Dr. Jose Luis Granja-Bruña*** [2], ***Mr. Valenti Turu*** [1], ***Dr. Alfonso Muñoz-Martín*** [2], ***Mr. Xavier Ros*** [3], ***Dr. Javier Fernández-Lozano*** [4], ***Dr. Rodrigo Soteres*** [5], ***Dr. Theodoros Karampaglidis*** [1], ***Dr. José Antonio López Sáez*** [6], ***Dr. Javier Pedraza*** [2]

The glacial chronology in the Central System of the Iberian Peninsula (ICS) has been obtained mainly by applying Cosmogenic Radionuclides Exposure (CRE) techniques. The desirability of validating these data from sedimentary sequences housed in lacustrine depressions associated with ancient glaciers, made necessary specific investigations combined geological, geomorphological, and geophysical techniques. Here we present the most recent results obtained with one of these works carried out in the sedimentary infill of El Cervunal depression (CD). The CD is a flat plateau located at 1800 m asl (average altitude) in the interfluve between the valleys of Gredos and Pinar, two former glaciers (paleoglaciers) whose lateral moraines were the ones that carried out a process of obturation of this depression, forming a semi-endorheic basin during the last glacial cycle. The study of the sedimentary infill of CD means of a combined interpretation of near-surface geophysical techniques supported by geomorphological and borehole data. A set of 1D and 2D near-surface geophysical methods, including electrical (Vertical Electrical Sounding and 2D Electrical Resistivity Tomography), seismic (2D Seismic Tomography and 1D Refraction Microtremor) and Magnetic Resonance Sounding techniques, were used to test their applicability in providing better insight on the infill nature and geometry. As a result of the study, we obtained three geophysical units and five sub-units with their geological interpretation. Unit 1, includes alluvial-plain and alluvial-fan deposits, classified as a postglacial sequence (post ~10 ka). Units 2 and 3 below the postglacial unit were interpreted as glacial sequences including kame (glaciogenic and fluvio-glacial) and morainic deposits, respectively (from ~10-12 ka to ~25-27 ka). As a global result, we can say that the CD had a complex evolution where erosive-sedimentary processes predominate, but structural factors must also be considered. Finally, five well-differentiated stages can be established: pre-glacial, maximum glacial extension, trough obturation, glacial retreat and periglacial-postglacial.

Evolutionary sequence of Pleistocene glaciation in the Sierra de Guadarrama National Park

***Dr. Javier Pedraza** [1], **Dr. Rosa M. Carrasco** [2], **Dr. Javier Fernández-Lozano** [3], **Dr. Rodrigo Soteres** [4], **Dr. Theodoros Karampaglidis** [2], **Mr. Valenti Turu** [2], **Dr. María José Gil-García** [5], **Dr. Blanca Ruiz-Zapata** [5], **Dr. Javier Villa** [2], **Dr. Jose Luis Gallardo-Millán** [2]*

***1.** Departamento de Geodinámica, Estratigrafía, y Paleontología, Universidad Complutense de Madrid, **2.** Departamento de Ingeniería Geológica y Minera, Universidad de Castilla-La Mancha, **3.** Departamento de Tecnología Minera, Topografía y de Estructuras, Universidad de León, **4.** Centro de Investigación Gaia Antártica, Universidad de Magallanes, **5.** Departamento de Geología, Geografía y Medio Ambiente, Universidad de Alcalá*

The Sierra de Guadarrama (SG) occupies the eastern sector of the Iberian Central System, the central part of which corresponds to the Sierra de Guadarrama National Park (SPNG). It is a medium-range Mediterranean mountain, segmented by fault blocks, with a predominance of crystalline rocks (variscan and pre-variscan basement) and, in local areas, sedimentary cover (Cretaceous and Tertiary lithologies) and Quaternary superficial deposits. The summits in the SGNP rise to more than 2000 m asl (Pico de Peñalara, 2428 m asl) with frequent morphologies originated by ancient glaciers. In this area, 79 palaeoglaciers developed between 2413 m asl (maximum altitude glacial cirque) and 1490 m asl (minimum altitude melt front) have been identified. Most of these glaciers were cirque and slope glaciers and only exceptionally valley or plateau glaciers. All glaciers belong to the last glacial cycle (LGC) and their evolutionary sequence and chronology has been established in three main stages that agree with the regional model developed in other areas of the Central System: the Maximum Ice Extension (local MIE), assigned to both MIS2 (around 26 ka BP) and MIS3 (around 35 ka BP); a later stage of retreat-advancement-stabilization, ending around 17/15 ka BP; and deglaciation ending around 11-10 ka BP. The estimations allow the establish the ELA during the Glacial Maximum at 1926 m asl, indicating a 1000-1200 m of depression compared with the estimated present-day ELA.

Fingerprinting abrupt climate change in the West of Ireland: A high-resolution timeline of deglaciation and landscape evolution

Mr. Chris Stewart [1], ***Dr. Gordon Bromley*** [2]

1. *University of Galway,* ***2.*** *Geography and Palaeoenvironmental Research Unit, University of Galway*

Thoroughly codifying and examining paleoclimatological data ("fingerprinting") from diagnostic sites provides unique insights into the environmental past that are rarely achievable by model simulations. Fingerprinting a site tells a robust, high-resolution story of climate change for a specific location, allowing for a continuous timeline to be reconstructed through various methodologies that will ultimately refine models of larger scale. The concept of fingerprinting has been tested at a site on the west coast of Ireland, situated adjacent to the North Atlantic Ocean. This unique setting allows multiple techniques to be applied to reconstruct the nature of climate variability on Europe's maritime margin since the end of the Last Glacial Maximum (LGM). Techniques employed focus on the use of glacial geology coupled with lacustrine sedimentology and geochronology. Numerous glacial features have been identified at the site that provide evidence for the timeline of deglaciation and evolution of the landscape; this is supported with dating techniques and lake sediment core analysis. Cosmogenic Beryllium-10 dating has been employed to return direct ages from glacial evidence by using erratic boulders with beryllium-containing quartz. Using a previous study (N=11) and adding additional samples (N=9) at multiple elevations on and next to Ben Bury mountain in the Mweelrea massif, we have produced a directly dated timeline of ice sheet deglaciation since the LGM and subsequent cirque glaciation. Concurrently, a sediment core extracted from an adjacent lake contains a continuous record from its formation to the beginning of the Holocene. Dating methods including Carbon-14 and varve counting allow this core to match and fill-in the record of deglaciation obtained from cosmogenic dating of glacial deposits. Our preliminary results suggest that current paradigms of recent abrupt climate change may need refining. Fingerprinting Ben Bury has provided a yardstick for local deglaciation through direct dating across different elevations and the following snowline reconstruction. Zero-degree isotherms indicate that the local snowline was high as early as 18ka, suggesting deglaciation was occurring rapidly no later than the end of the LGM, and there is no distinct Younger Dryas advance afterward.

Subdivision of the Little Ice Age in the Alps

Dr. Kurt Nicolussi [1], Dr. Melaine Le Roy [2], Prof. Christian Schlüchter [3], Prof. Markus Stoffel [2], Dr. Lukas Wacker [4]

1. Department of Geography, University of Innsbruck, 2. Institute for Environmental Sciences, Climate Change Impacts and Risks in the Anthropocene (C-CIA), University of Geneva, 3. Institute of Geological Sciences, University of Bern, 4. Ion Beam Physics, ETH Zurich,

The “Little Ice Age” (LIA) can be considered, on the one hand, as a period of repeated and far-reaching glacier advances during the last millennium, on the other hand this term is also used to address the period of relatively low temperatures following the Medieval Climate Anomaly (MCA) and preceding the modern warming. The end of the LIA in the Alps is in general set to the mid-19th century, i.e., to the approximate date of the last glacier maximum. However, the onset of the LIA is not so well defined and is now usually placed in the 14th century and thus around the first general glacier maximum after the MCA. New results, based on tree-ring dating of several hundred years old and in-situ buried trees at Mont Miné and Morteratsch glaciers, show that this glacier advance preceding a 14th century maximum began no later than in the second half of the 13th century.

This early-LIA advance of Mont Miné and Morteratsch glaciers is consistent with results obtained at other Alpine glaciers and coincides with relatively cool summer temperatures in the late 13th and 14th century. The first LIA-advance phase in the Alps culminated in the late 14th century, followed by a retreat period with reduced glacier extents and minor advances, which was finally followed by the historically well-known LIA-advance period from the end of the 16th century onwards. The Alpine glacier record in combination with summer temperature reconstructions suggest a subdivision of the LIA (approx. 1260 to 1860 CE) in the European Alps into an early phase (1260-1380), an intermediate period (1380-1575) and a main phase (1575-1860).

Chronology and Equilibrium Line Altitudes of paleoglaciers along the southern fringe of the European Alps during the Last Glacial Maximum

Mr. Lukas Rettig [1], Dr. Sarah Kamleitner [2], Prof. Susan Ivy-Ochs [2], Dr. Giovanni Monegato [3], Prof. Paolo Mozzi [1], Prof. Adriano Ribolini [4], Dr. Franco Gianotti [5], Prof. Matteo Spagnolo [6]

1. Department of Geosciences, University of Padova, 2. Laboratory of Ion Beam Physics, ETH Zürich, 3. CNR IGG, Padova, 4. Department of Earth Sciences, University of Pisa, 5. Department of Earth Sciences, University of Turin, 6. School of Geosciences, University of Aberdeen

During the Last Glacial Maximum (LGM), most of the European Alps was covered by an extensive and complex palaeoglacier network. Only along the external fringes of the Alps did isolated, smaller valley glaciers and ice caps in the order of 1 to 100 km^2 develop. These smaller glaciers constitute excellent palaeoclimate proxies as they likely responded very dynamically to changes in temperature and precipitation. However, they have been studied only in a few areas so far, without the application of a consistent methodological approach.

Here we present a new synthesis of isolated mountain glaciers along the southern fringe of the Alps during the LGM, ranging from the Carnic and Julian Prealps in the East to the Maritime Alps in the South-West. Geomorphological surveys were carried out both using remotely sensed data and through targeted fieldwork. Based on these data, palaeoglacier 3D geometries and Equilibrium Line Altitudes (ELAs) were reconstructed numerically in a GIS environment. Age control is selectively provided through ^{10}Be and ^{36}Cl surface exposure dating on moraine boulders. This allowed not only to assign moraine ridges to an LGM age, but also to evaluate if ice advances occurred simultaneously across different parts of the mountain chain and if they were in or out of phase to larger Alpine glaciers.

We demonstrate that ELAs across the southern Alpine fringe were highly variable during the LGM, reflecting the diverse climatic conditions that characterised the individual mountain ranges. This provides important insights into the larger scale atmospheric circulation and may be used to validate glacier and palaeoclimate modelling studies.

Real-time coarse cryogenic cave carbonate formation in a Pyrenean ice cave

Dr. Miguel Bartolomé [1]***, Dr. Marc Luetscher*** [2]***, Prof. Christoph Spotl*** [3]***, Dr. Maria Leunda*** [4]***, Dr. Mª Cinta Osácar*** [5]***, Dr. Pilar García-Orduña*** [6]***, Dr. Ánchel Belmonte*** [7]***, Prof. Sergio Henrique Faria*** [8]***, Dr. Carlos Sancho*** [5]***, Dr. Ana Moreno*** [9]

Coarse cryogenic cave carbonates (CCC_{coarse}) are rare crystals and aggregates thereof that form in caves when water freezes in a semi-closed system in ice pools. Freezing provokes the loss of CO_2 and the segregation of solutes, leading to the precipitation of CCCs. That pool model is accepted for the formation of CCC_{coarse}; however real-time formation of CCC_{coarse} has never been observed. Since 2018 we have observed the formation of CCC_{coarse} in two pools in a small gallery in the Sarrios 6 ice cave (Central Pyrenees). The floor and ceiling of this gallery are covered by ice. The mean annual air and rock temperatures have remained below 0°C since 2014, thus indicating the presence of permafrost in this gallery. However, many dripping points feed a pool located at the entrance of the gallery. After intense rainfalls or days of snow melting, the drips feed that pool and eventually lead to flooding of the gallery. We have observed the formation of two pools since the gallery opened due to the ice retreat in 2016. The CCCs form ball-shaped aggregates 9-10 cm in diameter. These balls, locally called comuños, consist of thousands of carbonate crystals, including elongated, rhombohedral, and globular crystals (≥2 mm) showing in radial structure. These crystals are supported by an ice matrix. Analyses using single crystal cryogenic X-ray diffractometry performed on frozen samples indicate that the crystals are calcite. The first presence of these CCCs was noticed in December 2018 in a pool with a highly degraded ice cover. In Spring 2019, the same pool was covered by a new ice layer and some comuños were present, one of them hanging from the ice cover, as well as in a nearby pool. These observations, and the study of stable isotopes, will help to refine the pool model for the formation of CCC_{coarse}.

Unprecedented cave ice melting over the last 6100 years in Southern Europe

Current global warming is the main cause of the observed dramatic decline in glaciated surface and permafrost extension worldwide. Less is known, however, about the impact on ice caves, cryospheric environments poorly studied but highly exposed to environmental changes. A294 ice cave is located in the Central Pyrenees (Cotiella massif), and hosts an ice deposit (firn) which spans from 6100 to 1880 cal. years BP. This exceptional deposit is suffering a dramatic ice decline in recent years, and its imminent demise is feared. The ice body stratigraphy comprises detrital layers (unconformities) representing decadal-scale ablation periods. Three of these unconformities, however, represent periods with low ice accumulation at 5515 - 4945, 4250 - 3810 and 3155 - 2450 cal. years BP related to drier and maybe warmer winters. Information about current conditions in the cave is extensive and evidence a dramatic ice lost which is unique in the long history of this ice deposit. Thus, twelve years of cave monitoring, historical cave surveys, photographs, and ice measurements indicate a continuous retreat of the ice body (ca. 8 - 140 cm a^{-1}), and a rise of the cave air temperature (ca. 1-1.5°C). The increase in cave air temperature is related to the increase of winter temperatures, which controls the cave temperature during the open phase, while during the closed phase it depends on the previous open phase and the heat transfer via drip water. Thus, less waters freezes every year, triggering a fast ice retreat which is also favoured by a continuous decrease in snowfalls. Our current observations clearly manifest that a phase of drastic melting conditions, as the one evidenced currently, is absent in the ice stratigraphy. If a similar melting phase/s than the one the deposit is experiencing today would have occurred in the past, the ice stratigraphy would have shown truncated strata and important high angular unconformities due to the melting and the accommodation of the following snow aggradation phase/s. These observations in conjunction with regional palaeoclimate data indicate that the ice decline in the A294 ice cave is unprecedented in the context of the last six millennia.

A glacial-geologic vantage on MIS-2–1 tropical climate variability from the Colombian Andes

Dr. Gordon Bromley [1], ***Prof. Meredith Kelly*** [2], ***Dr. Alice Doughty*** [3], ***Mr. Jordan Herbert*** [2], ***Dr. Sergio Restrepo*** [4], ***Dr. Daniel Ruiz*** [5]

As the primary source of energy, water vapour, and latent heat export for Earth's atmosphere, the tropics dominate our climate system both on long and short timescales. Recent research even suggests a driving role for the tropics in the abrupt climatic shifts that characterised the Late Pleistocene and which, potentially, represent Earth's preferred mode of changing climatic state. Therefore, tropical mountain glaciers and geologic records of former glacial change afford a unique opportunity for exploring the timing and magnitude of past climatic variability and thus testing new hypotheses for global change. Yet high-quality glacial-geologic records from low-latitude settings remain relatively scarce and consensus on how the planet's single largest climate zone contributes to global climate has yet to emerge. To help address this shortcoming, we present a new glacial-geologic record from the Sierra Nevada del Cocuy, Colombian Andes (6°N), spanning MIS-2 and the early Holocene and resolved with cosmogenic ^{10}Be surface-exposure dating. Coupled with glacier-climate modelling, we also use this record to assess the potential influence of topography on glaciers' response to climate.

Well-preserved moraine landforms in the Lagunillas and Bocatoma valleys describe a Late Pleistocene mountain glacier system that, at its maximum extent, terminated at ~3600 m elevation, approximately 700 m below the local Little Ice Age limit. Beryllium-10 ages constrain the outer complex to the period spanning the Last Glacial Maximum (LGM: ~30–19 ka) and also reveal the fine structure of glacier–and therefore climate–fluctuations during the LGM. Inboard of the LGM, our record constrains not only the onset of and protracted retreat of tropical ice during Termination 1, but also the timing of multiple, brief readvance events that punctuated overall warming. In both Lagunillas and Bocatoma, a longer and more pronounced readvance occurred during the Lateglacial, yet clear discrepancies in the relative timing of these events potentially reveals the influence on mass balance of topography. More broadly, comparison of the glacier-inferred Cocuy climate record to other datasets generated via the same methodology, both within and beyond the tropics, has revealed key similarities and important disparities in the timing and nature of natural climate variability.

The sedimentology of Austria's dying glaciers

Prof. Daniel Le Heron [1]***, Mr. Christoph Kettler*** [2]***, Ms. Paulina Mejías Osorio*** [3]***, Dr. Bethan Davies*** [4]

The dramatic shrinkage of Austria‘s glaciers records unprecedented change. However, the sedimentary record left by downwasting or retreating Alpine glaciers provides a potential opportunity to better understand this process, and also to inform our understanding of the complexity of Pleistocene glacial deposits preserved in mountainous landscapes. Drawing on examples from three glacier forefields, it is shown that dying glaciers in Austria are associated with unique landsystems and sedimentary facies. For the Pasterze Glacier, disconnections from the accumulation area, rapid elevation loss at the snout and flow stagnation are characteristic, and a complex delta system is observed building out on a large lake at the top of the buried, stagnant ice at the margin. Observations from 2018 and 2021 show extensive cannibalisation and lobe switching interpreted to result from downwasting of the underlying ice. At the flanks of the Gepatschferner in the Ötztal Alps, a 10 m thick subglacial till blanket was exposed in 2021. This till blanket, which may have partly supported the ice margin before a major phase of downwasting by July 2022, is mantled by a series of small (50 cm high, 50cm wide, 5 m long) ice parallel ridges. Such ridges are ice-margin parallel and are also very well expressed in front of small glaciers in Pitztal. These are tentatively interpreted as passive fills to crevasses (i.e. material sliding of the glacier surface into marginal crevasses). Detailed textural investigation of these structures, coupled with ongoing detailed mapping at multiple scales, is warranted to understand the significance that this association of facies holds in writing the last chapters of Alpine glaciers.

Glacial Lake Speight: A tale of two hypotheses

Dr. Jenna Sutherland [1]***, Dr. Nicholas Patton*** [2]***, Prof. James Shulmeister*** [3]***, Prof. Tammy Rittenour*** [4]***, Ms. Michelle Nelson*** [4]***, Prof. Jonathan Carrivick*** [5]***, Prof. Tim Davies*** [6]***, Dr. Liam Taylor*** [7]

Palaeo-lake shorelines are well-preserved on several voluminous fans in the middle Waimakariri River catchment in the Southern Alps of New Zealand. These shorelines are a key piece of evidence in the concept of 'Glacial Lake Speight', originally interpreted in the late 1950s to have temporarily occupied the valley during deglaciation from the local Last Glacial Maximum ice extent. The existence of this former lake is well-known within the local Quaternary community, and it is often considered a type-site for river-blocking events and consequent lacustrine development. Despite this, its proposed mechanism of damming remains under scrutiny by two competing hypotheses. The original view postulates that terminal moraine and debris-covered stagnant ice dammed the lake, which persisted for hundreds of years. However, the relative age of landforms in the valley conflicts with this interpretation. Surface stratigraphy reveals that the lake must have been younger than previously proposed because the fans, upon which the shorelines are preserved, would not have survived glacial occupation of the valley. An alternative hypothesis for the river-blocking is a co-seismically-triggered landslide, for there is an abundance of scars on surrounding hillslopes and the proposed damming site lies in close proximity to several active faults. Constraining the age of this lake is therefore critical to determine the valley-damming mechanism and to obtain a better understanding of landscape development in the region. In our new study, the detailed evolution of valley-damming is reconstructed from observed sediment sequences and optically stimulated luminescence dating. With carefully targeted chronological data from the lake shorelines, we confirm that the damming was likely triggered by changes in the extent and thickness of glacial ice and that the original interpretation as a glacial lake still stands. The discrepancy between geomorphological evidence and chronological control is still apparent however, and for this interpretation to hold true, it requires contemporaneous fan building and shoreline erosion. Our re-evaluation suggests that perhaps the hypotheses are not mutually exclusive after all, but that it is possible for a seismic event to have occurred during or shortly after deglaciation allowing post-glacial fan activity to fit within the geochronological sequence of events.

Timing of Glacial Extents on Cerro Chirripó during Termination I using 10Be and 3He Surface Exposure Dating

Mr. Caleb Okpala [1], ***Prof. Meredith Kelly*** [1], ***Ms. Liesel Robbins*** [1], ***Dr. Alice Doughty*** [2], ***Dr. Maxwell Cunningham*** [1], ***Ms. Victoria Halvorson*** [1], ***Dr. Michael Kaplan*** [3], ***Dr. Adolfo Quesada-Román*** [4]

The role of the tropics in past climate changes including the last glacial-interglacial transition (known as Termination 1) is poorly understood. Here we aim to improve the understanding of past tropical temperature change during Termination 1 using the extents of mountain glaciers in the inner humid tropics (~10 degrees N to 10 degrees S latitude), where glacier mass balance is sensitive to changes in temperature. We present new data on the timing of the Last Glacial Maximum extents on Cerro Chirrpó (3820 m asl, ~ 9.48 N, 83.49 W) in Cordillera de Talamanca in Costa Rica. We apply ^{10}Be and ^{3}He surface exposure dating of glacial moraines and glaciated bedrock. Our results thus far show that glaciers in Valle las Morrenas and Valle Talari near Cerro Chirrpó reached their maximum extents at ~21-19 ka. Subsequently, glaciers receded rapidly, with high-elevation bedrock surfaces near the heads of the valleys indicating ice-free conditions by ~17.5 ka. We compare these results to other records of tropical glacial extents during Termination 1 including those in South America and East Africa. This comparison suggests a consistent pattern of tropical terrestrial cooling during the global Last Glacial Maximum (~26-19 ka) followed by rapid warming at ~19-17.5 ka.

Age of the oldest Quaternary sediments in the northern Swiss Alpine foreland

The northern Alpine foreland was extensively glaciated and witnessed multiple phases of alternating deposition and incision within the Middle and Early Pleistocene. These processes have created the present landscape with elevated plateaus separated by deeply incised overdeepened valleys. On top of these plateaus can be found the oldest Quaternary glaciofluvial sediments in Switzerland called Deckenschotter (DS) – traditionally divided into two phases of formation: Higher Deckenschotter (HDS) and Lower Deckenschotter (TDS). The stratigraphic relationship of HDS and TDS is inverted and their elevations differ by approx. 100-150 m. The time of their deposition is important for understanding long-term landscape evolution of the northern Alpine foreland. We aim to reconstruct the chronology of the alternating phases of deposition and incision of the Deckenschotter gravel units. Our focus is placed on Deckenschotter deposits outcropping at several locations in northern Switzerland, where we selected two HDS (Tromsberg and Feusi) as well as four TDS (Iberig, Hungerbol, Cholfirst and Schwändihalden) sites. In this study we implement the isochron-burial dating technique with the pair of cosmogenic nuclides, ^{26}Al and ^{10}Be, to date the Deckenschotter sediments (Granger, 2014). Furthermore, we utilize P-PINI (Particle Pathway Inversion of Nuclide Inventories), a new burial-dating model proposed by Knudsen et al. (2020) that applies a source-to-sink approach to further examine and refine the question of the timing of deposition of the various Deckenschotter units. However, due to a lack of clear topographic channel constraints and overriding by subsequent glaciers at some sites, terrace correlation is not a straightforward task. Furthermore, recent dating results fired a debate on DS correlations. Therefore, we combine these time constraints with results from a GIS-based morphostratigraphic analysis of the glaciofluvial plateaus by testing paleofluvial pathways and related terrace correlation. This contributes to better understanding of the spatial and topographic relationships between the several Deckenschotter deposits as an aid to deciphering the Early to Middle Pleistocene evolution of the Alpine foreland.

Ice Memory Italian drilling: a research project to collect heritage ice cores from Alps, Apennines and Arctic region

The last IPCC special report on the cryosphere states that the glaciers will lose substantial mass by the end of the century, all over the word. Glaciers decline is going to cause the loss of climatic information stored in the ice layers. It is therefore strongly urgent to take action to preserve this information. Ice Memory (IM) is an international research project that aims to drill ice cores from mountain glaciers from all over the world, to characterize their climatic and environmental records and store them in the coldest place in the world: Antarctica.
The Italian team of Ice Memory is working to collect six ice cores from ice bodies with different characteristics: a) two glaciers located over 4000 m asl on Grand Combin (GC) and on Mt. Rosa (RS) (Pennines Alps); b) the Marmolada Glacier (MR), which is the largest glacier of the Dolomites, located below 3000 m slm; c) the Montasio Glacier (MS), which is the lowest glacier of the Italian Alps, located at around 1900 m slm on the Giulian Alps; d) the Calderone glacieret (CL), which is the southernmost European ice body, located in the middle of Appennines at around 2700 m asl; and e) Holthedlafonna glacier (HO) which is a large glacier in the north part of Svalbard Islands at 1100 m. HO glacier area is equal to 600 km2, MR, MS, and CL are characterized by glacier area lower than 1.5 km2, whereas MS and CL are smaller than 0.05 km2. To date, three of the six missions have been accomplished on GC, RS and CL. The drilling survey on HO, MR and MS are scheduled for 2023 and 2024.
Although the presence of cold firn is an essential characteristic to preserve climate information, could low altitude and smaller ice bodies give us useful information about past climate? The challenge is to collect these samples before their complete disappearance, projected in the next few decades. For these reasons, IM represents the last chance to secure the information stored in these ice bodies.

Heavy Mineral Assemblages Indicating Dynamic Sediment Source of the Assam Basin in Response to Early Uplift Stages of the Eastern Himalayas

Mr. Rahul Kumar [1]***, Prof. Ashraf Uddin*** [2]***, Prof. Jogendra Nath Sarma*** [3]***, Ms. Owishi Sarkar*** [4]***, Ms. Jasmin Naher*** [2]***, Prof. Adam Switzer*** [5]

1. *Asian School of the Environment, Nanyang Technological University,* ***2.*** *Department of Geosciences, Auburn University,* ***3.*** *Department of Applied Geology, Dibrugarh University,* ***4.*** *Department of Earth Sciences, Indian Institute of Technology Bombay, Mumbai,* ***5.*** *Earth Observatory of Singapore, Nanyang Technological University Singapore*

Sedimentary rocks preserve the record of paleoenvironmental and paleotectonic conditions as the constituting sediments develop in close relation with the prevailing climatic conditions and the source rock type. In this study, we used the integrated approach of heavy mineral assemblages and the petrographic analysis to understand the temporally changing sediment source that fed the Assam Basin, India, during the early uplift stages of the eastern Himalayas.

The early upliftment and denudational history of the eastern Himalayas are recorded in the Oligocene siliciclastic sediments of the Assam Basin, which can be revealed by sandstone modal analysis and heavy mineral distributions. The Oligocene Barail Group exposed in the Digboi-Margherita area in the Assam is thick (~5 km), deposited mainly in brackish water to deltaic environments primarily consisting of the fine to medium-grained sandstones. The Barail Group constitutes three distinct formations: Naogaon ($Qt_{69}F_6L_{25}$), Baragolai ($Qt_{66}F_{12}L_{22}$), and Tikak Parbat ($Qt_{82}F_4L_{14}$) from old to young, respectively. We collected 16 representative sandstone samples from different formations in the Barail Group and separated heavy minerals using heavy liquid (tetrabromoethane) for quantitative analysis. The assemblages of heavy minerals are mainly dominated by opaque minerals (around 80 wt. percent), along with non-opaque varieties including ultra-stable heavy minerals (zircon, tourmaline, and rutile), garnet, apatite, epidote, hornblende, muscovite, topaz, chlorite, chloritoid, and prehnite. The concentration and diversity of heavy minerals increase up section, suggesting changing sediment source type. Total heavy mineral concentrations vary from negligible to up to 1.5 wt. percent in entire succession with the minimum value in lowermost Naogaon Formation and the maximum value in uppermost Tikak Parbat Formation. Although the concentration of heavy minerals increases with time, the ZTR index decreases from 20% in Naogaon to 3.65% in Tikak Parbat Formation, indicating decreasing compositional maturity of heavy mineral assemblages with time. There is also an increase in the concentration of garnet, staurolite, andalusite and a decrease in the concentration of chlorite, chloritoid, prehnite, epidote in the up-section, suggesting a change in the source type from lower to intermediate grade metamorphic rocks. Further understanding of heavy mineral chemistry can unveil the sediment source information at a higher resolution.

Europe’s Lost Frontiers: New Perspectives, New Insights.

Dr. Simon Fitch [1], ***Prof. Vince Gaffney*** [1], ***Dr. Rachel Harding*** [1], ***Prof. Richard Bates*** [2], ***Dr. Andrew Fraser*** [1]

1. *University of Bradford,* ***2.*** *University of St. Andrews*

Europe’s Lost Frontiers was the largest, directed archaeological research project undertaken in Europe to investigate the inundated landscapes of the Early Holocene North Sea – the area frequently referred to as ‘Doggerland’. Funded through a European Research Council Advanced Grant (project number 670518), the project ran from 2015 to 2021, and straddled both Brexit and the onset of the Covid pandemic. Despite suffering the curse of interesting times, more than 30 academics collaborated within the project, representing institutions spread geographically from Ireland to China. A vast area of the seabed was mapped, and multiple ship expeditions were launched to retrieve sediment cores from the valleys of the lost prehistoric landscapes of the North Sea. This data has now been analysed to provide evidence of how the land was transformed in the face of climate change and rising sea levels.

This presentation will present some of the results of the Europe’s Lost Frontiers project (Gaffney et al. 2022), that demonstrate that the utilisation of spatially extensive data allows the recovery of information pertaining to the actual Mesolithic landscape of the North Sea and that extensive mapping of the region is now possible. This information not only reveals the diversity of this landscape but will suggest that the project will provide benchmark data for future research on the environmental and cultural heritage of Doggerland. This is increasingly important as it is clear that contemporary climate change, and the rush for green energy, is pushing development within the North Sea at an unprecedented rate. In the face of such change, it will be argued that it is vital that academics, developers and curators work together to assist green development, but also to continue exploration of Europe’s largest and best-preserved prehistoric landscape.

Investigating the Holocene storm flood history of East Frisia – geomorphological studies near Dornum (North Sea coast, Germany)

Mrs. Hannah Wahlen [1], ***Dr. Friederike Bungenstock*** [2], ***Dr. Timo Willershäuser*** [1], ***Dr. Peter Fischer*** [1], ***Prof. Andreas Vött*** [1]

1. *Johannes Gutenberg University Mainz, Institute of Geography, Mainz, Germany,* ***2.*** *Niedersächsisches Institut für historische Küstenforschung*

Since the end of the last Ice Age, the landscape of East Frisia (Lower Saxony, Germany) has been shaped by a sharp rise in sea level and a resulting loss of land. Storm surges have repeatedly flooded populated areas, especially since the Middle Ages. Man tried to counteract this development, for example by building dykes.

The data and results presented here originate from the marsh near Dornum in East Frisia, located inland of the Accumer Ee tidal inlet. Due to this location, the study area was particularly exposed to storm surges in the past. Between the barrier islands of Baltrum and Langeoog, the water could flow towards the coast unhindered. A port near the present-day Dornum was first mentioned in AD 1289. During the 1st Grote Mandrenke (or St. Marcellus' flood) in AD 1362, the dyke was breached and a bay between Dornum and Westeraccum was created. Several attempts to repair the dyke failed. Efforts to close the bay succeeded almost 100 years later, largely along the dyke line from before AD 1300.

It can be assumed that past storm surges have left their mark at the research site. Geophysical investigations and vibracoring at selected locations were carried out with the aim to find evidence of past storm surges and to reconstruct the landscape history of the region. Vibracores ACC 1A and ACC 3A as well as the results of geophysical investigations document several Holocene extreme events. Geochemical and microfauna analyses support these results, radiocarbon dating was used for establishing a geochronostratigraphy.

Let's go to the red mountain – Preliminary results of and future plans for Late Pleistocene - Early Holocene palaeolandscape reconstruction off the Heligoland coast

***Mrs. Stine Detjens* [1], *Dr. Arne Lohrberg* [2], *Prof. Wolfgang Rabbel* [3], *Prof. Sebastian Krastel* [2], *Prof. Berit Eriksen* [1]**

1. *Centre for Baltic and Scandinavian Archaeology,* ***2.*** *Institute of Geosciences, Christian-Albrechts-Universität zu Kiel,* ***3.*** *Christian-Albrechts-Universität zu Kiel, Institute of Geosciences, Kiel, Germany*

In a vast and dynamic Late Glacial landscape in the southeastern North Sea, Heligoland must have been of immense importance. It was a landmark, vantage point and source region of unique red flint, which was extracted there and transported into the present inland since the Late Palaeolithic. The reconstruction of Late Palaeolithic living and migration conditions in not-yet flooded areas of the North Sea, especially around Heligoland, is one of the central unresolved questions of today's Stone Age research for northern Central Europe.

High-resolution sediment echo sounding data has been acquired near Heligoland during cruises AL496, AL511 and MSM98/2. The preliminary analysis of this data reveals a high density of shallow channels that exhibit (apparent) widths of 200 m to 600 m. Our first results suggest an extensive Late Pleistocene - Early Holocene drainage pattern. We aim to reconstruct this drainage pattern for the Heligoland area, as it will allow us to determine probable locations of hunter-gatherer settlements and related migration paths on land and water through the period in question.

However, as the line spacing of available sediment echosounding profiles is not close enough with respect to target size, correlating channels and other landforms between profiles is not always possible. Furthermore, the extension of the channel network to Heligoland is yet unknown. Future fieldwork (German Research Foundation cruise TRAPA, planning pending) is intended to remedy this. We plan to map a 20x23 km wide area northeast of Heligoland with a Teledyne Parasound system at very high lateral resolution. Ground truthing and dating of land surfaces will be achieved by means of a 6 m Vibrocorer.

Is this waterscape connected to the present river Eider and/or the tidal stream Heverstrom? Does the channel network continue towards Heligoland and thus serve to guide reindeer herds and their hunters past the red massif? How dynamic is this palaeolandscape likely to have been? Are the courses of major rivers stable, or do they change on a shorter than millennial time scale? So far, there are lots of questions and the promise of answers once we venture at sea.

Analysis of a buried post-Eemian erosional feature in the Southern North Sea

Mrs. Despo Kyriakoudi [1]***, Ms. Morgan Vervoort*** [1]***, Dr. Ruth Plets*** [2]***, Prof. Marc DeBatist*** [1]***, Dr. Thomas Mestdagh*** [3]***, Dr. Tine Missiaen*** [2]

1. *Department of Geology, Ghent University, Belgium,* ***2.*** *Flanders Marine Institute (VLIZ), InnovOcean Campus, Jacobsenstraat 1, 8400 Oostende, België,* ***3.*** *Flanders Marine Institute (VLIZ), InnovOcean Campus, Jacobsenstraat 1, 8400 Oostende, Belgium*

The southern North Sea has been significantly affected by glacial and interglacial cycles during the Middle and Late Pleistocene. The offshore stratigraphic record can be used to understand the regional response to these climatic changes and reconstruct the Quaternary palaeo-landscape evolution of the area.
During the Eemian Interglacial (MIS 5e) and the Weichselian Early Pleniglacial (MIS 4) periods, the regional climate underwent significant changes and sea level fluctuated considerably. The global sea-level record illustrates a period of rapidly rising sea level towards the Eemian highstand, reaching values close to the present, followed by a drop of 40-50m during the Early Pleniglacial lowstand. During the Eemian- Weichselian transition, a widespread 5-20m thick unit composed of clay-rich, brackish-marine sediments was deposited across the southern North Sea. This deposit is known as the *Brown Bank Formation (BNB)* or *Brown Bank Member* in the British and Dutch sectors, respectively. Although it is easily identifiable on seismic profiles as a unit composed of (sub)parallel reflectors, its chronology and depositional environment remain poorly defined.
For this study, high-resolution seismic data and sediment cores were collected in 2022 from the wider area of the North Axial Channel, a major NS-oriented palaeo-river system. The seismic data reveal the presence of a buried and infilled channel-like feature that locally incises the older sediments of the BNB. This NS-oriented feature has a total length of more than 20km, a width of up to ~1.5km, and a max. depth of ~25m below the seafloor; core data show the infill consists of fine-grained sediments. The geomorphology of the channel and sedimentary infill pattern imply a period of extensive erosion of the BNB followed by rapid infilling with younger sediments. We aim to examine the newly acquired datasets to better understand (a) the processes that shaped the erosional surface within the BNB, (b) the genesis, age, and morphology of the enigmatic channel, and (c) the depositional environment and processes in the region. Any information derived from this study will be a valuable contribution to understanding and reconstructing the stratigraphy, sedimentary architecture, and depositional history of the southern North Sea during the late Quaternary.

In search of seismic and sedimentary evidence for proglacial North Sea lakes: Insights into their distribution and role during the Elsterian and Saalian glaciations

Ms. Morgan Vervoort [1]***, Mrs. Despo Kyriakoudi*** [1]***, Dr. Ruth Plets*** [2]***, Dr. Thomas Mestdagh*** [3]***, Dr. Tine Missiaen*** [2]***, Prof. Marc DeBatist*** [1]

1. *Department of Geology, Ghent University, Belgium,* ***2.*** *Flanders Marine Institute (VLIZ), InnovOcean Campus, Jacobsenstraat 1, 8400 Oostende, België,* ***3.*** *Flanders Marine Institute (VLIZ), InnovOcean Campus, Jacobsenstraat 1, 8400 Oostende, Belgium*

During the Middle and Late Pleistocene, ice sheets occupied parts of the North Sea during three major glaciations, the Elsterian (MIS 12), the Saalian (MIS 10-6) and the Weichselian (MIS 4-2). The exact limits of these expanded ice sheets and the dynamics and chronology of the expansions are, however, still a point of discussion. Nevertheless, most offshore studies support the idea of the presence of proglacial lakes in some form and at some point in time in front of these ice sheets. Solid geomorphological and sedimentological indications for the presence of these lakes are, however, scarce and evidence is mostly circumstantial. The existence of an Elsterian proglacial lake is e.g. used in the argument that glacial outburst floods created the erosional features preserved in the Dover Strait.

As part of the WALDO project ("Where are All the (proglacial) Lake seDiments in the NOrth Sea Basin?"), this project aims to test the hypothesis that proglacial lakes were important landscape features in the southern North Sea during the Elsterian, Saalian and Weichselian glacial periods, based on the analysis and interpretation of marine geophysical and geological data. In the framework of this project, two surveys with RV Belgica have been conducted, during which high-resolution geophysical data (multibeam bathymetry and backscatter, acoustic and seismic data) have been acquired in parts of the southern North Sea where proglacial lakes have been inferred to have existed in previous studies. The first data presented here are retrieved from the Southern Bight area and are used to update the lithostratigraphic framework and regional palaeo-geography, in order to gain a better understanding of the landscape evolution during the Elsterian and Saalian glacial periods.

Spatial variability in isotopic composition of surface snow along the East Antarctic International Ice Sheet Traverse (EAIIST)

Mrs. Agnese Petteni [1], Prof. Barbara Stenni [1], Dr. Giuliano Dreossi [1], Dr. Ilaria Crotti [1], Dr. Mathieu Casado [2], Dr. Amaelle Landais [3], Dr. Joel Savarino [4], Dr. Andrea Spolaor [1], Dr. Massimo Frezzotti [5], Prof. Barbara Delmonte [6]

1. Ca' Foscari University of Venice, 2. Laboratoire des Sciences du Climat et de l'Environnement, 3. LSCE, 4. Université Grenoble Alpes, CNRS, IRD, Grenoble INP, IGE, 5. Roma tre University, 6. University of Milano-Bicocca

The isotopic signal of oxygen and hydrogen, archived in the Antarctic ice sheet through snow precipitation, is an important proxy of climatic conditions. This signal depends on several parameters such as local temperature, climatic conditions in the moisture source areas and air mass pathways. Moreover, the isotopic composition may be affected by spatial variability induced by the interactions of the snow surface with the overlying atmosphere along the direction of the prevailing winds. In regions where the snow accumulation is very low, interactions between the atmosphere and the snow surface could modify the pristine signal through isotopic exchanges, sublimation processes and mechanical mixing originated from wind action.

The EAIIST (East Antarctic International Ice Sheet Traverse) traverse, which took place during the 2019-2020 Antarctic field season, starting from Concordia Station towards the South Pole, provides a perfect path of study. Along the EAIIST traverse, areas with homogeneous accumulation rates can be compared to areas influenced by wind scouring and mega-dunes formation. Extremely low accumulation and wind-surface snow interaction observed in these areas could be representative of glacial period conditions in the Antarctic Plateau.

Here we present the isotopic composition (dD and d18O) of surface (a few cm of depth), bulk (1 m depth) and snow pit (2 m depth) samples along the EAIIST traverse to evaluate the parameters explaining the spatial variability of this proxy. The dD, d18O and the deuterium excess will be evaluated with respect to geographical features (elevation, latitude, distance from the coast, slope) and climatic conditions (temperature, accumulation, wind speed and direction). Wind action is expected to play a major role in explaining the isotopic spatial variability in these areas.

Understanding the spatial variability in the deposition process, which strongly decreases the ratio between signal and noise, is essential to better interpret high-resolution isotopic profiles from firn and ice cores, collected along the EAIIST traverse, which will be analyzed soon.

The anthropogenic footprint through a high-resolution analysis of trace organic compounds in an Antarctic ice core

This work focuses on the reconstruction of the anthropogenic fingerprint over the last 150 years through the analysis of organic compounds preserved in Antarctic ice. The ice core (length: 50 m; diameter: 100 mm) was retrieved at GV7 during the 2013/14 austral summer campaign. This is an ideal archive for studying the "Great Acceleration" since it spans the last 150 years and it was extracted in a highly significant site. The GV7 site (70°41'S, 158°51' E, 1950 m a.s.l.) presents a high snow accumulation rate (241 ± 13 mm we yr^{-1}) which ensures high temporal resolution. Indeed, this feature is not easily found in archives covering such a recent period and it is crucial for performing high-resolution analyses on trace organic compounds that require relatively large amounts of matrix.

In the last decades, several pollutants have been subject to international bans and restrictions aimed at reducing their industrial production due to their high toxicity and persistence in the environment. As a result, limitations on one compound have led to increased industrial emissions of other pollutants. The recently developed multi-proxy analytical method for snow and ice samples employed in this work enables to detect trends in well-established and emerging pollutants preserved in the ice resulting from successive international bans on several POPs. Furthermore, volatile personal care products can provide information about changes in household habits. Specifically, fragrances from domestic sources have exponentially increased over the past 50 years. Therefore, the unprecedent high-resolution study of these substances in Antarctic ice enables one to recognize the evolution of single compounds over time, in response to international agreements and social changes. Thus, the anthropogenic signal is mainly described by semi-volatile and highly persistent tracers which are carried over long distances in the atmosphere to the polar regions, where they accumulate as result of cold condensation processes.

Trace organic compounds were determined by using solid-phase extraction (SPE) combined with gas chromatography coupled to triple quadrupole mass spectrometry (GC-MS/MS). The samples preparation was carried out entirely in a stainless-steel cleanroom to minimize organic contamination, achieve low detection limits and increase the analytical signal.

Deciphering the Oxidizing Capacity of the PAST atmosphere (ERC Doc-Past) by switching from elemental to molecular isotope ratios

Atmospheric chemistry is an essential component of the functioning of the Earth's climate. It determines the atmospheric lifetime of most climatic agents impacting the nature and concentrations of aerosols, greenhouse gases, cloud formation. Determining how this chemical reactivity has evolved in the past is essential, both for evaluating chemistry-climate models (CCM) and for establishing future climate trajectories. The chemical activity of the atmosphere is driven by highly reactive atmospheric compounds that have a very short lifetime in the atmosphere. Because of this ephemeral nature, they are not archived in the paleoclimate record. Reconstructing this chemical activity over time remains a difficult exercise that has not been successful to date. Using ice cores, the multidisciplinary DOC-PAST project proposes to develop new tracers of this chemical activity by taking advantage of the revolution introduced by clumps and isotopic anomalies. The aim is to use a variety of ice cores covering all latitudes to highlight key elements of the chemical reactivity of the atmosphere. This poster will present the main hypothesis of the Doc-Past ERC as well as the strategy and new analytical means to reveals the past oxidation state of the atmosphere.

New chronology of EPICA Dome C (EDC) ice core over the last 800 ka using the Bayesian tool Paleochrono and new records of elemental and isotopic composition of air trapped in the core.

To understand the phase relationships between external forcing and climate change, precise ice cores chronologies are crucial. However, dating ice cores is particular since they require two chronologies: one for the ice and one for the younger air trapped in bubbles. The EDC ice core covers the last 800 ka and was dated in the framework of AICC2012 chronology, established for five ice cores: EDC, EDML, NGRIP, VK and TALDICE using the following method. A sedimentation model is used to calculate prior age scales from a background scenario of three variables: snow accumulation, ice thinning and Lock-In-Depth, the lowest depth where air is locked in bubbles (LID). A Bayesian tool then statistically adjusts the age scales, and the three variables, so that they respect chronological observations (dated horizons, dated intervals, stratigraphic links between cores, ...). The AICC2012 chronology is associated with an uncertainty around 2,500 years, reaching 8,000 years at the bottom of the core mainly due to orbital dating uncertainty. Here, we present new data on EDC ice core reducing the new chronological uncertainty.

New data consist in: 1) additional absolute age constraints spanning the last 800 ka derived from radioisotopes (^{40}Ar, ^{81}Kr) measured in air trapped in EDC ice core, and 2) new orbital age constraints obtained by synchronising EDC ice core records with their orbital target. These records include the air isotopic composition ($\delta^{18}O_{atm}$, $\delta O_2/N_2$), recently measured at high-resolution over the last 800 ka, and the total air content (TAC) signal now spanning the entire core. Volcanic bipolar synchronisation provides additional stratigraphic links, relating EDC to other cores and reducing the uncertainty on recent periods. Finally, the estimation of the LID allows to connect ice and air timescales, therefore it is an essential ice core dating tool. Here, we present new information constraining the LID, including highly-resolved measurements of air isotopic composition ($\delta^{15}N$) and firn modelling estimates when data are missing. Then, the Bayesian dating tool Paleochrono is used to construct new air and ice chronologies over the last 800 ka. The associated uncertainty is of 1,700 years on average, mainly decreased over the last 650 ka.

"A new Hybrid Continuous Flow Analysis (CFA) system coupled with Fast Liquid Chromatography - Tandem Mass Spectrometry (FLC-MS/MS) for Biomass Burning (BB) tracers' analysis in ice cores. Applications for paleoclimatological characterizations."

One of the main challenges the paleoclimatic scientific community is currently facing is represented by the achievement of high-resolution measurements for chemical markers in ice cores, while limiting time efforts for sample processing and analysis. Therefore, a new Continuous Flow Analysis (CFA) system has recently been realized at Ca' Foscari University of Venice, in collaboration with the CNR Institute of Polar Science (CNR-ISP). The novelty of this technology is allowing for on-line measurements of meltwater flow and the contemporary collection of samples for subsequent discrete analyses. Coupled with Fast Liquid Chromatography – tandem Mass Spectrometry (FLC-MS/MS) for continuous high-resolution measurements of organic markers in ice cores, the CFA is capable of 1 cm of spatial resolution. After optimizations, this approach has been applied to the quantification of specific biomass burning tracers, such as vanillic acid, syringic acid, and levoglucosan, obtaining one measurement every 30 s. To assess the robustness of the system with real samples, we tested the system using an alpine ice core. Together with organic compounds, insoluble dust particles and conductivity records can continuously be acquired, while the discrete samples collection from dedicated lines offers the opportunity to subsequently analyze trace and crustal elements, major ions and water stable isotopes.

Investigation of the in situ production of N2O in Antarctic ice cores using isotope analysis

Ms. Lison Soussaintjean [1]***, Dr. Jochen Schmitt*** [1]***, Dr. Joel Savarino*** [2]***, Dr. Barbara Seth*** [1]***, Prof. Thomas Röckmann*** [3]***, Prof. Hubertus Fischer*** [1]

Nitrous oxide (N_2O) is a trace gas in the atmosphere involved in stratospheric ozone destruction, and a potent greenhouse gas whose concentration has varied substantially in the past. Ice cores represent the only direct paleo-atmospheric archive that would allow the reconstruction of the past N_2O atmospheric concentration over the last 800 000 years. However, such a long continuous record is still missing, as some sections of Antarctic ice cores corresponding to dust-rich glacial intervals are affected by *in situ* production of N_2O. These sections show elevated N_2O concentrations.
Using isotopic analysis, this study aims to identify the processes responsible for N_2O *in situ* production, in order to eventually correct the N_2O signal. We observe clear deviations of the nitrogen ($\delta^{15}N$) and oxygen ($\delta^{18}O$) isotopic composition of N_2O in glacial Antarctic ice affected by *in situ* production from the atmospheric values (as defined by the almost unaffected Talos Dome ice core record). The $\delta^{15}N(N_2O)$ signature of the *in situ* fraction becomes systematically more enriched with decreasing accumulation rate, while its $\delta^{18}O(N_2O)$ signature shows no systematic dependence on accumulation rate. Since nitrate (NO_3^-) shows the same enrichment with decreasing accumulation rate, NO_3^- could be the precursor for high $\delta^{15}N$ values of *in situ* N_2O at low accumulation sites. To test this hypothesis, we carried out joint measurements of $\delta^{15}N$ and $\delta^{18}O$ of N_2O and NO_3^- in samples from the EDC, EDML, and Talos Dome ice cores. The resulting $\delta^{15}N$ values of NO_3^- and *in situ* N_2O appear to be highly correlated with a slope of 0.5, whereas the $\delta^{18}O$ values show two distinct clusters for low and moderate accumulation sites. Our results support the hypothesis of a denitrification reaction with an oxygen isotopic exchange between the nitrite intermediate and water. However, the N isotopic data show that NO_3^- is probably not the only precursor and that one of the N atoms may originate from another nitrogenous compound. This investigation will be narrowed down by additional isotopic analyses and site preference measurement of ^{15}N in N_2O, which, by differentiating nitrification and denitrification, would allow to determine the reaction mechanism.

On the use of a new 800 ka Total Air Content record to improve the dating of the EPICA Dome C ice core

Accurate absolute chronologies of ice cores are crucial to interpret paleoclimatic records and to decipher their relationship to external and internal forcings. The chronology of the deeper part of Antarctic ice cores is mainly constrained by orbital age markers inferred from tracers measured in air trapped in ice. In particular, age markers deduced from the alignment of the Total Air Content of the ice (TAC) on a local integrated summer insolation curve were used to constrain the AICC2012 chronology of the EPICA Dome C (EDC) ice core over the past 440 ka. However, a full understanding of the physical processes influencing TAC variations is still missing together with a quantitative estimate of the age uncertainties attached to TAC-based age makers.

Here, we present new TAC measurements on EDC at a ~2 ka resolution extending the published record back to 800 ka. First, we investigate the imprint of orbital periodicities in the 800 ka TAC record using spectral analyses. We identify that the last 500 ka of the record is characterised by a dominant period related to obliquity but its strength decreases significantly in the oldest part. Second, we investigate the most relevant orbital tuning target to infer age markers based on a comparison between the TAC record and a selection of local summer insolation curves, and our understanding of how the insolation signal could get imprinted in TAC. Third, we quantify the age errors attached to TAC-based markers considering sources of uncertainties related to (i) the choice of the orbital target, (i) the filtering band for TAC, (iii) the record alignment method and (iv) the loss of visual resemblance between variations in TAC and its orbital target. Age uncertainties vary from ~2 ka to more than 6 ka.

The comparison of a TAC-based chronology with the AICC2012 chronology over the last 600 ka suggests ages differences of 1.4 ka on average and they vary within the stated AICC2012 age uncertainties. Finally, we compare the TAC dating constraints with those deduced from O_2/N_2 and we discuss implications for a joint use of these orbital tools in order to date old ice.

New Zealand volcanic eruptions captured in Antarctic ice cores

Changes in the Earth's climate and environment have been documented after historic volcanic eruptions, however, the magnitude of explosive eruptions in the geological record far exceeds those witnessed in modern history, by up to one hundred times. New Zealand provides an ideal opportunity to assess the impacts of huge volcanic eruptions on the climate and environment due to a number of large and well preserved large eruptions occurring over the last million years. Here we present tephra geochemical results of the Taupō (232 CE) and Oruanui (25.5 ka) eruptions recently identified in multiple Antarctic ice cores. The identification of ash from New Zealand eruptions in multiple ice core records will help refine ice core chronologies and provide insights into the regional and global environmental impacts of these huge volcanic eruptions. For example, the large ash plumes, rich in limiting micronutrients such as iron, likely covered vast areas of the Southern Ocean supplying bioavailable iron nutrients required for phytoplankton blooms and marine primary production; a process which converts atmospheric carbon dioxide into organic matter. We outline our plans to investigate iron fertilisation and the response of marine primary production in the Southern Ocean following the large explosive volcanic eruptions using novel ice core proxies.

Using ice core records to understand interannual-multidecadal patterns, trends and drivers of Antarctic Ice Sheet accumulation changes

***Ms. Jess Macha* [1], Prof. Andrew Mackintosh [1], Dr. Felicity McCormack [1], Dr. Benjamin J. Henley [2], Prof. Helen McGregor [2]**

__1.__ Securing Antarctica's Environmental Future, School of Earth, Atmosphere and Environment, Monash University, __2.__ Securing Antarctica's Environmental Future, School of Earth, Atmospheric and Life Sciences, University of Wollongong

The Antarctic Ice Sheet (AIS) is currently losing mass. However, the causes of these changes are not fully understood and the rate and magnitude of future AIS mass loss remains highly uncertain. The extent of potential ice sheet mass loss offset by increases in future Antarctic precipitation is unclear. Rising near-surface atmospheric temperatures will cause an associated increase in the atmospheric moisture-holding capacity, resulting in increasing Antarctic precipitation and accumulation, however, the resultant amount of precipitation increase is uncertain.

Satellite records extend 40 years, but ice sheets respond to climate from seasonal to greater than centennial timescales, meaning hundreds of years of observational data are required to understand the physical processes driving AIS surface mass balance. Therefore, paleoclimate data is necessary to characterise variability and to differentiate between trends and variability in surface mass balance. This research addresses these critical gaps by characterising variability in surface mass balance changes in Antarctic ice core accumulation records over the past 2000 years. Ice cores provide annually resolved records of accumulation changes and climate signals dating back through recent centuries. This study utilises regional composites of ice core data, which provide a circum-Antarctic perspective. We use a formal statistical approach for detecting trend shifts, and find statistically significant changes in accumulation trends during and across both pre-industrial and post-industrial periods. Accumulation trend shifts in some regional composites align with periods of low solar activity, such as the East Antarctic Plateau. We find significant changes in accumulation trends in post-industrial periods across almost all regions of Antarctica, especially the Antarctic Peninsula. We decompose the accumulation records into different frequency components and explore the potential links to large-scale modes of variability. Our results highlight the possible emergence of an anthropogenic signal in Antarctic accumulation rates in the context of natural past variability from Antarctic ice cores. However, our findings are limited by the resolution and spatial availability of Antarctic data, highlighting the need for innovative analysis of high-resolution Antarctic accumulation, over both the palaeo and instrumental period, in order to better establish and constrain the signature of anthropogenic forcing across different AIS regions.

Laser Ablation – Cavity Ring Down Spectrometry: A new technique for water isotope measurements on ice cores

Ms. Eirini Malegiannaki [1]***, Dr. Vasileios Gkinis*** [2]***, Mr. Simon Alexander Munk Wael Fassel*** [1]***, Dr. Daniele Zannoni*** [3]***, Dr. Giuliano Dreossi*** [4]***, Prof. Barbara Stenni*** [4]***, Prof. Hans Christian Steen-Larsen*** [3]***, Dr. Pascal Bohleber*** [4]***, Prof. Carlo Barbante*** [5]***, Prof. Dorthe Dahl-Jensen*** [1]

The Beyond Epica – Oldest Ice Core (1.5 Myr) which is being drilled in Antarctica will be a valuable paleoclimate archive and the water isotopic signal imprinted in the ice core layers will be one of the most important parameters to be measured. The extremely thin nature of the deep ice core layers requires measurements at very high resolution together with high precision and accuracy. A novel and promising measurement technique, which is being developed, couples Laser Ablation (LA) with Cavity Ring Down Spectrometry (CRDS) aiming to obtain high quality measurements. Laser Ablation (LA) is used as a micro-destructive sampling method, which is important for using the minimum amount of the valuable ice core samples, and allows not only high spatial resolution, but also fast and direct transition from solid to gas phase, when appropriate laser systems are employed. Craters, created on ice after the laser ablation process, are to be characterized along with varying laser parameters for the optimization of the controlling factors which lead to efficient LA sampling. Furthermore, designing an ablation chamber and a transfer line with the optimal shape and size is crucial for collecting the ablated material which should reach the high precision CRDS analyzer with minimum delivery disturbance.

Characterisation of insoluble particles in the EastGRIP ice core with the single particle extinction and scattering method (SPES)

Ms. Chantal Zeppenfeld [1]***, Dr. Tobias Erhardt*** [2]***, Prof. Hubertus Fischer*** [1]

1. *Climate and Environmental Physics and Oeschger Centre for Climate Change Research, University of Bern, Switzerland,* ***2.*** *Helmholtz Centre Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany*

Ice cores contain information about past climatic conditions, such as the composition of the atmosphere. Aerosols, including insoluble particles, are deposited on the ice sheets and preserved in the ice. Analysing these particles provides the information needed to reconstruct past changes, for example, in circulation patterns and radiative transfer. Changes in the source regions of the aerosols, transport, and deposition mechanisms are reflected in alterations in the concentration, size distribution, and mineralogy of the particles.

To quantify the past changes in concentration and properties of insoluble particles, the Classizer One instrument, which is based on the novel single particle extinction and scattering (SPES) method, has been incorporated into the continuous flow analysis set-up in Bern. Previously available continuous particle sizing methods have typical lower detection limits of around 1 µm. However, the peak in the number size distribution of dust particles in ice cores is expected to be below 1 µm. Thus, while most of the mass of mineral dust could be observed, the majority of the particles could not. The SPES method allows for high-resolution, continuous, and simultaneous measurements of particle concentration, diameter, and refractive index in the size range of 0.2 to 2 µm. Therefore, its measurement range covers the maximum of the number size distribution.

The instrument was used to characterise particles in the EastGRIP ice core from 8000 to 16000 years b2k, covering the Younger Dryas (YD) to Holocene transition. We observe a decrease in number concentration from $2.7 \cdot 10^6$ ml^{-1} in the first half of the YD to $1.1 \cdot 10^6$ ml^{-1} in the second half, while the mean diameter increases over the course of the YD. This is followed by an abrupt decrease in the concentration by a factor 6 and a drop of approximately 80 nm in mean diameter at the transition to the Holocene. Previous studies have shown that the majority of dust particles originates from the East Asian deserts in the glacial. While the concentration and size distribution exhibit sudden changes, the refractive index increases gradually by 0.2, suggesting a long-term trend in the mineralogy, hence the relative contributions of different dust source regions.

Recent Antarctic sea ice variability in the context of the longer term records: Extending the Law Dome MSA sea ice proxy record to 2020.

Antarctic sea ice plays multiple crucial roles in the Earth system, and understanding the long term (centennial-scale) trends (variability and change) in its coverage is crucial to the interpretation and attribution of observed rapid fluctuations (increases and decreases) in Antarctic sea ice extent (SIE). Ice core records have been used as an important proxy for past SIE around Antarctica prior to the satellite era, by extending the short-term satellite record back hundreds of years. One of the first studies to correlate ice core data with modern satellite SIE records used the ice core from Law Dome (East Antarctica) and was based on Methanesulphonic acid (MSA), which relates to primary productivity in the sea ice zone, and multiple other regional studies have followed. Here, we present an update to our 2003 study by extending the Law Dome record with MSA data up to 2020, and investigate the recent changes in Antarctic sea ice coverage in the context of the longer proxy record (back to the 1840s). We also extend the proxy calibration period using old Nimbus I satellite information from the mid-1960s to the mid-1970s

36Cl as a dating tool for deep ice

Mr. Niklas Kappelt **[1]*, Prof. Raimund Muscheler*** **[2]*, Dr. Mélanie Baroni*** **[3]*, Prof. Grant Raisbeck*** **[4]*, Prof. Juerg Beer*** **[5]*, Dr. Marcus Christl*** **[6]*, Dr. Christof Vockenhuber*** **[7]*, Prof. Eric Wolff*** **[8]**

The $^{10}Be/^{36}Cl$ ratio has the potential to be a dating tool for old ice, as it decays with a combined half-life of 3.84 * 10^5 years and is thought to be independent of production and dilution effects affecting the individual radionuclide concentrations in ice cores. Chlorine, however, suffers from post-depositional loss at low accumulation sites in Antarctica, which interferes with the decay signal and complicates dating. Comparisons of the $^{10}Be/^{36}Cl$ ratio from Little Dome C, the new Beyond EPICA Oldest Ice Core drilling site, with sea-salt chlorine and previous research suggest that little to no chlorine loss occurs during glacial times. The $^{10}Be/^{36}Cl$ ratio was therefore measured in ice from several glacial periods covered by the EPICA Dome C ice core Antarctica to test its potential as a dating method, with the oldest sample reaching back 746,000 years in time. We will discuss to which extent the measured $^{10}Be/^{36}Cl$ values show a decay signal and assess how unexplained variations diminish the accuracy and precision of the $^{10}Be/^{36}Cl$ dating method. While the selected samples are thought not to have suffered a major chlorine loss, possible additional interferences are likely the result of changes in climatic conditions and will be the focus of future research in order to correct for these changes and, therefore, improve the accuracy and precision of the $^{10}Be/^{36}Cl$ dating method.

Holocene sea ice variability in the Arctic: exploring diatoms in the ReCAP ice core as a new proxy

The Arctic is warming faster than the global mean affecting the ocean, the cryosphere and arctic ecosystems. Furthermore, the decreasing sea ice is affecting the climate system on both a regional and global scale, possibly pushing the state of the climate into irreversible changes and undermining unique sea-ice dependent species. Understanding sea ice dynamics at high latitudes is, therefore, crucial in terms of better predicting future climate scenarios. Several Arctic sea ice proxies are routinely used based on marine sediment records (e.g. the lipid biomarker IP25, diatoms, and dinoflagellate cysts) and land ice cores (Bromine enrichment (Br_{enr}), Sodium (Na^+) and methanesulphonic acid (MSA)). However, as all proxies, they have some limitations. Here we aim to investigate if marine diatoms from land ice cores can be utilised to reconstruct past sea ice changes. With this goal, we analysed samples from the 584 m ReCAP ice core from Renland, East Greenland, which has a well-resolved Holocene. Here we present results on diatoms recovered from the ReCAP ice core, and discuss their potential as a sea ice proxy for the Northern Atlantic and Nordic seas. Furthermore, we evaluate how these relate to more established sea ice proxies from ice cores such as Na^+ and Br_{enr} and how our findings align with broader patterns of Holocene climate variability.

A 10-year record of the isotopic composition of precipitation at Concordia station, East Antarctica

The atmospheric dynamics determining the isotopic composition of precipitation on the Antarctic Plateau are still under investigation.

At Concordia station, East Antarctica, daily precipitation has been continuously collected on raised surfaces (height: 1 m) placed in a clean area, about 800 m from the station. Samples have been analyzed for $\delta^{18}O$, δD, and deuterium excess (d). The on-going monitoring of precipitation isotopic composition represents a unique record in inland Antarctica.

Surface temperature (T_{2m}) from the Dome C Automatic Weather Station of the Italian National Antarctic Research Program (PNRA) was correlated with isotopic data of precipitation collected from 2008 to 2017, in order to better understand the relationship between local temperature and the isotopic signal of precipitation. A robust positive correlation between $\delta^{18}O$ and δD of precipitation and T_{2m} is observed when using both daily and monthly-averaged data. $\delta^{18}O$ and δD of precipitation were also compared to the simulation from the isotope-enabled atmospheric general circulation models ECHAM5-wiso and ECHAM6-wiso, with the most recent version showing a significant improvement.

The spatial deposition of volcanic sulphate in Antarctica over the past 2000 years

Dr. Liz Thomas [1], ***Dr. Diana Vladimirova*** [2], ***Dr. Dieter Tetzner*** [2]

1. British Antarctic Survey (BAS), Natural Environmental Research Council (NERC), High Cross, Madingley Road, Cambridge CB3 0ET, UK., 2. British Antarctic Survey

The sulphate [SO_4^{2-}] records from deep ice cores have been invaluable in reconstructing the earths volcanic history over a range of timescales. Large volcanic eruptions inject sulphur into the stratosphere, producing near-synchronous deposition of sulphate in Antarctic and Greenland ice cores. Key studies linking bi-polar sulphate records have greatly improved our understanding of the frequency of large volcanic eruptions, and the impact on global climate. They also provide an important reference horizon to date and synchronise Antarctic ice core chronologies. However, most studies have been based on a limited number of deep ice cores, predominantly from high elevation and inland sites.

Here we present a new compilation of sulphate records from 103 Antarctic ice cores spanning all, or part, of the last 2000 years. The compilation includes records from both continental and lower elevation, coastal sites. The improved geographical coverage allows us to explore the spatial variability of sulphate deposition, demonstrating key differences in the magnitude of several known eruptions. Despite the higher background of biogenic sulphate at coastal sites, they provide a valuable record of tropospheric transport from more proximal eruptions. Enabling us to explore the frequency and magnitude of lesser studied Southern Hemisphere, sub-Antarctic, and Antarctic eruptions over the past 2000 years.

Ice core fatty acids as novel tracers of Southern Ocean sea ice change

Ms. Roseanne Smith [1], ***Dr. Liz Thomas*** [2], ***Dr. Chiara Giorio*** [3]

1. *British Antarctic Survey,* ***2.*** *British Antarctic Survey (BAS), Natural Environmental Research Council (NERC), High Cross, Madingley Road, Cambridge CB3 0ET, UK.,* ***3.*** *University of Cambridge*

Satellite observations expose an increasingly complex picture of sea ice change around Antarctica: steady increases in sea ice extent between 1979 and 2014 have since been undermined by a series of unprecedented lows. Models have failed to reproduce these trends, partly because they rely on a 44-year long observational record that may be too short to capture the full range of natural variability. Proxy reconstructions of sea ice change covering the decades preceding the satellite era are essential to place the observed trends in the context of longer-term climate variability.

A range of biogenic, isotopic and geochemical sea ice tracers from Antarctic ice cores have been developed so far, yet each of these has its limitations. Additional sea ice tracers are needed so that each proxy can be tested against a suite of others, and more reliable sea ice reconstructions can be developed for new Southern Ocean sectors.

Here, we present work to develop fatty acids (FAs) as novel organic sea ice tracers. FAs originate from the same sea ice-edge algal blooms as the commonly used sea ice proxy MSA, but their structural diversity and algal-taxonomic specificity yields potential for a greater depth of sea ice climatic information. Yet, determining their concentration in polar ice is challenging owing to their low (ppb-ppt) concentrations. So far, only one study has analysed FAs at high resolution in an Antarctic ice core, revealing strong positive correlations between the FA oleic acid (C18:1) and nearby winter sea ice extent.

This study uses high-resolution liquid chromatography-mass spectrometry to analyse fatty acids archived at trace (ppt) levels in a 12-m long ice core from Peter I Island (Bellingshausen Sea). The data are compared with satellite observations of regional sea ice change, and with a range of other sea ice proxies measured from Peter I and nearby cores. The efficacy of fatty acids as novel tracers of past sea ice variability in the Bellingshausen Sea is evaluated.

Stratigraphic architecture of the Isarco-Pusteria valley junction (European Alps) showing the interaction between two major alpine glaciers during the Late Pleistocene

Dr. Giovanni Monegato [1], ***Dr. Gianfranco Fioraso*** [1], ***Mr. Gianluca Benedetti*** [2], ***Mr. Federico Sciascia*** [2], ***Prof. Lisa Borgatti*** [3], ***Mr. Stefano Rodani*** [4], ***Prof. John Menzies*** [5]

__1.__ CNR - IGG, __2.__ ENSER srl, __3.__ Department of Civil, Chemical, Environmental and Materials Engeneering, University of Bologna, __4.__ Italferr, __5.__ Department of Earth Science, Brock University

The European Alps were composed of a complex network of valley glaciers during the Pleistocene, especially during the Last Glacial Maximum (LGM). The inner catchment of the Adige system is the largest of the southern side of the Alps; it is characterized by trunk valleys that hosted large valley glaciers. The Isarco and Pusteria (Rienza River) valleys were two of the largest tributary systems. Their junction is now located at Bressanone. Field surveys and a large number of drillings in the area between Bressanone and Varna/Sciaves allowed the stratigraphic architecture of the valley to be known during the late Pleistocene. Four distinct ice advances can be recognized. The thickest deposits are related to the LGM and are characterized by a fine-grained subglacial traction till up to 30 m thick. Two Lateglacial stadial moraines can be ascribed to the Isarco glacier, showing that the Modern Rienza lower valley was carved out as ice downwasted at the close of the LGM. A pre-LGM fluvial-lacustrine system filled the area, with contribution from both the valleys, indicating that the junction was located northwards with respect to today. Below, an older glacial unit made of a coarse subglacial traction till characterizes the succession, indicating that the fluvio-lacustrine phase represented an ice-free phase between two large advances. At the base, the cores drilled in the Isarco valley show a fluvial deposit pertaining to the Pusteria valley catchment, suggesting the presence of a narrow lower reach of the Rienza River. This suggested a persistence of the river valley at the valley junction in the Varna area a long before onset of the LGM. The presence of two large landslides testifies that the valley experienced also important slope dynamics; these were buried by LGM glacial deposits, while post-LGM slope accumulations are mostly related to minor events.

Assessment of the geochemical processes of groundwaters from the Continental Intercalaire (CI) aquifer in Dahar piedmont (Southern Tunisia)

***Dr. Zahra Dhaoui* [1], *Dr. Jean Denis Taupin* [2]**

***1.** Sfax University, **2.** Hydrosciences-Hydropolis, University of Montpellier, IRD, CNRS, 34090, Montpellier, France*

The association of environmental tracers with hydrogeochemical methods for the study of the CI in Southern Tunisia has determined the groundwater origin, the diffusive processes and the geochemical evolution of groundwaters from the Dahar uplands.
The isotopic analysis using heavy isotopes have shown depleted contents registered in groundwaters from the upper aquifer which is explained by the long residence time of water in the aquifer and its paleorecharge under a wetter climate. However, the enriched signals were registered in shallow boreholes indicating the contribution of the infiltrated rain water in the local recharge from Dahar outcrops. This spatial variability in stable isotopes signatures is related to the spatial distribution of precipitation, which is associated to longitude and seasonality. This reflects the irregular rainfall and climate changes. Also, this variability is governed by the proximity of the Mediterranean Sea and is materialized by the increase in precipitation from the continent towards the coast.
This evolution is consistent with the analysis of radiocarbon contents of the investigated system. The spatial distribution of radiocarbon revealed significant activities for some shallow wells from the lower aquifer, more particularly located near the Tataouine wadi. This confirms the dominant role of this wadi in the recharge of the aquifer. The paleoclimatic effect is confirmed by the ages calculated from carbon isotopes (14C/13C) and which vary from less than 2ka to more than 27ka.
The combination of these isotopic tracers indicates an evolution of groundwaters which might be interpreted as mixing processes between old and recent waters from the CI. The study of climate variability has shown that the recharge process is related to heavy rainfall involving surface flows through the wadis which represent the main recharge process spatially limited in this arid to semi-arid context.

2400 years of climate-human interaction over the Iranian Plateau: A multi-proxy record from Almalou Crater Lake, NW Iran

Dr. Arash Sharifi [1], ***Dr. Morteza Djamali*** [2], ***Dr. Ali Pourmand*** [3], ***Ms. Danielle Schimmenti*** [4], ***Prof. Larry C. Peterson*** [5], ***Prof. Peter K. Swart*** [5], ***Dr. Abdolmajid Naderi Beni*** [6], ***Dr. Hamid Alizadeh K. Lahijani*** [6]

1. *1-Department of Marine Geosciences, Rosenstiel School of Marine, Atmospheric and Earth Science, University of Miami, 2-Isobar Science,* ***2.*** *Institut Méditerranéen de Biodiversité et d'Ecologie,* ***3.*** *Neptune Isotope Lab, Department of Marine Geosciences, University of Miami, Rosenstiel School of Marine, Atmospheric and Earth Science,* ***4.*** *Texas A&M University, Department of Geology and Geophysics,* ***5.*** *Department of Marine Geosciences, Rosenstiel School of Marine, Atmospheric and Earth Science, University of Miami,* ***6.*** *Iranian National Institute for Oceanography and Atmospheric Science*

Despite the significance of the Iranian Plateau in the development of human civilization little is known about climate variability and its impact on human societies in this region due to the paucity of paleoclimate data. Almalou Crater Lake sustains the growth of plants inside the crater of a dormant volcanic cone which is exclusively fed by rainfall during the spring and fall and snowfall during the winter. The ombrotrophic nature of Almalou Lake and preservation of the organic matter within the crater can potentially record changes in atmospheric deposition and paleo-environmental conditions over this region. Here, we present a high-resolution (sub-decadal) multi-proxy record of climate variability during the last 2400 years from a 3-m peat core recovered from the crater peat bog. Radiocarbon dates of eight samples along the core show a nearly constant rate of accumulation (average of 0.14 mm yr^{-1}, R^2=0.98) since 2404±25 cal yr BP. Downcore variations of selected conservative lithogenic elements as well as redox-sensitive elements reveal three short episodes (~ 150-y) at 450-600, 1150-1300, and 1400-1550 cal yr BP, and one prolonged period (500 y) of dust accumulation from 1600 to 2070 cal yr BP. which are coincide with historical records of drought and famine in Iran since 2000 yr BP. Total organic carbon (TOC) and the stable isotope composition of organic carbon ($\delta^{13}C_{TOC}$) values are positively correlated with the variation in lithogenic elements, while the significant drop in $\delta^{13}C_{TOC}$ values centered at ~80 yr BP reflects post-industrial anthropogenic input of carbon to the environment. Pollen data for anthropogenic herbs indicates several periods of expanded cultivation activities in the region from 2300-1950 B.P., 1600-1500 B.P. (middle part of the Sasanian Empire), 1000-900 B.P., 650-550 B.P., and 350-150 B.P. corresponding with the periods of low dust (wet periods). Wavelet analysis conducted on the first 1500 years and on the entire record (2400 year) for Si and Al show a significant periodicity centered at 261 y and 488 y corresponding to De Vries (~210 y) and 520-year solar cycle through internal climate feedbacks.

Magnetic susceptibility and elemental geochemistry from Shira Lake sediments reveal climate and environmental changes over the past 900 years in central Altai, Russia

Dr. Dilyara Kuzina [1], Prof. Hong-Chun Li [2], Mrs. Anastasiya Yusupova [1], Prof. Danis Nurgaliev [1], Dr. Satabdi Misra [2], Dr. Tzu-Tsen Shen [2]

1. Kazan Federal University, 2. National Taiwan University

A 30-cm gravity core (GC4) from Shira Lake in central Altai region of Russia has been dated with 210Pb, 137Cs and AMS 14C methods. The detailed dating results not only show that the depositional history of the core was from AD 1115 to AD 2020, but also provide the sedimentation rates of 0.041 cm/yr, 0.006 cm/yr and 0.206 cm/yr during AD 1115~1460, 1460~1950 and 1950~2020, respectively. The core was subsampled at 1-cm interval. Magnetic susceptibility (MS) was measured for all samples on MFK-1A (AGICO) and calibrated to mass. Weight loss of acid-leach (0.5N HCl) (ALWL%) was conducted and its solution have been measured by ICP-OES for multiple elements on all samples. Loss of ignition at 1100°C (LOI%) and XRF analyses have performed on every second samples. TOC% and TON% were measured by EA. Based on the results, the sedimentation in Shira Lake over the past 900 years can be classified into four stages. Stage A: AD 1115~1255, strong surface runoff under wet climatic conditions brought more terrestrial input with low TOC and TON but relatively high magnetic minerals and acid-leachable elements. The lake was in oxide, fresh and oligotrophic conditions. Stage B: AD 1255~1460, the lake came deep with more lake productivity to produce organic matters. The acid-leach weight loss reached highest and MS became the lowest. Strongly increased Na_2O% during this period probably reflected strongly increased alpine glacier activity since Na_2O came from rock flour produced by glaciers. Stage C: AD 1460~1950, cold and dry conditions during the Little Ice Age resulted very low sedimentation rate. The lake was covered by ice most of the time, and productivity of the lake was very low. However, the organic decomposition was also low so that TOC content in the sediments kept unchanged. Stage D: AD 1950~2020, strongly warming condition and human impact allows strong increase in organic matter and salinity (Cl%) in the lake. The lake becomes more nutrification shown by strongly increased TOC, TON but decreased MS and reduction indicated by strongly decreased AL Fe and AL U concentrations.

As a net exporter of moisture and heat, the tropics play a major role in the global climate system. Exactly what role the tropics played in past climate changes, including in glacial-interglacial cycles, remains unclear, in a large part due to the lack of tropical terrestrial temperature records. Reconstructions of tropical sea surface temperatures (SST) and air surface temperatures at low altitudes have been debated but generally show a modest cooling (2-4°C) during the Last Glacial Maximum (LGM; ~26,000-19,000 years before the present). In contrast, proxies for tropical terrestrial temperatures suggest LGM temperatures ~5-6°C below modern, representing a long-standing discrepancy between the estimations of LGM temperature departures from marine and terrestrial records.

Here we focus on New Guinea, located in the heart of the Indo-Pacific warm pool, a massive zone of warm surface ocean water with a global climate influence. We investigate the magnitude and spatial pattern of LGM ELAs on New Guinea using newly available 1- arcsecond Shuttle Radar Topography Mission digital elevation models and the GIS tool GlaRe. With these tools, we reconstruct former glacier surfaces and calculate ELAs across the Highlands Region of Papua New Guinea and in the Mt. Jaya region in western New Guinea. We use prior work to estimate the ages of past glacier extents and modern ELAs. Our results show that glaciers on the island of New Guinea have LGM ELAs of ~3,400-3,700 m asl, corresponding to roughly 1,000 m of ELA change from the modern. Our results document a narrower range of LGM ELAs than previously reported across New Guinea, suggesting a relatively uniform temperature depression during the LGM.

Paleoclimatic and paleoenvironmental changes in the Pantanal region during the Holocene based on speleothem records

Dr. Valdir Novello [1], ***Ms. Magdalena Ritzau*** [1], ***Dr. Francisco Cruz*** [2], ***Prof. Kira Rehfeld*** [1]

1. *University of Tübingen,* ***2.*** *Universidade de São Paulo*

The Pantanal is a large region located in the central parts of South America (140,000 km2) with a unique climate and vegetation setting. This region is subjected to seasonal floods which makes the Pantanal the biggest wetland on the planet, home of high biodiversity. In this region occur transitions between different biomes, such as the Amazon Forest, Cerrado (Brazilian Savanna), and Atlantic Forest, located to the North, East, and South of this region, respectively. The area also serves as a moisture pathway for the South American Summer Monsoon (SASM), which connects the Amazon Basin with the La Plata Basin. The two major drainage basins of South America. Due to the complex hydrology of the rivers and lakes of this region, it is necessary to combine multiple proxy archives from different parts of the Pantanal basin to understand its climate and vegetation evolution during the Holocene.

Here we present isotope records from stalagmites collected at sites located at the northern and southern borders of the Pantanal. Hiatuses in speleothem deposition during the mid-Holocene identified in several stalagmites indicate overall dry conditions in the region at this period. However, the drier conditions recorded at the northern portion of the basin precede similar conditions in the South by approximately two thousand years. Furthermore, summer insolation seems to drive the intensity of the SASM at the North Pantanal while its influence is weaker in the southern part. This establishes a gradient of moisture between a wetter North and drier South during the late Holcene. Our record also shows a strong multidecadal to centennial variability, which was probably responsible for the high hydrology complexity of the rivers of the Pantanal, which are subject to seasonal floods and migration of its channels and tributaries.

Coupled terrestrial and oceanic variability during marine isotope stage 19 reconstructed from biomarkers in the Chiba Composition Section

Dr. Hiroto Kajita [1], Dr. Osamu Seki [2], Prof. Masanobu Yamamoto [2], Prof. Makoto Okada [3], Dr. Yuuki Haneda [4], Dr. Ohkouchi Naohiko [5], Dr. Yusuke suganuma [6]

1. Hirosaki University, 2. Hokkaido University, 3. Ibaraki University, 4. Geological Survey of Japan, 5. Japan Agency for Marine-Earth Science and Technology, 6. National Institute of Polar Research

Chiba Composition Section, an on-land marine sedimentary succession in central Japan covering Marine Isotope Stage 19, is of paleoenvironmental importance because of its high sedimentation rate and climatological/oceanographical settings. We detected long-chain alkenones (LCAs) and normal alkanes (*n*-alkanes) in this section. Variations in the unsaturation ratio of LCAs and the average chain length of *n*-alkanes showed the glacial–interglacial cycles with the millennial-scale oscillations, which are interpreted in terms of past summer sea surface temperature and annual air temperature changes, respectively. Variations in carbon isotope ratios (δ13C) of *n*-alkane showed different patterns for each carbon length. It seems to be caused by the difference in *n*-alkane soursecs. The relatively long-chain (C33–35) *n*-alkanes and relatively short-chain (C25–27) *n*-alkanes are highly deriveded from woody plants and herbs, respectively. δ13C variations in the long-chain and short-chain components mainly reflect changes in temperature and C3/C4 plant ratio, respectively. Using the multiple biomarker analysis, we revealed the seasonal variations of water structures in the Kuroshio Extension Front, as well as those interactions with terrestrial climate changes.

Poster - sessions 18, 27, 32, 133, 140, 170, 193

Spatial Dansgaard-Oeschger signals in Greenland ice cores and 40 years of analytical progress

The 25 Dansgaard-Oeschger events, first named in the Greenland ice core dO18 signal from GRIP, are found in all deep Greenland ice cores with the significant corresponding signal also reflected in chemistry and impurities contained in the ice.Continuous flow analysis (CFA) is the preferred method nowadays to investigate the long Greenland ice cores for their impurity content and often includes NH_4^+, Ca^{2+}, and Na^+ ions, which besides being influenced by transport, provide information about forest fires, wind-blown dust, and sea ice, respectively. Here we present two datasets by CFA done at University of Copenhagen that covers Dansgaard-Oescheger events.

1. The Dye-3 ice core which was drilled to bedrock at the Southern part of the central Greenland ice sheet (65°11'N, 43°50'W) in 1979-1981. The southern location is characterized by high accumulation rates compared to more central locations of the ice sheet. Since its drilling, numerous analyses of the core have been performed, and the ice has been in freezer storage both in the USA and in Denmark. In October and November 2019, the remaining ice, two mostly complete sections covering the depths of 1753–1820m and 1865–1918m and represents both Holocene, Younger Dryas and Glacial sections (GS 5 to 12).
2. The RECAP ice core was drilled at the Renland ice cap all the way to bedrock in 2015 from an altitude above 2000 m and extends 584.11m. The glacial section is strongly thinned and covers just 20 meters of the ReCAP core, but nonetheless due to the high resolution of the CFA measurements all 25 expected DO events could be identified from the CFA analysis done in 2015 and 2016.

We compare the new high-resolution CFA record of Dye3 and the low resolution ReCAP with previous analysis done in the mid 80's and early 90's from the sites and thus evaluate the analytical progress made over the past 40 years. Further we compare overlapping time periods with other central Greenland ice cores and discuss spatial patterns of DO events in chemistry and impurities.

The regional expression of Late Pleistocene climate and environmental variability in the alluvial record of Côa River Valley (northeast Portugal)

***Prof. Luca Antonio Dimuccio* [1], *Prof. João Pratas* [2], *Prof. Joana Ribeiro* [2], *Prof. Nelson Rodrigues* [2], *Dr. Maurizio Zambaldi* [3], *Prof. Lúcio Cunha* [1]**

1. University of Coimbra, Centre of Studies in Geography and Spatial Planning - CEGOT, Department of Geography and Tourism, Largo da Porta Férrea, 3004-530 Coimbra, Portugal, 2. University of Coimbra, Faculty of Sciences and Technology, Department of Earth Sciences, Polo II, 3030-790 Coimbra, Portugal, 3. University of Coimbra, Centre of Studies in Geography and Spatial Planning - CEGOT, Largo da Porta Férrea, 3004-530 Coimbra, Portugal

In a fluvial setting, compositional and textural data of alluvial sedimentary deposits can provide crucial information on the paleoenvironments of the corresponding catchment when the geology and geomorphology of the source area, the mechanical selection processes during transportation, and possible recycling effects are considered in their interpretation. In this type of sediments, the clay minerals are commonly produced by weathering processes and, generally, the degree of chemical weathering is strongly controlled by climate. In the framework of the ongoing CLIMATE@COA project (COA/CAC/0031/2019) and giving continuity to a previous one (PALÆOCÔA - PTDC/EPH-ARQ/0326/2014), a ~3.5-m-thick floodplain sequence exposed at the Cardina/Salto do Boi archaeological site, in the Côa River Valley (northeast Portugal), was analysed. Some vertical variations in the sedimentary facies, bulk chemical composition (major and trace elements, including REE), degree of chemical weathering (by geochemical indices), grains size, and clay mineral assemblage, as well as in the petrographic characteristics and abundance of organic particles, were observed. Twelve luminescence ages, obtained on feldspars using a multi-grain pIRIR protocol, led to the establishment of a robust age-depth model for this alluvial body covering the time interval ~150-23 ka. The observed stratigraphic changes reveal the relationship between sedimentary environments and the degree of chemical weathering during the penultimate glacial-interglacial transition, the last interglacial and most of the last glacial cycle. Preliminary results suggest that late Marine Isotope Stage (MIS) 6 (~150-132 ka) and MIS 5e (~132-116 ka) were characterized by overbank sedimentation under low-intense precipitation with periods of enhanced effective moisture (rainfall seasonality). The MIS 5d-5a interval (~116-71 ka) seems to be dominated by low-water vertical sedimentary accretion linked to progressively colder but still humid conditions. During MIS 4, 3 and 2 (~71-23 ka), the alluvial sedimentation, punctuated by incipient pedogenic activity, witness the climatic variability documented for this period in the North Atlantic marine record. A sedimentary hiatus, without a clear erosion, is highlighted at around 40-32 ka. This multi-analytical approach, combining geomorphological, sedimentological, geochemical, petrographic, and geochronological analyses, brings new insights into the Late Pleistocene environmental changes and frames it within the regional evolutionary pattern of the western Iberia climatic variability.

Transition times of a particle driven by Lévy noise in a double well potential

Mr. Ignacio del Amo [1], ***Prof. Peter Ditlevsen*** [2]

1. University of Exeter, 2. Physics of Ice, Climate and Earth, Niels Bohr Institute, University of Copenhagen

Inspired by the previous evidence that the DO events can be modelled as transitions driven by Lévy noise, we perform a detailed numerical study of the average transition rate in a symmetric double well potential for a Langevin equation driven by Lévy noise. The potential considered has the height and width of the potential barrier as free parameters, which allows to study their influence separately. The results show that there are two different behaviours depending on the noise intensity. For high noise intensity the transitions are dominated by gaussian diffusion and follow Kramer's law. When noise intensity decreases the average transition time changes to the expected power law only dependent on the width on the potential and not on the height. Moreover, the symmetries of the equation allow to find a scaling under which the transition time collapses for all heights and widths into a universal curve, only dependent on α.

The role of saddles for transition paths in a multiscale dynamical landscape

Mr. Reyk Börner [1]***, Mr. Ryan Deeley*** [2]***, Mr. Calvin Nesbitt*** [1]***, Mr. Raphael Römer*** [3]***, Prof. Tobias Grafke*** [4]***, Prof. Ulrike Feudel*** [2]***, Prof. Valerio Lucarini*** [1]

1. *University of Reading,* ***2.*** *Carl von Ossietzky University of Oldenburg, Oldenburg 26129, Germany,* ***3.*** *University of Exeter,* ***4.*** *University of Warwick*

Climate proxy records feature a variety of abrupt transitions between competing climatic states on a hierarchy of scales. An intuitive framework to understand the metastable Earth system may be offered by the notion of a non-equilibrium dynamical landscape. In stochastic dynamical systems, the quasipotential introduced by large deviation theory generalises the concept of an energy potential to systems out of equilibrium. Transition paths are expected to cross at “mountain passes” between coexisting basins of attraction where the quasipotential takes local minima along the basin boundary, i.e. saddles, or Melancholia states. However, noise-induced transition paths do not always cross near a saddle. Here, we demonstrate this using simple conceptual models of bistable dynamical systems, such as box models of the Atlantic Meridional Overturning Circulation (AMOC). We discuss the conditions under which transition paths avoid Melancholia states, relating these cases to the boundary quasipotential curvature. This highlights the differing viewpoints of critical transitions taken in large deviation theory and fast-slow systems, which here we aim to reconcile. Furthermore, we debate to what extent the quasipotential generates a geometrically interpretable global landscape. Clarifying the role of Melancholia states for critical transitions marks an important step towards a better understanding of tipping mechanisms and probabilities.

Marine Isotope Stage 5: a better time interval to understand Dansgaard-Oeschger events during the last glacial cycle?

Prof. Xu Zhang [1]

1. *State Key Laboratory of Tibetan Plateau Earth System, Resources and Environment (TPESRE), Chinese Academy of Sciences (CAS)*

The last glacial cycle is marked by abrupt, millennial-scale climate changes known as Dansgaard-Oeschger events (DOs) that links to changes in the strength of Atlantic Meridional Overturning Circulation (AMOC). Paleoclimate proxies consistently show that DOs were much more active during Marine Isotope Stage (MIS) 3 (a time interval by far paid major attention for DO dynamics) than MIS 5 (a warmer period with less DOs). With aid of available proxies and climate modeling results, I propose that occurrences of DOs during MIS 5 might be mainly related to AMOC changes forced by changes in climate backgrounds (e.g. global ice volume and atmospheric CO2 level), while those during MIS3 are additionally associated with noise-induced and/or unforced spontaneous AMOC changes. This indicates that MIS3 characterizes a more complex nature of DO dynamics than MIS5 which might be a better time interval to understand deterministic mechanisms accounting for occurrences of DOs.

Late Pleistocene fluctuations of precipitation in the south-eastern Mongolia

Prof. Yukiya Tanaka [1], ***Ms. Kang sumin*** [1]

1. *Kyung Hee University*

Many paleolake depressions are distributed aces in the south-eastern Mongolia. The study area, Bayan-tohom Govi, is located at the Ongon Soum, the south-eastern Mongolia. This area is sensitive to the climatic change because it is located at the summer monsoon limit without glacier melting water. The present study elucidated the fluctuation of precipitation in Late Pleistocene through analysis of palaeo-lacustrine deposits obtained from desiccated saline lake. The results of analysis show that the contents of biogenic silica and organic matter fluctuated greatly with short period. This fluctuation occurred before 28 ka (OSL dating). Increase of organic matter and biogenic silica mean that of vegetation around the paleolake and that of precipitation. These results mean that fluctuation of precipitation with short period associating with D-O cycle. D-O cycle possibly affected the fluctuation of precipitation in the south-eastern Mongolia.

The last Neanderthals and first modern humans in Swabian Jura of southwestern Germany

Prof. Nicholas J. Conard [1]

1. Department of Early Prehistory and Quaternary Ecology, University of Tübingen, Schloss Hohentübingen, 72070 Tübingen, Germany

The caves of the Swabian Jura, particularly the site in the Ach- and Lone Valleys, provide one of the best records available for studying the lifeways of the late Neanderthals and the first modern humans in the Upper Danube region. Although changing environmental conditions and a gradual cooling characterized MIS 3 in the region, in many respects the environmental conditions of the late Middle Paleolithic, the period of the last Neanderthals, and the early Upper Paleolithic, when modern humans arrived in the region, were broadly similar. Thus the fluctuations in the region's flora and fauna and cannot explain the dramatic shift in material culture during this time. Drawing mainly on recent excavations at sites including Hohle Fels, Geißenklösterle and Vogelherd, this paper considers the changing lithic and organic technology of the late Middle Paleolithic and the early Upper Paleolithic. The talk also presents evidence for shifts in symbolic aspects of the material culture of this period between roughly 50,000 and 35,000 years ago. The archaeological record documents an occupational hiatus between the last Neanderthals and the first modern humans of the region's Aurignacian, as well as a clear change in the nature of human interaction and symbolic communication. This change in technology and the symbolic repertoire of the modern humans was accompanied by increasing population densities and a demographic expansion that continued to fostered social-cultural innovations that accelerated the geographic expansion of modern humans across Eurasia and beyond.

Can climate models simulate Dansgaard-Oeschger type events?

Dr. Louise Sime [1]***, Dr. Irene Malmierca Vallet*** [1]***, Prof. Kira Rehfeld*** [2]***, Dr. Sandy P. Harrison*** [3]

1. *British Antarctic Survey,* ***2.*** *University of Tübingen,* ***3.*** *School of Archaeology, Geography & Environmental Science, Reading University, Whiteknights, Reading, RG6 6AH, UK*

Dansgaard-Oeschger (D-O) events, millennial-scale climate oscillations between stadial and interstadial conditions (of up to 10-15°C in amplitude at high northern latitudes), occurred throughout the Marine Isotope Stage 3 (MIS3; 27.8 – 59.4 ka) period. By examining the behaviour of a range of climate models, we show that no model exhibits D-O like behaviour under pre-industrial conditions. Not all, but likely the majority of models, exhibit D-O like oscillations under MIS3 and/or full glacial conditions, when run for long enough under the optimal MIS3 configuration. Greenhouse gases, orbital, and ice-sheet configurations are crucial to model behaviour: intermediate ice-sheet configuration; medium-to-low MIS3 greenhouse gas values; and low obliquity are conducive to D-O type behaviour in models. These findings have allowed us to design a standardised protocol for a long MIS3 simulation with an optimal configuration to promote D-O events and which could be used for in-depth investigations of simulated D-O behaviour, alongside model tuning for tipping points.

Pre-Columbian land use and environmental impact in the Monumental Mound Region of Amazonian Bolivia

Mr. Joseph Hirst [1], Dr. Marco Raczka [1], Mr. Ezequiel Chavez [2], Prof. Frank Mayle [1]

1. University of Reading, 2. Museo de Historia Natural Noel Kempff Mercado

The rainforest-savanna mosaic landscapes of northern Bolivia (the Llanos de Moxos) display some of the strongest evidence for pre-Columbian (pre-1492 AD) landscape domestication across Amazonia. Between 400 and 1400 AD, people undertook earthwork engineering of these seasonally-flooded landscapes on a massive scale to produce the most complex pre-Columbian society yet discovered in Amazonia – the Monumental Mound Culture (MMC). This 'earth-moving' society built over 150 monumental habitation mounds, interconnected with each other and neighbouring lakes via a complex network of causeways, canals and artificial ponds. Emerging archaeological and palaeoecological evidence suggests that the MMC may have practiced intensive, large-scale maize agriculture in a region which, until very recently, was considered suitable only for cattle ranching. This discovery raises the fundamental question of how this complex society managed its natural resources. Did the MMC have a centralised maize-based economy which extended across the MM region (MMR), irrespective of local differences in natural resources? Or did diet and land use vary geographically across the MMR according to variations in natural resource availability; e.g. forest cover, rivers, flood/drought risk, soil quality?

Here, we attempt to address these questions by examining the environmental history of Laguna Loma Suarez, a small oxbow lake next to a habitation mound (Loma Suarez) in the western part of the MMR This is an ideal site because it has markedly different natural resources from those of previously studied sites in the centre of the MMR, in being situated in gallery forests of a major river (Rio Mamoré) which experience much greater seasonal flooding.

A high-resolution, multi-proxy approach was taken to reconstruct the environmental history of Laguna Loma Suarez – involving pollen and charcoal analyses, as well as x-ray fluorescence spectroscopy. The record is chronologically constrained using a Bayesian age-depth model, built from multiple radiocarbon dates. By comparing these data to other records obtained from the centre of the Monumental Mound Region, we will determine the extent to which different forms of land use (burning, deforestation, crop cultivation) varied across the MMR over the past two millennia.

From sea to summit: synchronous and asynchronous Holocene vegetation shifts across a transect in Northern Greece

1. *Institute of Plant Sciences & Oeschger Centre for Climate Change Research, University of Bern,* ***2.*** *Institute of Plant Sciences & Oeschger Centre for Climate Change Research, University of Bern & Departamento de Ciencias de la Vida, Universidad de Alcalá,* ***3.*** *School of History and Archaeology, Aristotle University of Thessaloniki,* ***4.*** *Institute of Plant Sciences, University of Bern,* ***5.*** *Institute of Archaeological Sciences & Oeschger Centre for Climate Change Research, University of Bern*

Holocene vegetation history has been driven by climate change, disturbances and land use. Especially the introduction of agriculture led to significant changes in the natural biomes and environments of Europe. The European neolithisation started in Northern Greece more than 8000 years ago, with the arrival of new crops and livestock. The interactions between human activities, climate and vegetation are complex, as they influence one another. Disentangling the contributions of climate and land use to vegetation change requires the investigation of different sites across vegetation and climatic gradients, and through time.

Here, we present Holocene vegetation changes along a transect from the Aegean coast to the Pindus mountains. The transect spans different vegetation types, from evergreen broadleaved woodlands to the tree line ecotone, and across altitudinal belts, from sea level up to 2000 m asl. We show the vegetation and fire histories from Limnes Volvi, Vegoritida, Zazari, Orestiás Kastorias and Drakolimni Smolikas, all located in Northern Greece.

The vegetation histories from the submediterranean lowland sites show the establishment of mixed deciduous oak forests at the start of the Holocene. During the Early Holocene we can detect synchronous phases of closed and open forest conditions, suggesting a predominance of regional drivers. Around 8,500 cal BP, the data show a significant decline in forests, together with an increase of steppe vegetation and the regular appearance of anthropogenic indicators. This combination may indicate that both climate and land use played a role. The vegetation histories from the coastal mesomediterranean and the subalpine site are still preliminary but are essential to contextualise the other results. Specifically, they provide insights into the linkages between climate, vegetation, fire and agriculture at coastal (mesomediterranean), intermediate (inland submediterranean) and marginal (subalpine) sites. The ability for agriculture to establish depends on several factors such as proximity to the Mediterranean Sea, duration of the growing season, moisture availability, frost occurrence, terrain accessibility and soil development. We hypothesise that specialised land use approaches such as summer farming or transhumance in very remote areas may have followed centuries or millennia after the introduction of agriculture at coastal and intermediate sites.

A threshold in the collapse and recovery of Atlantic Meridional Overturning Circulation in response to different interglacial conditions

Mr. Wei Liu [1], ***Prof. Feng Shi*** [2], ***Prof. Xiao Zhang*** [3], ***Ms. Huihong Xue*** [2], ***Dr. Qiuzhen Yin*** [1]

1. Earth and Life Institute, Georges Lemaître Centre for Earth and Climate Research, Université catholique de Louvain, Belgium, 2. Institute of Geology and Geophysics, Chinese Academy of Sciences, 3. Nanjing University of Information Science and Technology

Previous studies suggest that the Atlantic meridional overturning circulation (AMOC) is weakening in response to the global warming. Two equilibrium states are considered to exist in AMOC, which may rapidly push the current typical ('on') state to a collapsed ('off') state when the freshwater injection in the regions of deep-water formation across the threshold. Some simulation studies suggest that the threshold may be influenced by several factors, such as the region and the change rate of freshwater hosing. Paleoclimate records indicate that the change of AMOC occurred also during past interglacials. However, it is not fully clear to what extent the stability of the threshold could be affected by different interglacial boundary conditions. In this work, we conducted a set of sensitivity experiments with the Marine Isotope Stage 13 (the coolest interglacial over the last one million years) and the present interglacial boundary conditions employing two Earth system models, the Community Earth System Model and the LOVECLIM, to explore the AMOC and global climate response to freshwater hosing. Both models show a marked response of AMOC to a freshwater flux threshold of about 0.047 Sv in the Greenland-Iceland-Norwegian (GIN) seas. AMOC gets weakened (recovers) drastically when freshwater flux rises beyond (falls below) the threshold under the 'on' ('off') state. This threshold value is hardly affected by changes of orbital parameters or greenhouse gases between the two interglacials but is sensitive to hosing region and change rate of the freshwater. The threshold value of the freshwater flux found in our study is similar to the threshold suggested by proxy reconstructions below which rapid AMOC recovery and warming occurred at the end of the Oldest Dryas and the Younger Dryas. Further analysis reveals possible and apparent transitions of the magnitude and spatial pattern of the global climate response to freshwater hosing before and after the threshold during the MIS-13 interglacial. Our results imply that the relationship among AMOC, freshwater hosing and associated climate change during past interglacials could be a reference for future AMOC deceleration.

Decadal-scale ostracode assemblage records from two box cores detail changes in Beaufort Sea coastal areas during the last few centuries

Dr. Laura Gemery [1], ***Prof. Masanobu Yamamoto*** [2], ***Dr. Koji Seike*** [3], ***Dr. Leonid Polyak*** [2], ***Dr. Thomas M Cronin*** [1]

***1.** U.S. Geological Survey, **2.** Hokkaido University, **3.** National Institute of Advanced Industrial Science and Technology*

We examined ostracode assemblages from two high-resolution (decadal-scale) box cores collected in the Beaufort Sea during the 2022 Arctic Challenge for Sustainability (ArCSII) expedition, a project of the Japan Agency for Marine-Earth Science and Technology (JAMSTEC). Ostracoda (bivalved Crustacea) comprise a significant part of the benthic meiofauna in the Pacific-Arctic region, including more than 50 species, many with specific ecological tolerances. As a result, these meiofauna taxa hold potential as useful indicators of past and present ecosystem changes. Two relatively shallow coring sites, located near Barrow Canyon (BC2, 224m, 71.90, -154.15) and in the Mackenzie Trough (MT1, 57m, 69.97, -137.24) on the Beaufort Sea slope/shelf, are ideally located to record variations of the Bering Strait throughflow and Mackenzie River outflows during the past ~150-200 years. Investigation of the box cores, 26-30cm in length, will focus on the impacts of recent anthropogenic forcing on the coastal ecosystem in the Alaskan and Canadian Beaufort Sea. Assemblages from the cores' upper-most sediments will be compared to those documented from a nearby multicore collected in 2013 (HLY1302, MC29; Gemery et al., in press). Preliminary results show that ostracode abundance and distribution are related to bottom water temperature, salinity, organic carbon deposition, and sediment substrate, which are primarily tied to the transit of summer Pacific water masses. Radiocarbon dating of the cores and statistical analyses of the faunal data are underway that will enable inferences about the regional paleoceanography of these two areas. Overall, this study will offer unprecedented micropaleontological records that will provide insight into the impacts of recent temperature, salinity, sea-ice, and erosional change on the coastal Beaufort Sea ecosystem.

Late Holocene environmental changes on the Zackenberg Delta, NE Greenland

Mr. Rodrigo Osorio [1], _Dr. Santiago Giralt_ [2], _Prof. Alberto Sáez_ [1], _Dr. Marc Oliva_ [3], _Ms. Julia García-Oteyza_ [3], _Dr. Sergi Pla-Rabés_ [4]

1. UB-Geomodels Research Institute. Dep. Dinàmica de la Terra i de l'Oceà. Universitat de Barcelona, Spain., 2. Geosciences Barcelona (Geo3BCN-CSIC), Lluís Solé i Sabarís s/n, 08028 Barcelona, Spain, 3. Universitat de Barcelona, Department of Geography, 4. Center for Ecological Research and Forestry Applications (CREAF)

Arctic ecological research has sparked increasing interest among scientists because of the high vulnerability of this region towards ongoing anthropogenic climate warming. Even if Greenland's paleoclimatic records based on ice-cores are well known, paleoecological studies tracking the biotic response towards climatic oscillations are scarce. In this context, pollen analysis of Holocene sedimentary lacustrine records becomes a useful proxy to understand climate change in last thousands of years and to track its effect on the High Arctic vegetation of Northeastern Greenland.

The Lomsø sedimentary core was obtained from a lake located in the lowland delta formed at the end of the Zackenberg Valley, in coastal NE Greenland (74°N). The core was analyzed by a multi-proxy approach ranging from geochemical to biological studies. The age-depth model indicates this core records the last 4700 cal yrs BP with two very differentiated units showing the evolution from a fluvial/deltaic depositional environment to a thermokarst lake originated thanks to permafrost processes around 2400 cal yrs BP.

Pollen assemblage data shows that despite its vulnerability to climate change, the vegetation near lake Lomsø has remained stable, as shown by the lack of abrupt changes. The palynological record starts about a century after the onset of lacustrine sedimentation and displays four pollen zones: LOM-I (2300 – 1450 cal yrs BP), LOM-IIa (1450 – 700 cal yrs BP), LOM-IIb (700 – 70 cal yrs BP), and LOM-III (last century). Even with over-represented fen taxa Luzula/Juncus, which reigns on every single zone, the main vegetation types dominated by Poaceae, Cyperaceae, Juncaceae, Salix or Cassiope are well represented. This vegetation mosaic shows the persistence of high soil moisture conditions with overall cold climate and extensive snow-beds throughout the record, showing a weak warming short period that peaked around 1100 cal yrs BP followed by a Little Ice Age-related cooling trend. This trend is reversed towards the present owing to the anthropogenic-related global warming as shown by the expansion of dwarf shrubs on the latest samples.

Our results shows the strong resilience of lowland Zackenberg tundra vegetation despite Late-Holocene macro-climate changes, and its vulnerability towards recent climate change.

Boreal (Eemian) transgression in the northeastern White Sea Region: stratigraphy and high-resolution record of past environmental changes

***Dr. Ekaterina Taldenkova* [1], *Dr. Yaroslav Ovsepyan* [2], *Dr. Olga Rudenko* [3], *Dr. Anna Stepanova* [4], *Dr. Henning A. Bauch* [5]**

1. *Lomonosov Moscow State University,* ***2.*** *Geological Institute RAS,* ***3.*** *Turgenev Orel State University,* ***4.*** *A&M Texas University,* ***5.*** *Helmholtz Centre Alfred Wegener Institute for Polar and Marine Research c/o GEOMAR, Kiel*

In relation to the overall importance of reconstructing interglacial marine environments and water mass evolution in subpolar and polar northern regions we carried out a high-resolution investigation of a 455 cm thick sediment sequence of the Boreal (Eemian) marine beds directly overlying Moscovian (Saalian) till in Bychye-2 section on the Pyoza River. Evaluation of past events is carried out through analysis of changes in lithology, microfossils (foraminifers, ostracods, pollen, aquatic palynomorphs) and benthic foraminiferal isotopes ($\delta^{18}O$, $\delta^{13}C$). Stratigraphical subdivision is based on the succession of palynological zones that are correlated with the previously established regional zones. The latter are age constrained on the basis of correlation with dated western European palynological zones. Marine sediments of Bychye-2 section accumulated from the end of Moscovian glacial (>131 ka BP) until *ca.* 119.5 ka BP. Three successive phases in the evolution of the transgression have been identified: 1) a seasonally sea-ice covered relatively deep freshened basin of the initial phases of flooding (360-455 cm, >131-130.5 ka BP), 2) a deep basin of the maximum phase of flooding with less extensive sea-ice cover (290 -360 cm, 130.5-130.25 ka BP), and 3) a shallow basin with reduced seasonal ice cover (0-290 cm, 130.25-119.5 ka BP). The flooding of the territory by cold Arctic waters was rapid, as evidenced by both: the lithological contact between the till and marine clays and the composition of microfossil assemblages represented by river-proximal Arctic species together with the species preferring water depths of 40–50 m. The regression in the region started early, about 130 ka BP, which indicates that the glacioisostatic rebound of the territory was ahead of the global eustatic sea level rise. The most warm-water and taxonomically diverse assemblages of foraminifers and ostracods, containing species typical of the Baltic Sea, were recorded during the regressive stage, especially in the time interval from about 128 to 124 ka BP. This probably gives evidence for a long-lasting connection of the White and Baltic Seas for 6-7 thousand years in total starting from the onset of the transgression.

Paleo-proxy records covering the last glacial period have highlighted the global climate impact of Heinrich events. However, few terrestrial paleoclimate records with absolute chronologies in northern Africa are available, hampering the understanding of past abrupt climate change in this region. Here, we present dating results with U-Th techniques from a broken stalagmite collected from La Mine Cave, Tunisia. Results show that this stalagmite deposited from 190 to 40 thousand years ago (ka). The abrupt droughts of the last three hiatuses at 78.6±1.9-59.3±0.6, 58.7±0.8-54.0±0.4, and 51.9±0.6-44.5±0.3 ka correspond to intervals with low values of sea surface temperature in the eastern north Atlantic and the Mediterranean and matches the occurrence of Heinrich events 6, 5a, and 5. In comparison with previous marine records and with a transient numerical simulation, the multi-centennial-to-millennial droughts could be caused by weak Atlantic meridional overturning circulation (AMOC), which altered the westerlies away from northern Africa. Our results suggest that the regional hydroclimate was dominated by orbital forcing with modification of the internal forcing such as atmospheric and oceanic circulation.

Early Pleistocene dysoxia in circalittoral to shallow bathyal marine deposits of the island of Rhodes (Greece)

The eastern Mediterranean Sea is known for its sapropel deposition during the Pliocene and Quaternary. Sapropel formation is commonly attributed to an intensification of the African monsoon at times of northern hemisphere summer insolation maxima and related increase of riverine fresh-water and nutrient input, resulting in a temporary stagnation of deep-water masses.

On the island of Rhodes, marine fossiliferous sediments of late Pliocene to middle Pleistocene age are exposed in distinct locations along the eastern coast. The sediments of each location represent an individual depocenter, reflecting the paleoenvironmental and neotectonic history of the island.

Here we present a new benthic foraminiferal record from the Plimiri 5 sediment section, located at the south-eastern coast of Rhodes, which provides insights in the paleoenvironmental conditions during the early Pleistocene. Changes in the diversity and composition of the benthic foraminiferal fauna indicate periodic occurrences of dysoxic conditions at the sea floor, comparable to the sapropels of the deep Eastern Mediterranean basins. The recurring pattern of high abundances of eutrophic indicator species, of up to 99 percent, suggests transient phases of oxygen deficiency at shelf and upper slope environments, i.e. between water depths of approximately 100 and 270 m. The species identified within these layers (genera *Brizalina*, *Rectuvigerina*, *Stainforthia*) are associated with periods of dysoxic conditions. The dysoxia can be attributed to increased fresh-water and nutrient input from the island resulting in enhanced primary productivity of near-coastal waters and associated organic matter fluxes to the sea floor. Our data also suggest that the deposition of the Plimiri sediments took place in a basin, which experienced times of restricted exchange of waters with the open ocean due to orbital-driven and/or tectonical-driven sea-level changes.

Deglacial radiocarbon ventilation age changes in the central and eastern Mediterranean Sea

Prof. Giuseppe Siani [1] ***, Prof. Nejib Kallel*** [2] ***, Dr. Elisabeth Michel*** [3] ***, Dr. Sonda Zouari*** [2] ***, Prof. Christophe Colin*** [4] ***, Dr. Nadine Tisnerat*** [3]

Understanding the mechanisms underlying past circulation changes in the Mediterranean Sea during rapid climatic events and their impacts on the implementation of deposits rich in organic matter (ie ORL, sapropels) is a major challenge in the field of paleoceanography. We use water-column radiocarbon reconstructions to assess the structure and age of the intermediate and deep-water masses in the central and eastern Mediterranean Sea since the last deglaciation. Today, the vertical mixing and thus the mixing time of the water masses occurs very quickly at the scale of the Mediterranean basin resulting in a minimal surface-to-deep gradient in ^{14}C with a ventilation age of ~100 years. Here, we reconstruct past ventilation age changes of intermediate and deeper water masses by measuring the ^{14}C age difference of pairs of planktonic and benthic foraminifera taken from marine cores bathed by intermediate and deep water masses collected in the Sicily Strait and Levantine basin respectively. Our results show extremely ^{14}C depleted water masses between 11 kyr to 9 kyr associated to a reduction in Mediterranean convection and inducing significant water column stratification between □700–1200 m water depth. This phase was followed by a break-up of the stratification at 700 m in the Levantine basin at 6.3 kyr, while re-ventilation at 1200 m occurred only since 4.5 kyr as indicated by the Sicily Strait record.

Arid conditions in southern Iberia during the early-middle Holocene transition recorded by stable isotopes of gypsum in Laguna de Medina (Cádiz)

The southern Iberian Peninsula has been particularly vulnerable to climate changes during the Holocene. Such environmental variability was recorded by the sedimentary sequences of the numerous lakes of the Guadalquivir Basin. Here, we analyze the oxygen and hydrogen stable isotopes ($\delta^{18}O$ and $\delta^{2}H$) of structurally-bound hydration water of gypsum ($CaSO_4 \cdot 2H_2O$) from the sedimentary sequence of Laguna de Medina (Cádiz), in order to reconstruct the isotopic composition of the lake water in the past. Gypsum is particularly abundant in the sediments from 18 to 24 m deep, corresponding to ages from ~7.0 to ~9.0 cal. ky BP. The sediments of Laguna de Medina recorded an intense dry period around □7.7 cal. ky BP, as revealed by the presence of gypsum with elevated $\delta^{18}O$ and $\delta^{2}H$ values (up to 7.4% y 26.1%, respectively) of the paleo-lake water. This finding suggests that the original solution from which gypsum formed was highly evaporated. Such conditions may be attributed to an arid phase around 7.5 cal. ky BP, as described also in other western Mediterranean paleoclimate records. However, a connection with the cold/dry 8.2 ka event cannot be ruled out given the chronological uncertainties of the lake sedimentary record around this period. Research in progress aims to quantify climatic parameters (humidity and temperature) during this dry stage from the Laguna de Medina sediments and to improve the chronology resolution around this period.

The Mediterranean has been identified as particularly vulnerable to rapid climate changes (RCCs) during the Holocene. RCCs are assumed to be one of the main environmental factors causing distinct cultural and socio-economic changes. Within the Mediterranean, RCCs relate to the inflow of cold and dry continental polar air masses caused by intensification of the semi-permanent Siberian high-pressure zone leading to increased energy transfer between surface water and traversing winds. Although the number of high-resolution Holocene geoarchives in Greece has increased during the last decades, available proxies are often discontinuous or cover in detail only distinct Holcene time intervals leading to incomplete and partly diverging interpretations. In combination with chronological uncertainties, our understanding of the impact of RCCs on coastal and landscape evolution and their fingerprints within natural terrestrial archives requires further research.

We present a new sedimentary record from a palaeo lake in the Giannades polje on Corfu Island, Greece. Following geophysical prospection and in situ Direct Push electrical conductivity measurements, we retrieved a 16 m long sediment core partly containing finely laminated sediments composed of grey-clastic, dark-organic and yellowish-brown carbonaceous laminae. Our studies include high-resolution X-ray fluorescence (XRF) core scanning, grain size and magnetic susceptibility measurements, smear slide and microfaunal analysis as well as determination of total carbon and nitrogen contents. The age model is based on radiocarbon dates yielding consistent ages from ca. 7500 BC until 1700 AD, overall indicating an average sedimentation rate of 1.4 mm/a.

Observed changes in proxy data will be associated with environmental changes related to climate (RCCs) and human-impacts. In addition, we expect the Giannades polje geoarchive to comprise signals of local and regional seismo-tectonic events, as they have been evidenced by geoarchaeological investigations of regional coastal sites. Our studies are embedded in the joint research program SCaLES combining dendro- and sclerochronological and speleological studies on a larger spatial and temporal scale to increase the understanding of these environmental influences. This approach will allow detailed correlations with other regional to interregional archives of climate and environmental change.

Deglacial Mediterranean-basins link: old carbon-enriched eastern waters and collateral consequences for western aragonite mounds development

A Mediterranean Thermohaline Circulation slowdown related to deglaciation and monsoon dynamics have largely been discussed, but it yet remains insufficiently constrained. With the aim of investigating changes in water mass residence time (as a key parameter to elucidate inter-basin communication variations) and its potential environmental impacts, we present a multi-proxy-archive study in the Western Mediterranean mid-depth based on cold water corals radiocarbon ventilation ages, along with foraminiferal O_2 and $[CO_3^{2-}]$ qualitative inferences. At ~300m, we find: 1) two aged-water pulses at Younger Dryas and ~8.2 event, respired carbon enriched and coincident with low CWC mound growth, and 2) a well-ventilated water pulse in between, parallel to a CWC mound flourishing stage. Our results allow changes in ventilation rates to be shown, quantified, and timed in association with periodical phases of MedTHC weakening, as well as suggesting enriched respired carbon episodes as a potential cause of decreased mound growth rates via aragonite dissolution.

Past 20,000 years of climate history in the Northern Ionian Sea as recorded by Calcareous Nannofossil assemblages

Calcareous nannofossils are the fossil equivalent of unicellular marine algae whose ecology and vital functions are driven by environmental parameters within the photic zone (e.g. temperature, salinity, sunlight and nutrient supply). High-resolution quantitative analyses were performed on the sediment core ND14Mbis collected in the northeastern part of the Ionian Sea at 665 metres of water depth (Next-Data 2014 cruise). The core consists of 332 cm of greenish to greyish fine sediments in which is comprised the Sapropel layer S1 (105-126 cm) studied by Checa et al. (2020) and Cascella et al. (2021). The chronology of ND14Mbis core is based on 10 radiocarbon ^{14}C AMS measurements (Checa et al., 2020) and it indicates an extrapolated age of 20.66 kyrs BP at the bottom. Micropaleontological associations were statistically analysed with R-software and compared with sediment compositional proxies obtained through XRF-core scan.

Changes in abundance of the main surface oligotrophic species *Emiliania huxleyi* <4 μm and the deep dweller taxa *Florisphaera profunda* (N-Ratio) were used to reconstruct stratification/vertical mixing changes in the upper water column and the associated variations in paleo-productivity. Reworked specimens were analysed to acquire information on sediment transport and to reconstruct regional scale runoff and/or precipitation changes. The bulk elemental geochemical composition of Ba/Al ratio was used as a paleoproductivity proxy while the Si/Al ratio was used to detect inputs of aeolian dust. The cluster analysis, performed on calcareous nannofossil assemblages, highlights the principal climatic phases that occurred during the last 20,000 years (e.g. Heinrich Stadial 1, Bølling-Allerød, Younger Dryas, etc.). The boundary between Late Pleistocene-Holocene was confirmed by the drastic reduction of *E. huxleyi* >4 μm, *Gephyrocapsa muellerae* and small *Gephyrocapsa*.

Cross correlation analysis was performed on selected calcareous nannofossil groups (e.g. Upper and Lower Photic Zone, Placoliths, etc.), reworked specimens and geochemical proxies to highlight phase/antiphase periodicity occurred in the last 20 kyrs.

We acknowledge that this research has been financially supported by ECR-Consolidator TIMED project (REP-683237) and by INGV project 2019 (Paleoclimate variability during Late Holocene in the Central Mediterranean and Balkans: terrestrial and marine archive comparison).

The INGV-funded AMUSED project (https://progetti.ingv.it/index.php/it/amused) aims to reconstruct the climatic variability in the central Mediterranean region during the Middle-Late Quaternary by integrating paleoclimate multi-proxy data acquired from different paleoenvironmental settings. Specifically, we investigate lacustrine and marine successions and speleothems to evaluate, within a narrow geographical range and at different temporal scales and resolution, the expressions of the climate variability in three different sub-systems. We focused on: i) two parallel 116 m and 126.5 m-long cores recently retrieved from the Castiglione maar (central Italy) after a geophysical exploration survey, ii) speleothems collected from selected caves of the central Apennine area, and iii) two already available marine cores (NDT09 and NDT12) recovered in the Tyrrhenian Sea during the NextData2016 cruise. High-resolution multi-proxy investigations (including palynological, micropaleontological, geochemical, stable isotope, paleomagnetic, tephrocronological analyses on both lacustrine and marine sedimentary records, and stable isotope on stalagmites) are in progress on the selected archives. A robust chronology was obtained by combining both direct and indirect $^{40}Ar/^{39}Ar$ dating of the tephra layers, paleomagnetic analyses and ^{14}C dating of the lacustrine and marine sediments and by U/Th chronology for speleothems. Another objective of the project is to estimate the natural soil CO_2 emission in selected areas the city of Rome and the Colli Albani district and to made actions of mitigation of the emission in a selected high gas releasing zone by planting ad hoc CO_2 adsorbing vegetation.

The 8.2 ka event in the Dead Sea: tracking a high-latitude disturbance in the Mediterranean

The last deglaciation is an ideal time interval to investigate the effect of climatic and oceanic disturbances occurring at high latitude on the hydrological regimes of the Mediterranean Sea. In particular, a series of disruptions of the Atlantic Meridional Oceanic Circulation (AMOC) has punctuated the transition from glacial to interglacial conditions, with the so-called 8.2 ka event being the youngest one. After the publication of recent results showing the existence of instable climatic conditions in the Dead Sea during the Younger Dryas, we examine here the environmental record during the 8.2 ka event to illuminate the effects of the background climate (colder to warmer) on hydrological distrubances linked to AMOC disruptions. We performed a coupled limnological and geochemical analysis of sediments deposited in the deeper part of the Dead Sea (IDCP site 5017A), which showed the occurrence of repeated mass wasting deposits related to intense erosive activity in the watershed of the Dead Sea. Newly-acquired neodymium and strontium isotopes also show a rapid change in sediment provenance and a hiatus in outcrop sequences from western lake shores suggests a drop in lake level at that time. Ongoing classification of mass wasting events and the integration of other well-dated regional records and paleoclimatic simulations will provide additional insights on the erosional processes operating at that time, as well as the climatic regimes associated.

Rapid response of the Adriatic convection cell during the Sapropel S1: New insights from Nd isotopes

The Sapropel events are intrinsically linked to changes in the Mediterranean thermohaline circulation (MedTHC). These organic-rich sedimentary layers that typically appear in the E-Mediterranean, have been often attributed to the combination of enhanced biological production in the surface ocean and to a deficit in the renewal rate of deep waters leading to severe anoxic conditions that helped preserving organic matter in the sediment. There is a general lack of knowledge on how the main intermediate and deep convection cells in the E-Med responded during sapropels. In this work we present a new reconstruction of the changes of the MedTHC circulation system during Sapropel 1 using Nd isotopes (εNd) in the Adriatic-North Ionian Sea region. The study site is located at the convergence and mixing between the outflow of Adriatic Deep Waters (ADW) and the arrival of E-Med Levantine Intermediate Water (LIW). New results using Nd isotope ratios illustrate changes in the mixing proportions of these two endmembers (ADW vs. LIW), and clearly show two distinctive collapse intervals during the sapropel (S1a and S1b) as a result of reduced strength in the ADW convection cell and increased presence of LIW. The two sapropel intervals where rapidly interrupted but a relatively short period where ADW resumed its convection and outflow into the north Ionian Sea. Further support to this interpretation comes from U/Mn ratios measured in foraminifera, gran size measurements as well as benthic foraminiferal fauna supporting the idea that the changes in the intensity of deep water convection preceded both the establishment of anoxic conditions at depth and the increased organic matter export to the sediments. By using an stochastic box model of the Mediterranean Sea enabled for isotopic tracers in seawater following a Monte-Carlo approach we demonstrate that the Nd isotpe resutls measured in the north Ionian Sea are consistent with a complete shutdown of the ADW outflow during the sapropel events. The collapse of ADW convection cell led the deposition of the last sapropel layer and favoured the dominance of LIW at intermediate depths in the E-Med water column.

Present and past variability of the Mediterranean Outflow Water using Nd isotopes

***Ms. Sara Campderrós* [1], *Dr. Leopoldo Pena* [1], *Prof. Isabel Cacho* [2], *Dr. Jaime Frigola* [1], *Dr. Ester García Solsona* [1], *Dr. Eduardo Paredes* [1]**

The Mediterranean Outflow Water (MOW) is a source of heat and salt into the Atlantic Ocean, and it has been proposed that it preconditions the water masses that participate in the production of deep water into the north Atlantic, or the Atlantic Meridional Overturning Circulation (AMOC). Although some modelling and proxy studies have suggested that past changes in properties of the MOW could have consequences to the AMOC, this impact is still being debated. Seawater Nd isotopic composition (ε_{Nd}) has been used as a conservative water mass tracer in the modern ocean, but also as a paleo-circulation proxy measured in the Fe-Mn coatings of foraminifera. One of the advantages of using Nd isotopes is that this tracer can be used to calculate the mixing and export rates of water masses nowadays, but also in the sedimentary record, which could help estimate the mixing and exportation rates of the MOW into the North Atlantic in the present and in the past. But recently, some studies have shown processes that can modify the signal of ε_{Nd} in seawater and consequently, in the sedimentary archive (for example pore water reactions). In order to test the reliability of ε_{Nd} as a tracer for the MOW, we analyze ε_{Nd} from seawater samples, foraminifera Fe-Mn coatings and sediments from transects located in the Iberian Margin. Seawater results show that ε_{Nd} can be used to identify the different water masses located in the Iberian Margin. Considering that the ε_{Nd} values of the MOW differ from the values of the surrounding Atlantic waters, Nd isotopes seem to be a good tool to trace the MOW through the Iberian Margin. The comparison of these results with the ε_{Nd} values of core-top foraminifera and sediment samples provides us with enough information to infer how the geochemical signal of seawater Nd isotopes is transferred to the Fe-Mn coatings of foraminifera, and how to interpret these results on a palaeoceanographic context. This study aims to establish the basses to interpret ε_{Nd} reconstructions of MOW changes since the last glacial period in relation with AMOC changes.

Environmental conditions controlling Cold-water corals occurrence in western Melilla (western Mediterranean) since the last deglaciation

Ms. Mar Selvaggi Mallorquí [1]***, Dr. Maria de la Fuente*** [2]***, Dr. Claudio Lo Iacono*** [3]***, Dr. Negar Haghipour*** [4]***, Mr. Albert Català*** [2]***, Dr. Jose Noel Pérez Asensio*** [5]***, Prof. Isabel Cacho*** [2]

1. *Earth Sciences Department, University La Sapienza,* ***2.*** *Universitat de Barcelona,* ***3.*** *Institut de Ciències del Mar (ICM CSIC), Barcelona, Spain,* ***4.*** *Geological Institute, ETHZ, Zurich,* ***5.*** *Departamento de Estratigrafía y Paleontología, Universidad de Granada*

Cold-water corals (CWCs) are widely scattered in the southern Alboran Sea (westernmost Mediterranean), specifically in the so-called East and West Melilla CWC mound provinces (EMCP, WMCP). In this study, we present hydrographical changes in West Melilla from the sediment core MD13-3451 (370 m water depth) across the last ~14.2 kyr BP, followed by an integrated assessment of the WMCP complex evolution. The detected temporal mound occurrence allowed the identification of CWCs development' patterns since the last deglaciation, and relate them to distinct palaeoceanographic changes that potentially influenced the local environment framework. The performed analyses include both sedimentary characteristics (i.e., grain-size records), and geochemical measurements in benthic foraminifera calcite, i.e., stable isotopes and trace elements, such Mg/Ca as a proxy for deep-water temperatures (DWTs). Furthermore, seawater $\delta^{18}O$ ($\delta^{18}O_{sw}$) and seawater $\delta^{18}O$ corrected for the ice volume signal ($\delta^{18}O_{w-ivc}$) have been estimated via paired analyses of Mg/Ca and $\delta^{18}O_{carbonate}$. The generated data suggest: i) CWCs develop well with relatively warm DWTs and high currents intensities, although these factors are here not considered to be determinant in their formation. This also account for the oxygen content, where major changes does not seem to affect CWCs development. ii) Major changes concerning the hydrographical conditions occurred during the Early Holocene, where a rapid freshening of the waters is detected. The presented results, when combined with available records from neighbor sites, permitted to observe that CWCs proliferation or decline is closely coupled to the reorganization of the whole Alboran Sea' water column structure. For instance, the Holocene decrease of CWCs growth occur simultaneously when intermediate water properties above ~400 m water depth became very distinctive from those below, suggesting a higher influence of isotopically lighter water masses. This point to the important role of Mediterranean Circulation in driving the development of coral mounds. Overall, our data provide a high-resolution record of the most recent hydrographic changes in the southern Alboran Sea, and also reflect the importance of integrating a wide range of environmental variables to better understand the complex interplay that controls CWCs development.

Unveiling the variation in intermediate water mass circulation and its potential effects on Tunisian cold-water coral mound development during the last glacial cycle

Dr. Guillem Corbera [1]***, Dr. Claudio Lo Iacono*** [2]***, Mr. Adrià Tejero*** [3]***, Dr. Maria de la Fuente*** [1]***, Dr. Ester García Solsona*** [1]***, Dr. Eduardo Paredes*** [1]***, Dr. Leopoldo Pena*** [1]***, Prof. Isabel Cacho*** [3]

1. *GRC Geocencies Marines, Dept. de Dinamica de la Terra i de l'Ocea, Facultat de Ciencies de la Terra, Universitat de Barcelona,* ***2.*** *Institut de Ciències del Mar (ICM CSIC), Barcelona, Spain,* ***3.*** *Universitat de Barcelona*

To date, most thriving cold-water coral assemblages in the Mediterranean Sea are found within the water depths bathed by the Levantine Intermediate Water (LIW). In a similar way, coral mound development in this basin has been partly linked to the distance between the mounds' summit and the water mass interface found at the transition from Atlantic Water (AW) to LIW (ca. 200-250 m water depth). Water mass interfaces are characterised by sharp density gradients that promote the accumulation of particulate matter, mainly consisting of plankton. Additionally, the interaction between two water masses might promote the creation of internal waves that propagate along the interface, increasing sediment resuspension and vertical mixing, which could ultimately promote enhanced transfer of organic matter to the depths were the corals are found. Nonetheless, due to glacio-eustatic changes and other paleoclimatic variations, the depth and intensity of the AW-LIW interface are likely to change through time. In this regard, the present study aims to use gravity cores collected from on- and off-mound areas of the Tunisian Coral Mound Province to assess the potential variations in intermediate water mass circulation during the last glacial cycle and its effects on coral mound development. Specifically, we aim to use Nd isotopic analyses from both corals and foraminifera to describe the changes of water-mass influence in the area. These analyses will be complemented with grainsize and U/Mn data, extracted from foraminifera, in order to acquire a better understanding of the changes in intensity and oxygenation of the water mass bathing the mounds. The analyses of the samples is currently underway and thus, the preliminary data together with a corresponding discussion will be presented.

Implications of a revised varve-based deglacial chronology from Lago Grande di Monticchio for the Mediterranean region

Dr. Rik Tjallingii [1], ***Dr. Xueru Zhao*** [1], ***Dr. Arne Ramisch*** [2], ***Dr. Sabine Wulf*** [3], ***Dr. Markus Schwab*** [1], ***Prof. Achim Brauer*** [1]

1. *GFZ - German Research Centre for Geosciences, Section Climate Dynamics and Landscape Evolution, Potsdam, Germany,* ***2.*** *Institute of Geology, Innsbruck University, Austria,* ***3.*** *School of the Environment, Geography and Geosciences, University of Portsmouth, Portsmouth, United Kingdom*

Sediment records of Lago Grande di Monticchio have provided detailed insights in global climatic teleconnection patterns. Newly recovered sediment cores (MON16) from this lake provide a new and detailed deglacial record of the mostly varved sediment covering the termination of the last glacial period and the onset of the Holocene. These sediments consist of organic-clastic, diatomaceous, and organic varves that are interrupted by event layers and homogeneous intervals. The detailed stratigraphy of the last deglacial based on micro-facies analyses and XRF core-scanning reveals a stepwise transition from the last glacial into the Holocene. We present a revised chronology based on varve counting, tephra layers, radiocarbon dates, and a novel the Bayesian age-depth modeling approach. The new varve-counting results (CHRON-2022) reveals 8663 ± 123 counted varves, which is clearly more complete compared to previous studies (CHRON-1996). The varve counting results are used to parameterize the priors of the Bayesian age-depth modeling routine Bacon, which integrates both the error of the varve counting and radiometric dating uncertainties into the chronology. The floating chronology was anchored to the tephras of Mercato (8530±100 cal a BP), Pomici Principali (12037 ± 52 cal a BP), and NYT (14194 ± 172 cal a BP). The resulting ages are in good agreement with two radiocarbon dates of plant seeds, whereas three dated leaves revealed too old ages. In addition, the CHRON-2022 chronology revises the age uncertainties of at least 4 of the most prominent tephra layers in the MON16 sediment record. The combination of this varve chronology and tephra isochrons does not only allow to re-evaluate radiocarbon dating in lake Monticchio, but also provides a regional chrono-stratigraphic framework for identical tephra isochrons in the Mediterranean region. Such a regional chrono-stratigraphic framework provides a crucial basis for the reconstruction of regional and global palaeoclimatic teleconnections.

Mediterranean thermohaline circulation variability from the last deglaciation associated with changes in the eastern Mediterranean water outflow

The Eastern Mediterranean Sourced Water (EMSW) outflow through the Strait of Sicily and together with the Western Mediterranean Deep Water (WMDW) contribute with different proportion to the Mediterranean outflow waters (MOWs) that exit into the Atlantic Ocean through the Strait of Sicily. In this work, we investigate changes in the EMSW outflow from the last deglaciation, with special focus in two periods characterized by important hydrographic changes, 1) The Younger Dryas (YD) and 2) the Last sapropel (S1). For that, we analyze Neodymium isotopes in planktic foraminifera coatings, stable oxygen isotopes and Mg/Ca ratios from both benthic and planktic foraminifera as well as grain-size from a sediment core recovered at the western flank of Sicily channel at 1066 m depth (W-Sicily; NDT-6-2016). At present, this site is located below the hydrographic boundary layer between the eastern and western sourced water-masses and then, it is suitable to evaluate changes in the EMSW outflow. Our data suggests that enhanced and high-salinity flow of eastern Mediterranean sourced waters (EMSWs) during the YD resulted on an intensification of Mediterranean outflowing waters (MOWs) currents. We proposed that this enhanced MOW could have favored the reactivation of the Atlantic meridional overturning circulation (AMOC), which was operating in a weak mode. An important reduction of the EMSW flow during the S1 resulted in a reduced surface Atlantic water eastward flow, reducing its influence at W-Sicily. During the last part of the S1 (S1b) very distinctive hydrographic conditions developed both at surface, with strong mixing, and at depth with the appearance of a high salinity water mass. We propose that regional climate conditions led to an increase of the evaporation/precipitation, which would have favored deep water convection processes, promoting the formation of a high-salinity intermediate-water mass over the Tyrrhenian Sea area during this S1b period.

Last deglacial reorganization of the western Mediterranean thermohaline circulation: evidences from sedimentological and Nd isotopes proxies

Dr. Jaime Frigola [1], Dr. Leopoldo Pena [1], Ms. Sara Campderrós [2], Mr. Albert Català [3], Dr. Maria de la Fuente [3], Dr. Ester García Solsona [1], Mr. Carlos Martin [1], Mr. Alex Merchan [1], Dr. Eduardo Paredes [1], Ms. Mar Selvaggi Mallorquí [4], Dr. Judit Torner [5], Dr. Sergi Trias-Navarro [1], Dr. Giulia Margaritelli [6], Dr. Jose Noel Pérez Asensio [7], Prof. Fabrizio Lirer [8], Prof. Isabel Cacho [3]

***1.** GRC Geocencies Marines, Dept. de Dinamica de la Terra i de l'Ocea, Facultat de Ciencies de la Terra, Universitat de Barcelona, **2.** Departament de Din, **3.** Universitat de Barcelona, **4.** Earth Sciences Department, University La Sapienza, **5.** University of Barcelona, **6.** Consiglio Nazionale delle Ricerche, Istituto di Ricerca per la Protezione Idrogeologica (IRPI), **7.** Departamento de Estratigrafía y Paleontología, Universidad de Granada, **8.** Department of Earth Sciences of Sapienza University of Rome*

Last glacial/interglacial transition involved significant changes in western Mediterranean (Med) thermohaline circulation that culminated with the formation of an organic rich layer (ORL) in the Alboran Sea from 14.5 to 9 ka BP. This event pre-dated the eastern Med stagnation associated with the Last Sapropel (S1: 10.8-7.1 kyr BP). Here we aim to gain in the understanding that those two events had in the oceanography of the westernmost Med and ultimately its impact on the Med outflow waters (MOW). Our approach combines sedimentological indicators (grain-size and XRF-core scanner data) with Nd isotopes measured in foraminifera diagenetic coatings as a proxy of water mass source. The studied material includes a set of cores covering a depth range from the Alboran Sea (from 300 to 1800 m) combined with a core from the Balearic Basin and another from the Gulf of Cadiz.

Grain-size measurements confirm that major changes in current intensity happened within Heinrich stadial 1. While deepest currents (2400 m) in the vicinity of the Gulf of Lion convection cell became weaker, records from the Alboran Sea show a reinforcement at deep and intermediate levels (1800-600 m) that surprisingly maintained during the whole ORL. During the Younger Dryas Nd isotope values converge along the whole water column, supporting the arrival of more radiogenic waters at the intermediate layer (900-300 m), which are further exported into the Gulf of Cadiz. This event coincides with maximum current speeds above 900 m in the Alboran Sea but also in the Gulf of Cadiz, in agreement with a reinforcement in the arrival of Eastern Med Source Waters (EMSW). In contrast, with the formation of S1 in the E-Med, Nd values between intermediate and deep waters diverge, confirming the reduced influence of more radiogenic EMSW during this period, a signal further exported into the MOW, whose currents reached minimum intensities. These data indicate that during the studied period E and W-Med convection cells changed their operation way compared to the present day and presented an heterogeneous response to deglacial-Holocene climate forcings.

Reconstructing Mediterranean Sea water paleo-pH over different time scales using boron isotopes

Atomic Energy Agency, Principality of Monaco

The Mediterranean Sea is considered a climate change hotspot given its relatively small basin size, restricted water exchange connections, and much shorter turnover time than the global oceans. It is especially vulnerable to ocean acidification resulting from the drastic anthropogenic increase in atmospheric CO_2 since the Industrial Revolution. Indeed, instrumental measurements confirm the seawater acidification trend in this basin, not only at surface but in the whole water column. In this context, reconstructing paleo-pH in the Mediterranean Sea is key to understand the evolution of the carbon system and to project future changes in ocean chemistry and climate. In this work, boron isotopes were analysed on planktonic and benthic foraminifera from Mediterranean Sea sediment cores, allowing us to reconstruct surface and sub-surface sea water pH over time. Sample cleaning, preparation, chemical purification and isotopic analyses were carried out at the University of Barcelona. For this, we set up the methodology, including the purification of boron from the foraminifera carbonate matrix using microsublimation, as well as the boron isotopes analysis using a Nu Plasma 3 Multi Collector Inductively Coupled Plasma Mass Spectrometer (MC-ICPMS). We focused on a series of sediment cores from the Strait of Sicily and the Gulf of Valencia, which allowed us to reconstruct pH over different timescales and temporal resolutions: from the last centuries to glacial/interglacial cycles. Preliminary results point towards an acidification trend during the last century, correlated with the anthropogenically induced rise in atmospheric CO_2, and also to pH decreases associated to glacial/interglacial transitions.

Tracking environmental change in Eastern Australia: a multi-lake chrono-stratigraphic approach

Dr. Tim Cohen [1], ***Dr. Zenobia Jacobs*** [2], ***Dr. Haidee Cadd*** [3], ***Dr. Matthew Forbes*** [4], ***Mr. Bryce Sherborne-Higgins*** [3], ***Dr. Sam Marx*** [5], ***Mr. Alexander Francke*** [6]

Many Quaternary studies often only utilise single cores to reconstruct environmental change for a given locality lending themselves to a 'single-record' bias. The Thirlmere Lakes Research Program represented a unique sub-surface investigation of the five independent lakes within the Greater Blue Mountains World Heritage area, involving 347m of coring/drilling with over 40 cores collected from the five lakes and deep drilling undertaken on the lake margins and on the alluvial sills adjacent to the lakes. It has involved the development of a robust geochronological framework with 60 optically stimulated luminescence (OSL) and 45 radiocarbon ages, along with a suite of palaeoecological and geochemical analyses. To date, this data set represents the most thoroughly investigated Quaternary sequence in the Sydney basin. The chrono-stratigraphy shows excellent internal consistency with the upper lake sediments comprising 2 – 5 m of organic-rich sediments (thickness of peat varying between lakes) with very low bulk density (0.174 ± 0.103 g/cm^3), very high moisture content (83 ± 9%) and up to 40% total organic carbon (TOC). These organic-rich peaty sediments represent the onset of Holocene climatic conditions and they unconformably overlie a distinct oxidised clastic silty clay that underlies all lakes. This oxidised unit represents a distinctive marker horizon in the lake sediments and also varies in thickness (up to 60 cm) across and within a given lake. This unit has been dated across all five lakes to be 21,000 to 12,000 years (the last glacial maximum [LGM] and the deglacial) and represents a massive hydrological change where Thirlmere lakes dried and the lake sediments were sub-aerially exposed and weathered (oxidised). The oxidised silty clay unconformably overlies older lacustrine sediments that are 60 to 100,000 years in age but the depth of fill and deep-drilling (along with OSL ages) indicates multiple glacial cycles of sediment accumulation. This poster presents the chrono-stratigraphic results, including three master cores using a Bayesian age-depth modelling approach.

The potential of grass phytoliths for palaeoenvironmental reconstruction in northern Australia.

Ms. Kelsey Boyd [1]***, Dr. Haidee Cadd*** [1]***, Dr. Carlos Cordova*** [2]***, Dr. Cassandra Rowe*** [3]***, Dr. Tim Cohen*** [1]

1. *ARC Centre of Excellence for Biodiversity and Heritage, School of Earth, Atmospheric and Life Sciences, University of Wollongong,* ***2.*** *Oklahoma State University,* ***3.*** *ARC Centre of Excellence of Australian Biodiversity and Heritage and Centre for Tropical Environmental and Sustainability Science, James Cook University, Cairns, Queensland, Australia*

Phytolith analysis often provides insight into palaeoenvironmental change in regions where other proxies preserve poorly. The highly durable nature of opal phytoliths means that they are highly resistant to a range of environmental conditions, including aridity. Additionally, phytoliths are produced in large quantities by the Poaceae (grass) family and can be differentiated at the subfamily level or below for the reconstruction of grassland dynamics. Since grass subfamilies are closely associated with environmental and climatic conditions, this suggests that grass phytoliths may be potentially useful for palaeoclimatic reconstruction.

Despite this, phytoliths have rarely been utilised as a proxy for palaeoenvironmental reconstruction in Australia, where semi-arid and arid conditions dominate across 70% of the continent. This is partly due to the lack of available modern reference material collections from plant and soil samples. Such collections are time-consuming and intensive to produce but are necessary for establishing relationships between phytoliths and environmental conditions, as well as for accurate phytolith identification and consideration of taphonomy.

This study will develop a modern reference collection of grass phytoliths for northern Australia and will assess the potential of these short-cell grass phytoliths for palaeoenvironmental reconstruction. 36 grass species were collected from across the semi-arid (grassland) and tropical (savanna) zones of the Northern Territory, Australia, and examined for phytolith production utilising both qualitative shape and quantitative size classifications. Relationships with grass subfamilies, environmental factors, and a range of climatic variables are then statistically examined using correspondence analysis. These relationships will be used to assess the potential of grass phytoliths are a proxy for palaeoenvironmental and palaeoclimatic reconstruction in northern Australia.

Radiocarbon dating, dendrochronology and charcoal analysis applied to the relationship between fire and the growth dynamics of the critically endangered Dinosaur tree Wollemi Pine

Dr. Heather Haines [1]***, Dr. Berin Mackenzie*** [2]***, Mr. Andrew Benson*** [3]***, Mr. Steve W Clarke*** [4]***, Dr. Chris SM Turney*** [5]***, Dr. Scott Mooney*** [6]

1. *Chronos 14Carbon-Cycle Facility, Mark Wainwright Analytical Centre, University of New South Wales, NSW, 2052, Australia,* ***2.*** *Science, Economics and Insights Division, NSW Department of Planning and Environment, NSW, Australia; Centre for Ecosystem Science, University of New South Wales, NSW, Australia; Wollemi Pine Recovery Team, NSW, Australia,* ***3.*** *NSW National Parks and Wildlife Service, Australia,* ***4.*** *Wollemi Pine Recovery Team, Sydney, NSW, Australia,* ***5.*** *Division of the Deputy Vice-Chancellor, Research, University of Technology Sydney, Sydney, NSW 2017, Australia,* ***6.*** *Earth and Sustainability Science Research Centre, University of New South Wales, Sydney*

In this study we report several lines of evidence, including the radiocarbon dating of wood, dendrochronology, climate assessment and charcoal analysis to consider the relationship between fire events and the growth dynamics of the critically endangered conifer *Wollemia nobilis* (Wollemi Pine). *W. nobilis* was known only from the fossil record until it was rediscovered in 1994 and hence it has been dubbed the Dinosaur tree in recognition of its living fossil status. *W. nobillis* is a tall tree when mature and is located in only a few sheltered locations, approximately 150 km from the city of Sydney, within the Greater Blue Mountains World Heritage Area, Australia. It has been suggested that this restricted distribution is perhaps related to fire, and recent fire events (e.g., The Black Summer fires of eastern Australia 2019-2020) continue to be a challenge for the survival of this iconic species.

Here we present evidence of annual ring boundaries in *W. nobillis*. The methods applied to analyse this species and the identified relationships to climate will be discussed. This demonstrates potential to expand dendrochronological research within a region where other high resolution climate proxies are lacking and instrumental climate data is limited to the last century or two at most. We also synthesise the accumulation of charcoal from 13 sites in the region surrounding Wollemi National Park to provide a longer temporal perspective of fire in this landscape. This data suggests that area burnt has been on the increase over the last ~600 years, and this adds further to the challenges of managing this critically endangered species.

Our work provides both an improved understanding of the growth dynamics of this iconic species and insight into the impact of fire, on the individuals within the population, and in the surrounding landscape. We apply this information to the future management of the remaining Dinosaur trees.

Post-glacial environmental change in the Snowy Mountains, Australia, recorded in a suite of high-resolution lake sediment cores

Prof. Douglas Clark [1], ***Mr. Aidan Burdick*** [2], ***Ms. Emma Mickelson*** [1], ***Ms. Natalie Culhane*** [1], ***Dr. Lydia Mackenzie*** [3], ***Prof. Adrian McCallum*** [4], ***Prof. James Shulmeister*** [5], ***Ms. Jessa Clark*** [1]

***1.** Department of Geology, Western Washington University,* ***2.** Northwestern University,* ***3.** School of Earth Sciences, Zhejiang University,* ***4.** Faculty of Engineering and Science, University of the Sunshine Coast,* ***5.** University of Canterbury*

Tarns in the highest part of the Snowy Mountains, the only glaciated region in mainland Australia, have captured sediments continuously since deglaciation, ca. 18,000 yr B.P. Analysis of an 8.5 m core collected in 2016 in the largest of these, Blue Lake, demonstrates that the tarns preserve high-resolution, high-fidelity sedimentary records of environmental change since the onset of Termination 1. In particular, the record indicates that south-eastern Australia experienced several dramatic shifts in climate (cold/dry vs. warm/wet) between ca. 18-11 ka, the last two of which may correlate to the Antarctic Climate Reversal and Younger Dryas, respectively. Although the Holocene portion of the core documents a more consistent climate (warm/wet overall), it is punctuated by two notable episodes of somewhat cooler/dryer conditions at ca. 10.8-9.7 ka and ca. 2.2-1.2 ka.
To test and confirm these results, we collected a suite of new cores from two other lakes in the area, Club Lk and Lk Albina, in August 2022. Preliminary analyses of these cores demonstrates that they also preserve detailed, highly structured stratigraphy similar to that in Blue Lake. Although we do not yet have direct age control on the new cores, comparisons to earlier cores indicate that the Club Lake cores span most or all of the Holocene, and the Lake Albina cores extend back to initial deglaciation, equivalent to the Blue Lk core. Because there are multiple overlapping cores from each lake, we anticipate they will provide more robust age models than are available for the Blue Lk core. This in turn will allow us to refine the timing and possible correlations of the events recorded at Blue Lk. Furthermore, because Blue, Club, and Albina all occupy cirques in different drainages, the new cores will allow us to assess local vs. regional influences and coherence of the climatic events recorded in the cores. Full results of our analyses will be presented at the meeting.

The relationship of subfossil diatoms to environmental variables for the fifty lakes on the Burin Peninsula (Newfoundland, Canada).

Mr. Cyprian Kowalczyk [1], ***Prof. Mikołaj Kokociński*** [2], ***Prof. Karina Apolinarska*** [3], ***Prof. Les C. Cwynar*** [4], ***Dr. Krzysztof Pleskot*** [5]

__1.__ Department of Hydrobiology, Faculty of Biology, Adam Mickiewicz University in Poznan, __2.__ Hydrobiology Department, Faculty of Biology, Adam Mickiewicz University, __3.__ Institute of Geology, Adam Mickiewicz University, Poznań, __4.__ Department of Biology, University of New Brunswick, Fredericton, Canada, __5.__ Geohazards Research Unit, Institute of Geology, Adam Mickiewicz University, Poznań, Poland

Coastal lake ecosystems often vary in such characteristics as salinity, pH, or phosphorous concentrations even at the local scale. This variation influences the diversity of the lake-dwelling organisms, including diatoms, of which remains serve as essential indicators in paleolimnological studies. Although reconstruction of past lake environments can substantially benefit from an application of diatom analysis, such studies require proper data on the relationships of the organisms with their environment, which is seldom available for remote coastal areas. This study aims to establish the relationship of subfossil diatoms to multiple lake water and catchment characteristics on the Burin Peninsula (Newfoundland, Canada). Fifty lakes were surveyed for the measurement of chemical, physical, and morphometric parameters and collection of surface sediment samples in August 2022, which were analyzed for the composition of diatoms and sediment. Although all the lakes are relatively shallow (0.1 – 4.8 m), they differ markedly in other characteristics. For instance, we found a noticeable difference in such characteristics as salinity (0.015 – 28.92 PSU), pH (4.83 – 8.52), or size (0.07 – 43.9 ha), as well as in catchment vegetation. Our results will provide important insights into the diatom compositions in this remote area and their ecological requirements. The obtained data can be further used in the planned paleolimnological studies, focused on the reconstruction of lake ecosystem responses to past marine inundations and climate fluctuations.
The research is carried out as a part of an OPUS project (2020/37/N/ST10/02614) financed by the Polish National Science Centre.

Those chilly Tropics: reconstructing 1,200 yr of climatic and vegetational changes in Nicaragua by creating an ad-hoc Pollen Atlas

Ms. irene torreggiani [1], ***Ms. Lina Cabrera Saenz*** [2], ***Mr. Eldetello Castilla*** [3], ***Dr. William J. Harvey*** [1]

1. *School of Archaeology, University of Oxford,* ***2.*** *Florida Institute of Technology,* ***3.*** *Comunidad de Aguas Buenas*

The Pollen Atlas Project aims to understand the effects of climate change and anthropogenic activity on Nicaraguan Dry Tropical Forest by combining botanical surveys, fresh pollen collections, pollen traps and paleoenvironmental reconstruction. The Atlas has been an essential tool for the identification of fossil pollen from a 1,200 yr lacustrine sediment record from El Tigre-Asososca lake (León). This paper will explore the interdisciplinary approach that led to the creation of the PAP, alongside its practical applications and new discoveries. Specific attention will be given to the multi-proxy palynological analysis of El Tigre natural reserve and on those identified taxa that hold the potential of providing new insights into paleoclimatic changes and prehispanic anthropic activity in central Nicaragua. Among all, the identification of various species of *Pinus* in association with *Psidium guineense* unveils a past different landscape and climate to what we see nowadays in central Nicaragua. The Pollen Atlas is freely available on the open-source (https://globalpollenproject.org/) and on social media (https://www.instagram.com/thepollenatlasnicaragua/), and provides information on local uses, ecology, taxonomy and pollen morphology for over 200 species.

Incorporating introduced biota: the changing ecosystem of a Late Neolithic lakeshore community

Ms. Amy Holguin [1], *Prof. Mike Charles* [2], *Dr. Eva Panagiotakopulu* [3], *Prof. Amy Bogaard* [2]

1. University of Oxford, 2. School of Archaeology, University of Oxford, 3. University of Edinburgh

A key characteristic of the spread of agriculture into continental Europe is the introduction of new biota. Here, we offer the case-study of the lakeshore, pile-dwelling site of Ploča, Mičov Grad, Lake Ohrid in North Macedonia, to explore how introduced crops and their associated pests were incorporated into Late Neolithic lifeways. A thick organic layer associated with the settlement was extracted through lake cores, as part of the interdisciplinary and international ERC-funded EXPLO project. Within this cultural layer, the waterlogged archaeobotanical remains offer a rich record of human subsistence from the mid-5th millennium BCE, with a main occupation phase constrained by radiocarbon and dendrochronological dating to c. 120 years. The population used a broad spectrum of edible plants including a mix of introduced and native species: cultivated cereals and pulses, oil-seed crops and gathered fruits and nuts. The excellent preservation of the plant remains enables us to consider both the ways by which this population cultivated crops and through which they processed and transformed plant items into plant foods. Lying in a transitional zone between Mediterranean, Alpine and Continental biogeographic zones in the southern Balkans, the site rests within a pivotal, but under-researched region, for understanding the cultural, geographic, and ecological stimuli and barriers underpinning the spread and maturation of early European agriculture.

delta2Hn-alkane and delta18Osugar biomarker proxies from leaves and topsoils of the Bale Mountains, Ethiopia, and implications for paleoclimate reconstructions

The hydrogen isotopic composition of leaf wax-derived *n*-alkane (delta$^2H_{n\text{-alkane}}$) and oxygen isotopic composition of hemicellulose-derived sugar (delta$^{18}O_{sugar}$) biomarkers are valuable proxies for paleoclimate reconstructions. Here, we present a calibration study along the Bale Mountains in Ethiopia to evaluate how accurately and precisely the isotopic composition of precipitation is imprinted in these biomarkers. *n*-Alkanes and sugars were extracted from the leaf and topsoil samples and compound–specific delta$^2H_{n\text{-alkane}}$ and delta$^{18}O_{sugar}$ values were measured using a gas chromatograph-thermal conversion-isotope ratio mass spectrometer (GC-TC-IRMS). The weighted mean delta$^2H_{n\text{-alkane}}$ and delta$^{18}O_{sugar}$ values range from −186 to −89 per mille and from +27 to +46 per mille, respectively. Degradation and root inputs did not appear to alter the isotopic composition of the biomarkers in the soil samples analyzed. Yet, the delta$^2H_{n\text{-alkane}}$ values show a statistically significant species dependence and delta$^{18}O_{sugar}$ yielded the same species-dependent trends. The reconstructed leaf water of *Erica arborea* and *Erica trimera* is ^{2}H– and ^{18}O–enriched by +55 ± 5, and +9 ± 1 per mille, respectively, compared to precipitation. By contrast, *Festuca abyssinica* reveals the most negative delta$^2H_{n\text{-alkane}}$ and least positive delta$^{18}O_{sugar}$ values. This can be attributed to “signal-dampening” caused by basal grass leaf growth. The intermediate values for *Alchemilla haumannii* and *Helichrysum splendidum* can be likely explained with plant physiological differences or microclimatic conditions affecting relative humidity (RH) and thus RH-dependent leaf water isotope enrichment. While the actual RH values range from 69 to 82 percent (Mean = 80 ± 3.4 percent), the reconstructed RH values based on a recently suggested coupled delta$^2H_{n\text{-alkane}}$ – delta$^{18}O_{sugar}$ (paleo-) hygrometer approach yielded a mean of 78 ± 21%. Our findings corroborate (i) that vegetation changes, particularly in terms of grass versus non-grassy vegetation, need to be considered in paleoclimate studies based on delta$^2H_{n\text{-alkane}}$ and delta$^{18}O_{sugar}$ records and (ii) that the coupled delta$^2H_{n\text{-alkane}}$ – delta$^{18}O_{sugar}$ (paleo-) hygrometer approach holds great potential for deriving additional paleoclimatic information compared to single isotope approaches.

Do Mediterranean deltas behave as alternative state systems? A paleoecological perspective

Dr. Xavier Benito [1]***, Dr. Carles Alcaraz*** [1]***, Dr. Miquel Vilà*** [2]***, Dr. Liviu Giosan*** [3]

Although borrowed to illustrate the impacts of overfishing, the term shifting baselines, or the extent to which each human generation accepts a degradation of the environment and perceives it to be “natural”, can also be applied to other pressing disturbances, such as eutrophication, salinization, and hydrological alteration. This is the case of Mediterranean deltas, where major transformation through agricultural expansion and catchment modification took place during the pre-instrumental era, and hence a long-term vision is needed. In this contribution we will present preliminary results of a combined limnological-paleolimnological approach to characterize multiple shifting baselines in the Ebro Delta (NW Mediterranean). We use a 9800 cal yr BP record to identify feedbacks between proxies for natural disturbances in the delta (pulse events such as lobe switching and climate or fluvial regimes), and ecosystem responses, using XRF techniques and foraminifera community time-series data, respectively. We also compared fossil foraminifera trajectories to a regional data set characterizing the full range of modern communities from marine to deltaic plain habitats, to validate drivers of community change, using a space-for-time substitution approach. Preliminary paleolimnological-scale analyses suggest that following the post-glacial sea level rise, significant peatland-type habitats developed. Thereafter the delta has gone through three ecological states (submerged-vegetated habitats) by crossing two tipping points that marked synchronous changes in both XRF and foraminifera changes. Hierarchical Generalized Additive Models were used to model rate of change and variance which preceded deltaic ecosystem shifts, hence validating their use as resilience loss indicators. Millennial-scale analyses combined with contemporary data provided a robust quantitative framework of habitat regime shifts. The novelty of our paleolimnological-scale resilience analysis is that we should be able to make contributions towards ranking past habitat states in terms of, for instance, sensitivity to variables or combination of variables (sea-level rise, sediment type, salinity) for assessing different lines of evidence for multiple reference baselines at local and regional scales against which to define management and restoration efforts in the Ebro Delta.

Exploring biological responses to climatic change in benthic and pelagic communities during the Holocene within the Arctic region

Dr. Alice Carter-Champion [1], ***Dr. Katrine Elnegaar Hansen*** [1], ***Prof. Marit-Solveig Seidenkrantz*** [2], ***Dr. Christof Pearce*** [1]

1. *Department of Geoscience, Aarhus University,* ***2.*** *Paleoceanography and Paleoclimate Group, and iClimate Centre, Dept. of Geoscience, Aarhus University, Aarhus, Denmark*

The Arctic is experiencing unprecedented (for the Holocene) warming, with increasingly evident impacts on ecosystems of the Arctic Ocean and adjacent seas, as well as physical changes to currents, sea-ice extent and seasonal temperatures. Although a suite of observational datasets for recording these changes has existed for over half a century, longer-term changes in ecosystem stability are harder to quantify. It is vital to constrain changes from a 'natural' baseline, to best predict the future effects of anthropogenic warming. This is also crucial for understanding the positive and negative feedback loops between ecosystems and climate systems in this highly sensitive region. Compilation of multiple palaeoecological datasets over space and time will enable the drivers of climatic change to be characterized, alongside reconstructions of the associated ecological responses to these shifts.

This research presents a compilation of biological proxy assemblages in the Arctic region during the Holocene, with specific focus on the responses of benthic and pelagic communities to different types of climatic change (i.e. abrupt vs gradual). In conditions potentially analogous to the modern-day, meltwater inputs to the Arctic region were common in the early Holocene, as the North American Ice Complex and Eurasian ice sheets melted. These are clearly visible within sedimentological records from the Labrador Sea and Arctic more broadly. Several records also contain multiple proxy time-series of benthic and pelagic communities at high-resolution, predominantly including dinoflagellates, benthic foraminifera and diatoms. The different responses of these communities will be quantified and compared within the same cores, as well as their spatio-temporal distributions within the Arctic region more broadly. This provides a baseline for the biological responses to past climate-driven physical changes within the Arctic region prior to human impact. The spatial component of these analyses may also shed light on the potential extent of meltwater-induced perturbation of different biological communities with implications for future meltwater impacts.

Variations of Primary Productivity in the Northwestern Arabian Sea during the last 23,000 Years and Their Paleoclimatological Implications

Dr. Xinquan Zhou [1], ***Dr. Stephanie Duchamp-Alphonse*** [2], ***Dr. Masa Kageyama*** [3], ***Dr. Franck Bassinot*** [4], ***Dr. Catherine Kissel*** [4]

***1.** Tongji University,* ***2.** Paris Saclay University - GEOPS Laboratory,* ***3.** Laboratoire des Sciences du Climat et de l'Environnement,* ***4.** LSCE*

The Arabian Sea (AS) is one of the most productive oceanic regions in the world due to several monsoon-related processes that can increase nutrient contents in the euphotic zone. Previous studies of the imprint of oceanic Primary Productivity (PP) in AS sediments yielded diverse results depending on the studied area and the chosen proxies, with unprecise paleoclimatic interpretations. Here, we provide multi-decennial PP and coastal upwelling dynamic records off northern Oman over the last 23 kyr, based on the analysis of coccoliths from sediment core MD00-2354 (61.48°E, 21.04°N, 2740 m). The last 23 kyr encompasses a glacial-interglacial transition, an entire precessional cycle, and millennial-scale fluctuations in the Atlantic Meridional Overturning Circulation (AMOC) and is therefore a perfect case study to explore the impact of key climate forcing mechanisms on PP for both, past and future climate conditions.

Our results have been compared with previous paleoenvironmental records as well as modelling data (IPSL-CM5 and TraCE-21) to get precise paleoclimatic interpretations. We document higher PP and weaker coastal upwelling during the Last Glacial Maximum (23–19 ka) relative to the Holocene, and significant millennial-scale variations over the last deglaciation (19–11 ka) corresponding to the fluctuations of the AMOC strength. Higher PP and weaker upwelling are found during the cold stadials Heinrich Stadial 1 (17–14.8 ka) and Younger Dryas (12.9–11.8 ka), while lower PP and stronger upwelling during the warm period Bølling–Allerød (14.8–12.9 ka). We propose that the increases of PP were driven by increased bioavailable nutrient content in surface waters under both, stronger winter monsoon conditions that strengthened the convective mixing, and higher aeolian inputs. Over the Holocene, stronger upwelling and slightly lower PP are found during the Early-Mid Holocene (10–8 ka), when higher summer insolation triggered stronger summer monsoon. At that time, the lower PP was probably the result of restricted advection of summer upwelling seawater under negative wind stress curls and less aeolian inputs.

Holocene vegetation, climate and human impact in the mid-Kama region (pre-Urals, Russia)

Mrs. Vlada Batalova [1], ***Ms. Elizaveta Orlova*** [2], ***Mr. Mikhail Pereskokov*** [2], ***Mr. Pavel Sannikov*** [2], ***Dr. Lyudmila Shumilovskikh*** [1]

1. Department of Palynology and Climate Dynamics, Georg-August-University Göttingen, 2. Perm State University

The Ural Mountains form a unique bioecological and climatic border between Europe and Asia, simultaneously uniting them by cultural, ethnic and economic relations throughout history. To shed light on the natural and land use history of this region in high temporal resolution, we obtained a seven-meter peat core Shabunichi-I from the Paltinskoe peatland located on the fluvial terrace of the Middle Kama River Basin (Perm region, Russia). Here we present the new results from palaeoecological studies of vegetation, fire and settlement history over the last 9200 years based on AMS radiocarbon dating, loss-on-ignition, macro-charcoal, pollen and non-pollen palynomorphs. In our study we focus particularly on the Iron Age when human impact on the natural environment in the region increased due to a significant rise in the number of settlements. Since 9200 cal yr BP, the vegetation was presented by Siberian taiga and forest-steppe. The vegetation along with frequent local fires testify to the dry climate in the early Holocene. By the mid-Holocene, the spread of spruce and broad-leaved species together with the absence of a local fire signal indicate the humification of the regional climate. Since 4000 cal yr BP, the maximum expansion of broadleaved species is combined with the appearance and spread of Siberian fir. Signals of anthropogenic changes in vegetation are marked in the pollen assemblages since the Bronze Age (~3900 cal yr BP). However only since ~2000 cal yr BP, the vegetation dynamics was strongly influenced by anthropogenic activity and human-induced fires. Archaeobotanical data from archaeological excavations are in line with palynological investigations, showing that the Iron Age cultures practiced agriculture with barley and emmer and gathering of wild plants such as raspberries, strawberries and elder. Wood anatomy studies provide new insights in selective usage of wood, showing use of linden and birch for artifacts production and charcoals of Scots pine and spruce in burial rituals.

Changing organic carbon sources in the Chukchi Sea sediments with sea ice retreat over recent centuries

Mr. Liang Su [1] ***, Dr. Jian Ren*** [1] ***, Dr. Marie-Alexandrine Sicre*** [2] ***, Dr. Youcheng Bai*** [1] ***, Dr. Jianfang Chen*** [1]

1. *Second Institute of Oceanography, Ministry of Natural Resources of China,* ***2.*** *LOCEAN, Sorbonne Universités (UPMC, Univ Paris 06) -CNRS-IRD-MNHN, Paris, France*

Assessment of sources and burial of organic carbon in Arctic sediments and their temporal evolution with sea ice retreat is important to better understand the alteration of the organic carbon cycle and its impact in the Arctic Ocean region and the global carbon budget. Here, we characterize the major sources of organic carbon in sediments using bulk organic parameters and highly branched isoprenoids (HBIs) in surface sediments across the western Arctic Ocean. Sympagic, pelagic, and terrestrial sources were characterized using HBIs, sterols and bulk parameters (total organic carbon, total nitrogen, $\delta^{13}C_{org}$, and $\delta^{15}N$).

Then, downcore profiles were generated to explore compositional changes of organic matter and how they have been affected by retreating sea ice over the last two centuries in the northern Chukchi Sea. We found that the organic carbon pool was mainly constituted of land-derived material under severe sea ice conditions, which has been decreasing from the 19th century onwards with shrinking sea ice as indicated by rising sympagic and pelagic organic carbon, in particular in the last decades when sea ice decline accelerated.

A comparative study of Cultural Interactions between Harappan and Jiroft Civilization in middle of the 3rd Millennium BCE

Ms. Neda Amirmahmoudi [1]***, Prof. Vasant Shinde*** [2]***, Dr. Nasir Eskandari*** [3]

1. *Department of AIHC & Archaeology, Deccan College PGRI, Pune,* ***2.*** *CSIR centre for cellular and Molecular Biology, Hyderabad,* ***3.*** *Department of Archaeology; University of Tehran, Tehran*

Harappan Civilization (HC; Indus River) is a well-established culture, with multiple stages of cultural groups coexisting in large regional urban centres in Pakistan (i.e., Harappa, Mohenjo-daro) and India (i.e., Rakhigarhi and Dholavira), spread over the northwestern part of the South Asian region dated from 2600 to 1900 BCE. It was distinguished by systematic town planning, intricate drainage systems, granaries and the standardization of weights and measures. Simultaneously, another culture flourished in Iran called Jiroft Culture (JC; Halil River) during the same period. So the important research question is whether those cultures (HC and JC) had any connection or any similarities. This research aims to understand the cultural affiliations between JC and HC and study these connections with special reference to glyptic art on the seals that has been used to unravel the interactions.

The present research is based on the newly excavated materials from Halil River Basin and earlier reports retrieved from cultural materials of both the civilizations. To achieve this goal, a closer look has been taken at the iconographic scheme and the techniques of depicting the symbols and other visual elements on the seals during the 3rd Millennium BCE. The result shows different kinds and size of stamp seals (mostly made on Bronze, Terra cotta, Alabaster and White stone) and also some wares which were found in both the civilizations. In addition, the motifs on the Unicorn, Zebu bull and crocodile symbols which were found in Iranian stamp seals were known to be found only in HC. The depiction of similar kind of animal symbols found in both the civilizations show that they had some shared connection through trading relationship via the possible sea and land routes during the time.

The research will focus on these icons, symbols and an attempt has been made to understand the exchange of ideas and thoughts across the huge span of landscape covering the present-day Indian sub-continent and the Iranian Plateau. These results will bring new discovery of antiquity and show how cross-cultural interactions happened between the aforementioned two highly complex urbanized systems.

The Critical Zone is exposed to a multitude of external forcings (including climate) that condition its environmental evolution and available resources. Understanding the geological processes behind these changes is a challenging task.

Alluvial systems are the response to intertwined climatic, tectonic, (palaeo-)geographic and anthropic drivers over the last millennia, being in consequence very suitable proxies for the Critical zone. The characterization of alluvial sediments, which provide valuable information about the environmental conditions at the time of their deposition. allows indirect assessments of these drivers.

Against this background, quartz mineral is an ideal tracer of the alluvial system's evolution because of its ubiquity and absence of strong weathering. Quartz are also characterised by some differences in their composition and behaviour in response to various stimuli (light, irradiation, ...) related to its initial conditions of formation, and perhaps also to its sedimentary history.

In the ANR QUARTZ project, we aim to develop a multi-technique methodology that uses quartz grains as markers of sedimentary dynamics. The ANR QUARTZ project explores (i) how each quartz grain holds a source-specific signature, and (ii) how this signature evolves over time across sediment routing systems. This 3-year project started in December 2021 and focuses on three French river catchments draining the Vosges, the Alps and the Massif Central: the Strengbach, Séveraisse and Creuse, respectively. Modern river borne sediments from the main trunk and tributaries, along with bedrock sources, were extensively sampled in the two first catchments. River terraces of the third catchment will be sampled in 2023.

In this project, the luminescence and paramagnetic properties of the river sediments will be studied along with their elemental composition. The variations in quartz grain characteristics will help to estimate evolution over time of their origin(s) and mode of transport as well as the response of the system to external changes, including volumes of sediments transported from a source-to-sink perspective.

Deciphering the Rates and Dynamism of Glacial Erosion in Alpine Catchments Through a Novel Application of Thermoluminescence Thermochronometry

Mr. William Wenban [1], ***Prof. Edward Rhodes*** [2], ***Dr. Darrel Swift*** [1], ***Dr. Nathan Brown*** [3]

1. Department of Geography, University of Sheffield, 2. Landscape Dynamics, Department of Geography, University of Sheffield, Sheffield S10 2TN, UK, 3. Department of Earth and Environmental Sciences, University of Texas Arlington

Mountain landscapes across the Earth have been profoundly shaped by periods of successive glaciation, creating unique landforms such as U-shaped valleys, cirques, aretes and large bedrock steps. These features can significantly impact the behaviour and evolution of mountain glaciers and suggest a strong spatial variability to glacial erosion.

Previous research on the spatial and temporal dynamics of glacial erosion have largely been confined to the study of cirques and headwalls, or through topographic study of landscape hypsometry, whilst the dynamism of catchments and glacial profiles as a whole have been explored conceptually within numeric models. Erosion is commonly modelled numerically in a simplified relation to ice sliding velocities based on limited observations and data, which has led to a variety of proposed exponent values. As such, there is a continuous need for empirical evidence of erosion rates at the sub-catchment scale in order to better constrain the dynamic variability of erosional processes throughout the catchment profile and to test hypotheses derived from topographic and numerical analysis.

By applying a method of thermoluminescence thermochronometry (TLT), we can begin to explore the near-surface cooling history of bedrock as it is exhumed by processes such as glacial erosion. We target feldspar minerals in samples of exposed glacially-eroded bedrock along the profile of contemporary glacial catchments in the Swiss Alps. By exploiting the novel ability of TLT as a very low temperature thermochronometer we can decipher rates of glacial erosion throughout these catchments over 10 ka timescales.

Combined with landscape evolution modelling using the integrated Second Order Shallow Ice Approximation (iSOSIA), we can gain insight into the spatial and temporal rates of glacially-induced landscape evolution backed by empirical data. Further, this can be used to test different numerical laws for glacial erosion by combining TLT data and ice sliding velocities.

Finding Quaternary Seismogenic Activity along the Eastern Periadriatic Fault System: Dating of Fault Gouges using Trapped Charge Methods

Mr. Erick Prince [1]***, Dr. Sumiko Tsukamoto*** [2]***, Dr. Christoph Grützner*** [3]***, Prof. Marko Vrabec*** [4]***, Prof. Kamil Ustaszewski*** [3]

1. *Institute for Geosciences, Friedrich-Schiller University Jena, Germany,* ***2.*** *LIAG,* ***3.*** *University of Jena,* ***4.*** *University of Ljubljana*

The Periadriatic Fault System (PAF) is among the most important and largest post-collisional structures of the Alps; it accommodated between 150-300 km of right-lateral strike-slip motion between the European and Adriatic plates from about 35 until 15 Ma. Recent GPS data suggest the Eastern Alps are still accommodating Adria-Europe convergence. However, according to instrumental and historical seismicity, seismotectonic deformation is mostly concentrated in the adjacent Southern Alps. In this contribution, we aim to show which segments accommodated seismotectonic deformation during the Quaternary by applying Electron Spin Resonance (ESR) and Optically Stimulated Luminescence (OSL) dating to fault gouges produced by the fault system. The method is especially useful for dating shear heating during earthquake activity at near-surface conditions due to its dating range (a few decades to ~1 Ma) and low closure temperature (below 100°C). For ESR, we measure the signals from the Al center in quartz following the single aliquot additive (SAAD) and single aliquot regenerative (SAR) protocols, focusing on the 100-150 µm grain size fraction. For OSL, we use the SAR protocol and measure the infrared stimulated luminescence (IRSL) signals at 50°C and 225°C on potassium feldspar aliquots of the 100-150 µm grain size fraction. Our ESR results indicate the PAF system accommodated seismotectonic deformation during the last 1 Ma, while the minimum ages obtained via OSL suggest that the events are not likely younger than 0.4 Ma.

Deciphering Past Desert-Margin Dynamics in Matmata, Tunisia

Dr. Sebastian Kreutzer [1]***, Dr. Sascha Meszner*** [2]***, Dr. Christoph Schmidt*** [3]***, Dr. Tobias Lauer*** [4]***, Dr. Melanie Kranz (née Bartz)*** [5]***, Dr. Mathieu Duval*** [6]***, Dr. Moncef Bouaziz*** [7]***, Dr. Christopher-Bastian Roettig*** [8]***, Dr. Ulrich Hambach*** [9]***, Prof. Dominik Faust*** [10]

The terrestrial dust archives around Matmata (Tunisia) are unique in their morphological setting and grain-size composition. Located in front of the Grand Erg's in a critical zone at the northern edge of the Saharan desert, up to 35 m thick plateau-like loess accumulations cover past landscapes. Sandy loess and intercalated palaeosols attest to rapid and large-impact climate boundary shifts. Some of them may have severely threatened ancient regional cultures, and future changes may put modern settlements and agriculture projects in the region at risk. Palaeolandscape reconstruction, supported by reliable chronologies, charts past and predicts possible future scenarios.

The 'desert-loess' records around Matmata seem to engulf a wide temporal range back to Marine Isotope Stage (MIS) 9. Trapped charge dating techniques, such as luminescence and electron spin resonance (ESR) dating, are versatile tools for deciphering the timing of past landscape changes in this area. We provide new luminescence (Infrared-Radiofluorescence, optically stimulated luminescence) and electron-spin resonance dating results from seven different sites and attempt to link our findings to regional climate fluctuations and drainage alterations observed for the large endorheic salt lakes in the Matmata plateau's close purlieu.

Detection of the bomb peak 14C for the onset of the Anthropocene

The unprecedented environmental changes resulting from anthropogenic activities initiated during the Great Acceleration of the mid-20th century can be traced using radiocarbon analysis. The cosmogenic isotope ^{14}C, which is produced in the atmosphere, is well-known as the geochronological tool applied to archives of the last 55 thousand years. However, during the last 200 years, the natural signal of ^{14}C in the atmosphere and connected reservoirs (biosphere, ocean, soils, etc.,) has been perturbed by human activities. Two anthropogenic effects are observed: a decreasing trend observed in ^{14}C concentration of the atmosphere (Suess effect) which has been temporarily reversed by aboveground thermonuclear tests of 1950/60s.

The excess of the artificially produced ^{14}C (bomb pulse) is a useful time marker for the mid-20th century and the detection of the bomb peak in natural archives has thus been proposed as a tool to locate and date the onset of a proposed new epoch, the Anthropocene.

Here we present the results of radiocarbon analysis conducted as a part of the research dedicated to establishing the Global boundary Stratotype Section and Point (GSSP) for the proposed Anthropocene. The studied sites include corals (Flinders Reef, AU and Flower Garden Banks, USA), peat (Śnieżka peatland, PL), lake sediment (Crawford Lake, CA and Searsville Lake, USA), and marine sediment (East Gotland Basin, Baltic Sea). The variety of records (different carbon reservoirs) required site and sample-specific treatment prior to analysis and site-specific interpretation of the measured ^{14}C. Nevertheless, the mid-20th century bomb peak was detected at all but one site. In all records, the observed onset of the ^{14}C bomb peak always postdates 1954, the year of the first atmospheric ^{14}C bomb increase. The specific reservoir effects and corrections will be discussed.

A Siderastrea siderea Coral from Flower Garden Banks Records Human Impacts as a Candidate for the Global Boundary Stratotype Point for the Anthropocene

Corals are unique in the suite of proposed Anthropocene Global Boundary Stratotype Section and Point (GSSP) sites since they are living organisms that produce aragonite exoskeletons that can be preserved in the rock record. Corals also contain highly accurate and precise (<±1 year) internal chronologies, similar to tree rings, that can be confirmed by high-precision uranium-thorium dating. The proposed Anthropocene GSSP candidate site of West Flower Garden Bank (27.8762°N, 93.8147°W) is an open ocean location in the Gulf of Mexico with a submerged coral reef and few direct human impacts. Here we present results from a large *Siderastrea siderea* coral (core 05WFGB3; 1755–2005 CE) sampled with annual and monthly resolutions that show clear markers of global and regional human impacts. Atmospheric nuclear bomb testing by-products have clear increases in this coral starting in 1957 CE for ^{14}C and the first increase in 1956 CE for $^{239+240}Pu$ (potential bases for the Anthropocene GSSP). Coral $\delta^{13}C$ declines especially after 1956 CE consistent with the Suess Effect resulting from the burning of fossil fuels. Coral skeletal $\delta^{15}N$ starts to increase in 1963 CE corresponding with the increase in agricultural fertilizers. Coral mercury concentrations (1933–1980 CE) loosely track fluctuations in industrial pollution and coral Ba/Ca increases from 1965–1983 CE when offshore oil operations, which use barite, expanded after 1947 CE. Temperature proxies (coral Sr/Ca) contain the 20th-century global warming trend whereas coral $\delta^{18}O$ reveals an increase in salinity. Furthermore, coral growth declines during this interval. As the scientific community debates the GSSP site, year, and marker for the start of the Anthropocene, coral reefs are projected not to survive. Yet corals will continue to record their last years in their skeletons, passively archiving the changes in their environment, chronicling the stressors, pollutants, and damage done to these otherwise multi-centenarians living organisms.

Ecosystem and human responses to recurrent climate changes at the Pleistocene-Holocene transition in the Scheldt basin (southern North Sea area, NW-Europe)

Prof. Philippe Crombé [1]

1. *Ghent University*

The last decades intensive high-resolution interdisciplinary research into the Late Glacial and Early Holocene in the Scheldt basin of Belgium, northern France and southern Netherlands has provided new insights into the ecosystem and human responses to successive climate fluctuations, both warming (GI-1e, GI-1c, a, and Early Holocene) and cooling (GI-1c2, GI-1b, GS-1, and Holocene IRD-events). Evidence suggests that while environment became more attractive to humans during the warm episodes, as a result of the denser and wider availability of wild resources and freshwater, they temporarily were confronted with stress situations due to increased wildfires and fluctuating water levels in lakes, ponds and rivers. In addition they had to face the consequences of repeated short but abrupt cold reversals which led to a temporal opening of the landscape (increase of herbs, grasses and sedges), a reduction of thermophilic plants (e.g. hazel) and renewed aeolian activity, the latter transforming the landscape (dune migration, infilling dune ponds and lakes). In my presentation I will highlight some of these environmental changes and the associated human response, ranging from decreased population density, over adaptation of the hunting equipment to changing mobility and land-use.

Deforestations, tribe to state transition and Cistercians impact on nature - a high-resolution multi-proxy 1000-year's record from the Eastern Germany kettle-hole peatland

Peatlands are exceptional archives; they store information about climate and human impact. Recently, our focus has been placed on the critical transition connected with the loss of pristine ecosystems in the last millennium. Several sites in western Poland show distinct patterns associated with deforestation and fires triggered by Europe's rapidly developing economy and population growth. The new study aimed to fill the gap in the high-resolution palaeoecology of Central Europe using the peat archive of a well-preserved Sphagnum-dominated kettle-hole located in Eastern Germany. Based on the former studies, we hypothesized that deforestation related to Cistercian's' economic impact triggered cascading effects on the peatland ecosystem leading to hydrological instability.

Furthermore, we aimed to date the tribe-to-state transition and loss of old growth forests leading to landscape openness and the arrival new economy supported by Christianity. First data show a clear shift linked to the local land-use changes and increasing fires ca 1300 CE. At this time, there was a transition to grazed woodlands, as indicated by the high proportion of oak pollen (up to ca. 40%) with the simultaneous high landscape openness and more substantial human impact. This impact is also visible in the taxonomic change of testate amoebae and the appearance of *Criptodifflugia oviformis*, and the decrease of mixotrophic species such as *Hyalosphenia papilio* and *Archerella flavum*. Our study shows that deforestation led to water loss on pristine peatlands. In the future steps, we aim to correlate palaeoecological signals to the historical events and economic increase in Eastern Germany.

Late Pleistocene and Holocene Caribbean mangroves: responses to climatic, eustatic and anthropogenic drivers of ecological change

Dr. Valentí Rull [1]

1. Botanic Institute of Barcelona (CSIC), Barcelona

Mangroves are keystone ecosystems, as they provide habitat for many terrestrial and marine species and are globally linked via atmospheric processes, participating in the global carbon cycle as an important carbon sink. Currently, mangroves are among the world's most threatened ecosystems. Since the 1980s, these forests have experienced a global cover loss by deforestation of 25-30%, which would lead to their disappearance within the next century. Major threats are agriculture, aquaculture, wood extraction, urbanization and global-warming-driven effects, such as sea level rise, increasing extreme weather events or invasion by alien species, among others. Understanding how mangrove ecosystems respond to natural and anthropogenic drivers of change is essential for informing conservation and restoration practices. In this sense, the responses of mangroves to climatic, eustatic and anthropogenic pressures of the last centuries and millennia may be of great utility, as they provide a natural laboratory where to study the potential effects of the main threats. This work reviews the available multiproxy information, with emphasis on palynological records, for Late Pleistocene and Holocene times in the Caribbean region. The first records date from the Last Interglacial (Eemian; MIS 5e) when global average temperatures and sea levels were slightly higher than the present and mangroves grew in locations and conditions similar to today. During the Last Glaciation (Weichselian; MIS 5d to MIS 2), SSTs and sea levels were ~4°C and 80-120 m below the present, respectively, and Caribbean mangroves were far from their present locations, especially in areas with shallow and extensive continental shelves. Caribbean mangroves progressively attained their present configuration during the Late Glacial-Early Holocene warming and sea-level rise, in the absence of anthropogenic pressure. Human influence began to be important in the Mid-Late Holocene, especially during the Archaic and Ceramic cultural periods, when sea levels were already at their present heights and climate-human interactions were the most influencing factors. During the last millennium, the most relevant drivers of ecological change have been the episodic droughts linked to the Little Ice Age and the European contact and their further consequences.

The ups and downs of Polish statehood - paleoecological insights from Lake Lednica (western Poland) during the last 1500 years

Greater Poland, which is the historical region of west-central Poland is regarded as the center of the emerging Polish state in the 10th century. However, the settlement and its time frames before the formation of the center of power related to Piast's dynasty in this region are poorly explored. Therefore, paleoenvironmental reconstructions of high chronological control could increase knowledge about past societies' economic activity and related environmental transitions. In this study, we analysed a 2-meter long profile from Lake Lednica (in the central part of Greater Poland) for pollen, selected coprophilous fungi, microcharcoal, geochemical composition via µXRF scanning, and grain-size distribution supported by 24 AMS radiocarbon ages. The aim was to explore the impact of socioeconomic processes on the local environment.

The results show the regeneration of oak-hornbeam forest from the end of the 5th century. It was a time of low human impact, however, sufficient for a gradual selective hornbeam clearing, as reflected by *Carpinus betulus* pollen decline from ca. 580 cal. CE. The largest environmental changes associated with intensive human activities took place from ca. 850 cal. CE and were probably related to the formation of power centres around Lake Lednica (or on its islands). We observed during that time increase in Fe/Mn ratio, indicating anoxic bottom water conditions in the lake, possibly caused by increased nutrient supply to the lake.

Since then, a decline in arboreal pollen and a rise in ruderals as well as cultivated pollen are recorded. Moreover, since ca. 940 cal. CE Fe/Mn ratios show a distinct peak that could be related with construction of bridges between 963 and 964 CE connecting the island to the mainland.

After 1050 cal. CE, a sharp decline in cereals pollen is recorded, which was probably related to the Bretislav invasion recorded in 1039 CE and led to depopulation and massive damage of strongholds including Ostrów Lednicki. This condition lasted until around 1300 cal. CE, when a return to the pre-crisis state started. Rapid deforestation and an increase in agriculture were recorded from around 1450 cal. CE, which was probably related to the establishment of surrounding villages.

Human-environment interactions at the central Mediterranean site of Motya (Sicily, Italy)

Dr. Claudia Moricca [1]***, Prof. Lorenzo Nigro*** [2]***, Dr. Federica Spagnoli*** [2]***, Dr. Federico Cappella*** [3]***, Dr. Nina Ferrante*** [3]***, Dr. Lucrezia Masci*** [4]***, Dr. Sharon Sabatini*** [2]***, Prof. Laura Sadori*** [5]

1. *Department of Environmental Biology, Sapienza University of Rome,* ***2.*** *Department Italian Institute of Oriental Studies (ISO), Sapienza University of Rome,* ***3.*** *Department of Classics, Sapienza University of Rome,* ***4.*** *Department of Earth Sciences, Sapienza University of Rome,* ***5.*** *University La Sapienza*

The island of Motya, found in the Marsala lagoon in western Sicily, has been the object of archaeological excavations by "Sapienza" University of Rome for over 60 years. Known for its Phoenician occupation (8^{th} century – 397 BC), the small island (ca. 40 ha) was inhabited since the 17^{th} century BC.

Systematic archaeological studies have been integrated with multi-analytical approaches in the fields of archaeozoology, petrography and metallurgical techniques. The more recent introduction of archaeobotanical and palynological studies has allowed to expand our knowledge of the use of plants by the past inhabitants of Motya, complementing archaeological information with data concerning diet, food and flower offerings, land exploitation, past vegetation, environmental changes, and the introduction of plants from other areas of the Mediterranean. Pollen data describe an open environment, with scarce tree cover and characterized by complex anthropic activities. Anthracology shows a prevalence of Mediterranean taxa, such as *Quercus* evergreen, *Pistacia lentiscus*, and *Olea europaea* throughout the studied period. In terms of land exploitation, both disciplines support the archaeological hypothesis that *Vitis vinifera* was cultivated on site, also suggesting an abundance of olive trees. Furthermore, the presence of chaff and different sized weeds, as well as cereal pollen indicate local crop processing. As far as diet is concerned, a preference for barley can be seen in pre-Phoenician Motya, gradually integrated with naked wheats from the 8^{th} century onwards. Interesting is the introduction of *Punica granatum* (pomegranate) from the East, previously hypothesized based on the find of a globular pottery vessel with an indented rim resembling the fruit, which was confirmed by the retrieval of six exocarp fragments in a disposal pit (8^{th} - mid-6^{th} century BC). Other plants likely introduced to Motya by Phoenicians include *Juglans regia* and *Pinus pinea*. Additional considerations can be done concerning grapes and wine. While the vast repertoire of Phoenician and Proto-Corinthian drinking vessels indicates wine consumption at Motya, and tartaric acid has been detected in dental calculus of 6^{th} century BC Phoenician inhabitants of the island, morphometric analyses of *V. vinifera* seeds allowed to obtain preliminary results concerning the consumed grape varieties.

Coastal resources in Fuego-Patagonia's Paleodiets: a micro-scape and temporal stable isotope approach.

Dr. Marta Alfonso Durruty [1], ***Dr. Nicole Misarti*** [2], ***Dr. Flavia Morello*** [3], ***Dr. Manuel san román*** [4], ***Dr. Jimena Torres*** [3], ***Mr. Noah Clayman*** [5], ***Dr. Luis Alberto Borrero*** [6]

Fuego-Patagonia (46-52° S), the southernmost region of the Americas, has a long history of human occupation (~10,500 BP-present), which is characterized by the presence of groups that utilized coastal resources to varying degrees. In Fuego-Patagonia, stable isotope (SI) analyses have been used to identify the dietary contribution of coastal resources among pre-contact groups. The identification of coastal resources in the diet, and the estimation of their dietary contribution, has been characterized by a broad approach but does not consider SI variability within the same species in time and space. The current study analyzes SI data collected from coastal resources (e.g. seals, sea lions, penguins, shellfish, fish, and cormorant) recovered at archeological sites in Fuego-Patagonia. We also include some plant remains known to be part of historic diets. To identify micro-scape and temporal differences in these resources' stable isotope signature, the archaeological sites and SI data are organized into two periods (Middle vs. Late Holocene), and ten areas distributed from the Atlantic Ocean' to the Pacific Ocean' shores, including areas located along the Magellan and Beagle Straits. Analyses indicate significant differences in the SI of resources by area. When human dietary reconstructions are conducted considering this variability, the results strongly indicate that these interpretations must consider micro-scape variabilities of resource species, which could also contribute to our understanding of human mobility patterns, and the changing interaction between humans and their environments. Future studies could also benefit from this approach, and further enrich our understanding of the flexible strategies used by hunter-gatherer groups in the past. Our analyses re-affirm that any conclusions drawn from Bayensian analyses to identify past isotopic niches must consider the lack of visibility/identification of foods that preserve poorly in the archaeological record may lead to incomplete or misleading dietary reconstructions.

An integrative approach of soil mapping, geophysical surveys and historical accounts to locate a 14th century plague mass grave in Erfurt, Germany

In the 14th century, Central Europe was struck by several catastrophes, leading to a prolonged state of socio-economic and agrarian crisis. Among these events were weather-induced crop failures that caused the largest famine in European history – known as the Great Famine (1315-21) – and the Black Death pandemic (1346-53), extinguishing 30-50% of Europe's population. For the city of Erfurt in Thuringia, substantial human losses and corresponding mass graves in nearby deserted villages are well-documented for the two events in historical archives. Erfurt is therefore a unique place to study both fatalities and to explore their possible links to one another, and to destabilizing climates towards the onset of the Little Ice Age. In this pilot study, funded by the German Research Foundation (DFG), the first priority lies on the localization of the mass graves in order to advance our future archaeological, anthropological, archaeogenetic and palaeoenvironmental research.

Here we present our integrative approach of historical, pedostratigraphical and geophysical investigations to identify the location of a Black Death cemetery in the deserted village of Neuses, municipality of Erfurt. Within the area of interest (AOI), constrained by historical accounts and GIS implementations, we applied vibracoring (n = 56, ≤ 5m coring depth) and near-surface geophysical methods (electrical resistivity tomography and ground-penetrating radar).

Combined geophysical and coring sections help elucidate the late Quaternary sedimentary processes and allow for the designation of pedogeographical units as an essential natural background for more detailed geoarchaeological prospections. Two such pedogeographical units delimit each other within the AOI and display consistent stratigraphical and pedogenic sequences: (1) a *Chernozem* zone and (2) a *Black Floodplain Soil* zone. Conceivably, the distribution and extent of these zones co-determined the positioning of the former village Neuses and its presumed associated Black Death cemetery. Based on that, our set of methods enabled a preliminary reconstruction of the medieval subsurface architecture within the AOI, despite large-scale ground modifications carried out there in the 20th century. A few of the identified buried structures have a high potential of representing an actual mass grave due to their sizable dimensions. This will be clarified during upcoming excavations.

Landscape evolution in Central Macedonia (Greece) during the last four millennia

Dr. Lucrezia Masci [1]**, *Dr. Cristiano Vignola*** [2]**, *Dr. Adam Izdebski*** [3]**, *Dr. Georgios C. Liakopoulos*** [3]**, *Dr. Katerina Kouli*** [4]**, *Dr. Jakub Sypiański*** [5]**, *Dr. Alessia Masi*** [1]

1. *University La Sapienza,* ***2.*** *Dipartimento di Biologia Ambientale, Sapienza Università di Roma, Roma (Italy),* ***3.*** *Max Planck Institute for Geoanthropology,* ***4.*** *Department of Geology and Geoenvironment, National and Kapodistrian University of Athens,* ***5.*** *Johannes Gutenberg-Universität Mainz, Germany*

Balkan vegetation and climate have shown a great variability during the last 4 millennia. Ecosystem richness and geomorphological variability of the habitats have been continuously shaped by human societies but are also susceptible to environmental and climate changes. Within this, Central Macedonia (Greece) is characterized by complex vegetational and historical dynamics. The present landscape is the result of cultural, political, and socio-economic factors and environmental evolution over thousands of years.

Landscape reconstruction based on two natural archives, Paliouras lagoon and Volvi Lake, are herein palynological studied and compared to offer a new and detailed assessment of the last 4000 years history of Central Macedonia.

Pollen results reveal an environment dominated at regional scale by shrubs and trees of the mediterranean vegetation with the predominance of evergreen oaks that characterized the arboreal cover of the two sites. The replacement in the last centuries of thermophilous mixed forest with xeric-adapted taxa at Paliouras are influenced by both climatic and human factors. Instead, human impact is the main reason behind the opening of the landscape and the reduction of arboreal vegetation in the last millennia at Lake Volvi. Agricultural activities are evidenced by the presence of cereals (*Avena/Triticum* group, *Hordeum* group and *Secale)* and cultivated trees (e.g., *Juglans* and *Castanea*) and intensified during the Roman rule of the region. The wide presence of weed and ruderal taxa such as Cichorieae, *Plantago lanceolata, Rumex* and *Galium*, highlights herding as the main human activity in both areas. The palaeoenvironmental reconstruction has been flanked by a punctuated study of written sources for the surroundings of the two sites that give a detailed picture for the Byzantine and Ottoman periods. The increase of human activities in the last centuries of the Byzantine empire and later with the Ottoman rule is driven by both agriculture as well as animal husbandry as evidenced in the pollen record. High-resolution pollen data and historical sources revealed an altered landscape associated with land-use changes according to the historical events in the region. Late Holocene climatic fluctuations have contributed to modify the environment and had spillover on society and land management.

Intensive anthropic activity in Central Spain as driver of vegetation turnover: the pitch kiln evidence of Sierra de Gredos

Dr. Juan Manuel Rubiales [1]

1. *School of Forest Engineering and Natural Resources, Technical University of Madrid*

Forest products derived from resin, such as pitch or tar, have played a crucial role in past societies for many centuries. Research in the Gredos Mountains (central Spain) has revealed the existence of a dense network of pitch kilns at the 1200-1800 m asl altitudinal interval. Intensive efforts have been made to locate these structures in the central section of the Massif, where more than 50 kilns have been identified, showing a high density of these archaeological structures. In most of these kilns, charcoal have been recovered for anatomical study, showing extensive evidence of the use of *Pinus* gr. sylvestris as the main fuel source. Radiocarbon dating has provided Holocene dates for the Pinus charcoal remains (ca 400 -1200 cal AD). Palynological data, as well as macrofossils and charcoals from soils have revealed the dominance of pine forests in these mountains during most of the Holocene, with a significant disappearance in the last 1,500 years. Climate, grazing and the increase of the use of fire have been suggested as the principal causes of the forest demise and the subsequent dominance of today's fire-prone scrubland. The data presented here, together with other historical and toponymic information, suggest that human activities in mountain areas included intensive industrial practices, not only in the Gredos Mountains, but also in other subcontinental sierras of Iberia. It also shows that tar extraction may have played an important role in shaping mountain vegetation in Iberia during the late Holocene.

Simulation of past agricultural landscapes in Konya Plain coupled with changing climates and communities

Ms. Neriman Erdem [1], ***Prof. Bülent Arıkan*** [1]

1. *Istanbul Technical University, Eurasia Institute of Earth Sciences, 34469 Maslak, Istanbul*

The Konya Plain, located on the Anatolian plateau, has always been an important agricultural production center, for the communities and civilizations which settled in the region since the Neolithic (ca. 12,000 cal. BP). Past agricultural practices and climatic conditions have cumulatively shaped the current vegetation and landscape of the region. The region faces remarkable ecological problems today such as salinization, aridification, and excessive groundwater use for irrigation. The plain's current ecological vulnerability and abundance of archaeological settlements in the area have increased scholarly interest. Despite numerous paleoenvironmental and archaeological studies in the region, achieving a temporally and regionally integrative and long-term dataset is tricky. First, this research aims to reveal the climatic changes in the region throughout the Holocene quantitatively. Macrophysical Climate Model (MCM) and CHELSA-TraCE21k dataset were used to obtain the paleoclimate in the region numerically. Second, it seeks to comprehend how agricultural production and landscape have evolved along with regional climatic and social changes. In this study, archaeological evidence, paleoclimatic reconstructions, and historical records from the region were integrated, and past agricultural production was simulated using agent-based modeling (MedLanD). MedlLanD Modelling Laboratory is a hybrid modeling platform that simulates long-term socio-ecological transformations regarding agricultural production and landscape evolution. Preliminary findings from the MCM point to the wetter and warmer periods in the Early Holocene, similar to isotope proxies in the region. Precipitation declines at the end of the Early Holocene, and the Middle Holocene has drier climate conditions. Although the MCM and CHELSA-TraCE21k data present similar temperature values, there are significant differences between precipitation values. Due to this variation in precipitation values, the model results were compared with the proxies and evaluated. Using the MedLand model and climate data, base maps (i.e., digital elevation, bedrock, soil depth, vegetation maps) for modeling agricultural production were created, and test runs for various time periods were performed. In the advancing parts, this research will be focusing on select periods, which represent cultural (i.e., the emergence of complex societies) or environmental (e.g., increased aridity or higher anthropogenic impacts) challenging phases in Konya Plain.

Local ecological consequences of the Black Death against background regional post-pandemic changes – the case of the Szurpiły settlement micro-region, NE Poland

Prof. Mirosława Kupryjanowicz [1], ***Dr. Magdalena Fiłoc*** [2]

1. University of Białystok, 2. Department of Paleobiology, Faculty of Biology, University of Białystok, Poland

The Black Death (AD 1347-1352) was the most renowned pandemic in human history, believed by many to have killed half of Europe's population. However, our knowledge of the Black Death remains limited, based primarily on qualitative remarks in medieval written sources available for some areas of Western Europe. A. Izdebski and co-authors recently presented a new approach to this issue, using palynological data to evaluate the Black Death's mortality on a regional scale across Europe. This study shown that the Black Death had a devastating impact in some regions, while it had negligible or no impact in others. The picture of regional environmental changes in a consequence of the plague is, however, a considerable "unification" of local data. In our opinion, in the case of some settlement microregions, the local changes caused by the pandemic could be significantly different from those reconstructed for larger regions to which they belonged. To prove this, we present high-resolution pollen data from annually laminated sediments of Lake Szurpiły located in NE Poland – for this region A. Izdebski and co-authors suggest post-pandemic agrarian growth, reflecting limited Black Death mortality. Our data document almost complete disappearance of anthropogenic plant communities and significant reforestation of the studied lake vicinity already at the transition of the 11th and 12th centuries, long before the outbreak of the epidemic. This event is well correlated with reconstructed by F.C. Ljungqvist cooling on the extra-tropical Northern Hemisphere, which was the first signal of the coming Little Ice Age. Thus, Black Death encountered an area around Lake Szurpiły that was very sparsely populated (low values of human pollen indexes) and covered with dense forest (high proportion of tree pollen). This state of affairs lasted until the middle of the 16th century and the colonization during the reign of the Grand Dukes of Lithuania. In the palynological record, the only signal of Black Death-induced mortality is the proportion of human pollen indicators noted in a sample dated at ca. AD 1350, which is the lowest in the entire profile.

The lacustrine record of the Anthropocene in central Chile

Prof. Magdalena Fuentealba [1], ***Prof. Claudio Latorre*** [1], ***Dr. Sergio Contreras*** [2], ***Dr. Ana M. Abarzua*** [3], ***Dr. Juana Alejandra Martel-Cea*** [4], ***Dr. Blas Valero-Garcés*** [5]

1. *Pontificia Universidad Católica de Chile,* ***2.*** *Universidad Católica de la Santísima Concepción,* ***3.*** *Universidad Austral de Chile,* ***4.*** *Centro de Estudios Avanzados en Zonas Áridas (CEAZA),* ***5.*** *Consejo Superior de Investigaciones Científicas, Instituto Pirenaico de Ecologia*

Human driven Global Change has widely impacted Earth System dynamics at least since the industrial revolution and particularly during the Anthropocene Epoch. Although such impacts on terrestrial ecosystems, surface processes, biogeochemical cycles and climate have become stronger during the last century, it is likely that these have occurred at variable intensities since long time ago. These human activities have had important effects not only in the terrestrial ecosystems, but also in the aquatic ecosystems due to the hydrologic linkages between both. For this, lakes are important sink of sediment from its basin and plays a key role for environmental reconstructions. Here, to improve our knowing about the influence of human activities in the past in Central Chile, we compare different historical periods (e.g., Spanish colonization, beginnings of the Republic of Chile, great acceleration -1950 onwards-) and their impact on the contributions of sediments and nutrients to four lakes. These lakes are Laguna Matanzas, Laguna Aculeo, Lago Vichuquén and Lago Lanalhue, all of them with human influences during the last centuries. The main result shows a high organic matter content and input of Nitrogen with the increased of forest plantations and intensification of agriculture. The knowledge about lake-watershed dynamics is key to unravelling and mitigating any negative effects that human-driven processes have on terrestrial and aquatic ecosystems and improve our understanding in the context of Global Change.

Attempt to reconcile discrepant luminescence and radiocarbon ages of trans-Himalayan (Ladakh) palaeo-lake sediments

***Ms. Priyanka Singh* [1], Dr. Morthekai P [2], Dr. Sheikh Nawaz Ali [2], Dr. Madhav Krishna Murari [3], Dr. Pankaj Baghel [4]**

***1.** Birbal Sahni Institute of Palaeosciences, 53 University Road, Lucknow – 226 007; Centre of Advanced Study, Department of Geology, Banaras Hindu University, Varanasi - 221 005., **2.** Birbal Sahni Institute of Palaeosciences, 53 University Road, Lucknow – 226 007., **3.** Geochronology Group, Inter-University Accelerator Centre (IUAC), New Delhi, 110067, India, **4.** Geochronology group, Inter-University Accelerator Centre (IUAC), New Delhi,110067, India.*

Even after numerous attempts, it is still difficult to establish a reliable chronology and understand the dynamics of western disturbances (a non-monsoonal precipitation pattern), a major source of winter moisture in the Trans-Himalayan region. Radiocarbon and luminescence dating methods have their own sets of a specific issues that must be resolved for faithful past climate reconstruction. To highlight the discrepancy, published luminescence ages of sediment from Spituk Lake at a height of ~ 20 m from the basement that were measured at different times, are 72 ± 2 ka, 58 ± 3 ka, and 30.2 ± 1.8 ka whereas the radiocarbon age is 3.3 ± 0.1 ka.

Overestimation of luminescence ages can be due to 1) poor sensitivity of quartz to ionizing radiation ($cts.Gy^{-1}.mg^{-1}$) and 2) incomplete resetting of luminescence prior to the deposition. Thus, to overcome the lower signal-noise ratio, researchers use larger aliquots and ended up having more poorly bleached grains in the aliquots that overestimated the ages. From this premise, we deduced a hypothesis - the luminescence ages based on smaller sized aliquots might correspond to the depositional event. So, we extracted pure quartz grains of size 90 -150 μm of one sample from Saspol Lake (Khalsi) and that was dated using big (BA: ~ 60000 grains), medium (MA: ~ 2300 grains) and small (SA: ~ 300 grains) aliquots. The estimated luminescence ages are 20.1 ± 0.8 ka (BA), 18.0± 1.0 ka (MA) and 5.5±0.4 ka (SA) whereas the radiocarbon age of the nearby sample is 11 ka. This observation supports our hypothesis. Radiocarbon ages from this region also have issues such as 1) hard water effect and 2) fresh water reservoir age.

To reconcile both the luminescence and radiocarbon ages with adequate explanatory mechanism(s), we collected samples for both dating methods from the same strata of two palaeo-lakes, Spituk (9 samples) and Saspol (5) from Ladakh. Radiocarbon ages are apparently older (18 ± 0.1 ka) and stratigraphically inconsistent. Luminescence ages are being estimated using bigger and smaller aliquots of quartz grains, We would like to elucidate the results in the conference for better understanding.

Towards the timing of the infill of glacially overdeepened basins using single grain pIRIR feldspar luminescence dating.

Mr. Gustav Firla [1], ***Prof. Christopher Lüthgens*** [1], ***Mr. Clemens Schmalfuss*** [1], ***Dr. Stephanie Neuhuber*** [2], ***Mr. Sebastian Schaller*** [3], ***Mr. Bennet Schuster*** [4], ***Prof. Frank Preusser*** [5], ***Prof. Markus Fiebig*** [1], ***Mr. DOVE scientific team*** [6]

The multinational pan-alpine research project ICDP - DOVE (International Continental Scientific Drilling Program - Drilling Overdeepened Alpine Valleys) currently investigates overdeepened structures on the northern side of the Alps. The infill of these overdeepened basins potentially provides a geo-archive for the reconstruction of depositional processes and paleoenvironmental conditions in the Alpine realm. Deciphering this valuable information requires a numerical chronology, which in the ICDP - DOVE project is going to be achieved by implementing a combination of different dating methods, including luminescence dating approaches. The expected age range covers time beyond the last glacial cycle. As the age range of quartz does not allow the calculation of reliable ages in this time frame. Therefore, signals from potassium-rich feldspar are used. The expected incomplete bleaching in the depositional environment (glacial waterlain deposits) is being investigated and discussed. As shown by previous studies and initial measurements, multigrain aliquots very likely represent age overestimation, often even limited by signal saturation. To circumvent this issue single grain (SG) measurements of potassium-rich feldspar using the pIRIR225 (post infrared, infrared stimulated luminescence @ 225°C) single aliquot regenerative (SAR) dose protocol is applied. We present first results from initial samples of complementary glacial overdeepenings with a focus on applicability of the pIRIR SG dating approach, reliability of the detection of incomplete bleaching, and establishing a maximum dose range for the different overdeepened basin catchment areas. Furthermore, preliminary IR and pIRIR ages are presented.

When were the Nazca Lines (Peru) created? New data from rock surface burial dating

Dr. Christoph Schmidt [1]***, Dr. Kerstin Hartsch*** [2]***, Mrs. Christiane Richter*** [3]***, Prof. Silvia Rosas*** [4]***, Dr. Luis Muro*** [5]***, Prof. Georgina King*** [1]

1. *Institute of Earth Surface Dynamics, University of Lausanne, 1015 Lausanne, Switzerland,* ***2.*** *IPROconsult GmbH,* ***3.*** *Dresden University of Applied Sciences,* ***4.*** *Pontifical Catholic University of Peru,* ***5.*** *The Field Museum of Natural History*

The Nazca Lines at the south coast of Peru are among the world's most enigmatic geoglyphs and a UNESCO world heritage site. Drawn on the desert by the Paracas and Nazca cultures (800 BC–AD 700), they comprise large (up to a few km) geometric structures such as lines, trapezoids and spirals, as well as figurative depictions (spiders, birds). They were created by removing the dark, patinated stone layer from the desert pavement, exposing the lighter silt layer beneath and accumulating heaps of stones on their edges. Beside their actual purpose, there are still many open questions about their chronology and when they were made, such as the temporal relationship between geometric and figurative depictions, and why and when some geoglyphs were superimposed onto previous ones.

To address these questions, we took 57 rock samples for luminescence burial dating from a spiral, superimposed trapezoids and one zoomorphic design. Preferentially felsic samples devoid of patina were chosen such that they were most likely re-located by the Paracas and Nazca people during geoglyph construction. Drill cores were obtained from the lower (shielded) surfaces of these stones and luminescence-depth profiles measured from cut slices. A plateau of normalized natural luminescence intensity within the first few mm below the surface served as an indicator of an archeological dose corresponding to the burial of rock surfaces during construction. Additionally, we sampled the silt layer beneath the desert pavement to assess the temporal scales involved in the formation of this geoarchive.

Results indicate the general datability of the geoglyphs and that granite is the most suitable lithology. This contribution presents new data on unravelling the temporal relationship of superimposed structures and the age of a figurine drawing. We outline the problems encountered in the dating process and discuss the robustness of the chronometric results. Further geochronological analyses show that the desert pavement exists since at least MIS 4-3, indicating that this geomorphic form has endured several major climatic fluctuations.

Extension of quartz luminescence chronology using the multiple aliquot regeneration technique in the Drzovice loess profile, Czech Republic

***Mr. Dávid Filyó* [1], *Dr. György Sipos* [1], *Dr. Daniel Šimíček* [2], *Dr. Tamás Bartyik* [1], *Mr. Gergő Magyar* [1]**

***1.** University of Szeged, Geomorphological and Geochronological Research Group, Department of Geoinformatics, Physical and Environmental Geography; Egyetem u. 2-6, H-6722 Szeged, Hungary, **2.** Palacký University of Olomouc, Department of Geology, 17. listopadu 12, 77146 Olomouc, Czech Republic*

The extension of quartz luminescence chronologies is a key issue when investigating dust accumulation rates in the last glacial cycle since by using traditional single aliquot regeneration (SAR) protocols the upper limit of dating is usually at around 50-70 ka, and in many applications, MIS 3 and MIS 4 accumulation rates can hardly be investigated this way. Although other, feldspar-based protocols (e.g. post-IR IRSL) are available for these periods, but uncertainties related to these, caused mainly by residual doses and anomalous fading, are considerably higher than in the case of quartz.

The multiple aliquot regenerative dose (MAR) protocol is one of the potential solutions to extend the quartz age range, as based on saturation tests and other luminescence characteristics, it might be applied up to 100 ka. However, we have limited data on the reliability of MAR-derived luminescence ages in comparison to other protocols.

In our study, four samples were selected from the Drzovice loess profile, covering the LGP and the MIS 5 paleosol. First, the fine-grain quartz fraction of samples was subjected to SAR and, MAR measurements. Then, to validate quartz MAR ages $pIR_{50}IR_{290}$ measurements were made on the polymineral fraction. As MAR ages in two cases exceeded pIRIR-derived ages, we determined pIRIR fading rates and calculated α-efficiency values for both fractions. We found that quartz MAR ages correlate well with fading-corrected pIRIR ages, and have a significantly lower uncertainty. We propose therefore to apply the quartz MAR protocol when establishing age models for LGP Moravian loess deposits.

Age and genesis of diamictons in the Mologa-Sheksna Lowland and adjacent areas

Mr. Maksim Ruchkin [1]***, Dr. Dmitrii Sadokov*** [2]

1. Karpinsky Russian Geological Research Institute (VSEGEI), Sredny Prospect 74, 199106, Saint Petersburg, Russia, 2. Darwin Nature Biosphere reserve

The Mologa-Sheksna lowland (MShL) is located in the north-west of the East European Plain. In the Late Valdai (Late Weichselian) the margin of the Scandinavian Ice Sheet (SIS) reached the MShL, however the limits of the maximum ice sheet expansion are still debatable. According to Garkusha (1965), the margin passed south of the Sheksna river and the most part of the MShL was occupied by the ice lobe. Pursuant to Gey (1990), the margin ran north of the MShL along the Belozersk-Kirillov and Tikhvin end moraine ridges.

We investigated five key sections with diamictons north and west of the Rybinsk reservoir, to reveal whether the SIS reached its current basin. The genesis of diamictons found at Abakanovo (N59°15’29.4”, E37°40’51.4”) and Shenskoye (N58°30’24.4”, E37°06’42.3”) is debatable and requires further studies. At Abakanovo the diamicton is covered by loessoid with quartz OSL age *ca.* 20 ka and underlain by fluvioglacial sand and gravel with quartz OSL ages 155–118 ka (K-rich feldsparp $IRIR_{290}$ ages 299–212 ka). At Shenskoye the diamicton is underlain by lacustrine and alluvial sediments with quartz OSL ages 73–62 ka.

In sections Gorinskoye (N58°24’09”, E37°32’34”), Timonino (N58°15’02”, E37°53’28”) and Suscheva (N58°15’23”, E37°52’06”) the diamictons can be steadily interpreted as subglacial tills. In all three sections the tills are overlain by loessoids or alluvial sand with quartz OSL ages 22–15 ka. At Gorinskoye the till is underlain by deformed fluvioglacial sand and gravel with quartz OSL ages 112–72 ka (K-rich feldspar $pIRIR_{290}$ ages 227–204 ka). Orientation of a huge overfold near the till bottom suggests that the glacier moved from north-east to south-west. At Timonino and Suscheva the tills are underlain by deformed sand and gravel with quartz OSL ages 163–103 ka (K-rich feldspar $pIRIR_{290}$ ages 447–324 ka). According to the orientation of folds and faults in the glacitectonites, the glacier moved from north-west to south-east at both sites. We consider quartz dates obtained for the submorainic deposits as minimum ages due to saturation effect at high equivalent doses (>150 Gy) and K-rich feldspar dates as maximum ages because of possible incomplete bleaching.

The potential of violet stimulated luminescence (VSL) to extend the chronology at the Fantasma Site in Atapuerca, Burgos, Spain

Dr. Alicia Medialdea [1], ***Mrs. Miren Del Val*** [2], ***Dr. Ana I. Ortega*** [3], ***Prof. Josep M Pares*** [1], ***Dr. Josep Vallverdu*** [4], ***Dr. Marcos Terradillos-Bernal*** [5], ***Prof. Eudald Carbonell*** [4], ***Dr. José María Bermúdez de Castro*** [1]

1. *Centro Nacional de Investigación sobre la Evolución Humana (CENIEH),* **2.** *Centro Nacional de Investigación sobre la Evolución Humana,* **3.** *Fundación Atapuerca,* **4.** *IPHES-CERCA, Institut Catala de Paleoecologia Humana i Evolucio Social,* **5.** *International University Isabel I de Castilla*

Over the past decades, optically stimulated luminescence (OSL) dating has become a key tool in the study of Quaternary sedimentary records. It can provide absolute ages ranging from decades to several hundred ka using standard procedures. Despite the power of the technique, demand for extending the age range has increased significantly in the past years, resulting in a large concentration of effort in this respect. Violet stimulated luminescence (VSL) has been proposed as one approach for meeting this objective. It has been shown that VSL yields a luminescence response that saturates at higher doses than the conventional blue-OSL signal from quartz. This study focuses on the application of VSL to sedimentary quartz samples from Fantasma Site in the UNESCO World Heritage archaeological sites of Atapuerca in Burgos, Spain.

Five samples from a 10 m-thick cave infill have been the target of this study. The conventional blue-OSL response increases at increasing depths, as expected, but the signal of the deeper-most sample is near the saturation limit of the signal, compromising the reliability of the age estimation. This also limits the possibility of dating the sedimentary units below (not included in the present study) using standard procedures of luminescence dating. VSL from the quartz extracts of these samples show a reproducible response which saturates at higher doses than the blue-OSL signal providing therefore, the possibility of reaching older ages. An extensive experimental study using VSL, including analyses on the effect of the stimulation temperature, the normalizing dose or the bleaching of the signal among other tests have been carried out to determine the most suitable measurement protocols and to confirm the reliability of the method to recover a given dose. Based on the results, equivalent doses using VSL up to 500 Gy can be recovered, in contrast to a maximum dose around 300 Gy that can be reached with conventional blue-OSL.

This study shows the potential of VSL to extend the age range beyond the limits of conventional luminescence dating in this site.

Environmental dose rate calculation for deep ocean sediments: Measure, model or guess?

Prof. Simon Armitage [1]

1. *Centre for Quaternary Research, Department of Geography, Royal Holloway University of London, Egham, UK*

Luminescence dating of deep ocean sediments is complicated by disequilibrium in the ^{238}U and ^{235}U decay series, which cause the environmental dose rate to vary as the sediment ages. Production of insoluble isotopes (^{230}Th and ^{231}Pa) in the water column overlying the sample site causes the incorporation of these isotopes in excess. This excess activity decays over time, leading to a progressive decrease in dose rate due to excess isotopes. In anoxic sediments, uranium can be incorporated into sediment without its decay products, leading to an increase in dose rate as the sediment ages and this "authigenic" uranium tends towards secular equilibrium. Direct measurement of excess and authigenic isotopes is possible via mass spectrometry, but this is time-consuming. Furthermore, accurate differentiation of authigenic and minerogenic uranium is challenging. However, while direct measurement of disequilibrium is usually preferable, it may be possible to derive good approximations of the excess and authigenic isotope concentrations via modelling. The primary controls on excess isotope concentrations are water depth (production) and sedimentation rate (dilution). Where these quantities are known, burial activities of excess ^{230}Th and ^{231}Pa may be estimated. Authigenic uranium concentration may be estimated as total uranium minus minerogenic uranium. The latter quantity can be calculated assuming a fixed abundance/activity ratio of minerogenic U/^{232}Th, since the latter can be assumed to be invariably minerogenic. This poster presents methods for calculating dose rates for deep ocean sediments, using either direct measurements or modelling of excess and authigenic contributions, and identifies situations where the latter approach may be inappropriate.

Environmental DNA and geochemical proxies track Dorset/Thule transition on Somerset Island in Arctic Canada, part II

Dr. Tyler Murchie [1]***, Ms. Jennifer Kissinger*** [2]***, Dr. Jules Blais*** [2]***, Prof. Hendrik Poinar*** [1]

1. *McMaster University,* ***2.*** *University of Ottawa*

Favourable sedimentary ancient DNA (sedaDNA) preservation in archaeological freshwater ponds on Somerset Island in Arctic Canada has allowed for not only a rich taxonomic profiling of flora and fauna through the Dorset/Thule transition as discussed previously by Kissinger and colleagues in part I, but the richness and abundance of faunal sedaDNA have also allowed for species-specific phylogenetic analyses. Here in part II, we continue the multi-proxy report from Kissinger et al., presenting preliminary results on wolf/dog and bowhead whale phylogenies using mitochondrial genomes reassembled from the same freshwater pond sediments. The presence of what appears to be Greenlandic dog mitochondrial genomes supports early archaeological evidence of sled dog use in the area. Thereafter, we discuss coeval changes in microbial community composition as observed with sedaDNA which appear to be associated with subsistence and ecological transitions at the site. We conclude with a discussion of how ancient environmental DNA and complementary proxies have helped to redefine the information potential of sediments by providing novel insights into hunter-forager palaeoecologies in the high arctic.

The first mitogenome records of European woolly rhinoceroses (Coelodonta antiquitatis), isolated from coprolites of cave hyenas (Crocuta crocuta spelea)

***Dr. Peter A. Seeber* [1], *Ms. Anna Luiza Jaime Chagas* [1], *Dr. Keiko Kitagawa* [2], *Dr. Elena Marinova* [3], *Dr. Maria Spyrou* [2], *Prof. Cosimo Posth* [2], *Dr. Yvonne Tafelmaier* [4], *Prof. Laura Epp* [1]**

__1.__ Limnological Institute, Department of Biology, University of Konstanz, __2.__ 1. Senckenberg Centre for Human Evolution and Palaeoenvironment, University of Tübingen; 2. The woolly rhinoceros (*Coelodonta antiquitatis*) is an iconic species of the Pleistocene megafauna, which was abundant in Europe in the Pleistocene until its demise beginning approximately 10,000 years ago. Despite the wide distribution of this species throughout northern Eurasia and numerous findings of remains in western Europe, comparably little genomic information is available, and all currently published mitogenomic data of woolly rhinoceroses stem from Siberian findings, whereas DNA data from European populations is to date limited to short fragments. Two coprolites of cave hyenas (*Crocuta crocuta spelea*) were recovered from late Middle Palaeolithic horizons in two caves in southwest Germany (Bockstein-Loch [BS] and Hohlenstein-Stadel [HS]). The BS specimen was retrieved during excavations in 1934, and the HS coprolite was recovered during excavations between 2008 and 2013. We extracted DNA from approximately 100 mg of each sample, and mammalian DNA was enriched through targeted hybridization capture. After high-throughput sequencing, we assembled the first two (albeit incomplete) mitogenomes of European woolly rhinoceros, in addition to cave hyena mitogenomes. The assembled mitogenomes produced a coverage of 81% (*C. antiquitatis*) and 59% (*C. crocuta*) from one coprolite (BS), and of 27% for both species from the other (HS). The recovered DNA was highly degraded and showed considerable damage, which complicated molecular dating and phylogeographic analyses with respect to divergence time of the European and Siberian woolly rhinoceros populations. However, our phylogenies, which include all previously published mitogenomes of woolly rhinoceroses, suggest a plausible pattern of divergence of the European and Siberian woolly rhinoceros clades. In addition, our cave hyena phylogenies placed our European isolates in an ancient European clade which has diverged earlier from the three modern African spotted hyena clades than two other ancient European ones. Further genomic insights could be gained through increased sequencing depth and using larger sample mass for DNA extraction. Our results provide, for the first time, genomic information on European woolly rhinoceroses and will thus help further resolve the phylogeography of ancient Rhinocerotidae.

How the exceptional preservation at Schöningen opens new perspectives on hominin lifeways during the Middle Pleistocene of Northern Europe

Since the 1990s, systematic excavations by the Heritage Office of the State of Lower Saxony and the University of Tübingen in Schöningen have exposed several thousand square meters of thick deposits from the Reinsdorf Intergracial Complex dating to roughly 300,000 years ago. These waterlogged lakeside sediments on the edge of an open-cast lignite mine provide an ideal archive for reconstructing the past environmental conditions, ecological dynamics and hominin behavior during the late Lower Paleolithic. This paper presents a view of the rich geological, botanical, faunal and archeological records from Schöningen and focuses on how these sources of information allow a uniquely complete reconstruction of the ecosystem in the surroundings of this former lake basin. We then use the exceptional archaeological record, including numerous wooden artifacts, to reconstruct what is likely the most detailed and compelling reconstruction of hominin lifeways and technological responses to changing environmental conditions from the Middle Pleistocene. The setting in Schöningen allows us to consider how our views or the past are strongly shaped and often limited by the taphonomy and site formation processes.

Late Glacial paleoseismicity in Carinthia (Eastern European Alps): lake sediment studies of strong seismic shaking events and a coseismic surface rupture.

Prof. Jasper Moernaut [1]***, Mr. Christoph Daxer*** [2]***, Prof. Marc DeBatist*** [3]***, Prof. Michael Strasser*** [2]

1. *Department of Geology, Innsbruck University, Austria,* ***2.*** *Department of Geology, University of Innsbruck, Austria,* ***3.*** *Department of Geology, Ghent University, Belgium*

Numerical models and paleoseismic records often suggest enhanced seismic activity during several millennia after regional deglaciation. To better understand how stress field changes related to deglaciation and postglacial isostatic rebound may govern earthquake occurrence, additional strategically-located paleoseismic records are needed.

Glacigenic lakes Wörthersee and Klopeinersee are located in the Eastern European Alps at the eastern edge of LGM ice extent. The tectonic regime of the region is governed by several dextral strike-slip fault zones, along which large historical earthquakes took place in AD1690 (M_w~6.5) and AD1348 (M_w~7). We investigated the sedimentary infill of the lakes for traces of past seismic shaking in the form of multiple mass-transport deposits (MTDs) and turbidites. We combined reflection seismic profiles (pinger and sparker) with long sediment cores, which were analyzed by X-CT scanning, Geotek MSCL, Itrax XRF scanning and grain-size measurements. Bayesian age-depth models were constructed based on ^{14}C dating of terrestrial macroremains.

We focused on the Late Glacial part of the sedimentary sequences characterized by clastic input in proglacial and/or periglacial environments. In Klopeinersee, this covers the period ~18 to ~16 cal ka BP in which we identified 6 event horizons, 5 of which involve multiple MTDs. In Wörthersee, we identified 3 event horizons with multiple MTDs. The latest event occurred at ~14.1 cal ka BP, generated large landslides in all sub-basins and involved a large volume of 29×10^6 m^3. In the western basin of Wörthersee, these mass-transport deposits directly overly a locally disrupted seismic stratigraphy that can be traced for ca. 4 km along the basin axis. This “disrupted area” typically shows chaotic reflections bordered by reflection hyperbolae. It forms basin-like depressions that are 1-2 m deeper than the intact sediment units. We interpret this as a SW-NE oriented surface rupture related to the major earthquake at ~14.1 cal ka BP. The small depressions could represent sag ponds related to transtensional deformation along a dextral fault. Interestingly, these observations coincide with a non-studied “assumed” fault on the local geological map, the hazard potential of which has not been considered yet.

Preliminary neotectonic assessment of the central segment of the Acazoque fault in the southern Andean Plateau (Puna), north-western Argentina

Dr. Victor Hugo Garcia [1]***, Dr. Laura Giambiagi*** [2]***, Dr. Andrés Echaurren*** [2]***, Mr. Rodrigo Quiroga*** [2]***, Ms. Macarena Bertoa del Llano*** [2]***, Dr. Matías Barrionuevo*** [2]***, Dr. Julieta Suriano*** [2]***, Mr. Lucas Lothari*** [2]***, Ms. Daniela Espinoza Tapia*** [3]***, Prof. Manfred R. Strecker*** [3]

__1.__ Departamento de Ingeniería Facultad de Ciencias e Ingeniería Pontificia Universidad Católica del Perú (PUCP) Av. Universitaria 1801 San Miguel, 15088, Lima Perú, __2.__ Instituto Argentino de Nivología, Glaciología y Ciencias Ambientales (IANIGLA-CONICET), Mendoza, ARGENTINA., __3.__ Institut für Geowissenschaften, Universität Potsdam

The Acazoque fault is a NNE-striking crustal-scale structure that can be traced for 200 km in the southern Andean Plateau of the Central Andes in Argentina; the fault can be divided into a southern, central and northern segment. The southern segment is 53 km long, oriented N23° and defines the eastern border of the southernmost part of the Salar de Antofalla basin. The 66-km-long, N28°oriented northern segment, controls the western limit of the Salar del Hombre Muerto and juxtaposes Ordovician basement rocks over Cenozoic sequences. The N48° striking central segment is approximately 80 km long and constitutes the structural link between the northern and southern segments.

Analysis of a TanDEM-X digital elevation model combined with high-resolution satellite images (Google Earth, Bing Maps), and field inspection allowed the identification of a series of morphostructures interpreted to be related to Quaternary dextral strike-slip deformation along the central segment, two of which are described here.

First, the Salitral Potrero Diaz (25°28'S, 67°20'W) is a 2-km-wide rhomboidal salt marsh located on a releasing bend of the central segment of the Acazoque fault. A N52° striking, 1.5-km-long fault scarp with an apparent normal sense of motion, has ruptured the northwestern sector of the Salitral, uplifting its northwestern block. Immediately to the southwest, two subparallel scarps affect an adjacent alluvial braidplain, defining a 2-km-long, 300-m-wide graben. Kinematic data on Pliocene lavas cropping out along the southwestern margin of the basin supports the notion of a transtensive regime with a dextral strike-slip component.

Second, about 13 km southwest of the Salitral Potrero Díaz, two 2-km-long, N20° oriented, subparallel hills have developed in a restraining bend of the central segment of the Acazoque fault. While the western hill is 100 m high, the eastern one is only 35 m, suggesting eastward migration of deformation. This interpretation is further corroborated by a subparallel 1-m-high fault scarp 500 m east of the eastern hill affecting the most recent alluvial braidplain sediments.

This sector of the southern Puna is characterized by Quaternary transtensional/transpressional deformation, superseding regional shortening in the orogen interior since the Late Pliocene.

Characterizing the seismogenic potential of the Hengchun offshore structure, southern Taiwan, using uplifted coral colony records

***Prof. J. Bruce H. Shyu* [1], *Mr. Sze-Chieh Liu* [1], *Prof. Chuan-Chou Shen* [2]**

***1.** Department of Geosciences, National Taiwan University, **2.** High-Precision Mass Spectrometry and Environment Change Laboratory (HISPEC), Department of Geosciences, National Taiwan University, Taipei 10617, Taiwan, ROC*

Offshore southernmost Taiwan, a Hengchun offshore structure has been proposed by some previous studies to be located to the west of the Hengchun Peninsula. This structure would be a potentially seismogenic fault, and may be responsible for the coastal uplift of the western peninsula. However, the presence of this structure is under debate, and some argued that the area may be uplifting aseismically by mud diapirism, because no record of paleo-earthquakes related to the structure was identified. We utilized fossil coral colonies along the western Hengchun Peninsula as paleo-sea-level indicators to identify paleo-earthquakes probably produced by this structure over the past 2.5 kyr. Uplifted Porites coral colonies were found at multiple sites along the coast, and can be separated into six groups based on their elevations and ages. At one site, corals in the same age group have similar elevations, and corals found at different sites along the coast can all be correlated into the six groups. These observations suggest that these coral colonies likely recorded co-seismic uplifts of six paleo-earthquake events of the proposed Hengchun offshore structure. Our results suggest that the Hengchun offshore structure is capable of producing substantial earthquakes and poses significant regional seismic hazard potentials in the future, whereas mud diapirism is not the primary structural mechanism in the area.

Soft-sediment deformation structures as natural seismographs: What are the key controlling factors?

<u>*Ms. Ariana Molenaar*</u> [1], *Dr. Katleen Wils* [2], *Prof. Maarten Van Daele* [3], *Prof. Marc DeBatist* [2], *Dr. Arne Ramisch* [1], *Prof. Jyh-Jaan Steven Huang* [4], *Prof. Liang-Chi Wang* [5], *Prof. Nathalie Dubois* [6], *Mr. Christoph Daxer* [7], *Prof. Michael Strasser* [7], *Prof. Jasper Moernaut* [8]

Soft-sediment deformation structures (SSDS) are commonly used as paleoseismic indicators in lacustrine sedimentary sequences. Recent studies suggest that SSDS can be used to reconstruct the shaking strength of past earthquakes and not only recurrence rates. The use of SSDS from different lacustrine settings for quantification of seismic shaking strength requires a thorough understanding of the modulating effect of i) lithology, ii) slope morphology, and iii) sedimentation rates.

Here we evaluate the influence of lithology and sedimentation rate by linking sedimentary basin sequences from ten different lakes from all over the world to strong historical earthquakes in each region. The lakes have different lithologies and are all located in active seismotectonic regions with different types of seismogenic sources (i.e. interplate, intraplate and intraslab). We evaluate if time horizons of strong seismic shaking within the sedimentary sequence are marked by positive or negative evidence of deformation (i.e. earthquake-triggered SSDS present or not). We assess lithological differences using high-resolution XRF-scanning chemical element profiles and density differences using radiodensity measurements (i.e. based on X-ray computed tomography scans) and gamma density. Our data suggests that deformation in basin sequences only occurs within sediments in a certain density range. To evaluate the effect of slope morphology and clastic deposits intercalated within background sediment, we investigated 25 earthquake-related SSDS within 17 sediment cores taken on different slope angles from lake Riñihue, Chile. We find that higher slope angles lead to thicker SSDS, but also that the burial depth of clastic deposits during seismic shaking modulates SSDS thickness as the first stratigraphically available clastic deposit often functions as basal shear surface. In addition, the thickness of the deforming sequence modulates the intensity of deformation, as earthquake-induced shear energy is more concentrated within thinner deforming sequences, thereby leading to stronger deformation.

Our study aims to advance paleoseismology based on SSDS records and to push its potential to reconstruct shaking strength of past events.

Imaging active submarine faults using ultra-high resolution methodologies: Preliminary results of the STRENGTH 2023 cruise in the Alboran sea

Dr. Hector Perea [1], Dr. Sara Martínez-Loriente [1], Dr. Jaume Llopart [2], Ms. Ariadna Canari [1]

1. Institut de Ciències del Mar (ICM CSIC), Barcelona, 2. Institut de Ciències del Mar (ICM CSIC), Barcelona, Spain

The fault seismic potential is usually characterized based on active tectonics and paleoseismology analyses, which provides information such as fault geometry, slip rate, recurrence period, displacement per event and elapsed time since the last event. These are parameters commonly used in seismic hazard assessment. In addition, these type of analysis are of special importance in areas of relatively slow tectonic deformation with faults capable to generate moderate to large-magnitude earthquakes (Mw > 6), with long recurrence intervals (10^3 to 10^4 years), such as those in the Alboran Sea (westernmost Mediterranean). During the last decade, we have been able to map the main fault systems in the Alboran Sea, such as the Carboneras, the Yusuf, the Al-Idrissi and the Alboran Ridge fault systems. The next step in the characterization of these submarine active faults is to acquire ultra-high resolution datasets using the most advanced technologies in marine geosciences, such as Autonomous Underwater Vehicles (AUV) and Remotely Operated Vehicles (ROV). During the STRENGTH cruise (March-April 2023), we have used these type of vehicles to acquire bathymetric and backscatter datasets with 1 meter pixel resolution, seismic profiles with centimeter vertical resolution and video cameras to image interesting areas along the different identified active fault systems in the Alboran Sea. These new dataset will allow a better characterization of the seismogenic potential of these fault and, thus, improve our knowledge about seismic and tsunami hazards in the surrounding coastal areas.

Looking at the opportunities for tectonic basin sedimentation record in Java Island

Mr. Januar ridwan [1]***, Prof. Noriko Hasebe*** [2]***, Mr. Aan Dianto*** [3]

1. *Graduate School of Natural Science and Technology, Division of Natural System, Institute of Nature and Environmental Technology, Kanazawa University,* ***2.*** *Institute of Nature and Environmental Technology, Kanazawa University,* ***3.*** *Shimane University*

Java Island is one of the world's most populated islands and is Indonesia's central strategic Island. As part of the pacific rim region, this Island faces the threat of earthquake disaster. Understanding paleo-seismology is an essential step in developing an effective mitigation system. However, unlike Sumatera, due to characteristics of the Java tectonic setting, the interval between the destructive earthquake events becomes longer. Even though some earthquakes have been noticed in the historical record, most ancient destructive earthquakes become untraceable. Volcanism, bioturbation, weathering, and anthropogenic factor degrade the tracks from the geological outcrops. The sediment records from tectonic lakes would be a beneficial source of information. However, the research on paleo-seismology using tectonic lake sediment in Indonesia needs to be improved. Especially on Java Island, exploring information from the existing natural tectonic lakes is more complicated. Along active faults, there were several basins, which were recognized as lakes, and the wetland became dried and transformed into farms or settlements. This paper will reveal the trace of ancient fault activities preserved in some basins with morphological features suggested as tectonic basins. This paper reviews the published literature and proposes a simple interpretation of the morphology of the basin using Google Earth satellite images and the Digital Elevation model to increase the level of analysis. The focus area is the sag ponds located along two active faults in Java Island, Lembang fault, West Java, and Kalibening- Wanayasa Banjarnegara, Central Java. The sag ponds along the Lembang fault area provide the sequence that shows signs of major destructive events and have been the research targets by paleo-seismology experts. On the other hand, the Kalibening basin consists of quaternary alluvium sediment hypothetically identified as the lakes formed in the releasing bend area of the Kalibening-Wanayasa active fault. This paper's result will show the usefulness of the sediment sequences as records of paleo-seismology on Java Island.

Down to earth: on the origin and the seismogenic potential of the major transverse lineaments crossing the Italian landmass

Dr. Umberto Fracassi [1]***, Dr. Paola Vannoli*** [1]***, Dr. Pierfrancesco Burrato*** [2]***, Dr. Gianluca Valensise*** [1]

1. *Istituto Nazionale di Geofisica e Vulcanologia (INGV),* ***2.*** *Istituto Nazionale di Geofisica e Vulcanologia, Rome (Italy)*

The last few decades produced a vast body of knowledge concerning Italy's seismotectonics, spurred by the pivotal 23 November 1980, Mw 6.9 Irpinia earthquake. Indeed, normal faulting was (and is) paramount along the backbone of the Apennines, and dominates the landscape, with contraction having built up the core of the edifice and now prevailing along sectors of the leading edge.

Yet, a set of oblique regional features is somewhat masked within the tectonic edifice, bearing an unclear seismogenic role. These long-ranging and long-studied features have been hypothesized to accommodate the geodynamic evolution of the central Mediterranean and the tectonic transport leading to the Apennines' build-up, or have been described as lineaments.

Earthquakes affecting the Italian landmass occur primarily along the axis of the Apennines, mimicking their poly-arcuate shape associated with an essentially cylindrical tectonic style, with kinematics encompassing all faulting mechanisms. However, a number of strong historical and instrumental earthquakes appear to elude this general interpretation; some of them have been associated with sources that are deeper-seated or farther into the foreland.

Based on their location with respect to geodynamic province, focal mechanisms, and structural position, we highlight three primary categories of such events:

- those occurring along major inherited Mesozoic, poly-phased structures, affecting the Adriatic and Maghrebian foreland. These faults, likely resulting from the Tethyan break-up, have caused some of the most destructive events of the Italian record;
- those resulting from differential motions between adjacent panels of retreating subduction. Such mechanism may be responsible for some of the long-discussed lineaments identified across the northern Apennines;
- those thought to occur along segments of the hard edge accommodating the differential motion between forwarding, outer fronts of the southern Apennines and the retreating slab beneath the Calabrian arc (STEP).

We aim at breaking these spatially and tectonically diverse transverse features down into a coherent hierarchy, to contribute to deciphering seismogenic processes affecting the Italian landmass. Our goal is to create an interpretive tool of active deformation and help recasting past, elusive earthquakes, to infer whether specific segments of inherited transverse structures may be the causative source(s) of future damaging earthquakes.

What if a strong earthquake hits again Spain? Risk Estimation of historical earthquakes in Present times

Dr. Javier Elez **[1]*****, Prof. Pablo G. Silva*** **[1]*****, Dr. Jorge Luis Giner Robles*** **[2]*****, Dr. Raúl Pérez-López*** **[3]*****, Dr. Teresa Bardají*** **[4]*****, Dr. Elvira Roquero*** **[5]*****, Dr. Yolanda Sánchez Sánchez*** **[1]**

1. *Universidad de Salamanca,* ***2.*** *Universidad Autónoma de Madrid,* ***3.*** *Instituto Geológico y Minero de España IGME-CSIC,* ***4.*** *Universidad de Alcalá,* ***5.*** *Universidad Politécnica de Madrid*

Few significant earthquakes affected mainland Spain, during the 20th and 21st centuries. Most of them of moderate magnitude (c. 5.0 Mw) and intensity VII to VIII ESI-07/EMS-98 as is the case of the 1956 Albolote, 1964 Galera, 1992 Mula and 2011 Lorca seismic events, the last causing a total of 11 casualties. From 1971 to 2018 the compensations due to earthquake damage rise up to 536.5 M€ (updated) from which 517.6 corresponds the Lorca event.
However, the 19th century records at least 5 strong events of magnitude 6 to 7 Mw with intensities ranging from VIII to X ESI-07/EMS-98. This is the case of the 1829 Torrevieja (IX-X) and the 1884 Arenas del Rey (IX-X) events which caused important casualties (389 and 900 respectively) and quite significant economic losses. Ground motion scenarios (ShakeMaps) of these two historical events compiled from ESI-07/EMS-98 macroseismic data allow the further implementation of the USGS PAGER routines (Prompt Assessment of Global Earthquakes for Response) to explore the extent of damage and economic losses for strong historical earthquakes in Spain. Combined with actual databases of the population in each Intensity zone PAGER estimates Seismic Risk (economic losses and fatalities) for a precise event. Loss models are empirically based and offer country specific results. The estimated losses define a color-coded alert, which determines the suggested levels of response: from no response needed (green) to international response (red).
Obtained PAGER loss scenarios from the Torrevieja and Arenas del Rey applied to present day population databases show alarming results as they incorporate the notable increase in vulnerability and exposure related to urban expansion experienced since the last quarter of the 20th century. In all explored scenarios the obtained response levels are red (International Response needed) with very important economic loss and prominent number of fatalities. Estimated losses exponentially rise when risk scenarios incorporate the increase of population during touristic seasons. The magnitude of the obtained loss indicates that today Spain is not prepared for such kind of strong events, damage scenarios are not even contemplated in official regulations and mapping for seismic risk in Spain. Funded by MINCIN-FEDER 2021-123510OB-I00.

Cave paleoseismology insights for Costa Rica: Cases of studies and future applications into the LATAM region

Mr. Alejandro Arguello [1], *Dr. Andres Ulloa Carmiol* [1]

1. Centro de Investigacion en Ciencias Geológicas, Universidad de Costa Rica

The use of caves in paleoseismology studies had positive research results in various cases of studies worldwide such as in Italy, France, Cuba, Bulgaria, Switzerland, and Slovakia. Caves are favorable zones to preserve the fault's deformations in a three-dimensional space that can give valuable data for the paleoseismology and structural characterization of the fault rupture. In tropical regions, the density of vegetation, and soil is sometimes difficult registration of continuous and reliable structural data. In caves near fault systems, you can find various of structural-active tectonic data, e.g., tilts chambers, broken/tilts speleothems, deformed sediments, and stretching lineation. Cave patterns also gave a lot of data for structural lineation and fracture characterization of the zone. Detail recent studies along the 3 principal karstic zones in Costa Rica, had shown different speleotectonic characteristics to be studied. Venado of San Carlos karstic zone is emplaced into an active transtensive system, the caves in the zone show deflected passages, basculated speleothems, strain lineations, and secondary mineralogy. The principal cave "Gabinarraca" follow the principal fault trace heading. This zone has been impacted due to local earthquakes e.g., 1970s Tilaran Earthquake (6,5 Ms) and Cañas Earthquake (7,7 Ms). Barra Honda, located in Nicoya, show different basculated speleothems and flooded zones, broken and deflected chambers that can be associated due to the Nicoya subduction earthquakes e.g., 1950 (~7.7 Mw), 1990 (7,3 Mw), and 2012 (7,6 Mw). South Costa Rica Karstic zone had different varieties of cave-tectonics characteristics such as deflected chambers, broken and basculate speleothems, and different vertical displacements along fractures. This zone has also been influenced by subduction earthquakes 1904, 1941 and 1983 from magnitudes above 7 Mw. This work brings out some of the new cave tectonics findings along the different Costa Rica karstic zones, that have been or can be studied as complementary data for fault characterization, paleoseismology, and earthquake cycle using different technology as LIDAR, photogrammetry, and structural data. These different findings and applications of tropical cave tectonic studies can be also be applied along the LATAM region as a complement to enforce the fault characterization, risk assessment, and seismic zoning studies.

Tectonic geomorphology and transient landscape response of the Sparta Fault (Greece)

Mr. Cagatay Cal [1], ***Dr. Sarah Boulton*** [1], ***Dr. Zoe Mildon*** [2]

***1.** University of Plymouth, **2.** School of Geography, Earth and Environmental Sciences, University of Plymouth, UK*

The Sparta Fault is a major active normal fault in southern Greece, it is 64 km long and forms the western margin of the Sparta basin. The last known rupture of the fault was in 464 B.C. during a ~7.2 M_w earthquake that severely damaged the antique city of Sparti and caused ~20,000 deaths. This rupture is hypothesised to have occurred along the southern section of the fault owing to a well-preserved post-glacial fault scarp with > 10 m accumulated throw over 15±3 ka. In contrast, along the northern segment of the fault there limited to no records of post-glacial fault scarps, leading some researchers to conclude that the northern segment is less active. We investigate the Quaternary activity of the entire structure using a combination of tectonic and fluvial geomorphology to reveal uplift effects on river channels and the distribution of post-glacial surfaces. The river profiles of rivers flowing across the fault were extracted from the ALOS World AW3D30-DEM to determine Quaternary fault activity, and the height of the post-glacial fault scarp was investigated through fieldwork and DEM analysis, with dip/dip direction and slip vectors measured along the fault. The longitudinal profiles of rivers contain slope-break knickpoints along the entire length of the fault, with the normalised steepness index downstream of the knickpoint showing a normal but southerly skewed distribution, thus indicating higher fault activity in the southern section. From fieldwork on the post-glacial scarp, the dip varies along the length of the fault, with the central section dipping more shallowly (~45°) than the northern and southern sections (~60°). Finally, we report a new post-glacial fault profile recording 8.45±1.69 m of throw, corresponding to a slip rate of 0.56±0.16 mm/yr on the northern segment of the fault. In comparison, published slip rates fall in the range 0.45 to 1.07 mm/yr. Therefore, our data show that it is likely that the entire length of the Sparta Fault should be considered as an active fault. In particular, the northern segment which was previously stated as inactive is here shown to be active during the Quaternary.

The AD 1909 Benavente Earthquake: Seismic source modelling from the analysis of ESI-07 environmental data

Dr. Jorge Luis Giner Robles [1], ***Dr. Raúl Pérez-López*** [2], ***Dr. Javier Elez*** [3], ***Prof. Pablo G. Silva*** [3], ***Dr. Carolina Canora*** [1], ***Dr. Miguel Ángel Rodríguez-Pascua*** [2], ***Dr. Elvira Roquero*** [4], ***Dr. Yolanda Sánchez Sánchez*** [3], ***Ms. Maria A. Perucha*** [2], ***Dr. Teresa Bardají*** [5]

1. *Universidad Autónoma de Madrid,* ***2.*** *Instituto Geológico y Minero de España IGME-CSIC,* ***3.*** *Universidad de Salamanca,* ***4.*** *Universidad Politécnica de Madrid,* ***5.*** *Universidad de Alcalá*

This work presents a macroseismic analysis of the AD 1909 Benavente Earthquake by means of the combination of intensity data derived from the EMS-98 scale and the ESI-07 scale (Environmental damage). The Benavente earthquake happened on April 25, 1909 with a maximum intensity of X EMS-98 in the vicinity of the towns of Benavente and Lisbon, with an assigned magnitude of 6.0 Mw, affected all of Portugal and was felt in many towns in western Spain, covering an area of more than 20,000 km^2. More than 150 records of EMS-98 intensity and about 70 records of secondary earthquake environmental effects (EEEs) have been used to define intensities, focused on the vicinity of the mouth of the Tagus River in Lisbon (ground cracks, liquefaction processes, anomalous waves, hydrogeological anomalies, etc.). A modeling of the seismic source has been performed from ShakesMaps using the intensity data (EEE and EMS-98) inventoried for this earthquake. With this analysis we have tested the location and extent of the possible seismic sources defined for this event. Research funded by the MINCIN-FEDER 2021-123510OB-I00 (QTETC-SPAIN-USAL).

Elemental Composition (XRF) of Modern Tidal Wetland Sediments and their Potential for Reconstructing Land-level Change along Cascadia Coastlines

Mr. Anthony Giang [1], ***Dr. Isabel Hong*** [2], ***Dr. Jessica Pilarczyk*** [1], ***Ms. Louise Riou*** [1], ***Dr. David Huntley*** [3], ***Mr. Roger MacLeod*** [3]

1. *Department of Earth Sciences, Simon Fraser University,* ***2.*** *Villanova University,* ***3.*** *Geological Survey of Canada, Natural Resources Canada*

Understanding the relationship between modern salt marsh sediments and tidal inundation along a coastline is critical for reconstructing past sea- and land- level change. Established methods for reconstructing such changes predominantly rely on microfossil assemblages which zonate vertically within a marsh as a result of exposure to tidal inundation. In this study, we investigate the utility of elemental compositions on bulk surface sediments (upper 1 cm), obtained through x-ray fluorescence (XRF), as an indicator of tidal elevation from two tidal wetlands along the Cascadia subduction zone.

A total of 108 samples from eight transects were collected from Willapa Bay, WA, USA (5 transects; 75 samples) and Port Alberni, BC, Canada (3 transects; 33 samples). At both locations, transects span the full marsh gradient and have been shown to zonate with respect to the tidal frame using diatoms (Willapa Bay) and foraminifera (Port Alberni). To test whether elemental compositions will also zonate with respect to tidal inundation, we analyzed each surface sample using an Itrax-XRF Core Scanner. Principle Component Analysis (PCA) on preliminary results from Willapa Bay indicate that elemental composition can distinguish between the high marsh, low marsh/tidal flat, and the subtidal zones. Results show that bromine, silicon, aluminum, titanium, and the incoherent/coherent scattering ratio are dominant vectors controlling the differentiation between the marsh subenvironments. At Willapa Bay, the elemental composition of the same set of surface samples revealed similar grouping compared to a previously published modern training set showing that diatoms in the region respond to tidal inundation. The excellent agreement between the two datasets highlights the applicability of elemental geochemistry, a rapid and high-resolution technique, as a proxy for developing critical training sets for sea- and land-level reconstructions along Cascadia coastlines.

Morphotectonic evaluation and Paleoearthquakes studies of the Himalayan frontal belt bounded by the Main Boundary Thrust (MBT) and Himalayan Frontal Thrust (HFT), Kumaun Central Himalaya

Mr. Mitthu Dhali [1], ***Prof. Javed Malik*** [1], ***Mr. Mohd Azhar Ansari*** [1]

1. *Department of Earth Sciences, Indian Institute of Technology Kanpur*

The Himalayan frontal belt, bounded by the Main Boundary Thrust (MBT) and Himalayan Frontal Thrust (HFT), is one of the most active mountain belt in the world. It is essential to understand the landscape evolution in the foothill zone of the Himalaya, which has been significantly influenced by the ongoing deformation and associated earthquake events. In the Haldwani-Tankapur region of Kumaun central Himalaya, fault-related-fold growth generally formed various geomorphic markers like the diversion of the river from its original course and formation of wind gaps, formation of river terraces, and such geomorphic markers can be utilized in the reconstruction of deformational events in tectonically active regions. The terraces along the major rivers like Gaula, Sarda, and Nandhaur river crossing MBT and HFT provide good constraints on the incision/uplift rates, where rivers are forced to cut down into the rising anticlines of the Siwaliks rocks resulting in abandoned paired/unpaired strath terraces. We have mapped the geomorphic markers of the region with the help of high resolution Cartosat-1 (2.5 m spatial resolution), prepared a detailed tectono-geomorphic map of the region, conducted detailed field investigations, and collected samples for the OSL dating. The ages from the youngest strath terraces of the Gaula river along MBT suggest the abonnement of the terrace between 1775-1871 AD, and the youngest terraces of the Nandhaur river and Haldikhal Gad along the HFT suggest the abonnement between 1282-1623 AD. The large earthquake in the Garhwal Himalaya in 1803 AD can be correlated with the terrace abonnement along the MBT, and the great Central and Western Nepal earthquake of 1505 AD can be correlated with the terrace abonnement along the HFT. This shows that the 1803 AD Uttarakashi earthquake reached the eastern Kumaun region up to the Nepal Border and released strain along the MBT, and the great 1505 AD earthquake reached up to the Kumaun Himalaya and released strain along the HFT.

Holocene activity of the secondary strand of the Tanna fault revealed by sediment core analyses and ground penetrating radar profiling, the Izu Peninsula, Japan

Dr. Haruo Kimura [1], ***Prof. Toshimichi Nakanishi*** [2], ***Ms. Mei Yukawa*** [1], ***Mr. Takashi Hosoya*** [3], ***Dr. Ki-Suck Sung*** [4], ***Prof. Wan Hong*** [5]

1. *Central Research Institute of Electric Power Industry*, **2.** *Museum of Natural and Environmental History, Shizuoka*, **3.** *Chuo Kaihatsu Corporation*, **4.** *Carbon Analysis Lab. Co., Ltd.*, **5.** *Korea Institute of Geoscience and Mineral Resources (KIGAM)*

The active left-lateral strike-slip Tanna fault is one of the major faults of the NS-trending Kita-Izu fault zone, which ruptured during the 1930 Kita-Izu earthquake (M_{jma}=7.3). The fault zone is located in the Izu Peninsula, northern tip of the Izu–Bonin–Mariana arc, at about 100 km southwest from Tokyo. In order to reveal the Holocene activity on the Tanna fault, we surveyed the near-surface structure of an offset valley across the fault by radiocarbon dating of sediments obtained from arrayed four drilling cores and ground penetrating radar (GPR) profiling. The drilling sites were located across the NS-trending secondary strand that runs parallel to the northern part of the main strand of the Tanna fault approximately 50 m to the west. The main strand of the Tanna fault was ruptured during the 1930 earthquake, but Holocene activity of the secondary strand surveyed by us have not been revealed in the previous research. The GPR surveys were conducted along the arrays of the drilling sites. The GPR profiling data were collected by common-offset modes using pulseEKKO PRO GPR systems manufactured by Sensors and Software Inc., and we also acquired common-midpoint ensemble data to estimate the electromagnetic wave velocity used in the time-to-depth conversion of the GPR sections. We interpreted several dipping horizons showing sedimentary structure on the geological cross-sections. The horizons were dated by AMS radiocarbon ages of plant fragments and organic soil samples that were measured by Carbon Analysis Laboratory (CAL) and Korea Institute of Geoscience & Mineral Resources (KIGAM). The results explained the Holocene vertical offsets associated with the oblique slip of the Tanna fault. This result of the Holocene activity of the secondary strand parallel to the main strand suggests that deformation along the Tanna fault zone occurs not only on the main strand but also over a broader area. This work was started as a research project funded by the Izu Peninsula UNESCO Global Geopark and supported by Grants-in-Aid for Scientific Research (KAKENHI) JP15K01255 and JP18K03768 from the Japan Society for the Promotion of Science (JSPS).

Distribution of instrumental, historical and archaeological records of seismicity in the Carpathian-Pannnian region

Prof. Miklos Kazmer [1], *Dr. Erzsébet Győri* [2], *Dr. Krzysztof Gaidzik* [3]

1. Eötvös Loránd University, 2. Kövesligethy Radó Seismological Observatory, Budapest, 3. University of Silesia, Institute of Earth Sciences, Faculty of Natural Sciences, Sosnowiec, Poland

M>=5, instrumentally recorded earthquakes are displayed on the neotectonic map of the Carpathian-Pannonian region. Additionally, historical data from the past millennium and archaeological data from the past two millennium are shown. Sites from Austria are Roman Carnuntum (next to Vienna) and Magdalensberg (in Carinthia), from Slovenia the old town of Ljubljana and the Roman excavations of Celeia (modern Celje), from Croatia Roman Siscia (modern Sisak), from Hungary the Medieval old town of Sopron, Roman roads of Savaria (modern Szombathely) and Salla (modern Zalalövő), the donjon and churches of Nagyvázsony, the Roman town of Brigetio (modern Komárom), the Medieval donjon and monastery of Visegrád, and from Transylvania the Roman town of Napoca and Medieval churches of Cluj and environs, and the rural church of Inlaceni.

These three kind of data do not show much overlap. Neither is there much connection with faults considered active. There are Austrian and Slovenian sites located along the well-known, seismically active Mur-Mürz Fault and the Periadriatic Fault zone, respectively. All other sites need careful studies to find their causative faults. Historical data inherently carry a lot of human error of the messenger and of the historian who put the information on parchment or paper. Those, who suffered from the earthquake, often see it as overly large, those living far away tend do reduce its significance. Poor localization of the area hit by seismic destruction is common. Precisely located archaeological sites do not suffer from these problems. However, distinction among seismic and non-seismic, natural or man-made destruction is important.

Seismic hazard is routinely assessed based on instrumental and historical data. However, inclusion of archaeological data is imperative. Each of these sources indicate that destructive earthquakes occurred not only along but between known active faults, too. Temporal distribution of seismic events outline 'reliably' active Mur-Mürz Fault, Periadriatic fault zone, and the Vrancea zone; however, most of destructive past earthquakes have very large, centennial to milennial recurrence intervals. Lithospheric stresses, generated by the indentation of the Adriatic promontory into the Alpine range, are alternatingly released at different faults. This is probably a characteristic of intraplate deformation.

Normal fault scarp characterization using convolutional neural network: application to the Trans-Mexican Volcanic Belt

Dr. Léa Pousse-Beltran [1], ***Dr. Sophie Giffard-Roisin*** [1], ***Dr. Laurence Audin*** [1], ***Dr. Pierre Lacan*** [2], ***Mr. Theo Lallemand*** [1], ***Mr. Andres Nuñez Meneses*** [2]

1. Université Grenoble Alpes, CNRS, IRD, Grenoble INP, IGE, 2. Centro de Geociencias, UNAM, Queretaro

Fault marker characterization is necessary to understand past fault activity, the physical processes that govern fault rupture. The geomorphological characterization of these markers is currently a time-consuming step with expert-dependent results, often qualitative and with uncertainties that are difficult to estimate. To overcome those issues, we are developing a bayesian supervised machine learning method using convolutional neural networks (CNN) trained on a database of simulated topographic profiles across normal fault scarps, called ScarpLearn. The CNN ScarpLearn is applied to normal fault scarp on topographic profiles perpendicular to the fault. ScarpLearn is able to automatically give the scarp heigth with an uncertainty, and to show the area of the profile containing the scarp. We apply ScarpLearn for the characterization of normal active faults in the Trans-Mexican Volcanic Belt, a across Ameca-Ahuisculco fault system. From this specific case study, and by comparing ScarpLearn with with other methods (non based on deep learning), we explore the progress (computation time, accuracy, uncertainties) that machine learning methods bring to the field of morphotectonics, as well as the current limits (such as bias).

Long-term lateral slip rate of the Yangsan Fault, SE Korea

***Dr. Taehyung Kim* [1], *Dr. Jin-Hyuck Choi* [1], *Dr. Hoil Lee* [2], *Dr. Dongeun Kim* [1], *Dr. Yire Choi* [1], *Dr. Tae-Ho Lee* [3], *Dr. Youngbeom Cheon* [1], *Dr. Chang-Min Kim* [3]**

1. *Korea Institute of Geoscience and Mineral Resources (KIGAM),* ***2.*** *KIGAM,* ***3.*** *Korea Institute of Geoscience and Mineral Resoiurces*

The Yangsan fault is one of the seismogenic strike-slip faults within the intraplate interior. Several paleoearthquake surface ruptures were detected along this fault zone, but only one study related to the lateral slip rate was reported. We conducted a geomorphic analysis using the high-resolution (0.5 m/pixel) LiDAR data to determine the lateral offset. To cross-check geomorphic offset, we mapped the lithology distribution of the study area and investigated pebble origin along each stream. Alluvial fans and streams originating from the eastern mountain were displaced by the Yangsan Fault about 300 m right-lateral strike-slip sense. The result of sediment origin analysis is well matched after reconstructing about 300 m left-lateral slip sense. The cumulative lateral slip rate is calculated at 0.32-0.45 mm/yr based on the alluvial fan's burial age (at 850 ka) yield through the cosmogenic nuclides age dating method.

Holocene seismic activity in southeastern Switzerland: Evidence from the sedimentary record of Lake Silvaplana

***Dr. Benjamin Bellwald* [1], *Dr. Valentin Nigg* [2], *Dr. Stefano Fabbri* [2], *Dr. Lukas Becker* [3], *Dr. Adrian Gilli* [4], *Prof. Flavio Anselmetti* [5]**

__1.__ Norwegian Geotechnical Institute, __2.__ Institute of Geological Sciences and Oeschger Centre of Climate Change Research, University of Bern, Switzerland, __3.__ Ramboll Norway, __4.__ Geological Institute, ETH Zürich, __5.__ Univ. of Bern

High-alpine regions are prone to a large variety of geohazards, among which earthquakes have the strongest impact on landscape and local population. Southeastern Switzerland has few historic earthquake chronicles due to the low population density, resulting in a poorly constrained seismic event catalogue. The aim of this study is to evaluate the paleoseismic activity for southeastern Switzerland by using the sedimentary record of Lake Silvaplana in the Engadine Valley. We use a dense grid of high-resolution 2D seismic profiles, high-resolution bathymetry, and a 10 m long sediment core from the deepest basin to investigate the lake stratigraphy. The bathymetry reveals a flat basin, flanked by steep slopes to the northwest and southeast. The acoustic basement consists of four ridges, and gently-dipping fans to the southwest and northeast. Multiple coevally-triggered chaotic mass-flow deposits have been detected along ten horizons in the seismic data. We interpret these ten event layers to be triggered by paleo-earthquakes in eastern Switzerland or northern Italy. The four most recent of these deposits are cored and radiocarbon dated to ~230, 310, 960, and 1330 cal yr BP, indicating four overregional seismic events that triggered large slope failures in Lake Silvaplana in the last 1400 years. Correlation with sedimentary deposits of Lake Sils, Lake Como and Lake Ledro within radiocarbon uncertainties indicate a large earthquake around 1330 cal yr BP. Within their age ranges, the postulated earthquake at 310 cal yr BP (1640 CE) further correlates with a moment magnitude Mw ~5.4 event in Ftan in 1622 CE, and the 960 cal yr BP (990 CE) with a Mw ~5.2 earthquake in Brescia in 1065 CE. Six mass-movement deposits that were not reached by the sediment core have a suggested age between 7800 and 11300 cal yr BP and are also suggested to be caused by earthquakes. Thus, Lake Silvaplana sediments provide the first reliable record of seismic activity for the mid- and Late Holocene in this region. Basement ridges following the Engadine Line, a major fault zone running along the main valley, further indicate the potential that the Engadine Line is a neotectonically active structure.

Characterization of active segments of the Alhama de Murcia Fault (SE of Spain) by using electric resistivity tomography in ramblas.

***Dr. Jose F. Mediato* [1], *Mr. Felix M Rubio-Sánchez* [2], *Dr. Julio López-Gutierrez* [1], *Mr. Arturo García-García* [2], *Mrs. Maria Rodrigo-Viñuela* [3], *Mr. Jose M Llorente-Delgado* [1], *Dr. Begoña del Moral González* [1], *Mr. Francisco J Fernández-Naranjo* [1], *Mrs. Paula Fernández-Canteli* [1], *Dr. Raúl Pérez-López* [1]**

***1.** Instituto Geológico y Minero de España IGME-CSIC, **2.** Instituto Geológico y Minero Español, CSIC, Madrid, **3.** Instituto Geologico y Minero de España, CSIC, Madrid*

The Alhama de Murcia Fault is one of the most active tectonic faults of Spain. Located southeast of the Iberian Peninsula, this fault is a left-oblique fault, reverse with a strike-slip component, and it was responsible for the last destructive earthquake in Spain. The Lorca earthquake occurred in 2011, killing 9 people and costing about 500 M€. This fault is NE-SW trending, NW-dipping, and 90 km long. Different active segments have been depicted and the maximum related potential earthquake is M ~ 6.4 ± 0.2. In this work, we have carried out an electric resistivity tomography with the aim to determine the spatial location of the fault in relationship with the Quaternary infilling of rambla and alluvial fans. Three profiles have been measured, located in Rambla Vilerda, Rambla La Hoya, and Rambla Lebor. The Vilerda profile was measured in a W-E direction, with an electrode separation of 15 m and 1200 m long. We used different configurations: Wenner, Schlumberger and Dipole-Dipole. The La Hoya profile was measured using an electrode separation of 15 m, and 1720 m long, NW-SE direction, and using a Wenner configuration. At Rambla Lebor, a profile with 15 m electrode separation 1200 m long and Wenner configuration, was measured following the rambla direction; due to the noisy character of the profile, mainly at its end, a new one with 5m electrode separation, 400 m long and Wenner configuration, was carried out in order to confirm the results obtained. The profiles show that the Alhama de Murcia Fault is composed of a series of vertical faults partially sealed by current deposits, which generally show a reverse component towards the surface. Fault activity is observed by changes in the depocenters of subactual deposits. The Vilerda profile in the SW zone of the fault shows a vertical displacement greater than 150 m. This throw fault is higher on the Rambla La Hoya and drops to a few tens of meters on the Rambla Lebor.

Investigation of vegetation change through fossil pollen from Anatolian peatlands: Golbasi lakes

Mrs. Sena Inkaya [1], *Dr. Hülya Caner* [1], *Dr. Jessie Woodbridge* [2], *Prof. Meral Avci* [1]

1. Istanbul University, 2. University of Plymouth

Fossil pollen analysis provides a valuable proxy for investigating the effects of human activities on the natural environment. This research area has undergone major changes in forest areas in southeastern Turkey, located in the transition zone between the Irano-Turanian and Mediterranean phytogeographic regions in the east of the Mediterranean basin. This region of lakes (Gölbaşı, Azaplı, İnekli) has a stepped relief feature consisting of high mountain areas around it. The interconnected lakes are among the ecologically important wetlands of Anatolia. In the pale coastal areas of the lakes there are peat formations exceeding 1 meter.

The aim of this study is to reconstruct the changes in Quaternary vegetation fossil pollen analysis. A 21 m long core was taken from the peat bog in the north of İnekli Lake in the study area. This study contains the first findings of the research. In this study, Carbon-14 dating will be made in sediment samples and changes due to human influence will be revealed, especially in the Holocene.

Key words: Fossil pollen analysis, Paleovegetation, Holocene, Human activities, Anatolia.

Sediment records suggest post British-invasion declines in diversity of wetland plant communities in the Koondrook-Perricoota Forest, Murray River, NSW

Dr. Michael Reid [1], ***Dr. Leah McIntosh*** [1], ***Dr. Samantha Capon*** [2], ***Dr. Craig Woodward*** [3]

1. *University of New England,* ***2.*** *Griffith University,* ***3.*** *ANSTO*

Floodplain wetlands support enormous biodiversity and a range of other vital ecosystem services. However, these wetlands are threatened by a range of processes. In the Murray-Darling system of southeast Australia, these processes include altered wetting regimes, cropping, grazing and invasive species. Detecting and monitoring changes to these systems is limited by poor benchmark data, which would otherwise provide the basis for establishing the degree and nature of changes as well as possible drivers. This study sought to establish benchmark conditions and temporal patterns of change in wetland plant communities by examining stratigraphic changes in preserved plant and animal remains and viable seeds of wetland plants, taking advantage of the capacity in many wetland plants for seeds to remain viable in the sediment for many years and to subsequently germinate upon wetting. Sediments from 12 wetlands in the Koondrook-Perricoota Forest were sampled at 2 cm intervals to depths of 30 cm to 40 cm. Lead-210 dating of the sediment profiles suggest the upper 10 to 16 cm of these records were deposited in the last century.

The preserved remains assemblages of the pre and post-invasion period were generally distinct, though the degree of change varied among wetlands. In general, the post-invasion period is characterised by declining richness and diversity and abundance in charophyte oospores in several of the wetlands. The seed banks trials showed general patterns of decline in seedling abundance, richness and diversity with depth, consistent with expected age-depth declines in seed viability. However, deviations from the pattern of decline-with-depth were observed in some wetlands and for some taxa, suggesting the abundance, richness and diversity of the seed bank has declined in the last century. While the specific cause of these changes is uncertain, they are likely a response to reduced flooding as a result of flow regulation and water abstraction. In the case of the apparent declines in charophytes, introduced grazers such as cattle could well have been a factor given that trampling and increased turbidity arising from their presence in and around the wetlands is likely to have been detrimental to these submerged plants.

Plants maintain climate fidelity in the face of dynamic climate change

Dr. Yue Wang [1], ***Dr. Silvia Pineda-Munoz*** [2], ***Dr. Jenny McGuire*** [3]

***1.** Sun Yat-Sen University, **2.** Amazon Conservation Association, **3.** Georgia Institute of Technology*

Plants will experience considerable changes in climate within their geographic ranges over the next several decades. They may respond by exhibiting niche flexibility and adapting to changing climates. Alternatively, plant taxa may exhibit climate fidelity, shifting their geographic distributions to track their preferred climates. Here, we examine the responses of plant taxa to changing climates over the past 18,000 y to evaluate the extent to which the 16 dominant plant taxa of North America have exhibited climate fidelity. We find that 75% of plant taxa consistently exhibit climate fidelity over the past 18,000 y, even during the times of most extreme climate change. Of the four taxa that do not consistently exhibit climate fidelity, three – elm (*Ulmus*), beech (*Fagus*), and ash (*Fraxinus*) – experience a long-term shift in their realized climatic niche between the early Holocene and present day. Plant taxa that migrate longer distances better maintain consistent climatic niches across transition periods during times of the most extreme climate change. Today, plant communities with the highest climate fidelity are found in regions with high topographic and microclimate heterogeneity that are expected to exhibit high climate resilience, allowing plants to shift distributions locally and adjust to some amount of climate change. However, once the climate change buffering of the region is exceeded, these plant communities will need to track climates across broader landscapes but be challenged to do so because of the low habitat connectivity of the regions.

Spatial explicit, quantitative reconstruction of past vegetation based on pollen or charcoal data as a tool for autecology of trees

***Mr. Vojtech Abraham* [1], *Mr. Matej Man* [2], *Dr. Martin Theuerkauf* [3], *Prof. Petr Pokorný* [4], *Dr. Premysl Bobek* [2], *Dr. Jan Novák* [5]**

__1.__ Department of Botany, Faculty of Science, Charles University & Center for Theoretical Study, Prague, Czech Republic, __2.__ Institute of Botany, CAS, __3.__ Institute of Botany and Landscape Ecology, University of Greifswald, Germany, __4.__ Charles University, Center for Theoretical Study, Prague, __5.__ Department of Botany, Faculty of Science, Charles University, Prague, Czech Republic

The determination of autecological preferences based on long-term vegetation dynamics is hampered by the lack of realistic estimates for past occurrence and abundance patterns. Palaeoecological record has still rather character of points than spatially continuous maps.
To infer long-term autecological preferences of trees from reconstructed vegetation. Compare reconstructions based on independent input data.
We employed to the regional training set of 60 sites the Extended Downscaling Approach (EDA) using nine topographic factors clustered in 8 habitat classes, data on pollen productivity estimates, fossil pollen, charcoal sequences from soil and archaeological contexts. Based on abundances and habitat preferences from the last 9 millennia, we calculated the autecological preferences of tree taxa, using multivariate statistics.
The significant spatiotemporal patterns between soil-charcoal and pollen-based EDA validated the reconstruction, the use of both records in the EDA, and the EDA model itself. One of the topographic indices - vertical distance to channel network - evidenced the following: the closest taxon to the groundwater is Picea; Abies, Betula, Pinus, Quercus have intermediate distances; Fagus grows far from the channel network and Corylus even further.
The EDA model linked past forest composition to realistic topography. Such a spatially explicit reconstruction produced by our new algorithm allows inferring the relationship between past plant communities and environmental variables. The long-term preferences of tree species to habitat characteristics match their current autecological demands. This might a breakthrough in quantitative plant paleoecology.

When geodiversity drives biodiversity: Bagno dell'Acqua alkaline lake, Pantelleria Volcano, Sicily, Italy

Bagno dell'Acqua Lake is part of the Pantelleria Island National Park (Sicily) and represents a site of extraordinary environmental and scientific relevance as the interactions between volcanic fluids, climate and morphology make the chemistry of the waters alkaline, with the development of rich biotic communities and of a very specific ecosystem, unique in Italy and rare in the world.

In recent years, the lake has been the subject of highly multidisciplinary and interdisciplinary studies which concerned almost all the microbial, faunal, geomorphological, hydrogeological, volcanological, geochemical and minero-petrographic aspects of the lake.

The lake has a sub-circular shape (350x450m), the maximum depth is slightly more than 12m. The composition of the water is controlled by the meteoric contribution and groundwater input, mixed with seawater and hydrothermal springs. Hydrothermal emissions are present along the entire perimeter of the lake and on the seabed. The gas emitted is mainly CO_2 (98%). The waters of the lake are rather homogeneous, with temperatures of 14-25°C and pH about 9. Lake Bagno dell'Acqua is the only alkaline volcanic lake in Italy and the only non-glacial one in Europe.

The most characteristic biota of the Lago Bagno dell'Acqua ecosystem is that of cyanobacteria, which represent the first level of the aquatic food chain and contribute to the biodiversity of the lake together with a vast range of other microbial organisms; the bacteria cover the seabed with thick felts, are responsible for the formation of a characteristic organic mud responsible for the white/turquoise color of the seabed (however back and anoxic immediately below the water/sediment interface) and generate microbialites (organo-sedimentary deposits with a relevant mineral component) along the shores and inside the lake.

From the point of view of biodiversity, the geological structure and the particular chemistry make the lake of Bagno dell'Acqua a real extreme environment and a biodiversity hot spot with characteristics that are unique in Europe and exceptional in the world. Biodiversity is always based on geodiversity (the set of geological structures and processes that determine the physical and chemical environment), but this interaction is particularly evident in extreme environments such as Bagno dell'Acqua lake.

Global drivers impact on geodiversity and geosystem services in Alagna Valsesia (Monte Rosa, W-Alps, Italy): Mapping and assessment for a sustainable development perspective

Dr. Michele Guerini [1], ***Dr. Rasool Bux Khoso*** [2], ***Dr. Alizia Mantovani*** [2], ***Prof. Marco Giardino*** [3]

1. *Department of Earth Sciences, University of Torino / EDYTEM, Université Savoie Mont Blanc,* **2.** *Department of Earth Sciences, University of Torino,* **3.** *Department of Earth Sciences, University of Torino / Sesia Val Grande UNESCO Global Geopark*

Over the last century, human activities and global drivers of change have added disequilibrium factors to the natural hazards occurring in mountain regions, deeply affecting them by resulting in huge alterations in the balance of these environments. One of the most visible effects of rising temperatures is the melting of glaciers, with a trend towards thinning and retreat of glacier fronts, leading to a change in pressure on contiguous slopes, and increasing their instability, thus proving to be a trigger for mass movements. Other evident effects are related to permafrost degradation and the growth of erosion in previously glaciated areas. These changes have an impact on increasing of natural hazards and in causing loss of geodiversity and ecosystem services, thus demanding the need to develop new conservation strategies to support mountain regions taking care of geoheritage protection. To better investigate how climate change and human activity impacts affect the geoheritage and the benefits that geodiversity provide to society we focused on Alagna Valsesia municipality, the highest elevation area of the Sesia Val Grande UGGp. Here we collected and examined available data in a GIS environment to map the geodiversity in the study area, recognize the geosites and assess them to understand the value of the present geoheritage. Geodiversity map has been used to evaluate and identify the ecosystem services. Regulating, provisioning, knowledge, cultural, and supporting services have been identified, with a broad view on evolutionary scenarios of human-nature interactions. Evaluation of global drivers of change allow us to understand the impact of the changes on services, and DPSIR approach, linked to geosystem services, led us to address the need of a strong planning and management strategies for the Sesia Val Grande UGGp and for sustainable development of human exploited and naturally vulnerable mountain regions, considering actions to promote geotourism. This approach provides the basis for understanding the natural and human-induced threats to geodiversity and makes it possible to consider geoheritage in planning and management to foster sustainable development actions.

Potential factors influencing past vegetation composition on Hallands Väderö island, SW Sweden

Dr. Chiara Molinari [1], ***Dr. Gina E. Hannon*** [2], ***Prof. Richard Bradshaw*** [2]

1. Università degli Studi di Genova, Dipartimento di Scienze della Terra, dell'Ambiente e della Vita - DISTAV, 2. University of Liverpool, School of Environmental Sciences, Department of Geography and Planning

Palaeoecological analyses over the last c. 3000 years have been carried out on Hallands Väderö, an island nature reserve situated off the south west coast of southern Sweden. The sample site is a small pond containing some of the oldest *Quercus, Tilia* and *Fagus* individuals present in Sweden and is characterised by a remarkably rich biodiversity of fungi, bryophytes, lichens and insects.

For exploring the relative importance of main drivers on forest composition, we statistically compared our palynological results with independent datasets of climate variations (winter temperature and relative summer humidity reconstructed from tree ring data) and fire activity (based on macrocharcoal data) over the last c. 1000 years. Furthermore, a unique historical record of numbers of grazing animals on the island since AD 1665 was used to explore the effects of domestic stock on selected important plant taxa.

The statistical analyses suggest that during the last millennium warm winter temperatures and summer humidity account for most of the variance for *Quercus, Alnus, Tilia* and *Corylus*. Instead, grazing was the main factor reducing population size of *Fagus, Alnus, Tilia* and *Corylus* on the island over the period AD 1665–2000, highlightening the importance of browsing for tree species composition.

We conclude that the survival of large numbers of red-listed species on Hallands Väderö is likely to be due to the continuity of large old trees, ancient forest composition and a distinctive disturbance history in a favourable climate. The deciduous trees associated with high levels of biodiversity among epiphytes and saprophytes that characterise the island make its future management of national significance.

MeSCAL Project: biodiversity and cultural heritage in southern California landscapes. A palaeoecological approach

Dr. Reyes Luelmo-Lautenschlaeger* [1], *Prof. R. Scott Anderson* [2], *Dr. Nathalie COMBOURIEU-NEBOUT* [3], *Dr. Yannick Miras* [3], *Prof. Alexander R. Simms* [4], *Dr. Aude Berger* [5], *Ms. Elisabeth Allain* [5], *Dr. Ana Ejarque* [1]

__1.__ ISEM, Univ Montpellier, CNRS, IRD, Montpellier, __2.__ School of Earth & Sustainability, Northern Arizona University, __3.__ CNRS, HNHP (UMR 8194), Museum National d'Hisoire Naturelle, __4.__ Department of Earth Science, University of California, Santa Barbara, CA 93106, USA, __5.__ Geolab, CNRS, Clermont-Ferrand

Mediterranean cultural landscapes have been built through time as a consequence of climatic and natural dynamics, as well as by anthropic processes such as migration, trading or colonial settlement. Land-use changes and the introduction of new socio-economic and cultural patterns had serious impacts on local ecosystems, biodiversity and floristic richness. While studies about the consequences of these interactions are still scarce in southern California (SoCal), the MeSCAL Project has been designed to fill this gap. The Californian coast is a biodiversity hotspot attesting to a rich history of human settlement over the last ~13ky. MeSCAL Project will analyze the spatial distribution of land-uses and plants following Late Holocene (~4ky) migratory and colonial processes, assessing their impact on SoCal native flora, biodiversity and landscape structure.
The MeSCAL Project proposes an interdisciplinary approach based on the combination of 1) multi-proxy palaeoenvironmental analyses –i.e. pollen, non-pollen palynomorphs (NPPs), fire history analysis, diatoms, sedimentology, geochemistry– in continental wetlands and marine records, providing local and regional information on vegetation and land-use changes; 2) calibration of fossil palaeoenvironmental datasets with modern analogues of vegetation and land-uses; 3) archaeobotanical analyses addressing information on past consumption and use of plants; and 4) comparison of paleoenvironmental results with archaeo-historical and ethnographic datasets. MeSCAL Project includes a micro-regional approach, with case-study locations distributed along a coastal-inland transect which also provides a local-scale perspective. This will allow a better understanding of the different landscape changes in areas under direct colonial control and those with smaller colonial influence. The MeSCAL Project will help to calibrate how human mobility and settling shaped the current SoCal landscapes, measuring the long-term impact of transported plants and introduced practices over the biodiversity in this territory marked by human migrations and colonial processes. As well, it will help to place value on the cultural heritage reflected in Californian landscapes, engaging citizens with their own history and identity through the environment they inhabit, and will provide information about ancestral land-uses. This will help to protect native cultural identities and traditional ways of life, but also provides tools for landscape management and the protection of his biodiversity hotspot.

Late Quaternary bioerosion pattern controlled by upwelling events: a case of study in Puerto Lobos (San Matías Gulf, Argentina)

***Ms. Luciana María Giachetti* [1], *Dr. Sebastian Richiano* [1], *Dr. Diana Elizabeth Fernández* [2]**

***1.** Instituto Patagónico de Geología y Paleontología (IPGP, CONICET-CENPAT), Boulevard Almirante Brown 2915, Puerto Madryn, Chubut, Argentina., **2.** CONICET - Universidad de Buenos Aires, Instituto de Estudios Andinos Don Pablo Groeber (IDEAN), Intendente Güiraldes 2160, Ciudad Universitaria - Pabellón II, Ciudad Autónoma de Buenos Aires, Argentina.*

The ichnological analysis of Quaternary marine deposits in Argentina has increased in the last decade; however, despite the geographic extension of these deposits, the studies continue to be scarce. In Puerto Lobos (San Matías Gulf -SMG-, Argentina), these deposits are represented by six beach ridges, parallel to the coast, which provide complete information since the Pleistocene. Recently, an ichnological study from Quaternary deposits from Patagonia described bioerosion traces in Puerto Lobos in shells from *Crepidula*. Nevertheless, there has not been an ichnological analysis that includes the diversity of molluscs present at this locality. Here, we describe the bioerosion recorded in shells from different taxa of molluscs from Quaternary marine deposits from Puerto Lobos. A total of 710 shells were observed in a *stereoscopic microscope* to register the absences/presences of bioerosion traces. As a result, more than 12 ichnotaxa are recorded for the first time, including macro- and microbioerosion traces, which allows us to interpret which environmental factor controls the bioerosion pattern in this area. The most abundant ichnotaxa from the Pleistocene are *Caulostrepsis* and *Entobia* while the Holocene and modern samples are characterised by *Iramena*, *Podichnus*, and *Oichnus*. The differences between the bioerosion pattern during the Pleistocene and Holocene-Modern suggested changes in the environment. The SMG presents upwelling coastal events that foment biological productivity. Palaeontological studies from northeast SMG suggested that this upwelling process is present since the Holocene in the gulf. Therefore, the increase in bioerosion traces produced by bryozoans together with a rich ichnodiversity in the Holocene samples could be related to a rise in nutrients, and not to a change in water temperature (lower Sea Surface Temperature) as has been interpreted in other Patagonian areas. Finally, the low decrease of ichnotaxa in the modern samples could be related to the northward movement of the Brazil-Malvinas Confluences in the mid-Holocene. In conclusion, the variation in the abundance and ichnodiversity in bioerosion traces during the Quaternary in Puerto Lobos are due to oceanographic conditions related to upwelling events that facilitated the availability of nutrients. These results are consistent with previous works in the SMG region.

Late Pleistocene paleowetlands in semiarid dunefields, Western Pampas of southern South America

Hydromorphic features, like rhizoliths and lithological properties of rocks/sediments, are indicators of special hydrological conditions in past environments, like variations in soil saturation, drainage, water table depths. They can be related to distinct landscapes and/or climatic conditions. The presence of these features in the Quaternary record of today drylands are key elements to infer wetter than present conditions. Among these features, rhizoliths are conspicuous megascopic structures that appear as root traces of massive or concentric-like mineral precipitations. They result from a total or partial replacement of root organic matter and indicate a paleolandscape with a high colonization of vascular plants. The Western Pampean Dunefield of central Argentina (34ºS, 65.3ºW), southern South America, is characterized by blowout dunes, several of them with km-long diameters, and showing superimposed smaller dunes over their depositional lobes. This eolian landscape is, at present, mostly stabilized by a savannah-like vegetation cover and agriculture fields. It exposes a record of profuse eolian activity along different periods of the late Pleistocene (~50-17 ka) and during most of the Holocene (~12-1 ka). A today notorious aspect of this dunefield is the hydrological state of the deflation basins of the blowout dunes, while in the eastern flank these basins commonly host shallow lakes, formed during, at least, the last millennium, in the western area the blowout dunes are dry, vegetated landscape. The sedimentary record at some blowout dunes includes hydromorphic features, including carbonate and ferruginous rhizoliths and calcareous crusts. They appear at a paleoshoreline position of current perennial shallow lakes, but also in blowout basins without a vestige of any kind of wetland during, at least, the last ~100 yr. The integration of geomorphology, sedimentology, micromorphology, and chronostratigraphic data allow defining/interpreting the sedimentary facies hosting the rhizoliths and related deposits, in the context of a dominated eolian landscape, and to discuss the geomorphological, climatic, and ecological conditions which allowed the formation of wetlands (lakes?) in such inland dunefields during, we infer, the deglaciation times.

Geochemical behavior and water age of multilayer aquifer in Andean valley of Cauca-Colombia: water use and availability in the present and future.

Dr. Jean Denis Taupin [1], ***Dr. Laurence Gourcy*** [2]

1. *Hydrosciences-Hydropolis, University of Montpellier, IRD, CNRS, 34090, Montpellier, France,* ***2.*** *BRGM, 3 Avenue Claude Guillemin, BP 36009, 45060, Orléans, France*

The studied area is located in the south-west of Colombia in the Cauca valley, close to the city of Cali, between the Western and Central Andean Cordilleras. The climatology is intermountain high plain type (Tannual=24°C, P=1400mm/y), the altitude is between 900 and 1000 masl. It is limited in the West by the Cauca River and in the East by the mountainside of Central Cordilleras with a maximum width of 30 km. The unconfined aquifer is composed by quaternary alluvial deposits brought by the Cauca river and other tributaries issue mainly from erosion of Andean volcanic formation and forms downstream a multilayer aquifer. This aquifer is formed by 2 levels, the upper level, A, and the lower level, C, which are separated by a continuous clay layer B differentiated only in the area close to the Cauca River, that implies upstream A and C are not distinct. The estimated annual recharge is about 270 Mm3 and takes place mainly in the alluvial cone based on the analysis of water isotope and possibly for a few part through the fault system which is standing in the Western and Central Cordilleras. The regional water flow is East-West, in direction of the Cauca River. The chemical results show a calcic bicarbonate facies in level A and in the highest undifferentiated zone linked to the regional geological silicate formation and a chemical evolution in confined level C characterized by the substitution of Ca^{2+} by Na^{+} (ion exchange process) through the layer clay B, and by chloride values increasing with time in the deepest boreholes in relation to the Tertiary marine formation located under the alluvial deposit. Based on carbon-14 measurement the confined part shows higher residence time from upstream to downstream, close to the Cauca river some boreholes were artesian in the past and with their intensive use, in particular the intensive cultivation of sugar cane, they lost this characteristic confirming a low renewable rate. On the opposite the residence time in the level A (14C and tritium), is younger with ages post nuclear atmospheric test. Inside this aquifer a differentiated water management is necessary

A detailed Holocene fire history reconstruction from the Araucaria forest and Grassland (Campos) vegetation mosaics in southern Brazil

Dr. Daniela Piraquive-Bermúdez [1], ***Dr. Walter Finsinger*** [2], ***Dr. Thomas Giesecke*** [1]

1. University of Goettingen, 2. ISEM, University of Montpellier, CNRS, EPHE, IRD, Montpellier, France

The forests-grassland vegetation mosaics in the *Araucaria* region of southern Brazil are hypothesised to be strongly controlled by fire. However, a fire history with sub-decadal resolution is hitherto not available and therefore detailed millennial-scale interactions between vegetation and environmental changes are largely unknown yet. To close this knowledge gap, we studied the well-dated 11-m long Holocene sediment infill of Lagoa Dourada, a small lake in the Paraná State highlands. Here we present the first high-resolution macroscopic charcoal record from this region that documents past fire-regime changes. We found that the amount of biomass burned was highest around 9500-8000 and 6300 cal BP, moderate around 5500-1000 cal BP, and increased during the past 100 years with land-use change. We will discuss interactions between fire and vegetation for two periods; one in the mid-Holocene between 7000-6200 cal yr BP and one in the late Holocene between 3300-3000 cal yr BP where pollen was analysed at the same high resolution as macro charcoal.

The coastal confined aquifer of the Golf of Uraba (Colombia), geochemical evolution and residence time : towards a rational water use.

***Dr. Jean Denis Taupin* [1], *Mr. Pedro Pablo Villegas* [2], *Dr. Teresita Betancur* [3], *Dr. Vanessa Paredes* [2], *Mr. Luis Eduardo Toro* [4]**

***1.** Hydrosciences-Hydropolis, University of Montpellier, IRD, CNRS, 34090, Montpellier, France, **2.** CORPOURABA, Apartadó, **3.** Universidad de Antioquia, Medellín, **4.** CORPORACION AUTONOMA REGIONAL DEL QUINDIO. SUBDIRECCION DE GESTION AMBIETAL*

The coastal confined aquifer in the Gulf of Urabá (Colombia) is an important water source for the banana agro industry as well as for urban and rural communities. Located in the north western of Colombia, under a tropical humid climate controlled by ITCZ (Tannual=28°C, P=2100-3800mm/y North-South), the study area covers 1,030 km^2 characterized by a smooth rolling topography, 0-200 masl until the Abibe hill (East limit, 30 km from the sea). The main surface water network flows across the León River basin, which discharges into the Gulf of Urabá and represents the South border. In northern part a geological barrier limits the aquifer extension.

The geology consists of Quaternary alluvial (Qal) deposits (phreatic aquifer) overlain on a sedimentary Tertiary sequence, the Corpa Formation (Pliocene), whom the confined aquifer (T2B) is limited by 2 aquitards, bottom (T2A) and top (T2C), crops out in the western flank of the Abibe aera which is also the recharge zone.

Hydrochemical analyses and stable isotope monitoring were conducted to determine its funcioning and its age, and the main processes governing groundwater chemistry.

The flow direction of the confined aquifer is East to West (Pacific ocean), with local artesianism close to the coast. The main hydrochemical processes are the silicate weathering and the dissolution of secondary carbonates. The samples close to the recharge zone, are generally characterized by their low mineralization with a HCO_3^-–Ca^{2+} facies. Along the flow direction TDS/EC increases and chemical facies is predominantly HCO_3^-–Ca^{2+}/Mg^{2+}; this system evolves to a HCO_3^-–Na^+ water type closer to the coast. The larger contribution of Na^+ with respect to Ca^{2+} indicates the influence of the ionic exchange process. $\delta^{18}O$ and δ^2H compositions combined with ^{14}C data highlight the difference in climatic conditions between the recharge zone and the confined section of the aquifer. ^{14}C ages give recent to 28,300 years BP in accordance with the more depleted water isotopes in flow direction suggesting a cooler recharge than the current climate conditions corresponding to the last glacial period (late Pleistocene). Despite the high local pluviometry the coastal part of the confined aquifer is non-renewable and its use should be monitored.

Linking Andean paleo-landslides to the probable triggering seismic source (31°–33°S)

<u>Dr. Stella Moreiras</u> [1]***, Dr. Sebastian Junquera-Torrado*** [2]***, Prof. Martin Jesus Rodriguez Peces*** [3]***, Prof. Sergio Sepulveda*** [4]

1. *Instituto Argentino de Nivología, Glaciología y Ciencias Ambientales (IANIGLA), Centro Científico Tecnologico CONICET, Mendoza, Argentina,* ***2.*** *Instituto Argentino de Nivología, Glaciología y Ciencias Ambientales (IANIGLA-CONICET), Mendoza, ARGENTINA.,* ***3.*** *Facultad de Ciencias Geológicas. UCM,* ***4.*** *Simon Fraiser University*

Landslides are maybe the most striking seismic environmental effect which impact scales with earthquake magnitude. However, the determination of the seismic source of paleolandslides is not fully understood, being a matter of discussion. In seismically active mountain regions, large-volume landslides clustered along active faults are assumed to be coseismic. Thus, shallow crustal earthquakes from nearby active faults assumed as the most likely source of slope collapses. To investigate this hypothesis, several prehistoric landslides in the Arid Central Andes were geomorphological, geological, and geotechnical studies. Newmark-type, limit equilibrium, and numerical modeling back-analyses methodology were also conducted. This methodology allowed us to identify the potential sources of earthquakes that may have induced the studied gravitational process. Moreover, the chronology obtained for some of these landslides disallows a probable climate forcing on slope instability in this arid region and our finding extends the regional neotectonics until the Late Pleistocene.

Last termination and Holocene Forest history and climate changes on the eastern slopes of the central Patagonian Andes

Dr. Rodrigo Villa [1] ***, Dr. Patricio Moreno*** [2] ***, Ms. Javiera Videla*** [3] ***, Dr. Isabel Vilanova*** [4]

1. *GAIA-Antártica, Universidad de Magallanes, Punta Arenas,* ***2.*** *Department of Ecological Sciences, Universidad de Chile,* ***3.*** *Departamento Ciencias Ecológicas, Universidad de Chile, Santiago, Chile,* ***4.*** *CONICET-Museo Argentino de Ciencias Naturales BR*

We report pollen and macroscopic charcoal records from lake sediments we retrieved from Lago Mano Negra (LMN, 45°23'S, 71°55'W, 840 masl) to document the vegetation, fire, and climate history east of the Andean divide in central Patagonia since ~18.5 ka. Our aim is to decipher the functioning of terrestrial ecosystem changes and their response to variations in Southern Westerly Wind (SWW) influence. The pollen record from LMN shows a gradual *Nothofagus* increase starting at ~18 ka, along with hygrophilous and cold-tolerant conifers characteristic of modern North Patagonian Rainforests (*Pilgerodendron uviferum*, *Podocarpus nubigena*) currently present along the humid coasts of western Patagonia. This portion of the record suggests an initially open landscape followed by arboreal encroachment under humid and cold conditions. The conifers reached maximum abundance between ~14.5-12.2 ka in the context of *Nothofagus*-dominated woodland, indicating peak precipitation regime. A sudden increase in *Nothofagus* at ~12.2 ka led to the establishment of closed-canopy forests, along with declines in hygrophilous and cold-resistant trees, herbs, shrubs, and peak fire activity, suggesting warm and dry conditions that persisted until ~11 ka. Highly resilient *Nothofagus* forests have lingered since then near LMN despite frequent explosive volcanic events and fires. European/Chilean disturbance started at ~0.2 ka in the form of deforestation along with increases of herbs and non-native plant taxa (*Rumex*, *Plantago*, *Pinus*). Our results suggest that scattered populations of rainforest trees inhabited the eastern periphery of the Patagonian Ice Sheet during the Last Glacial Maximum and that the early afforestation of this region started east of the Andes and proceeded westward into the Chilean channels and archipelagoes. The precipitation variations suggest strong influence of the SWW during the Last Termination, with a maximum influence between ~14.5-12.2 ka, followed by a weakening during the first millennia of the Holocene. Recent large-scale deforestation caused by human activities drove to the largest-magnitude shifts seen since 11 ka.

The eastern piedmont of the Sierras de C󠀠órdoba, central Argentina, is characterized by numerous outcrops of the fluvial to eolian succession of the Quaternary, whose paleoclimatic and paleoenvironmental values are still poorly studied. In particular, along the Río Carnero, the stratigraphic succession is composed of fossiliferous loess layers, paleosols, and fluvial sediments. We selected some sections along the Río Carnero to study using a multi-proxy analysis considering sedimentological, geochronological, malacological, and stable isotope data to reconstruct the past environmental conditions and the origin of the loess deposits. The loess sequence is rich in well-preserved *Epifragmophora* sp. that are particularly well suited for geochemical studies and inform us about local climatic conditions at the time of loess deposition. Preliminary radiocarbon dating suggest that the loess was deposited during MIS2-3. Geochemical analyzes (major and trace elements) and 87Sr/86Sr allow conclusions to be drawn about the origin of the loess particles and the impact on the past environment. Preliminary results show that the sequence begins with massive reddish-brown sediments composed of strongly bioturbated loess. Silty-sandy sediments continue across a clear boundary with fine sand and gravel interbeds and clay layers that average 4-5 m thick with calcareous concretions and irregular accumulations of tosca. Overlying this level are the remains of an eroded paleosol, partially covered by recent sandy sediments or showing the development of incipient soil. Geochemical analyzes are in the execution phase. This work highlights the importance of the study in continental mid-latitude sectors for the knowledge of glacial and interglacial periods, the contribution of which is fundamental to the understanding of environmental evolution during the Pleistocene and Holocene at regional and global scales.

Incorporation of anthropogenic materials in beachrock on Eleuthera Island through fast carbonate cementation, Bahamas

Ms. Michaela Falkenroth [1], ***Ms. Scarlette Hsia*** [2], ***Dr. Cornel Olariu*** [2]

1. TU Darmstadt, 2. The University of Texas at Austin

The abundance of anthropogenic debris along coastal regions is significant enough to start being preserved into the sedimentary record. Carbonate beachrock, which are bodies of beach sediment cemented with carbonate minerals, are useful archives of coastal evolution and also provide physical barriers to coastal erosion. Beachrock formation is known to permanently alter the morphodynamics of a coastline and lock sediment in place, while reflecting wave energy. The cementation forming beachrocks occurs on a scale of years or less, but observations of very young beachrocks with well constrained ages are still rare.

This study documents the first recorded instance of cemented anthropogenic debris on Eleuthera Island, the Bahamas. These debris, including fragments of man-made glass, and rubber/tar were found cemented into dissolution pockets of Holocene aged beachrock exposed along the modern-day coastline on the windward side of the island. Although our understanding of modern cementation processes is limited, observation on beachrock cemented debris will inform relationships between topographic heterogeneity along modern shorelines and coastal sediment erosion/accumulation.

In this study, we characterize and quantify the amount of anthropogenic materials being transported to coastal areas of Eleuthera Island and are incorporated by beachrock. We compiled previous work documenting anthropogenic pollution across coastlines around the globe and queried data by material and the relationship of the debris to a rock interface. The increasing frequency of debris found in beachrock and plethora of unconsolidated plastic found globally across beaches warrants a new classification scheme for anthropogenic "sediment" cemented into coastal cementation processes. Here, we discuss how anthropogenic debris is being preserved in carbonate coastlines. Implications of this work will feed into a new anthropogenic debris transport model for deposited anthropogenic material kept from drifting off to the open ocean. These results recognize that more robust efforts towards understanding modern-day cementation of anthropogenic debris will be major considerations in modelling future coastal changes and also have legal and regulatory implications regarding proper disposal and accountability of anthropogenic debris.

Climatic and hydrological impacts on a coastal subsiding plain: The case of Sybaris Plain

Dr. Chiara Cavasinni [1], ***Mr. Giuseppe Ferraro*** [2], ***Dr. Biagio Giaccio*** [3], ***Dr. Adam Izdebski*** [4], ***Dr. Patrizia Macrì*** [5], ***Dr. Sara Marino*** [1], ***Dr. Alessia Masi*** [1], ***Prof. Alessandro Vanzetti*** [1], ***Prof. Laura Sadori*** [1]

1. University La Sapienza, 2. Geofisica Misure snc, 3. Istituto di Geologia Ambientale e Geoingegneria, CNR, Roma, 4. Max Planck Institute for Geoanthropology, 5. Istituto Nazionale di Geofisica e Vulcanologia, Rome (Italy)

Coastal and deltaic plains represent vulnerable environments affected by natural processes (e.g. land subsidence, sea level rise, saltwater intrusion, and marine intrusion). Their impact is often exacerbated by increasing human-induced pressure due to land-use and hydrological changes. The Sybaris Plain (Calabria, Italy) represents a perfect case study for the analysis of environmental and climatic changes that occurred in a coastal subsiding plain in southern Italy during the Holocene.

A series of plain drillings was carried out to better locate the construction of a new highway as the territory is often flooded. On the basis of preliminary pollen and radiocarbon analysis the core S4 Bis (40 m long) was selected and a new complete core S4 Ter (39°73'N; 16°40'E, at 13 m a.s.l) was recently drilled to the same depth. The new core is now under study for the paleoenvironmental reconstruction through magnetic susceptibility, tephra, radiocarbon, microfauna and pollen analyses.

However, in order to deeply analyse the interactions between past populations and vegetational changes in the area through time, it is of primary importance to consider on-site pollen records from the plain. The plain hosted the Early and Late Neolithic site of "Favella della Corte", located in the middle of the coastal plain (39°68'N; 16°45'E), at 14 m a.s.l. The quaternary terraces around the plain were the seat of many Bronze and Iron Age sites. The plain was afterwards part of the agrarian and funerary landscape of the Greek colonies of Sybaris and Thurii, and of the Roman colony of Copiae, followed by a marshy Medieval and early modern phase.

Results of pollen analysis show an open environment dominated by herbaceous plants, in combination with a strong presence of microcharcoals and fungi spores. Swamps correlated to high-water tables are indicated by fern spores. Pollen signals are closely influenced by past water channels and artificial drainages. Vegetational indicators, integrated with the perspective of the historical trajectory, show resilient strategies adopted by archaic populations such as a model for a future water management in recent times.

A palaeoecological evaluation of Typha as a potential tool for wetland management in New Zealand. Part 2: cultural perspectives

Prof. Rewi Newnham [1]***, Dr. Xun Li*** [2]***, Dr. Marcus Vandergoes*** [2]***, Dr. Valerie van-den-Bos*** [2]***, Dr. Jamie Howarth*** [1]***, Dr. Andrew Rees*** [1]***, Dr. Susanna Wood*** [3]

1. Victoria University of Wellington, 2. GNS Science, 3. Cawthron Institute

Following the depletion of ~80% of New Zealand's (NZ) wetlands during the last 150 years, there is now a concerted restoration effort motivated by cultural, ecological and economic sustainability aspirations. Archaeological and palaeoecological records can inform this effort by providing valuable insights around indigenous practices and traditional ecological knowledge (TEK). Here we draw upon palaeoecological and anthropological records to trace the history of the wetland plant *Typha orientalis* (raupō) and consider its cultural significance in human-wetland interactions.

Along with the other ~40 species or hybrids of *Typha* worldwide, the NZ species is culturally iconic and has provided a rich source of food and materials for prehistoric peoples. We explore the wide range of reported usages of *Typha* by Māori, which shows strong synergies with usage by other traditional societies globally. In parallel, we are developing new pollen records from across NZ that consistently show the co-expansion of *Typha* and human settlement. NZ's short and recent prehistory reveals an apparent eco-cultural symbiosis between plant and people, whereby *Typha* expansion was both promoted and utilised by traditional Māori society up to and including the early European era. Together these anthropological and palaeoecological records raise questions as to the extent to which *Typha* was deliberately managed by Māori, including translocation by migrating tribes, and the extent of indigenous inter-generational knowledge and understanding acquired through these practices.

Our observations bring an additional, cultural, perspective to the role that *Typha* can play in wetland bioremediation, beyond promoting biodiversity, ecosystem health and resilience and carbon sequestration. In traditional Māori society, the health and vitality of communities and wetlands are inextricably linked and there is growing appreciation that NZ's modern conservation practice can be significantly empowered when it is allied with TEK. Our paleoenvironmental records suggest that it is possible for ecosystems and people to live and thrive alongside each other, supporting the contention that wetland restoration efforts will be more successful when they are culturally-informed. In a separate presentation at this congress, we show that a better understanding of *Typha's ecological* response to anthropogenic disturbance in prehistory can also help to guide wetland restoration strategies today.

Millennial-scale dynamics of pastures and livestock in the Central Pyrenees, NE Spain. A transdisciplinary approach

1. *Pyrenean Institute of Ecology-CSIC,* **2.** *Pyrenean Institute of Ecology - CSIC,* **3.** *Dept. of Evolutionary Biology, Ecology and Environmental Sciences, University of Barcelona,* **4.** *ARAID-IUCA, University of Zaragoza,* **5.** *Dept. of Prehistory, Autonomous University of Barcelona,* **6.** *Dept. of Antiquity Sciences (Prehistory), University of Zaragoza,* **7.** *Consejo Superior de Investigaciones Científicas, Instituto Pirenaico de Ecologia*

In the current Global Change context, with a warming climate and an on-going abandonment of traditional land uses, mountain areas face a challenging future and science-based management is needed to ensure the sustaining of their unique socio-ecosystems. Management plans should include long-term approaches, but they are commonly poorly integrated in environmental policies. For example, in the Pyrenees, to maintain a sustainable equilibrium of extensive livestock pastures a balance between an adequate grazing pressure to preserve biodiversity and traditional land uses is needed to avoid bush encroachment of subalpine and alpine pastures. However, little is known of when and how these cultural landscapes began, and how they have changed through time.

We present in this contribution, PASTORA, a transdisciplinary project focused on tracing the origin, determining the resilience patterns and the use of different subalpine and alpine pastures over time at the Central Pyrenees (NE Spain). The approach includes the combined use of several traditional and innovative palaeoecological tools: i) fossil pollen, *sed*aDNA and phytoliths from Holocene lacustrine sequences, ii) archaeological data since Neolithic times, including sites location and evidences of human presence, but also socio-economic practices extracted from dental micro-wear analyses of domestic animals, and iii) modern ecology techniques such as satellite geo-location livestock tracking next to traditional vegetation surveys of pasture plots.

This methodological approach will allow us to generate an integrated space-time vision of mountain pastures, reconstructing past history of the grasslands, determining the palatability of the grasses preferentially used at the beginning of the Neolithization in the Pyrenees, and quantifying the main grassland community shifts occurred since its origin. In addition, we will characterize the impact of the early livestock farming on the landscape by identifying changes in animal density, the dominant type of livestock in different periods, the social responses to environmental changes and the functionality of the pasture ecosystems for the last 8000 years.

Living on the Edge: surviving and thriving in the Holocene Humberhead Levels.

Mr. Luke Michno-Neville **[1], *Dr. M. Jane Bunting*** **[1], *Prof. Briony McDonagh*** **[2], *Dr. Helen Fenwick*** **[2]**

1. *School of Environmental Sciences, University of Hull,* ***2.*** *University of Hull*

The Humberhead Levels currently exists as a flat, lowland area that today is mostly used for the purpose of arable agricultural. For the majority of the Holocene however, the landscape looked drastically different. Prior to drainage works in 1626 AD, the area of the Humberhead Levels existed as a wetland environment featuring a complex system of rivers and streams. Archaeological evidence has shown the Humberhead Levels was attractive to human communities during the prehistoric, with lithic evidence for human occupation during the Mesolithic, Neolithic and Bronze Age situated near relict river courses and channels. Throughout the historic period, up until the drainage of the landscape, the economy of the area was one of traditional pastoralism, with residents using the seasonally flooded land for pasture and continuing exploitation of the wetland's natural resources. While there have been previous investigations into the archaeology and environmental history of the Holocene Humberhead Levels, the complex relationship between the palaeoecology of the landscape and human occupation and land-use has not been heavily investigated. This project examines the relationship between the changing blue-green landscapes of the Holocene Humberhead Levels and the human communities that thrived within them using a multi-disciplinary palaeoecological, archaeological and historical approach. With growing pressure for the restoration of blue-green landscapes today, understanding how human communities can exploit these areas sustainably is becoming increasing more important. The research of this project will be helpful for not only developing a better understanding of how human communities lived in the Humberhead Levels during the Holocene, but also for identifying possible ways in which human communities can live within blue-green landscapes today using subsistence practices of the past.

Can we use chemotaxonomy to reconstruct past food practices in Australian Aboriginal communities?

1. *University of Nottingham,* ***2.*** *School of Biosciences, University of Nottingham, Sutton Bonington Campus, Loughborough, United Kingdom,* ***3.*** *School of Culture, History and Language, College of Asia and the Pacific, Fellows Rd., The Australian National University, Acton,* ***4.*** *ARC Centre of Excellence for Australian Biodiversity and Heritage, School of Culture, History and Language, The Australian National University,* ***5.*** *St John's College and the McDonald Institute for Archaeological Research,,* ***6.*** *School of Geography, Earth and Atmospheric Sciences, The University of Melbourne,* ***7.*** *School of Geography, University of Nottingham, University Park, Nottingham, United Kingdom*

Across Australia, land management changed drastically after the arrival of Europeans, often leaving scarce evidence of the previous Indigenous cultural practices-. Because of this drastic change, the reconstruction of past landscapes and environmental conditions in pre-colonial Australia is not always straightforward. – Ethnobotanical and historical archives describe the use of yam daises (*Microseris lanceolata*, 'murnong'– Asteraceae Cichorioideae) as a staple food by Aboriginal Australians during pre-colonial times, indicating that local communities modified ecosystems for land exploitation and food production. Some palynological records from southeast Australia confirm the abundant presence of pollen types from the Asteraceae Cichoroideae subfamily. Nevertheless, accurate identification at the species level in the Asteraceae family is challenging. Most Cichoroideae pollen grains are indistinguishable under the light microscope and/or scanning electron microscope, meaning that the long-term dynamics and distribution *Microseris* plants cannot be explored yet using traditional palynological records.

Previous studies have successfully classified modern pollen grains of cryptic taxa (e.g. *Quercus* and Poaceae species) using their chemical spectra obtained by Fourier Transform Infrared (FTIR) spectroscopy. We have developed a modern library of FTIR spectra for taxa classification from native and introduced Asteraceae Cichorioideae species commonly found in Australia. Our dataset includes some introduced species and all the native daises of southeast Australia (e.g. *Taraxacum officinale, Reichardia tignitana, Hypochaeris radicata, Picris angustifolia, Hieracium praeltum, Sonchus hydrophylous, Picris aquarrosa, Cymbonotus lawsonianus, Taraxacum aristum, Acites megalocarpus*), including *Microseris* taxa (*Microseris lanceolata, Microseris scapigera* and *Microseries walteri*) from herbaria archives. We focused on the chemical fingerprint of single pollen grains, which have been treated with standard palynological procedures, and achieved classification success ranging from 55% to 75% at species level. Our results suggest that this approach can successfully classify sub fossil Asteraceae Cichorioideae pollen to species level. The implementation of this methodology can enhance archaeological and palaeoecological investigations around plant exploitation and land-use change in pre-colonial Australia and beyond. A deeper understanding of pre-colonial landscapes and the ecological effects of Indigenous Country-keeping practices can pave the way to more sustainable approaches to land management.

Towards a holistic understanding of past, present, and future human-animal-environment relationships in the Central Murray River Basin, south-east Australia

Ms. Chloe Stringer [1]***, Dr. Amy Prendergast*** [2]***, Dr. Jillian Garvey*** [3]***, Dr. Jan-Hendrik May*** [1]***, Dr. Nicole McCasker*** [4]***, Mx. First People of the Millewa-Mallee Aboriginal Corporation .*** [5]

1. *School of Geography, Earth and Atmospheric Sciences, The University of Melbourne,* ***2.*** *School of Geography, Earth and Atmospheric Sciences, University of Melbourne, Victoria, Australia,* ***3.*** *La Trobe Univesity,* ***4.*** *Institute for Land, Water and Society, Charles Sturt University,* ***5.*** *First People of the Millewa-Mallee Aboriginal Corporation, Mildura, Victoria*

Freshwater molluscs are commonly found in archaeological sites around the world and can provide important insight into past human-animal-environment relationships through traditional zooarchaeological and western scientific methods as well as through the lens of Traditional Ecological Knowledge. While these taxa continue to play an important environmental, cultural, and economic role, many extant freshwater mollusc species are at-risk of extinction today, as over half of freshwater gastropod and bivalve species are assessed as either 'At Risk' or 'Data Deficient' by the International Union for Conservation of Nature (IUCN). More research is seen as essential to helping conservation efforts. In this way, the analysis of modern specimens when establishing proxy archives or strengthening zooarchaeological interpretations can not only benefit interpretations of the past but may also strengthen knowledge about the present status of species which can then have implications for the species' future survival.

This paper considers an ongoing research project investigating freshwater bivalve species *Alathyria jacksoni* on Ngintait and First People of the Millewa Mallee Country in the Central Murray River Basin in south-east Australia. This species is assessed as 'Data Deficient' by the IUCN, and the state of the population in the study area is currently not well understood as the last major study of the species was completed 40 years ago. While the current research primarily aims to investigate *A. jacksoni* as a paleoenvironmental proxy archive for the region, ongoing collaborations between university researchers and the First People of the Millewa-Mallee Aboriginal Corporation has revealed the potential benefit of this research for understanding the present state of the species and, therefore, helping in any future protection efforts. The main methods used in this research have been the regular monitoring and collection of species during field work activity as part of a modern calibration study, and the application of sclerochronology to modern specimens, where analysis of the growth and corresponding geochemistry of the molluscs' shell can be related to the ambient environment and biological events. The cross-disciplinary implications of similar research should be considered.

Preserving archaeological landscape to lower soil erosion risk in mountainous areas: a modelling approach

Dr. Filippo Brandolini [1]

1. Newcastle University

Land degradation is a critical environmental issue worldwide. The latest projections on climate change indicate that increasingly severe storm intensity and runoff will induce greater soil losses by water erosion in the future than in the past decades. The 'FAO Global Symposium on Soil Erosion' noted that pre-industrial farming practices often contributed to maintaining healthy soils while modern intensive agriculture and mechanisation have frequently induced significant erosion. Archaeological sciences can contribute by exploring social and environmental interactions to examine the impact of different practices over long periods of time and considering what made different practices sustainable or unsustainable in terms of past soil management.

Historic Landscape Characterisation (HLC) uses a qualitative but formalised method to map historic landscapes' chronological and spatial complexity. Meanwhile, in environmental studies, the diachronic land-use-land cover (LULC) analysis has helped illustrate how different anthropogenic activities have altered the soil erosion rate in specific areas. Modelling can provide a quantitative and consistent approach to estimating soil erosion under a wide range of conditions. GIS integration with the RUSLE (Revisited Universal Soil Loss Equation) model has been applied to estimate soil loss at a regional scale. In previous HLC studies, LULC has been evaluated from the perspective of cultural heritage. In contrast, soil erosion modellers have used it as a proxy to estimate the soil erosion of an area.

In this study, HLC data were integrated in the RUSLE equation with the programming language R to evaluate the impact of archaeological landscape changes on contemporary environmental settings. This methodology has been tested through a case study in the Tuscan-Emilian Apennines (N Italy), an area particularly susceptible to landslide hazard. The study offers a new protocol that could be used by policymakers and stakeholders who need to develop strategies which encompass both natural and cultural values for landscape planning and management.

Into the Wild: reconsidering relationships between wilderness, re-wilding and archaeology

Prof. Nicki Whitehouse **[1]**, ***Dr. Emma Jenkins*** **[2]**, ***Dr. Hannah Fluck*** **[3]**, ***Dr. Kim Ward*** **[4]**, ***Dr. Philip Barratt*** **[5]**

1. *Department of Archaeology, University of Glasgow, UK,* ***2.*** *Institute of Modelling Socio-Environmental Transitions (IMSET), Bournemouth University, Poole, Dorset, BH12 5BB, UK,* ***3.*** *National Trust,* ***4.*** *School of Geography, Earth and Environmental Sciences, University of Plymouth, UK,* ***5.*** *University of Nottingham*

This paper explores the entangled relationships between rewilding, wilderness and the historic environment and the role that archaeology can play in rewilding initiatives. Rewilding is a term used to describe an array of global conservation and land management approaches that aim to restore ecosystem function and increase sustainability of biodiversity, ecosystems and landscapes. Re-wilding is both a captivating and controversial concept that attempts to address ecological degradation; however, its archaeological implications have not been well discussed so far.

As rewilding practice grows in popularity globally, there are concerns of the effects of rewilding on the historic landscape and its potential to ignore indigenous histories and traditional ecological knowledge. On a practical level, there is limited guidance for how rewilding initiatives can sensitively engage with the historic environment, yet rewilding initiatives have the potential to destroy cultural assets and change the historic character of a landscape. Moreover, human relationships with 'wilderness' and where we place ourselves within our conceived construct of 'nature', has shaped ecological and conservation thinking since the Enlightenment. These concepts make it difficult to reconcile the long history of human-environment interactions, living entangled lives with 'nature'. Indigenous peoples and many Eastern cultures have long understood that humans cannot be separated from 'nature'. These core beliefs are deeply entangled with Western Romanticism, national identity, and patriarchal colonialism, with 'Nature' often presented a-historically and removed from context. Wilderness, then, creates a problematic relationship for rewilding, which can fail to recognise cultural and historical contexts.

At the same time, we believe that archaeological and palaeoecological records also offer important insights for nature conservation and restoration initiatives, including rewilding. Archaeology, with its deep time perspectives, can help to demonstrate how our current, and future, environment is the result of human activity over millennia. This long-term lens can prepare people for the notion that places, landscapes, and ecosystems change and indicate how ecosystems might adapt to these challenges over time. We examine these issues from a philosophical and practical stand-point drawing upon case study examples (e.g. from Bere Regis, Dorset and Drumadoon Estate, Arran).

An accurate age-depth model for the long sedimentary record from Lake Chalco, Central Mexico: implications for volcanology, palaeoclimatology and palaeolimnology

Lake Chalco is an endorheic lake on the SE edge of Mexico City. Several drilling campaigns have taken place over recent years to address various scientific questions, including palaeoclimatic, palaeoenvironmental and volcanological reconstructions. In 2016, a drilling project funded by the International Continental Scientific Drilling Program (ICDP) focused on recovering the full lacustrine sequence at Lake Chalco, reaching a depth of c.550 composite meters below-the-surface (m_c). Due to the large number of active monogenetic and polygenetic arc volcanoes surrounding Mexico City, c.60% of the core is comprised of volcanically-derived deposits. The Chalco Sequence has been sub-divided into three stages, best reflecting changes in depositional processes and environments: (1) Stage I, Lava-dominated section, 448.86 – 553.93 m_c; (2) Stage II, Pre-lacustrine section, 293.71 - 448.86 m_c; (3) Stage III, Lacustrine-dominated section, 0 – 293.71 m_c. Stages I, II and III are interpreted to respectively comprise a succession of lavas, a primary volcanic collapse deposit and successive laharic deposits, and lacustrine sediments intercalated with laharic and tephra fall deposits.
To better understand the record at Chalco, an accurate age-depth model is crucial. From the 2016 cores, we have directly dated 12 samples by $^{40}Ar/^{39}Ar$ techniques, including 8 tephras (Stage III) and 3 lavas (Stages II and I). The age-model is further refined using tephrochronology, where we have been able to geochemically correlate fingerprinted tephras from the Xaltipan Ignimbrite eruption at Los Humeros caldera, Mexico and the Los Chocoyos (LCY) eruption from Lake Atitlan caldera, Guatemala, at 75 ± 2 ka and 164 ± 4.3 ka, respectively. We present a Bayesian-based age-depth model that accounts for these tephra ages, newly acquired ^{14}C ages for the upper c.50 ka, and fluctuations in sedimentation rate at lithostratigraphic contacts.
Our results reveal that the lavas at the base of the core erupted c.1.4 Ma, and the lacustrine sediments in the basin started to accumulate at c.450 ka. Since c.450 ka, at least 450 explosive eruptions have produced visible tephra layers within Lake Chalco and 13 Marine Isotope Stages (MIS) stages are recorded. This age-depth model permits detailed climatic investigations throughout these MIS stages for Central Mexico.

Unraveling the interactions between the Late Pleistocene megamammals and the earliest humans of the Pampas using stable isotopes

The Pampas of Argentina is one of the regions with the earliest evidence of human occupation in South America. Well-dated archaeological contexts as early as ~ 14.5 ky cal. BP imply at least 3.000 years of coexistence and possible interactions with the Late Pleistocene mega mammals. Previous archaeological studies on megafauna focused on two main issues: i) the impact of humans on the megafauna extinctions; and, ii) the importance of these large body-sized mammals in the subsistence of the first human groups of the region. Recently, it has been proposed that the arrival and expansion of human populations influenced the extinction of the megafauna during the latest Pleistocene. The human-driven extinction of mega mammals could have prompted an interruption in the hunter-gatherer population growth and a trophic niche shift. Nevertheless, there is a gap of about 2000 years between the oldest cultural and the oldest human skeletal remains in Pampas, and the evidence of anthropic exploitation of mega mammals is elusive. There is no evidence for the assumption of a specialized niche of mega mammal hunters, therefore it is important to evaluate the paleoecology of the Pleistocene mammal community of the Pampas. In this sense, we are focusing on building an extensive stable isotope database of well-dated samples for the last glacial-interglacial period ~ 17-8.4 ky cal. AP of the Pampas, to evaluate the structure of such a community and their response to climatic or anthropic drivers before their extinction. Here we present the first systematic reconstruction of the isotopic niche of several mega mammal species, evaluate their paleoecology, and infer possible interaction levels, from scavenging to secondary exploitation or even hunting. We measured the carbon, oxygen, and/or nitrogen isotope values on bone/tooth apatite and bone collagen of several fossil species, not only that few ones present in the archaeological contexts. We include more than fifteen herbivorous species as well as the largest felid of the Pampas, the sabretooth cat Smilodon populator, and the gigantic carnivore-omnivore short-faced bear Arctotherium tarijense.

Forensic archeoseismology: using disturbed and liquefied earthquake graves to unravel past seismic events

*Dr. Miguel Ángel Rodríguez-Pascua [1], Prof. Pablo G. Silva [2], Ms. Maria A. Perucha [1], Dr. Jorge Luis Giner Robles [3], Dr. Cesar Heras [4], Ms. Ana Bastida [4], Dr. Felipe Gómez Moreno [4], Dr. Raúl Pérez-López [1], Dr. Teresa Bardají [5], Dr. Elvira Roquero [6], Dr. Javier Elez [2], Dr. Yolanda Sánchez Sánchez [2]***

The ancient Roman city of *Complutum* (Alcalá de Henares, Madrid) was founded in the 1st century AD and it was one of the most important cities of Hispania. The old Roman city was partially destroyed and abruptly abandoned during the late 4th century AD by an earthquake. The new Roman city was relocated and rebuilt in a close settlement. In this work we show different Earthquake Archaeological Effects (EAEs) affecting the necropolis of *La Magdalena* site, an agricultural holding located 4 km away from the urban center of *Complutum*. The occurrence of a seismic event in the zone with a size ranging 5.0 – 6.6 Mw, according with the maximum surface rupture length of the Henares Fault, exceeded the minimum empirical limit of seismically-induced liquefaction. The main recognized EAEs are liquefactions (sand dikes and sand-gravel explosive craters), affecting Roman buildings such as water tanks (cisterns), houses and buried roman graves. Ground liquefaction generated significant soil cracks, explosive craters and folds in the foundations of the buildings. Ground liquefaction was apparently massive and affected several graves triggering significant displacements and dislocations in the bones of the buried skeletons. This allows us to obtain a radiometric age of the deformation by dating the disturbed carcasses within the graves. AMS ^{14}C dating to five well-preserved teeth throw consistent calibrated (2σ) ages of 240 – 360 cal BP. These dates place the deformation event between the late 3rd and the first half of the 4th centuries CE, which is consistent with archaeological dating by means of burial-related pottery, coins and the style of burial (coffins). The combination or radiocarbon data, archaeological information and *"post-mortem"* forensic evidence, make possible to locate the recorded event during the first half of the 4th century CE. The cadavers need some tens of years to decompose and allow free movement of the bones within the coffins.

Dynamical modelling of subglacial meltwater erosion during past and future glaciations

Ms. Runa Fälber [1], ***Dr. Anders Damsgaard*** [2], ***Prof. Jan Piotrowski*** [2], ***Prof. Jutta Winsemann*** [1]

1. *Institut für Geologie, Leibniz Universität Hannover,* ***2.*** *Department of Geoscience, Aarhus University*

A large portion of meltwater from ice sheets and glaciers drains along the ice-bed interface, influencing the ice-flow dynamics. It is known from the geological record and modern glacial systems that channelized subglacial drainage generates high erosion rates and can form overdeepenings and tunnel valleys. We use the geological record and numerical modelling to quantify the meltwater-driven erosive potential during future glaciations in northern Germany. To achieve this goal, we develop and deploy a next-generation dynamical model for subglacial meltwater erosion on soft beds.

First, we build a 3D subsurface model of northern Germany to facilitate the reconstruction of ice sheet and subglacial topography during past glaciations. The subsurface model is based on the depth maps of the Geotectonic Atlas of North-western Germany, geophysical data and borehole data (GTA3D, TUNB3D-NI). Subsequently, the sedimentary units and hydrogeological properties are integrated into a geological grid model. The subsurface model will allow us to tune numerical hydrology and erosion simulations with linked drainage systems consisting of distributed and channelized components.

The hydraulic model is based on the principles of subglacial channel formation and fluvial erosion and is parameterized against tunnel valley formation during past glaciations. This model framework will be the first to use realistic sediment mechanics and 3D geological geometries to assess subglacial channel stability, evolution, and erosion. It will be used to estimate meltwater-driven erosion and sediment transport during future glaciations, with special emphasis on quantifying the north-to-south distribution of the maximum depth of meltwater erosion and associated environmental challenges in northern Germany. A particular focus will be on scrutinizing a proposed critical erosion depth of 600-800 m, which is relevant for planning repository sites for high-level radioactive waste.

Evolving bed roughness below Finnish ice streams resting on hard crystalline beds; the key role of overridden proglacial sediment in mineral exploration.

Dr. Niko Putkinen [1]***, Mr. Syed Bukhari*** [2]***, Prof. Nick Eyles*** [2]

***1.** Geological Survey of Finland,* ***2.** Department of Physical and Environmental Sciences, University of Toronto at Scarborough*

Processes operating below modern and ancient ice streams are not well understood but are key to landform development, bed roughness and initiation and deceleration of streaming, and the response of the ice stream to climate and other variables. High resolution airborne LiDAR datasets are being employed by the Geological Survey of Finland (GTK) as part of a new national geological initiative (Glacial Features Database) to rapidly and cost-effectively map glacial landforms and sediments left by the last (Late Weichselian) Fennoscandian Ice Sheet on 'hard' crystalline rocks of the Fennoscandian Shield, 'soft beds' of overridden pre-existing sediment, and 'mixed' beds. This information is needed to inform mineral exploration projects by identifying beds composed of secondary recycled sediment from those resulting from primary subglacial erosion of bedrock. This presentation highlights information acquired from LiDAR, ground penetrating radar and outcrop data, and mapping of bed roughness by machine learning techniques, that identify changing bed roughness under ice stream in the Finnish Lake District that advanced to the Salpausselkä moraine system of Southern Finland during the Younger Dryas after 12,250 years before present. Ice streams advanced into shallow water of the Baltic Ice Lake flowing across an underlying soft bed composed of thick proglacial subaqueously-deposited fan-delta sediments and antecedent till that blanketed the underlying rough Shield surface. The soft bed was streamlined into drumlins and megascale glacial lineations by subglacial erosion to reduce basal drag; outcrop and many tens of kilometres of ground penetrating data show a thin till cap which functioned as an erodent layer which streamlined the underling soft bed. Continued subglacial stripping exposed large areas of hard mineral-bearing bedrock to erosion, producing dispersal trains of mineralized till, thereby increasing bed roughness, and contributing to deceleration of ice streams.

Erosional bedforms on hard beds in mid-continent North America cut by palaeo- ice streams of the Laurentide Ice Sheet

Mr. Syed Bukhari [1]***, Prof. Nick Eyles*** [1]***, Dr. Roger Paulen*** [2]***, Dr. Naki Akçar*** [3]

1. *Department of Physical and Environmental Sciences, University of Toronto at Scarborough,* ***2.*** *Geological Survey of Canada,* ***3.*** *Institute of Geological Sciences, University of Bern*

We evaluate the origins(s) of regionally extensive glacially scoured and megagrooved bedrock surfaces on the hard bed of the Great Lakes sector of the Laurentide Ice Sheet in mid-continent North America, using newly available high resolution LiDAR derived data. These surfaces occur on a range of bedrock lithologies from Precambrian crystalline strata of the Canadian Shield, together with offlapping Paleozoic shales and limestone escarpments and plains in Canada and the northern United States. Surfaces show a wide variety of streamlined bedrock morphotypes ranging from large km-scale rock drumlins and linear mega-grooves to 'tadpole' and cigar-shaped spindles and more sinuous grooves, including sichelwannen and muschelbruch. We discuss the formative processes acting to cut these forms, focusing on the relative roles of sediment carried by high pressure subglacial water, direct glacial abrasion by basal debris, and the abrasive action of a 'third layer' of overpressured sediment moving between ice and its bed and acting as an erodent layer. We highlight the regional geological and paleoglaciological context of scoured bedrock surfaces and are able to recognize the critical roles played by enhanced erosion below fast flowing palaeo-ice streams, and varying bedrock lithology. This study emphasizes the fundamental importance of 'tectonic predesign' where Precambrian terrane boundaries, faults and fractures, extending under offlapping sedimentary strata, control the paths of palaeo-ice streams, deep erosion of the Huron-Erie-Ontario Great Lake basins and the other large lake basins around the margins of the Canadian Shield.

Tunnel valleys in the southeastern North Sea: Complex incision patterns dating back to MIS16?

Dr. Arne Lohrberg [1], ***Dr. Jens Schneider von Deimling*** [1], ***Mr. Henrik Grob*** [1], ***Mr. Kai-Frederik Lenz*** [1], ***Prof. Sebastian Krastel*** [1]

1. *Institute of Geosciences, Christian-Albrechts-Universität zu Kiel*

Large Pleistocene ice sheets have produced glacial structures both at and below the surface in northern Europe. Some of the largest and most erosive structures are so-called tunnel valleys. Here, we present the distribution of tunnel valleys in the southeastern North Sea between Amrum and Heligoland based on a very dense grid of high-resolution 2D multi-channel seismic reflection data (400 m line spacing). Using newly acquired data, the known tunnel valleys in that area can now be traced in greater detail and further westwards, which results in an increased resolution and coverage of their distribution. Additionally, we were able to identify an even deeper and older tunnel valley, whose orientation parallels the thrust direction of the Heligoland Glacitectonic Complex (HGC). This observation implies a formation before the HGC during an early- or pre-Elsterian ice advance (MIS16?). For the first time, we acquired high-resolution seismic profiles precisely along the thalweg of known tunnel valleys. These along-profiles offer clear indications for an incision during high-pressure bank-full conditions. The fill indicates sedimentation in an early high-energy environment for the lower part and a subsequent low-energy environment for the upper part. Our results demonstrate that a very dense profile spacing is required to decipher the complex incisions of tunnel valleys during multiple ice advances in a specific region. We also demonstrate that the time- and cost-effective acquisition of high-resolution 2D seismic reflection data holds the potential to further our understanding of the distribution, complexity and incision depths of tunnel valleys in different geological settings.

Discriminating tills of mixed provenance in central Canada to decipher the influence of two major ice dispersal centres of the Laurentide Ice Sheet

Mr. Tyler Hodder [1], *Dr. Michelle S. Gauthier* [1], *Dr. Martin Ross* [2], *Dr. Eric Grunsky* [2]
1. Manitoba Geological Survey, 2. University of Waterloo

The Hudson Bay Lowland (HBL) region of central Canada contains thick sequences (up to 65 m) of tills and intertill sediments deposited over multiple glacial-interglacial cycles. The notion of laterally continuous till beds is disproved by recent stratigraphic work that instead documents a fragmented stratigraphy that makes most correlations highly uncertain. The HBL glacial sediments also show evidence of mixed provenance. This is due to spatiotemporal variability in both the strength of different ice domes and the subglacial processes, which caused subglacial sediments of different provenance to be deposited and subsequently preserved or partially re-entrained and mixed in places, and covered or replaced by newly-produced sediments elsewhere. This study first uses multivariate statistics (e.g. PCA, k-means clustering, LDA) to determine if tills can be differentiated based on their till-matrix geochemistry and clast-lithology counts. These till-provenance parameters are then compared to the field-based till stratigraphy, across multiple study areas, to assess the compositional heterogeneity of stratigraphic beds. The degree of compositional inheritance/overprinting needs to be evaluated when attempting to identify till units by composition, as there may not be a clear relationship to a single ice-flow direction and provenance region. More broadly, this will add essential constraints to ice sheet reconstructions that currently only integrates information from till stratigraphy in a very limited way.

Late Paleozoic glaciated landscape in northern Africa as an outstandingly well-preserved analogue to Quaternary deglaciated areas

Ms. Ricarda Wohlschlaegl [1], *Mr. Christoph Kettler* [2], *Prof. Daniel Le Heron* [1]

1. Department of Geology, University of Vienna, 2. Geological Survey of Austria

The Ennedi sandstone plateau in Chad in north-central Africa exposes an outstanding example of an ice stream paleo-landscape that is of Paleozoic age. This assemblage of paleo-glacial structures is of comparable quality to that found in Quaternary deglaciated landscapes. A wide range of exceptionally well-preserved proglacial, ice-marginal and subglacial features are visible due to the absence of vegetation in the desert environment. Paleo-ice stream pathways contain swarms of large-scale glacial lineations distributed over the whole plateau that tell the story of a dying ice sheet during the late Paleozoic. A putative grounding zone wedge within a paleo-ice stream pathway allows the position of the former coastline to be reconstructed as it is assumed that ice streams terminated into a former ocean basin. Based on the convex topography and its position orthogonal to the large-scale glacial lineations, we present the first geomorphological interpretation of a grounding zone wedge in the Paleozoic record. Additionally, a unique system of inverted channel sediments in close proximity to glacial structures might record different phases of meltwater release during ice retreat. In summary, the Ennedi paleo-glacial landscape provides an excellent natural laboratory to understand the spatial relationship between subglacial, ice-marginal and proglacial components of a former ice sheet, with emphasis on exceptional outcrop quality that can be used to further our understanding of some Quaternary glaciated landscapes.

Anatomy of a sandy soft-sediment ice stream bed

Ms. Sharman Jones [1], ***Dr. Marie Busfield*** [1], ***Prof. Daniel Le Heron*** [2], ***Dr. Tom Holt*** [1], ***Prof. Neil Glasser*** [1]

1. Aberystwyth University, 2. Department of Geology, University of Vienna

Links between ice sheet flow instabilities and processes operating at the ice bed are complex, non-uniform, and still not fully resolved. Detailed geomorphological studies of Quaternary palaeo-ice stream beds have driven major advances in our understanding of both hard- and soft-bedded ice-stream landsystems. Here we adopt techniques pioneered in Quaternary research and apply them to palaeo-ice stream beds of the Late Palaeozoic (~300 million years old), which represent an under-explored sandy end member in models of ice stream-bed interaction. We use a combination of drone-based and ground-based structure-from-motion photogrammetry to investigate the anatomy of a sandy, soft-sediment palaeo-ice stream bed at Oorlogskloof, Northern Cape, South Africa. Bedforms with a variety of morphometric characteristics were observed, including decimetre-scale sharp-crested flutes, centimetre-scale soft-sediment striated surfaces, horn-shaped transverse ridges, and tapered drumlinoid features. Analysis of aerial imagery revealed the variable distribution of these landforms across the preserved ice-stream bed, attesting to a complex spatial and temporal mosaic of areas of slip or stick. Here we quantify the morphometry of sandy sub-ice stream bedforms for comparison with their more widely studied heterogeneous counterparts, enabling us to test the influence of substrate composition on mechanisms of landform formation, subglacial drainage processes, and the nature of ice-bed coupling, with key implications for if and how substrate composition may influence flow instabilities such as streaming.

What can microtomography and micromorphology reveal about subglacial flute genesis?

Dr. Marie Busfield [1], ***Ms. Sharman Jones*** [1], ***Prof. Daniel Le Heron*** [2]

1. Aberystwyth University, 2. Department of Geology, University of Vienna

Debates continue on the formation mechanisms of streamlined subglacial bedforms such as flutes, drumlins, and mega-scale glacial lineations, and whether bedforms within and across these morphometric classifications have shared or variable genetic origins. A challenge facing exploration in contemporary settings is the lack of direct access to ice sheet beds. To overcome this challenge, we interrogate the fossilized remains of Late Palaeozoic ice sheets beds at Oorlogskloof, Northern Cape, South Africa. The Late Palaeozoic Ice Age (LPIA, ~360-260 Ma) is of particular interest as it represents the last time Earth transitioned from an icehouse to greenhouse climate; a warm end-member analogue for today's climate where glaciers and ice sheets are rapidly receding. Much like today, fast flowing ice streams drained continent-scale LPIA ice sheets, yet unlike the majority of well-studied Quaternary ice stream beds those of the Late Palaeozoic are unusually sandy. Here we demonstrate the value in combining 3D X-ray microtomography and 2D thin section micromorphology to dissect the internal structure, composition, and polyphase genetic history of sand-rich streamlined bedforms. This study offers insight into the basal processes operating at sandy soft-bedded ice streams, which holds broader implications for how glaciers and ice sheets may slip or stick over soft-sediment beds in ancient, Quaternary, and contemporary settings.

Quaternary Deposits in Northern Switzerland: correlation between facies distribution and paleo-topography

Ms. Michela Pierini [1]***, Dr. Marius W. Buechi*** [2]***, Ms. Valentina Zampetti*** [3]***, Dr. Gaudenz Deplazes*** [3]***, Mr. Claudio DiCelma*** [1]***, Mr. Pietro Paolo Pierantoni*** [1]

1. *University of Camerino,* ***2.*** *Institute of Geological Sciences & Oeschger Centre for Climate Change Research, University of Bern, Bern, Switzerland,* ***3.*** *NAGRA - Nationale Genossenschaft für die Lagerung radioaktiver Abfälle, Switzerland*

In order to develop and implement safe and sustainable long-term solution for the disposal of radioactive waste in Switzerland, Nagra cooperative is carrying out research for a repository site in line with the so-called "Sectoral Plan for Deep Geological Repositories" under the leadership of the Swiss Federal Office of Energy (SFOE).

The key decisive factor in determining the safety of a repository site is the stability of the underground conditions. Understanding and characterizing the subsurface is therefore the fundamental step in the site selection process. One of these criteria relates to future erosion and its importance for the long-term safety and long-term stability of a repository. For this purpose, several factors are considered, one of those is the erosion resistance of the overlying rock and the topography. Changes in topography over the last approximately two million years are used to derive various future developments in erosion for the area of interest in Northern Switzerland.

Starting from an eleven boreholes dataset from N Switzerland positioned in different morphological glacial settings (overdeepened glacial troughs, fluvial paleochannels, etc) Quaternary deposits have been systematically and consistently logged according to lithology and depositional environments.

Core data attributes (grain sizes, thicknesses, lithology and environmental facies) have been compared to the reconstructed Quaternary basemap reconstructed integrating regional well and 2D/3D seismic data, made available by Nagra. The well data have been overlapped on few available 2D seismic sections to trace correlations and reconstruct the filling deposits stratigraphy of the examined incised valleys.

The aim of this paper is to show how correlation trends can be successfully displayed using an integrated approach where Quaternary sediment characteristics can be quickly interrogated and compared against key controlling factors like Quaternary morphology and depositional environment. Such more regional trends are fundamental when predicting Quaternary sediment properties (velocity analysis and model for depth conversion, static models...) away from well control points.

Subglacial upper-flow-regime bedforms in a murtoo, Holocene SW Finland

Dr. Jussi Hovikoski [1] ***, Dr. Joni Mäkinen*** [2] ***, Mr. Sampo Soini*** [2] ***, Mr. Kari Kajuutti*** [2] ***, Dr. Adam Hepburn*** [3] ***, Prof. Antti Ojala*** [2]

1. *Geological Survey of Finland,* ***2.*** *Department of Geography and Geology, University of Turku,* ***3.*** *Geography and Environmental Management, University of Waterloo*

Compared to the efficient channelised meltwater flow associated with ice marginal eskers and proglacial environments we know little of meltwater flow in inefficient distributed systems beneath ice sheets. Previous studies have indicated the overall common presence of upper-flow-regime bedforms in glacigenic settings. However, facies expressions of subglacial density flows remain poorly documented. We excavated three ca. 3 m deep and up to 70 m long trenches across a murtoo-landform in a late-glacial to Holocene meltwater route in SW Finland. These excavations provide a detailed window into sediment structures presumably formed ca. 40-50 km from the coeval subaqueous margin of the Fennoscandian Ice Sheet (FIS). The aim of this study is to document small-scale density flow sediment structures of silty to gravelly lithologies, which characterize the proximal and central parts of the studied murtoo during its early evolutionary phase. Seven main facies types dominate the interval: current ripples and silt drapes; parallel lamination; sinusoidal lamination; sigmoidal cross-lamination and -bedding; scours with backsets; scours with structureless pebbly sand; and poorly-sorted gravel lenses. The facies commonly form compound bedforms on the concave-convex topography and are interpreted to include various upper-flow-regime bedforms. Our results confirm that meltwater processes play a critical role in murtoo deposition. Overall, the findings contribute to understanding of semi-distributed subglacial meltwater systems during the retreat of a continental ice sheet (FIS) in a rapidly warming climate.

Reconstructing LGM Rhine glacier ice-flow patterns based on subglacial landforms

Dr. Sarah Kamleitner [1], Prof. Susan Ivy-Ochs [2], Prof. Bernhard Salcher [3], Dr. Jürgen Reitner [4]

1. *Laboratory of Ion Beam Physics, ETH Zürich,* ***2.*** *ETH Zurich,* ***3.*** *Dept. of Environment and Biodiversity, University of Salzburg,* ***4.*** *Geological Survey of Austria*

We present a comprehensive inventory of subglacial landforms in the footprint of the LGM Rhine piedmont glacier, one of the largest glacier systems of the Alpine LGM ice cap. In a second step, we use orientation and morphometry of streamlined bedforms to deduce paleo ice-flow patterns thereby providing new insights into the dynamics of the Rhine glacier during the LGM. On the basis of high-resolution elevation data, we mapped ice-marginal moraines and more than 2500 subglacial landforms. Two main moraine complexes dominate: the Schaffhausen stadial moraines which document the maximum extent and the Stein am Rhein stadial moraines (Kamleitner et al. submitted). Our subglacial landform dataset is comprised predominantly of drumlins, but also includes glacial lineations and subglacial ribs (Rogen). Drumlins occur mainly in fields internal to the frontal moraines of the Stein am Rhein stadial. We interpret these as a coherent flow set that formed isochronously during the late LGM readvance to and the active stabilization at the Stein am Rhein ice margin. True readvance is documented by sedimentological evidence at several sites (Schreiner, 1992). Deviating bedform orientations in the flow set, like cross-cutting relationships or superimpositions are rare. Mapped bedform orientations of this flow set provide the basis for reconstructing basal ice-flow patterns during the Stein am Rhein stadial. We used a new kriging approach following Ng and Hughes (2019) to infer a continuous paleo flow field. The interpolated flow field demonstrates radial ice flow outwards from the mouth of Alpenrheintal as ice fanned out towards the frontal moraines. We see strong topographic control of basal ice flow during the Stein am Rhein readvance. Flow lines diverge due to deflection around topographic highs and converge in narrow valley sections. Combining gained flow lines with information on bedform elongation allows to delineate potential areas of relatively high basal velocities. These largely coincide with known overdeepenings. Geomorphological reconstructions are in accordance with predictions from numerical simulations that find highest sliding speed along Thur Valley, and in the Lake Constance and Lake Überlingen basins (Cohen et al., 2018).

Sardinia and Sicily: Two islands two worlds

Dr. Fabrizio Antonioli [1]***, Prof. Maria Rita Palombo*** [1]***, Dr. Valeria Lo Presti*** [2]

1. CNR IGAG, 2. DISTEM Palermo

The endemic faunas of Sardinia and Sicily, the two central Mediterranean's largest islands, underwent highly diverse evolutionary histories due to the two islands' different palaeogeographic evolution during the Cenozoic. Sardinia, an oceanic-like island, after its separation from Iberia approximately 30 Ma ago, was part of the Tusco-Sardinian palaeoarchipelago during the Late Miocene and became a completely isolated insular district by the end of the Messinian. Since the early Pleistocene, good swimmer large mammals have entered Sardinia during major sea level lowering phases. These active dispersal events and the passive arrival of small mammals through natural rafting led to faunal turnovers that reduced the biodiversity of the mammalian fauna, with an exception given for the arrival of the ancestors of four otter species in the Late Pleistocene. Conversely, the biodiversity of Sicilian endemic fauna increased progressively during the Pleistocene as a result of marked changes in the extension power of the barrier that separated the island from southern Europe. The diverse structure and composition of the endemic faunal complexes indicate a strong geographic isolation in the early Middle-Late Pleistocene and the presence of temporarily emerged and discontinuous land strips connecting the island to Calabria by the Middle Pleistocene end.

The time and mode of the colonisation of large Mediterranean islands by Palaeolithic humans is an open and hotly disputed question. In Sardinia, remains of Anatomical Modern Humans (AMH) are recorded in the early Holocene, while the hypothesis of the presence of Middle Palaeolithic hominins during the Last Glacial Maximum (LGM), if not earlier, requires confirmation by sound evidence. In Sicily, available evidence indicates that AMH colonize the island during the LGM, when a land bridge emerged.

Results of recent research on the Marettimo island (Sicily), obtained by cross-referencing radiometric datings with palaeogeographic, palaeontological, and relative sea level change data, suggests that seafaring in the western Mediterranean area began between the early Mesolithic and late Epigravettian, though it probably became a well-established practice since the Neolithic.

Palaeogeographic and palaeontological data is critical for disentangling the evolutionary dynamics of insular fauna and resolving the contentious topic of island colonization by prehistoric humans.

Island ecosystem ecology from deep prehistory to the Anthropocene

Prof. Eleanor Scerri [1], ***Dr. James Blinkhorn*** [1], ***Prof. Ian Candy*** [2], ***Dr. Huw Groucutt*** [3], ***Dr. RItienne Gauci*** [3], ***Dr. Mathew Stewart*** [1], ***Prof. Nicholas Vella*** [3]

Humans are fragmenting ecosystems into habitat 'islands', causing an unprecedented global collapse of large mammal populations just as science is discovering their essential ecological roles. The impact of these losses is such that our understanding of the contemporary biosphere is clearly shaped by a world artificially depleted of terrestrial giants. However, the causes of megafaunal extinctions over a much deeper, >50,000-year timeframe, remain strongly contested. How did specific anthropogenic and/or climate factors interact to transform and collapse megafaunal ecosystems and what implications did this have for human societies at different points in time? The feedbacks and ecological legacies of these older extinctions have important lessons for the current biodiversity crisis, yet the dearth of good quality fossil and contextual data from many regions, settings and species has prevented robust appraisal.

The ERC ISLANDLAB project (PI. E. Scerri) will explore these questions using the Maltese Islands as a frame of reference for the effects of anthropogenic ecosystem fragmentation. Pilot work has already uncovered an unprecedented deep-time record of pristine natural systems successively interrupted by waves of humans, with evidence of direct interaction between humans and the endemic megafauna. Extinctions can be documented from deep prehistory to Europe's first monumental civilizations, with exponential losses and subsequent faunal reintroductions lasting until the mid-Holocene. By building high-resolution ecological, climatic, and archaeological characterisations of Malta before and after human arrival and subsequent alteration of biotas, ISLANDLAB will therefore document long-term legacies and feedbacks between ecological changes, societal responses, and ecosystem resilience. More broadly, the results will shed light on extinction processes in current anthropogenic landscapes, elucidating the ecological and human dimensions of restoration pathways from an island paradigm at a pivot between Europe and Africa.

The first and last appearance dates of the dwarf elephant Palaeoloxodon falconeri on Sicily, based on new dates from Spinagallo Cave

Dr. Victoria Herridge [1], ***Dr. Dan Nita*** [2], ***Dr. Gianni Insacco*** [3], ***Prof. Laura Bonfiglio*** [4], ***Dr. Jean-Luc Schwenninger*** [5], ***Prof. Edward Rhodes*** [6], ***Prof. Rainer Grün*** [7], ***Dr. Gabriella Mangano*** [4], ***Prof. Adrian Lister*** [1], ***Prof. David Richards*** [8]

We present new dates for the Sicilian dwarf elephant *Palaeoloxodon falconeri*, from its richest and most important fossil locality, Spinagallo Cave. At 1m-tall, *P. falconeri* is the smallest elephant ever to have lived and – descending from the 4m-tall, 10 ton *P. antiquus* – the most extreme example of insular body size change in mammals. *P. falconeri* epitomises the Island Rule, is the focus of evolutionary and palaeobiogeographical research, and is key to palaeogeographic and palaeoenvironmental reconstructions, as well as the regional biochronology, of Sicily and Malta – and yet we cannot answer basic questions concerning its evolution and ecology owing to a lack of robust chronology. Using uranium-thorium, optically stimulated luminescence, and electron spin resonance dating, we took a 'range-finding' approach to constrain the age of both historically-excavated *P. falconeri* fossils, and remnant *P. falconeri*-bearing sediments within Spinagallo Cave, to show that *P. falconeri* had evolved by 334ka, 200ka later than previously thought. *P. falconeri* was still present on Sicily at 258ka, and likely persisted beyond this date. Our new dates place the evolution and extinction of *P. falconeri* within the palaeogeographic and palaeoclimatic framework of MIS10 to MIS6, a time of low-amplitude sea level change that ensured persistent insularity with respect to the mainland for the Siculo-Maltese paleaoarchipelago, but where transitory connections between Sicilian palaeoislands were also possible. This reconciles the existing conflict between palaeogeographic reconstructions of *P. falconeri* evolving within a discontiguous archipelago, and the clear biogeographic signal for connectivity between north and southeastern Sicily (e.g. the presence of *P. falconeri* in both Northern and Hyblean regions).

Spatial Reconstruction of Hominin Environment in Java

Homo erectus was firmly established in eastern Java a million years ago. A major portion of the Late and Middle Pleistocene fossil sites in Java is located in the eastern part of the island. To date, the palaeoenvironment of early hominins in Java has been studied for Sangiran and other sites, but the resulting environmental reconstructions are remain restricted to limited areas and only focused at one subject (i.e. palaeoenvironment, palaeoclimate, palaeogeography).

This study is the first step of a 'Living in Sangiran' project, focusing on analysing and testing the relationship between *Homo erectus* behaviour and environmental dynamics in Sangiran, Java. While functionally diagnostic find situations are absent for this early episode of settlements, such an approach allows the study of the preconditions, circumstances and effects of the relationships between human behaviour and environmental dynamics. In this study, we aim to develop a spatial reconstruction of the environmental and climatic conditions under which hominins lived based on present-day analogue, which polarized based on the palaeoenvironment and palaeoclimatic data available. A set of concerted maps on palaeogeography, palaeoclimate and palaeovegetaiton, based on each other, will provide spatial data on topography, coastlines, hydrology, rainfall patterns and plant cover for the eastern part of Java. The result of this study provides a more detailed, and for the first time, spatial sense of how the spectrum of available resources and their seasonal dynamics were distributed in the palaeolandscape of *Homo erectus* in the eastern part of Java.

Humans have for millennia managed and transformed the environments they inhabited, impacting regional biodiversity, climate and landscape. The material record of human alterations of the globe is deep and heterogeneous with important social, cultural and technological differences across time and space. Despite an increasing interest in the relationship of humans with their environments, major gaps remain in our understanding of the temporal trajectory as well as the environmental consequences of human exploitation of the Earth. Of particular interest in this context is the impact of human interactions with island ecosystems. How human societies colonised and transformed biotas and ecosystems of pristine islands worldwide, and in turn how these new environmental settings have transformed those societies, is a topic of global scientific interest exemplified by the ArchaeoGLOBE project. The ArchaeoGLOBE Island Extinctions Project explores the expansion of modern humans into island environments globally to test theories about the causes of species extinctions and extirpations in these unique ecosystems. The Mediterranean forms the first case study of this major collaborative project as one of the better studied regions globally and one that highlights where important scientific and methodological gaps remain in the study of global human history. Here we present the results of our data synthesis of the archaeological, palaeontological and ecological record for Mediterranean islands, and discuss the ecological consequences of human expansion to the region's island clusters, in particular habitat transformation and biodiversity loss as a result of human settlement, while highlighting the methodological challenges for this scale of project.

Stratigraphy and chronology of Pleistocene cave sediments and faunal remains from Għar Dalam, Malta

Dr. Christopher D. Standish [1], Prof. David Richards [2], Dr. Victoria Herridge [3], Prof. Adrian Lister [3], Mr. Neil Adams [4], Ms. Margrethe Johansen [5], Dr. Leila D'Souza [3], Mr. John Borg [6]

Għar Dalam, a cave site located in south-east Malta, is renowned for its late Pleistocene faunal assemblage. Amongst other species, numerous fossils of elephant, hippopotamus and deer have been recovered from the site, including several dwarf species. These were discovered during a long series of excavations in the late 19th and early 20th century led by researchers including Cooke, Despott, Caton Thompson, and Baldacchino. However, these deposits previously lacked sufficient chronological and stratigraphical control to definitively declare when these species were present on the island. This is a critical barrier to studies concerning the evolution of Malta's insular fauna and the role that climate fluctuations and sea-level change would have played.
To provide improved chronological constraint, a comprehensive suite of U-Th analyses have been performed on carefully selected in-situ speleothems (stalagmites, stalactites, flowstones) found in association with the cave's fossil-bearing stratigraphy. Based on the U-Th ages, we consider the earliest deposits - a bone breccia/conglomerate containing elephant, hippopotamus and deer - to pre-date 165.90 ka, indicating that these species existed on Malta during or prior to MIS 6d and before the penultimate glacial maximum. Overlying red earth deposits dating to between 167.27 ka and 151.19 ka (MIS 6c or 6b) also contain the same faunal species. Significant speleothem formation between c.152 ka and c.134 ka corresponds with the penultimate glacial maximum and suggests a break in sedimentation occurred during the last interglacial. Red earth deposits post-dating this period show evidence of reworking, making it difficult to constrain the age of fauna recorded from these layers, or to correlate with other regions in the cave, hampering assessment of species persistence beyond Stage 6. However, in situ material present in the remaining deposits offer some clues: whilst deer did survive, it is not clear whether this indicates continued occupation by the same population, or a phase of extinction followed by re-population.

Rise and fall of wetland habitat and megafauna interaction in mid-latitude North America during the last deglaciation

Dr. Eunji Byun [1]***, Ms. Martina Gjevori*** [2]***, Prof. Sharon Cowling*** [2]***, Prof. Sarah A. Finkelstein*** [2]

1. Yonsei University, 2. University of Toronto

In a previous work, we discussed multiple lines of evidence that suggest extensive wetland development in the American Midwest during the Bølling-Allerød (B-A). The Laurentide Ice Sheet meltwater was flowing southward through the Midwest before it was diverted to the northern fluvial routes close to the onset of Younger Dryas (YD) cold period. The combination of meltwater, remnant ice blocks, and increased precipitation potential provided water sources for the B-A wetland expansion across generally flat landforms of the Midwest. We showed that the B-A wetland expansion provided explanations on the overall vegetation openness as well as the temporal dynamics of major no-analog pollen taxa. For example, anomalously high *Fraxinus* pollen percentages during the B-A were indicative of widespread swamp forests with remaining areas flooded by meltwater rivers. The YD was followed by high abundance of *Larix* pollen that can tolerate cold conditions, and poor soil environments. Additionally, other available case studies support the presence of local wetland-like habitats for certain megafauna species. In this study, we expand on this idea of deglacial wetlands being last habitats for wetland-adapted megafauna species. Data were primarily obtained from two open-source databases, the Paleobiology Database (paleobiodb.org) and the Neotoma Paleoecology Database (www.neotomadb.org). Preliminary analysis of vertebrate faunal localities suggests major overlaps of fossil distribution and timing of three megafauna species known to have foraged in wetland environments, *Castoroides ohioensis* (Giant beaver), *Mammut Americanum* (American mastodon), and *Cervalces scotti* (Stag-mosse), with our earlier reconstruction of area grid cells for the B-A wetlands. With diminishing meltwater supply into the YD period, the wetland habitats were largely lost, supporting the idea that habitat loss may have contributed to end-Pleistocene megafauna extinctions. We also explore the recent paradigm of emphasizing active roles of megafauna on ecosystem evolution by further discussing that (1) those large animals were actively pursued and inhabited in the B-A wetlands and may have contributed to the observed increases in mid-latitude methane sources at this time period; and (2) their activities had lasting effects on the soil biogeochemistry that supported the following YD expansion of open *Larix* peatlands.

Sensitivity of varve biogenic component to climate in five Finnish lakes

Dr. Sarianna Salminen [1], ***Dr. Saija Saarni*** [1], ***Prof. Timo Saarinen*** [1]

1. *University of Turku*

Varved lake sediments provide a unique opportunity to examine the relationship of climate and lakes as well as lake catchments. Indeed, varve total thickness and clastic component thickness have been broadly used to study changes in past climate. In addition, varve biogenic component can form a notable part of varve total thickness and seasonal variations can influence the amount of deposited biogenic matter. However, the number of studies that discuss the varve biogenic component or its thickness is limited.

We investigated recent (100-year) varve records of five Finnish lakes with different catchments. The thickness of varve biogenic component and its sensitivity to growing season temperature and open water season precipitation was examined. The statistical analyses between varve biogenic component thickness and climate parameters confirm that the varve biogenic component thickness in the studied lakes is sensitive to the studied climate variables.

Lakes with high trophic status show positive correlation between varve biogenic component thickness and growing season temperature. For lakes with positive correlation between varve biogenic component and precipitation, the catchment soil type seems to be the factor behind the positive correlation. These findings indicate that warm summers and high precipitation lead to enhanced varve biogenic component thickness. Warm summers intensify primary production and higher precipitation enhances transportation of allochthonous biogenic material, both factors generally leading to thicker varve biogenic component. However, two of the studied lakes show more complex relation to climate. For instance, lake trophic status and abundance of coarse-grained material in the catchment seem to affect the correlations. Despite numerous human actions in the catchments of the studied lakes, the climate signal on varve biogenic lamina thickness, interestingly, is still detectable. Thus, this study reveals that varve biogenic component thickness has high potential for climate reconstructions.

MAGIC - MArgaritifera' shell : Geochemical Investigation of their Concretion to reconstruct past environment's variations.

1. *University of Bordeaux,* **2.** *ENSCL Ecole Supérieur de Chimie de Lille,* **3.** *CAPENA*

The fresh water mussel *Margaritifera margaritifera* can be found in different hydrosystems around the world. Its capacity to create pearls, together with its environmental specificities (umbrella species), made it an endangered and protected species. Previous geochemical studies on their shells had revealed its potential to record (and reconstruct) past physical parameters of the river, such as temperature. Microscopic analysis of yearly increments is also used to create a precise schlerochronology. Both features make it a potential robust paleothermometer archive.

This study aims at comparing schlerochronology with geochemical analysis of trace metal elements and stable isotope ratios ($d^{18}O$) performed on multiple mussel's shells from the Dronne River, located in South-West of France. Using a valuable paleothermometer's equation for carbonates (Epstein et al., 1953), together with reconstruction of the $d^{18}O$ signal of the river using nearby record of precipitation's $d^{18}O$ measured nearby between 1998 and 2012 (Genty et al., 2014), this study proposes a quantitative reconstruction of the temperature evolution over the last 60 years. The general trend of the river temperature evolution, including seasonal variations, will be compared to other regional records, and confronted to regional forcings, such as the North Atlantic Oscillation (NAO), as well as global forcings.

Anthropocene response of diatom and chironomid communities to external inputs and climate change in high mountain lakes

Mrs. Joana Llodrà-Llabrés [1], ***Dr. Oliver Heiri*** [2], ***Dr. Teresa Buchaca*** [3], ***Dr. Jose Maria Conde*** [1], ***Dr. Eloísa Ramos*** [1], ***Dr. Teresa Vegas-Vilarrúbia*** [4], ***Dr. Carmen Pérez-Martínez*** [5]

1. *University of Granada,* ***2.*** *University of Basel,* ***3.*** *CSIC CEAB,* ***4.*** *Department of Evolutionary Biology, Ecology and Environmental Sciences, University of Barcelona, Barcelona,* ***5.*** *Universidad de Granada*

Mediterranean high mountain freshwater ecosystems are particularly sensitive ecosystems to global change. Long-term sediment records provide cumulative paleo records of communities across the lake and their responses and changes over time. The main aim of this study is to evaluate the Anthropocene nature and timing of changes in Mediterranean high elevation lakes based on different proxies and assess whether they are consistent with recent warming. A sediment core was taken in Borreguil Lake (at an elevation of ~2800m a.s.l. in Sierra Nevada National Park) from the deepest area of the lake using a slide-hammer gravity corer and was extruded on-site with a high temporal resolution (intervals of 0.25 cm). The core was dated using ^{210}Pb, ^{226}Ra and ^{137}Cs by direct gamma assay establishing a chronology for the past ~150 years. Samples were processed and analyzed for diatoms, chironomids and algal group marker pigments. For each sample, a minimum of 300 valves and 50 head capsules were counted for diatoms and chironomids, respectively. Pigments were analyzed using liquid chromatography (UHPLC). Diatom assemblages were dominated by small benthic fragilarioid taxa such as *Pseudostaurosira brevistriata* as well as other taxa like *Achnanthidium minutissimum*, *Gomphonema* and *Pinnularia* species. The greatest compositional changes identified occurred during the 1960–80s and are indicative of alkalinization of the lake and an increased aridity since the 1960s. Chironomid assemblages showed a low taxonomic richness, consistent with an oligotrophic alpine lake, and with high abundances[OH1] of *Psectrocladius sordellus*-type and *Coryneura arctica*-type. Pigment analysis highlights a significant increase in the lake primary producers biomass from the year ~1700 onwards. Around 1970 there was a major shift and primary production moved from the bottom benthic zone indicated by diatom diatoxanthin (more transparent lake) to the pelagic zone with a greater contribution from cryptophytes (alloxanthin) growing at depth and chlorophyceae or green algae (lutein and zeaxanthin) growing in the pelagic zone. Thus, our results are indicative of significant changes in the lakes and their catchments along the Anthropocene that accelerated in the 1960s–1970s, concurrent with trends in rising regional air temperature and declining precipitation.

Between climate and anthropogenic forcing: Holocene paleoenvironmental evolution of the Somme valley peat sequences (Northern France)

Mrs. Chloé Garcia [1]***, Dr. Boris Brasseur*** [2]***, Mrs. Lou-Anne Mathieu*** [3]***, Dr. Agnès Gauthier*** [3]***, Dr. Pierre Antoine*** [3]

__1.__ EDYSAN (Ecologie et Dynamique des Systèmes Anthropisés) UMR 7058 CNRS-Université de Picardie Jules Verne – Amiens, France, __2.__ EDYSAN (Ecologie et Dynamique des Systèmes Anthropisés) UMR 7058 CNRS-Université de Picardie Jules Verne – Amiens, __3.__ CNRS, Universite Paris1

The fluviogenic peat (fen) are fragile environments that provide outstanding archives to describe environmental evolution. At the scale of northwestern Europe, the valley bottoms of the River Somme basin make remarkable wetlands characterized by a significant fluviogenic peat accumulation (5 meters on average) mainly over the last 12,000 years. The actual research has been initiated to highlight the respective roles of climatic and anthropogenic forcing factors (drainage, slope soil erosion) on peat formation/degradation processes and the modification of the related fluvial environments. This study is focused on a stratigraphic transect of 600 meters wide based on more than fifty manual boreholes and mechanical corings located in the large meanders of the Upper Somme Valley (Morcourt). The reconstruction of both sedimentation dynamics and palaeoenvironments evolution is based on a multiproxy approach combining sedimentology, geochemistry, palynology, and plant macro-remains identification, supplemented by thirty ^{14}C dates. This stratigraphic sequence reveals a first peaty event (14.6 - 14.0 ka cal. BP) preserved as small channel infillings during the Lateglacial period. Then peat formation restarted at the beginning of the Preboreal period around 12 ka cal. BP and rapidly extended to the entire valley bottom during the Boreal (0.07 cm/year). Until the Subboreal, typical peat (TOC values > 45%) continue to fill in the valley before a brutal reactivation of fluvial dynamics in a deep single meandering channel (3.3 ka cal. BP); slows down of peat accumulation rates (0,03 cm/year). Around 2.9 ka cal. BP, at the Bronze Age, peat is enriched with calcareous silts (15 to 60%) resulting from topsoil erosion of the slopes. Despite increasing signs of anthropization (increase of cereals and ruderal plants pollens and decrease of tree pollens), peat formation restarts in the early Middle Ages, highlighted by the development of *Cladium Mariscus*. From 0.8 ka cal. BP, again the hydrological system was disturbed and the peat system definitely transformed into drained wet meadows buried by the deposition of clayey silts fed by soil erosion. The paleoenvironmental history, combined with climatic and anthropogenic forcing factors, provides keys to understanding the current ecosystem and possible restoration trajectories for valley bottom peats.

Reconstruction of landscape paleohydrology using the sediment archives of humic lakes – study from northeastern Poland

Dr. Danuta Drzymulska **[1]*, Prof. Mirosława Kupryjanowicz*** **[1]*, Dr. Magdalena Fiłoc*** **[2]**

1. *University of Bialystok, Department of Paleobiology, Faculty of Biology, Białystok, Poland,* ***2.*** *Department of Paleobiology, Faculty of Biology, University of Białystok, Poland*

Sediment layers of uniform age within lakes (isochrones) and their patterns reflect accumulation processes which can be correlated with hydrological conditions in lake basins. The sedimentary archives in three small humic lakes in northeastern Poland (Wigry National Park) were described based on the correlation of local pollen assemblage zones in cores that were collected from the centers and margins of each lake. Past regional groundwater levels could be discerned from the morphology of the isochrones. The concave configuration of the isochrones in the studied lakes shows that regional groundwater levels remained mostly high and stable throughout their history. However, no single, common water level fluctuation pattern was identified in the three water bodies. High water levels throughout the Holocene was noted only in Lake Ślepe while other lakes in the region experienced a fall in water levels during the Boreal period. Lower water tables were identified in the older part of the Subboreal period in Lake Suchar II, whereas in Lake Suchar Wielki, this decrease persisted over a longer period, from the Younger Dryas to the Subboreal period. There were clearly some different trends in water level fluctuations in the Wigry Park lakes in comparison to those in other lakes in the region. This suggests that the lakes were influenced by local hydrological factors, in additional to regional climate, such as the size of catchment, catchment/lake ratio, shape of the lake basins (high slopes), groundwater hydrology, and development of local stream networks.

Hydrogen isotopic signatures of algal lipids as a new proxy for the reconstruction of past phytoplankton ecological dynamics

Ms. Antonia Klatt* [1], Dr. Cindy De Jonge [2], Dr. Daniel B. Nelson [1], Mrs. Marta Reyez [3], Prof. Carsten J. Schubert [4], Prof. Nathalie Dubois [4], Prof. S. Nemiah Ladd [1]

***1.** Department of Environmental Sciences, University of Basel, **2.** Geological Institute, ETH Zürich, **3.** Department Aquatic Ecology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), **4.** Department Surface Waters – Research and Management, Swiss Federal Institute of Aquatic Science and Technology (Eawag)*

Phytoplankton community composition plays a key role for biogeochemical cycling of carbon, nitrogen, and phosphorus as well as maintaining water quality. Therefore, changes in algal ecology due to environmental alterations virtually affect all ecosystems. To investigate phytoplankton ecological dynamics in response to past environmental changes, paleolimnologists have frequently analyzed microscopic algal remains preserved in the sediment, e.g., diatom frustules or dinoflagellate cysts. However, most taxa, including green algae and cyanobacteria, do not produce siliceous/calcareous parts, limiting estimation of their past abundance. Here, we focus on developing a new multi-proxy approach to reconstruct past phytoplankton community. This work targets the lacustrine algal response to human impacts in central Switzerland in the 20th century, as well as long-term changes during the Holocene.

Previous culturing and mesocosm experiments have shown that the relative offset in hydrogen isotope ratios of different algal lipids ($\varepsilon_{\text{Lipid1-Lipid2}}$) strongly differs among different phytoplankton groups. For example, $\varepsilon_{\text{palmitic acid-phytol}}$ values for green algae and cyanobacteria were ~350‰, whereas other taxa showed a much smaller offset (~200‰). To validate these results in a natural system, we collected algal biomass samples from the water column of Rotsee, a small eutrophic lake in central Switzerland, every second week from 2019 to 2020. Phytoplankton cell counts were also conducted for each sampling date. Consistent with past culturing and mesocosm studies, $\delta^2H_{\text{palmitic acid}}$ values increase with greater relative biovolume of green algae and cyanobacteria. We further present calculations of $\varepsilon_{\text{Lipid1-Lipid2}}$ for different lipid pairs including phytol and sterols in relation to the biovolume of phytoplankton groups and pair these with lipid distributions to develop a new multi-variate framework for reconstructing past algal community composition.

Following up on this, we apply our approach to a ~14 m long sediment core from Rotsee collected in 2021 spanning the past 13 kyr. We present a preliminary reconstruction of phytoplankton community dynamics during different time periods by calculations of $\varepsilon_{\text{Lipid1-Lipid2}}$ as well as the lipid distribution in the sediment– in this context, we compare the magnitude of change in the algal community in response to 20th century anthropogenic impacts (i.e., eutrophication) to the natural variability throughout the Holocene.

Exploring the environmental signals recorded in Holocene calcite varves from Diss Mere, England using a modern limnological monitoring approach

Ms. Laura Boyall [1], ***Mr. Jose Valcarcel*** [1], ***Dr. Poppy Harding*** [2], ***Dr. Armand Hernandez*** [3], ***Dr. Celia Martin-Puertas*** [1]

1. *Royal Holloway, University of London,* ***2.*** *University of Hertfordshire,* ***3.*** *Universidade da Coruña, GRICA group, Centro de Investigacións Científicas Avanzadas (CICA), Spain*

Diss Mere is a small natural lake located in the centre of the town Diss in Norfolk (England). The lake, which has been exposed to different stressors including climate variability and changing land use, has significant recreational, historical and environmental value. The Diss Mere sediments are annually-laminated for most of the Holocene (2.1 – 10.3 ka BP), which allows the study of the lake evolution and its response to past changing environmental conditions at an exceptionally high resolution. As with many mid-latitude, alkaline, eutrophic lakes, Diss Mere's sediments are formed of biogenic-calcite varves, resulting from the complex interactions between biological, chemical, and physical processes. We have conducted a 3.5-year lake monitoring survey including sediment trapping techniques to identify the main external drivers and seasonal processes contributing to lake sedimentation. Our results demonstrate that the modern lake is still forming seasonally-differentiated sediments today, suggesting varves are still forming in the present system. These varves however are unable to be preserved, likely due to the permanent oxygenation of the lake bottom resulting from the gradual lake shallowing. Seasonal sediment fluxes follow a general pattern of i) an early spring diatom bloom of predominantly *Stephanodiscus hantzschii* and *Cyclostephanos dubius;* ii) spring precipitation of medium-coarse endogenic calcite grains; iii) summer precipitation of smaller endogenic calcite grains; and iv) an autumn algal bloom, and endogenic calcite precipitation intermixed with benthic diatoms and micrite. Higher primary productivity occurs in autumn as a response to lake overturn, and nutrient recirculation and input to the photic zone. Whilst calcite precipitates throughout the whole year, peaks are observed in the epilimnion during the summer, followed by a secondary peak in autumn in the hypolimnion indicating either resuspension, biological-induced precipitation, or both. Seasonal lake sedimentation is driven by the annual mixing cycle of the lake, which is strongly influenced by air temperature and wind. This study shows that a modern analogue approach can be applied to the ancient varves revealing the potential for summer temperature reconstruction driving calcite precipitation, winter wind conditions enhancing larger diatom blooms and interannual climate variability through the Holocene.

Historic lake levels and paleoecological peatland and forested wetland extents driven by the same climatic changes, northern Alberta, 1394 to 1988 CE

Dr. Chris Larsen [1]

1. University at Buffalo

There is concern that ongoing global climate change in the boreal region will lead to lakes becoming shallower, and wetlands drying and becoming afforested. Historical and paleoecological records from Northern Alberta were evaluated to assess lake and vegetation responses to past climate changes.

Historical records of lake levels were obtained for four unregulated lakes in northern Alberta and southern Northwest Territories. Historical records of five climate variables and indices were obtained: mean annual temperature (MAT), total annual precipitation (TAP), summer PDSI, and indices of the Arctic Oscillation and Pacific Decadal Oscillation (PDO). Lake levels for the four lakes consistently exhibited positive Pearson correlations with TAP and PDSI and negative Pearson correlations with MAT, AO and PDO. Lake levels were thus shallower when conditions were warm and dry which tended to occur during positive phases of AO and PDO.

A fossil pollen and spore record was created from Ninisith Lake sediments at a continuous 2.5 mm resolution (n=96, range=1394 to 1988 CE). In 1988 CE the 1.0 ha lake was 3.2 meters deep and was surrounded by black spruce dominated wetlands which were in turn surrounded by peat wetlands. When smoothed using a lowess filter, pollen and spore records exhibit centennial scale patterns. Percentages and accumulation rates of Cyperaceae, aquatic pollen taxa and *Sphagnum* spores exhibit maxima in 1394, 1626, and 1856 CE, and minima in 1507, 1732, and 1919 CE. Percentages and accumulation rates of *Picea mariana* and *Pinus banksiana* pollen exhibit the inverse pattern of that for Cyperaceae, aquatic pollen taxa and *Sphagnum* spores.

Four annually resolved climate reconstructions were obtained and binned to the same years as the Ninisith Lake sediments: temperature, lake sediment $d^{18}O$, PDO and AO. Pearson correlations between the climatic reconstructions and the pollen and spore records indicate that warm temperatures, more negative $d^{18}O$ and high PDO correspond with forest closure and lake shallowing, while opposite climatic conditions led to forest opening and lake deepening.

Hydrological fluctuations and fires during the Holocene in the shadow of a changing climate and growing human impact in East European Plain based on the palaeoecological reconstruction of continental ombrotrophic bog

Dr. Dominika Łuców [1], ***Prof. Mariusz Lamentowicz*** [2], ***Dr. Milena Obremska*** [3], ***Prof. Piotr Kittel*** [4], ***Mr. Andrey Mazurkevich*** [5], ***Mr. Cyprian Kowalczyk*** [6], ***Dr. Karolina Leszczyńska*** [7], ***Prof. Michał Słowiński*** [8]

The large continental ombrotrophic peatlands in Eastern Europe are a unique archive of high-quality information about past hydrological dynamics (including long-term droughts) and fire activity. Still, paleoecological reconstructions based on testate amoebae and charcoal analyses for the Holocene are poorly documented. It remains unclear how large ombrotrophic bogs in the continental zone responded to dry climatic phases and increased human impact in the past and how natural fires and human activity have influenced these landscapes in this part of Europe. Therefore, we analysed testate amoebae and charcoal from the peat core from Gorodetsky Moch bog, one of the large continental raised bogs in the East European Plain. The main objective is to investigate the relationship between fire activity, droughts and climate changes over the last 4200 years (in the Meghalayan stage) based on palaeoecological reconstruction. For this purpose, testate amoebae analysis was used to reconstruct long-term hydrological dynamics. Micro and macro-charcoal analysis was used to identify a record of fire activity in detail. These data will be supported by the time scale based on plant macrofossil samples 14C-dated in high resolution and possibly tephrochronology. Furthermore, we performed analyses of plant macrofossils, pollen, and loss on ignition (LOI). The research is carried out as a part of a PRELUDIUM project (2019/35/N/ST10/03492) financed by the National Science Center (Poland).

Lateglacial- Early Holocene carbon accumulation in a Pyrenean peat bog

Dr. Teresa Vegas-Vilarrúbia [1]***, Mr. Arnau Blasco*** [1]***, Mr. Miguel Angel Calero Tomas*** [2]***, Dr. Sandra Garcés*** [3]***, Dr. Valentí Rull*** [4]

Peatlands cover approximately 3-4% of the Earth's land surface and store nearly 30% of soil carbon. Around 50 million hectares of peatland have been historically damaged; these areas contribute 4% of global human-induced greenhouse gas emissions annually. The best known carbon reservoirs developed in peatlands of northern latitudes during the Holocene. Less known are peatlands developed during post-glacial times, when CO_2 was lower and abrupt climate changes occurred, e.g. the Bölling/ Allerod (B/A) and the Younger Dryas (Y/D). We argue that extensive research of this pre-Holocene period would provide valuable information on how the rapid post-glacial climatic shifts influenced the pre-Holocene peatlands, mainly rates of change of carbon storage and hydric changes. Results would provide insights on the long-term evolution of peatlands and carbon accumulation without human influence. The present study focuses on peatland origin and evolution during pre-Holocene conditions and explores a record from a mountain peat bog (Southern Pyrenees). The Bassa Nera pond is located in a Pyrenean-protected area and the results obtained from this research are aimed at supporting conservation practices in front of global warming. The main goals are: 1) to trace the local changes in peat and carbon accumulation between 15,5-10 kyrs BP at subcentennial scale resolution; 2) to estimate the influence of post-glacial hydroclimatic variability patterns on carbon rates of change. A 11m core was extracted from the centre of the peat bog pond. An age-depth model was generated using radiometric ^{14}C analysis data. Detailed stratigraphic descriptions were performed applying standard methods and X-ray fluorescence core scanner analyses. To investigate the origin of the organic matter and its variability through time, organic proxies from bulk sediments samples are being analysed: carbon to nitrogen atomic ratio (C/N), total carbon (TC) and total organic carbon (TOC), total nitrogen (TN), as well as carbon and nitrogen isotopes (δ13C and δ15N). Paleoecological (pollen, diatoms) and geochemical variables will help deduce the concurrent environmental shifts occurred during the study period.

Understanding the dynamic of phytoplankton and managing rates of ecological change in a peri-urban lake (eastern China) in the Anthropocene

Dr. Shixin Huang [1]***, Prof. Ke Zhang*** [2]***, Dr. Qi Lin*** [1]***, Prof. JI SHEN*** [3]

1. *State Key Laboratory of Lake Science and Environment, Nanjing Institute of Geography and Limnology, Chinese Academy of Sciences, Nanjing, 210008, China,* ***2.*** *State Key Laboratory of Lake Science and Environment, Chinese Academy of Science,* ***3.*** *School of Geography and Ocean Science, Nanjing University*

Freshwater blooms of phytoplankton threaten public health and depress ecosystem services globally in the fast-changing Anthropocene. Understanding the long-term dynamics of the phytoplankton community is a priority for future lake management and restoration, especially for those intensively populated areas. Here we used a century-scale paleoecological investigation from a peri-urban lake Luoma Lake in eastern China to reconstruct the phytoplankton community composition, algal abundances and the historical ecosystem dynamics evidenced by sedimentary pigments. High-resolution analysis of phototrophic pigments revealed a substantial increase in abundances of total algae, cryptophytes, siliceous algae, chlorophytes, and cyanobacteria at a surprising rate after the 2000s, followed by a declined trend in recent years. The interaction of substantial nutrient loads from urbanization, aquaculture and agricultural practices, and climate warming was identified to account for the shift in the phytoplankton community of Luoma Lake. Whereas, both pigment assemblages and geochemical records captured the potentially ecological recovery signal of Luoma Lake recently, which was attributed to the nutrient reduction program in the watershed (e.g. limited aquaculture activities). Given the potential effect of future climate change on phytoplankton, especially cyanobacteria, we further projected the time series of future total algae and cyanobacteria abundances based on two different climate scenarios (shared socioeconomic pathway 1-2.6 and 5-8.5) to mid-21st century. On average, higher phytoplankton and cyanobacteria abundances were projected due to the rising temperature. Furthermore, rates of ecological response of phytoplankton will rapidly increase as the temperature accelerated even if the reduction in nutrients, suggesting the alleviated/diluted effect of reduced nutrients by climate warming in the future landscape. This study emphasizes the necessity of understanding the dynamics of phytoplankton, incorporating rate-focused strategies into future lake management and combining regional nutrient reductions with mitigating against global warming to avoid accelerating the nauseous phytoplankton blooms, especially for those urban/peri-urban lakes.

Response and recovery of a NE European Sphagnum peatland affected by cement dust pollution

Peatlands are important global sinks and stores of organic carbon. In recent centuries, many have been degraded by human disturbance, directly (e.g., by burning or drainage) and indirectly (e.g., by industrial pollution and climate change). Ombrotrophic (rain-fed) peatlands are particularly sensitive to aerosol pollution, as they receive their nutrient supply solely from the atmosphere.

In Estonia, atmospheric pollution emitted during the mid to late 20th century was unusually base-rich, consisting mainly of particulate emissions from industrial plants, such as the Kunda Nordic Cement factory. This site began large-scale production during the 1960s, emitting vast quantities of cement dust into the surrounding area. These emissions caused nearby peat-bogs to become more alkaline and drove declines in *Sphagnum*, an important peat-forming moss. By the late 1990s, filters were used to limit further emissions from the factory.

Our study aims to examine the impact of alkaline dust deposition on ecosystem functioning in a formerly ombrotrophic peat bog (Varudi bog, NE Estonia), as well as its subsequent recovery following the removal of the point source of pollution. We will apply a suite of palaeoecological methods to two peat cores from our study site, reconstructing past changes in acidity using testate amoeba as a proxy for pH. Our reconstruction will be compared with historical records of cement production from the Kunda factory to test its reliability. Finally, we will relate these pollution histories to the site's vegetation and carbon accumulation dynamics. This will allow us to define threshold values for shifts in ecosystem functioning in response to alkalinisation and thresholds for later recovery.

This work will improve our understanding of how peatland ecosystem dynamics have responded and continue to respond to past anthropogenic disturbances. This understanding can inform best practices for restoring and managing heavily polluted peatlands.

The resilience of small kettle hole peatland to the disturbance caused by climate change and land use during the last 2,000 years (N Poland)

The recent 2000 years have been marked by environmental changes caused by human impact and climate change. Intensive human activity on the environment (such as fire, deforestation, land use, or drainage) has had a significant impact on changes in the geomorphological processes, hydrological cycle, and vegetation. That is why it is so important to understand the dynamics of these processes and understanding the factors responsible for the transformation of the environment and the impact of these changes on the peatland ecosystem - important reservoirs of water, carbon, and archives of the past. Therefore, the main aim is to investigate the resilience of Nicemino peatland to the disturbance caused by climate change and land use during the last 2,000 years. For this purpose, we used a peat archive with high-resolution multi-proxy analyzes. The chronology of the peat monoliths is based on the twelve AMS^{14}C dates. To reconstruct local and regional vegetation changes we used pollen and plant macrofossils, whereas testate amoeba was used to reconstruct the past hydrological variability. Macro-charcoals have provided information about the paleo fires and geochemistry gives us an overview of the relationship between human activity, past hydrology, and catchment processes. The Nicemino is a small Sphagnum kettle-hole peatland (3 ha). The main reason why was selected this site as the object of the study was the presence of a large number of relict's charcoal hearths indicating the intensive transformation of the natural environment by man in the immediate vicinity of the peatland. Our preliminary results show a clear transformation of the vegetation species composition in the past, caused by climate variability and human activity (i.e., agriculture, forest management, or charcoal production in charcoal hearths), which undoubtedly could have caused changes in the peatland ecosystem. Despite the existence of many paleoecological studies in northern Poland, there is still a lack of high-resolution research multi-proxy with a detailed chronology that would support the history of changes in land use and would provide new paleoecological data from sediment archives not yet explored. This research is part of the project funded by the Polish National Science Centre (No. 2018/31/B/ST10/02498).

Plateau icefield glaciation of the Canadian Prairies: a geomorphic reconstruction

Dr. Sophie L. Norris [1]***, Dr. Nigel Atkinson*** [2]***, Dr. David Evans*** [3]***, Dr. Martin Margold*** [4]***, Mr. Benjamin Stoker*** [4]

1. University of Victoria, 2. Alberta Geological Survey, 3. Durham University, 4. Charles University

The Younger Dryas Stadial was a period of rapid, high magnitude cooling that occurred immediately prior to the onset of the present interglacial, and is one of the most intensively studied events in the palaeoclimate record. The response of glacial systems during this abrupt event offers a valuable analogue, allowing a better understanding of the rate of glacial advance and recession with respect to recent and future climate change. Within the Northern Hemisphere, renewed glacial conditions during the Younger Dryas led to the growth of plateau icefields. These localised icefields are particularly sensitive to variation in climate and therefore provide a unique record of local palaeoclimatic conditions. The development of Younger Dryas Stadial plateau icefields associated with regional ice sheet deglaciation has been well documented for regions covered by the Fennoscandinavian and British-Irish ice sheets, where the concept has been employed to make detailed local and regional palaeoclimatic reconstructions. In contrast, the potential existence of plateau icefields in regions deglaciated by the Laurentide Ice Sheet has so far been overlooked, despite the widespread occurrence of suitable topography and some evidence for Younger Dryas readvances in North America. Here we evaluate the evidence for potential, Younger Dryas aged, plateau icefields and their associated landsystem signatures within the Canadian Prairies using newly available high resolution LiDAR imagery.

Insights from calibrating Greenland Ice Sheet model simulations against the record of Last Glacial and Holocene ice marginal variations

Dr. Tancrede Leger [1], ***Prof. chris clark*** [1], ***Dr. Jeremy Ely*** [1], ***Ms. Carla Huynh*** [2], ***Ms. Sharman Jones*** [3], ***Dr. Sarah L Bradley*** [1], ***Ms. Rosie Archer*** [1]

1. Department of Geography, University of Sheffield, 2. University of Edinburgh, 3. Aberystwyth University

The Greenland Ice Sheet holds an estimated ~7.4 m of sea-level equivalent and is currently experiencing rapid recession due to global warming. While accurate projections of future ice sheet mass loss are essential to plan for sea level change, current projections of the Greenland Ice Sheet's response to present-day and future climate change yield large uncertainties and vary significantly between simulations. Because climate changes on shorter timescales than the response of continental ice sheets, recent work suggest the current Greenland Ice Sheet is not in equilibrium with climate and is instead affected by a complex product of past changes. This represents a challenge when starting projections of future ice-sheet evolution without accounting for past dynamics. The discovery of this lag in ice-sheet response and the growing library of geological observations enables us to ask the question: can a calibration of Greenland Ice Sheet model simulations against the geological record improve projections of its future behaviour?
To address this research question, we here show preliminary results from a new experiment that simulates the evolution of the Greenland Ice Sheet from the last glacial maximum (24 ka BP) to 1850 AD with the Parallel Ice Sheet Model (PISM). An ensemble of simulations was run at 4 km spatial resolution and forced by the latest transient palaeo-climate and ocean simulations of the isotope-enabled Community Earth System Model (iCESM 1.2 and 1.3). To compare these simulations against the empirical record, we also present a new database of Greenland-wide ice margin geomorphological mapping and a new compilation of radiocarbon and Terrestrial Cosmogenic Nuclide ages dating Greenland Ice Sheet Late-glacial and Holocene retreat patterns. The goodness of fit between a given ice-sheet simulation and this newly assembled empirical record of ice-sheet margin evolution is quantitatively assessed using a new set of algorithms developed internally as part of the PALGLAC project. With this investigation, our aim is also to provide new insight into the former Greenland Ice Sheet's response to transitional climatic phases including the last glacial termination, the Late-glacial/Holocene transition, and the Holocene thermal maximum.

Ice Sheet Speed-dating: Using Expert Elicitation to identify "good" simulations of the LGM North American Ice Sheets

Dr. Niall Gandy [1], Dr. Gemma Ives [2], Ms. Gwyneth Rivers [1], Dr. Lachlan Astfalck [3]

***1.** Department of Natural and Built Environment, Sheffield Hallam University, **2.** IT Services, The University of Sheffield,, **3.** School of Physics, Mathematics and Computing, The University of Western Australia*

After running a large ensemble of palaeo ice sheet model runs, it is common to either rank the simulations or determine which simulations are an acceptable match to observations and which are ruled out. This task requires human judgement, which is usually left only to the authors of the research. Tools have been developed to compare ice sheet simulations to empirical reconstructions numerically, but even this approach requires some human input on values for match thresholds.

An alternative is to use expert elicitation to identify "good" ice sheet simulations. Expert elicitation normally captures expert's beliefs in the form of a probability distribution; for something as complicated as ice sheet geometry this is much too arduous a task. Instead, we propose to elicit binary classifications of "good" and "bad" and find descriptions of plausible ice sheets through probabilistic inverse modelling. Experts can consider empirical ice sheet reconstructions, but also "soft-knowledge" about the sectors of the ice sheet it is most important to match, margin shapes considered to be glaciologically plausible, and an idea of the reasonable best-reconstruction a model will be able to provide. By seeking the input of many experts, it is possible to both lighten the task load of determining the quality of 100-1000s of simulations, and gain a wisdom of the crowd benefit to the results. Just like any other method of ranking ice sheet simulations, this method requires human judgement; in this case more explicitly than usual.

We are seeking expert input to rank an existing ensemble of North American Ice Sheet simulations. By asking experts at the INQUA 2023 Rome Symposium to spend 3-5 minutes sorting simulations using an online interface we will build up an average community view on which LGM North American Ice Sheet simulations are "good". This will provide a community resource to compare future ice sheet simulations against that is a justifiable representation of academic expert knowledge, adding to the current arsenal of model-data intercomparison tools.

Reconstructing Cordilleran Ice Sheet stability in western Canada during the Last Deglaciation

Dr. Christopher Darvill [1]***, Prof. Brian Menounos*** [2]***, Prof. Brent Goehring*** [3]***, Prof. Alia Lesnek*** [4]

1. *The University of Manchester,* ***2.*** *University of Northern British Columbia,* ***3.*** *Los Alamos National Lab,* ***4.*** *Queens College, CUNY*

The Cordilleran Ice Sheet in western North America was of comparable size and topographic setting to the modern Greenland Ice Sheet and exhibited similar dynamics. Ice streams channelled rapid flow and the western ice margin terminated in both marine and terrestrial environments. Reconstructing Cordilleran Ice Sheet retreat can therefore provide a helpful analogue for how the Greenland Ice Sheet may respond to changing climate and underlying topography in the future. Moreover, deglaciation in this region controlled routes available for early human migration into the Americas. Here, we present cosmogenic ^{10}Be nuclide exposure ages from glacial erratics and bedrock on the west coast of British Columbia (53.4°N, 129.8°W) that add to existing chronologies along ~600 km of coastal North America. Collectively, these data show deglaciation back to the present coastline by *ca.* 18–16 ka. Retreat then slowed and ice seemingly stabilised close to the present coastline for several thousand years until *ca.* 14–13 ka. Ice may still have been lost during this period of relative stability, but through vertical thinning rather than lateral retreat. We attribute initial retreat to destabilisation and grounding line retreat resulting from rising sea level and/or ocean warming in the northern Pacific. Subsequent stability at the present coast was likely due to the transition from marine to terrestrial margins despite increasing temperatures that may have driven ice sheet thinning. Hence, we show the importance of understanding both climatic and non-climatic drivers of ice sheet change through time. We also show that hundreds of kilometres of coastline were free of ice prior to an important period of early human migration into the Americas.

Shelf-edge terminating glaciation offshore of northeast Greenland during the Last Glacial Maximum and timing of initial ice sheet retreat

Prof. Colm O'Cofaigh [1]***, Prof. David Roberts*** [1]***, Dr. S. Louise Callard*** [2]***, Prof. Jeremy Lloyd*** [1]***, Ms. Georgia Ware*** [1]***, Dr. Katharina Streuff*** [3]***, Dr. Torsten Kanszow*** [4]

1. *Durham University,* ***2.*** *University of Newcastle,* ***3.*** *MARUM-Center for Marine Environmental Sciences, University of Bremen,* ***4.*** *Alfred Wegener Institute Helmholtz-Centre for Polar and Marine Research*

The Northeast Greenland Ice Stream (NEGIS) is the largest ice stream to drain the Greenland Ice Sheet (GrIS) today. The ice stream has undergone recent (post 2010) grounding line retreat and ice shelf loss but the longer-term history of the NEGIS, particularly on the adjoining continental shelf is poorly constrained. Marine geophysical data on seafloor geomorphology and acoustic stratigraphy, combined with radiocarbon dated sediment cores allow reconstruction of the maximum extent of the NEGIS at the LGM and the timing of initial ice sheet retreat on the outer continental shelf offshore of northeast Greenland. In this region two major cross-shelf bathymetric troughs, Westwind and Norske troughs, acted as pathways for offshore-directed ice flow across the wide northeast Greenland shelf during the last glaciation. The seafloor geomorphological and acoustic data reveal a range of flow parallel and flow transverse glacial landforms in the outer shelf sections of both troughs. Mega-scale glacial lineations record former streaming flow towards the shelf edge. Flow transverse landforms in the form of grounding-zone wedges record episodic grounding line retreat inshore from the shelf edge and across the outer-mid shelf during deglaciation. Sediment cores from the troughs recovered subglacial tills and grounding-zone proximal sediments overlain by deglacial stratified glacimarine sediments which record ice sheet advance and retreat. Beyond the shelf edge of Norkse Trough the continental slope is characterised by glacigenic debris flows typical of submarine slopes offshore of shelf-edge terminating palaeo-ice streams. Radiocarbon dating of deglacial sediments in the shelf cores indicate that initial post-LGM retreat of the palaeo NEGIS from the northeast Greenland shelf edge was underway relatively early in comparison to some other sectors of the GrIS and that retreat rates across the outer shelf were slow. The dates provide the first direct chronological support for a shelf-edge terminating GrIS offshore of northeast Greenland during the LGM.

Evidence for major British-Irish Ice Sheet expansion during Marine Isotope Stages 4 and 3 and implications for glacial-isostatic adjustment and high relative sea-levels

Prof. James Scourse [1]

1. *Department of Earth and Environmental Sciences, University of Exeter*

The recent integration of terrestrial and marine geomorphological, stratigraphic and geochronological data constraining the maximum advance and retreat dynamics of the last British-Irish Ice Sheet (BIIS) 31,000 to 15,000 years ago (BRITICE-CHRONO Project) highlighted some datasets and observations that could not be readily assimilated or that are anomalous against the weight of the independent evidence. Whilst some of these clearly relate to technical errors in e.g. geochronology, others, together, give clues as to the behaviour of the ice sheet prior to the Last Glacial Maximum (LGM) during the last cold stage. A series of independent datasets are reviewed here that together provide evidence for significant advance(s) of the BIIS prior to the LGM during Marine Isotope Stages (MIS) 4 and 3. These datasets include the timing of significant ice-rafted detritus flux into the adjacent deep northeast Atlantic, clearly indicating a calving margin; cosmogenic rock-exposure age dating of glacially-eroded surfaces in southwest England and in Wales indicating extensive and thick ice, and optically-stimulated luminescence (OSL) dating evidence for glacifluvial/deltaic sand deposition from northwest Lewis (Outer Hebrides). These data relating directly to ice sheet reconstruction are supported by OSL dating of raised beach sequences in southern Ireland, previously interpreted to be interglacial, to MIS 4 and 3. The most significant eustatic lowstand prior to the LGM was during MIS 4, of ~80 m. The elevation of the southern Irish raised beaches implies a glacial-isostatic adjustment (GIA) deflection of 80 m along this coast which equates to minimum ice thicknesses > ~ 400 m. High relative sea-level during MIS 4 and 3 serves to explain the existence of giant erratic boulders around the coasts of Britain, known but unexplained for over 150 years.

Evaluation of the role of the Baltic Sea depression during deglaciation of the last Scandinavian Ice Sheet: a landform-driven investigation

Dr. Izabela Szuman-Kalita [1], ***Dr. Jakub Z. Kalita*** [1], ***Prof. chris clark*** [2], ***Mr. Christiaan Diemont*** [2], ***Dr. Stephen J. Livingstone*** [3], ***Dr. Martin Margold*** [4]

1. Faculty of Geographical and Geological Sciences, Adam Mickiewicz University of Poznań, Krygowskiego 10, Poznań, 61-680 Poland, 2. Department of Geography, University of Sheffield, 3. Sheffield University, 4. Charles University

The landforms left behind by the Last Scandinavian Ice Sheet (SIS) offer an opportunity to investigate the controls on the ice sheet dynamics. The modern-day terrestrial sectors of the last SIS have seen considerable attention by landform and stratigraphic investigations. Due to a lack of bathymetric data in the Baltic Sea, this region has seen a more limited sector-scale investigation despite its geographical importance in understanding SIS dynamics during the last deglaciation. The Baltic depression hosted the extensive Baltic Ice Lake, which has been suggested to have had a considerable control on SIS dynamics, providing an aqueous calving front that may have resulted in a rapid collapse of this ice sheet sector. Both ice sheet scale investigations and regional studies at the southern periphery of the SIS have considered the Baltic depression as a conduit for ice towards the southern ice margin throughout the whole last glaciation. Here, we test these hypothesis by using newly available bathymetric data and peripheral topographic data. These data reveal, for the first time, an extensive landform suite stretching from Denmark (W) to Estonia (E) and southern European coast to Aland Sea (0.3 million km2 region) that allow us to reconstruct the ice dynamic history of the Baltic SIS sector. Landform evidence indicates a complex retreat pattern that changes from lobate ice margins and splaying lineations to parallel MSGL in the deeper depressions of the Baltic Basin. Ice margin still stands on underlying geological structures indicate the likely importance of pinning points during the ice retreat resulting in a stepped retreat pattern. Over the length of the study area we identify broad changes in ice flow geometry, from SE-NW to N-S and back to NW-SE, likely resulted from a migration and reconfiguration of ice divides during deglaciation.

Updating the limits of the postglacial marine transgression along western Hudson Bay in mainland Nunavut and northern Manitoba, Canada

Dr. Isabelle McMartin [1], ***Dr. Michelle S. Gauthier*** [2], ***Ms. Amaris Page*** [1]

1. Geological Survey of Canada, Natural Resources Canada, 2. Manitoba Geological Survey

The revised maximum limit (ML) of the Tyrrell Sea on the western side of Hudson Bay in mainland Nunavut and northern Manitoba provides robust constraints for glacio-isostatic adjustment models and the deglacial history of the region. The new compilation updates previous mapping of ML features, making use of high-resolution digital elevation models (DEM), new field-based observations and digital compilations of supporting datasets (marine deltas and sediments). DEM-extracted median elevations on 1595 features vary from 83 to 242 m asl (±1 m in Nunavut; ±1-15 m in Manitoba) between Churchill, Manitoba, and areas within the Arctic Ocean drainage basin in Nunavut. Regionally, the high values above the median of □140 m reflect the proximity to a former ice-load centre of the Laurentide Ice Sheet (i.e. Keewatin Dome). However, the high elevations >200 m on the west side of Committee Bay are interpreted to result from incursion of the sea into depressed areas during the early phases of deglaciation. In contrast, the particularly low elevations at 82-110 m in inner Wager Bay suggest that remnant ice masses under the Keewatin Ice Divide (KID) prevented incursion of the sea late during deglaciation. Similarly, low elevations at □100 m near Baker Lake indicate that ice remnants blocked invasion of the sea over the last position of the KID, as supported by relatively young ages on marine shells in this area. From Baker Lake, the ML increases westward to 150 m, and southward from 125 m, to 161 m at the Nunavut border and 165-175 m at Seal River, and then decreases to 145 m at Churchill River. These changes are related to contrasting ice loads associated with migration of the KID and/or different configurations and ages of the retreating ice margins. During deglaciation, proglacial lakes were also in contact with the ice margin, namely in the Thelon River basin and in northern Manitoba, complicating the delineation of accurate marine limits. More detailed mapping and additional ages are needed to decipher the location of, and drivers for, the changing marine limits in these areas and relationship with the history of the proglacial lakes.

Deglaciation of the Cairngorm plateau, constrained with in situ cosmogenic 10Be and 14C measurements

Dr. Sam Kelley [1]***, Prof. Graeme Warren*** [2]***, Dr. Nathaniel Lifton*** [3]***, Mr. Cormac O'Brien*** [1]***, Dr. Alice Doughty*** [4]***, Dr. Micheál Butler*** [2]

Highland landscapes in past-glaciated regions often have perplexed Quaternary geologists, as high-elevation exposures of weathered bedrock belie landscapes much older than glacially abraded landscapes found at lower elevations. This juxtaposition of geomorphic regimes is due to one of two scenarios: 1) weathered highland surfaces were nunataks during recent glaciations and underwent sustained sub-aerial weathering, 2) highland landscapes were encased by non-erosive ice during recent glacial periods. These regions are thus interesting targets for geochronology, as information gained from high-elevation sites has the potential to provide limiting constraints on ice sheet thickness, either over the course of a glaciation, if a nunatak existed, or due to thinning during deglaciation, if covered by non-erosive ice. Cosmogenic surface exposure dating is frequently used to constrain spatio-temporal patterns of ice cover, yet landscapes resulting from minimally erosive glacial ice cover, or lacking past ice cover, commonly exhibit apparent exposure ages much older than the timing of regional deglaciation, when using long-lived radionuclides such as ^{10}Be, ^{26}Al, or ^{36}Cl. These apparently 'old' exposure ages are due to nuclide inventories remaining from previous ice-free periods, which have not been removed during subsequent glaciations.

The Cairngorm Massif in central Scotland is a classic example of such a landscape reflecting long-term preservation and subaerial weathering, with numerous tors and blockfields. Previous studies in the Cairngorms, combining geomorphic evidence and paired cosmogenic ^{10}Be/^{26}Al, indicate a landscape preserved beneath non-erosive ice, perhaps for multiple glaciations. However, in situ cosmogenic ^{14}C has a 5.7 ky half-life that renders it most sensitive to deglacial histories only in the last ~20 ka. We use paired ^{10}Be/^{14}C extracted from bedrock and glacial erratic samples collected on the Cairngorm Plateau to investigate the timing of the most recent high-elevation deglaciation. This multi-isotope approach enables constraints on deglaciation timing and allows assessment of potential complex burial/exposure histories during deglaciation. These new measurements will thus constrain deglacial histories at our high-elevation sites, providing insight into ice mass thinning and the spatial pattern of glacial erosion.

From summits to cirques: Deciphering the nature and rate of ice loss from the last Welsh Ice Cap

Mr. Oliver Thomas [1] ***, Prof. PHILIP HUGHES*** [2] ***, Dr. Christopher Darvill*** [2] ***, Dr. Peter Ryan*** [2]

1. *University of Manchester,* ***2.*** *The University of Manchester*

Ice sheets are currently melting at unprecedented rates and through thinning and fragmentation will yield new, peripheral ice caps in the future. Understanding the stability of these peripheral ice caps through ongoing climate change is important for determining future meltwater production, but requires robust reconstructions of the development and demise of similar ice caps in the past. The British-Irish Ice Sheet covered most of Britain, Ireland and the North Sea during the Last Glacial Maximum (LGM), and comprised numerous accumulation centres including a substantial ice cap over Wales. The Welsh Ice Cap decoupled from the main ice sheet during deglaciation at 20-17 ka, with thinning and receding ice exposing upland areas prior to complete deglaciation. Consequently, Wales presents a unique geological testbed for examining peripheral ice cap development and loss: from an ice cap abutting an ice sheet, to separation, thinning, cirque glacier development, and complete deglaciation. However, despite substantial recent advances in our understanding of British-Irish Ice Sheet retreat, the nature and rate of Welsh Ice Cap deglaciation remains limited.

This study presents a compilation of glacial geomorphology from across Wales. We highlight gaps in the geomorphological record for targeted investigation and high-resolution mapping of smaller-scale ice recessional landforms in the future. Our new geomorphological mapping will be used to reconstruct the nature of Welsh Ice Cap retreat and guide a campaign of detailed geochronological work to better understand the rate of ice cap loss through time. Cosmogenic exposure dating of glacial landforms and radiocarbon dating inter-morainal lake/bog sequences will help establish chronological time-steps. Schmidt Hammer exposure dating will provide additional age control and biostratigraphy will also be used as to help subdivide moraine sequences. Improved constraints on the timing and nature of deglaciation in Wales will offer important insights into the development and loss of peripheral ice caps in mountainous areas in the future. Moreover, the response of Welsh ice to Late-glacial climate oscillations (Oldest Dryas, Bølling–Allerød, Younger Dryas) will add to our understanding of Northwest Europe's wider environmental history during the last termination.

Towards a high-resolution palaeo-ice sheet reconstruction on the Antrim Plateau, NE Ireland

Mr. Alex Clark [1], ***Prof. Simon Blockley*** [1], ***Dr. Adrian Palmer*** [1], ***Dr. Bethan Davies*** [2], ***Dr. Sam Roberson*** [3], ***Dr. Magret Damaschke*** [4]

1. Department of Geography, Royal Holloway University of London, London, United Kingdom, 2. Newcastle University, 3. Geological Survey of Northern Ireland, 4. British Geological Survey, Keyworth, Nottingham, NG12 5GG, UK.

Northeast Ireland presents an excellent testing ground for understanding the complex interactions between ice, landscape, and climate at the confluence of multiple major palaeo-ice streams. A combination of sea level rise, tidal forces, ice divide and thaw point migration, sea-surface temperature rise, and ice over-extension drove the collapse and demise of the Irish Sea, North Channel, and Malin Sea ice streams from c. 23-16 ka BP. However, even the most recent empirical and model British-Irish Ice Sheet reconstructions fail to capture the spatiotemporal complexity of their final demise. These reconstructions are hindered by relatively low-resolution glacial landform mapping and an absence of robust, precise chronologies, both in the onshore and offshore realms of NE Ireland. Consequently, this challenges our ability to constrain palaeo-ice sheet and ice stream retreat and terrestrial deglaciation over a substantial area, inhibiting out ability to understand the atmospheric, oceanic and dynamical factor driving mass balance changes.

This project aims to reconstruct palaeo-ice sheet dynamics on the Antrim Plateau (Northern Ireland) using high-resolution geomorphology and multiproxy chronostratigraphy. We seek to produce the first comprehensive combined tephrochronological and cosmogenic nuclide chronological framework to improve understanding of ice dynamics in NE Ireland. Geomorphological mapping on the Antrim Plateau using a 0.4 m resolution digital surface model is providing unprecedented detail on the nature of ice retreat. Our newly mapped ice limits challenge previous assumptions about the nature and extent of a Scottish readvance. The identification of widespread hummocky, kettle-kame topography provides insights into a large, stagnating ice mass on the plateau. Finally, with such high-resolution imagery, we can evaluate evidence for a (semi-)independent ice cap in the Antrim Hills, which could provide yet more insights into the influence of climate and ice dynamics at much smaller scales.

This presentation will display initial geomorphological mapping of the Antrim Plateau, including ~8,000 individual landforms and new ice margin interpretations. It will also provide discussion points on the future chronological work we aim to carry out as part of this project in order to produce a high-resolution ice sheet reconstruction on the plateau.

Ice-flow reconstruction and deglacial patterns in the west-central Keewatin Sector of the Laurentide Ice Sheet (Northwest Territories and Nunavut, Canada)

Dr. Etienne Brouard [1]***, Ms. Janet Campbell*** [1]***, Dr. Isabelle McMartin*** [1]***, Dr. Pierre-Marc Godbout*** [2]

1. Geological Survey of Canada, Natural Resources Canada, 2. Geological Survey of Canada

Reconstructions of the evolution of the Laurentide Ice Sheet (LIS) since the last glacial maximum (MIS2; <29 ka) provide a framework for understanding changes in ice extent and dynamics that are essential to a wide range of studies such as paleogeographic reconstructions, glaciological and glacial isostatic adjustment modeling, sea-level changes, ice-dammed lakes reconstructions, and mineral exploration. The LIS was comprised of three major domes located in northern remote regions of Canada that until recently, have not been the focus of extensive field studies and therefore, knowledge gaps remain. The Keewatin Dome formed one of these major domes and was located in Northwest Territories and mainland Nunavut (Canada) where recent work suggests complex glacial history resulting from ice divide migration, ice streaming, and landscape preservation over multiple glacial events. Yet, these landsystems remain mostly unmapped and undated, and therefore uncorrelated at the regional scale. To address this lack of regional knowledge on glacial history and building on a new compilation of glacigenic features and landsystems in eastern Keewatin (McMartin et al., 2021), an activity has been initiated as part of Canada's Geo-Mapping for Energy and Minerals (GEM) GeoNorth program (2021-2026) to provide a glacial geology framework for the west-central Keewatin region supported by targeted field investigations and high-resolution digital mapping. Here, we present preliminary results from the compilation and mapping activities showing how ice flow was organized around the ice divides and how it evolved during deglaciation. This high-resolution mapping also unveiled a suite of ice-marginal landforms (moraines, channels, spillways) that reveal the local ice retreat patterns and their implication in the development of glacial lakes. These preliminary interpretations will guide fieldwork investigations which will aim at collecting targeted geochronology (terrestrial cosmogenic, luminescence and radiocarbon) samples to support the refinement of known deglacial chronologies.

McMartin, I., Godbout, P.-M., Campbell, J.E., Tremblay, T., and Behnia, P., 2021. A new map of glacigenic features and glacial landsystems in central mainland Nunavut, Canada. Boreas 50, p. 51–75. doi:10.1111/bor.12479

Vegetation and hydrological reconstruction in the Makgadikgadi paleolake during the Cenozoic using biomarkers

***Dr. Julie Lattaud* [1], *Dr. Liviu Giosan* [2], *Ms. Nicole Russo* [1], *Prof. Timothy Eglinton* [1], *Dr. Zhixiong Shen* [3], *Dr. Niteshkumar Khonde* [4], *Dr. Florin Filip* [5], *Dr. Cindy De Jonge* [1]**

***1.** Geological Institute, ETH Zürich, **2.** WHOI, **3.** Coastal Carolina University, **4.** Birbal Sahni Institute of Paleosciences, **5.** University of Bucharest*

Understanding long-term climate change (Miocene to present) in Southern Africa is crucial to explain past hydrological variability in the region, but also to better predict future environmental changes. For example, during the warm Pliocene epoch, the pCO_2 was ~400 ppm and this region has been modelled to be wetter than present (dense vegetation and numerous lakes, Burls and Fedorov, 2017). This is in stark contrast to what has been forecasted by the current models (IPCC report 2014). The Makgadikgadi paleolake system (Northern Botswana) is centrally located, within a key region for understanding African vegetation history and the collapse of forest and woodland vegetation during the long process of Neogene aridification. A combined climate and vegetation study can elucidate the drivers in climate and vegetation change over the Cenozoic.

To reach this aim, we will reconstruct paleoenvironmental conditions (e.g., vegetation, aridity, soil input) in and around the Makgadikgadi Paleolake, where a 207 m-long sediment core was retrieved in 2022 (funded by an USA-NSF INTEGRATED EARTH SYSTEMS Collaborative Research and an ETH research grants). Specifically, we will target biomarker lipids, that are molecular remnants of bacteria, archaea, phytoplankton, plants and animals. Their structural diversity and isotopic composition can be related to the environmental condition in which their biological source organisms were growing. Following erosion of surface soils or settling from the water column, and incorporation in the sediments, these lipids constitute a part of the geological archive that allows to reconstruct unique biological processes. In particular, we will present data (of 50 samples) from branched GDGTs as indicator of temperature and soil aridity, archaeal membrane lipids as an indicator for salinity, as well as long-chain fatty acids to trace changes in vegetation in the catchment, and their specific isotopes to reconstruct changes in vegetation, precipitation and lake evaporation. We will frame this climate reconstruction in a preliminary age model.

Palaeoenvironments of the Cape Floristic Region: New research & current developments

Dr. Lynne Quick [1]***, Dr. Saúl Manzano*** [2]***, Dr. Marc Humphries*** [3]***, Dr. B. Adriaan Grobler*** [1]***, Dr. Manuel Chevalier*** [4]***, Prof. Michael Meadows*** [5]***, Dr. Phumelele Gama*** [6]***, Dr. Brian M. Chase*** [7]

***1.** African Centre for Coastal Palaeoscience, Nelson Mandela University, **2.** Área de Botánica, Dept. The Cape Floristic Region (CFR) is a key focus area within southern Africa due to its botanical importance in terms of high levels of biodiversity as well as its rich cultural and archaeological heritage. The area is highly sensitive to cycles of regional and global environmental change, and records obtained from the region provide valuable information regarding past climate variability. Prior to the last decade, few high resolution palaeoenvironmental records were recovered from the region, and its environmental history remains relatively poorly understood. This presentation summarises the research initiatives currently being undertaken by Nelson Mandela University's Palaeoecology Laboratory. This ongoing work aims to provide a comprehensive understanding of climate, biodiversity and human-environment interactions within the CFR, with a particular focus on the understudied eastern subregions.

The records presented are derived from unique natural archives found within the CFR including rock hyrax middens and coastal lowland wetland deposits. These archives are being analysed within a multi-proxy, multidisciplinary framework, using pollen, fungal spores, micro- and macrocharcoal, diatoms and geochemistry to elucidate changes in vegetation, herbivory, fire, hydrology and climate.

This work is designed to actively develop regional capacity, using the new Palaeolab and engage students and early career scientists from the area to contribute to the development of fundamental knowledge regarding their environment and history.

Climatic and Cultural Dynamics in West Africa's Sahel: a view from Surame, Nigeria

Mr. Aliyu Adamu Isa [1]

1. *Ahmadu Bello University, Zaria*

The development of large settlement mound complexes in parts of the West African Sahel in the early 1st millennium AD is seen as related to a more favourable climatic condition. Rainfall in the Sahel was much higher by that time. By the first half of the 2nd millennium AD, massive site abandonment was interpreted to have resulted from increasing aridity. Growing evidence suggest that in central West Africa, the fifteenth century AD saw the rise and/or expansion of states and empires, major shifts in settlement patterns, and growth of new trading connections between the forest and Sahel. This presentation responds by using excavations of two trenches (2 X 3 metres and 3 X 3 metres) of Surame's deposits to document and explore culture as an adaptive system, in the patterns of continuity and change in subsistence behaviour. Surame covers approximately 1, 214 hectares with its gateways within the inner and outer settlement walls, and numerous circular and rectangular surface structures which occur both singly and in groups.

Tracing the impact of Walker Circulation changes on pan-African climate variability during the past 550,000 years using proxy and model results

Dr. Stefanie Kaboth-Bahr [1], Prof. Neil Edwards [2], Dr. Philipp Holden [2], Prof. William Gosling [3]

1. University of Potsdam, Institute of Geosciences, Potsdam, Germany, 2. The Open University, Leverhulme Center of Climate Mitigation, Milton Keynes, United Kingdom, 3. University of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics, Amsterdam, The Netherlands

Spatio-temporal changes in the strength of the Walker Circulation, a belt of tropical convection cells along the equator, have been recently proposed as a predominant driver of pan-African climatic variability on quaternary time scales. These changes are thought to be strongly influenced by variability in the Earth´s orbital ellipse (i.e., eccentricity cycle) which varies on time scales of c. 400,000 and c. 100,000 years. This newly developed, tropically based, climate framework provides a new basis for understanding past vegetation change and testing hypotheses regarding hominin evolution, development, and the dispersal across the African continent. Insights into past Walker Circulation changes have thus far been exclusively gleaned from the small number of marine and terrestrial proxy records that detail Africa´s climate history over 100,000 of years. Therefore, to explore the spatio-temporal coherence of the Walker circulation variability framework across Africa this study aims to: (i) compare these proxy record results with output from an intermediate complexity Atmosphere–Ocean Global Climate Model (GENIE-PLASIM) during the past 550,000 years to reconstruct spatio-temporal changes in the Walker Circulation, (ii) elucidate potential driving mechanisms of Walker circulation changes through time and space, and (iii) assess the potential impact of these Walker Circulation changes on pan-African moisture availability and vegetation changes. The latter might provide new insights into the availability of resource-rich and stable ecotonal settings, thought to have been important to early modern humans, during the Middle and Late Pleistocene.

Towards Deep Drilling in the Turkana Basin (DDTB): Tracking the Environmental Forces Driving Hominin Evolution

Dr. Verena Foerster [1]***, Prof. Catherine Beck*** [2]***, Dr. Melissa Berke*** [3]***, Prof. Craig S. Feibel*** [4]***, Dr. Anders Noren*** [5]***, Prof. Lydia A. Olaka*** [6]***, Prof. Helen M. Roberts*** [7]***, Prof. Christopher Scholz*** [8]

Sci., USA,* ***6.*** *University of Nairobi, Department of Geology, Kenya,* ***7.*** *University of Wales at Aberystwyth, Institute of Geography And Earth Sciences, UK,* ***8.*** *Syracuse University, Department Of Earth Sciences, USA*

The Turkana Basin (TB), Kenya, in the East African Rift System (EARS) provides an unparalleled opportunity to recover a continuous and high resolution 4 Ma record of the Earth-life system through scientific drilling. This archive will be unique as it **a)** tracks the tectonic and magmatic development of the TB and EARS, **b)** constrains controls on regional climate and hydrological responses, **c)** links dynamics of faunal/floral communities and cultural development with environmental parameters, **d)** spans the range of hominin evolution from ~4 Ma to present, and **e)** covers the interval of significant hominin technological (i.e. stone tool) development. The Deep Drilling in the Turkana Basin (DDTB) project aims to recover a novel, long sedimentary record to minimize the impact of spatial paleoenvironmental variability on paleoclimatic and tectonic reconstructions, and provide insight into the sequence and significance of climate and environmental change over the last 4 Ma in this key paleoanthropological locality. The project will significantly advance existing paradigms surrounding rift development, climatic and environmental change, and the evolution of hominins and their associated ecosystems.

Here we present the outcomes of our ICDP-funded scientific drilling workshop, held in July 2022 in Nairobi, highlighting the communities' need for a record that will address questions in the four topical core areas: paleoclimate, paleoenvironment, basin evolution, and modern lake systems. The proposed two-phase scientific drilling campaign will facilitate the retrieval of long cores in an onshore transect in West Turkana that will comprise 4 Ma –750 ka and a series of offshore cores from the modern lake covering the last 750 ka BP. Together these records will complement and leverage previous outcrop and core investigations, fill critical gaps in existing paleorecords, and enable a more complete integration of environmental records with the unique evolutionary archive of the basin.

Terrestrial ecosystem change during critical periods of early hominin evolution in SE Africa over the past 4 Ma

Mr. Laurin Kolb [1], ***Dr. Andreas Koutsodendris*** [1], ***Dr. Melissa Berke*** [2], ***Dr. Audrey Taylor*** [2], ***Prof. Jörg Pross*** [1]

1. Institute of Earth Sciences, Heidelberg University, Heidelberg, Germany, 2. University of Notre Dame

To study the nature and tempo of terrestrial ecosystem change in SE Africa during critical periods of hominin evolution in the Plio/Pleistocene we have generated a continuous environmental and climate record for the region spanning the past 4 Ma at an orbital-scale resolution (c. 15 kyrs). This record is based on multi-proxy analyses from IODP Site U1478 (Mozambique Channel), which is a sensitive recorder of sedimentological changes in the Limpopo River catchment area of SE Africa. To gain insight into vegetation variability we generated palynological and plant wax-derived carbon isotope ($\delta^{13}C$) data, and performed pollen-based climate reconstructions. We subsequently compared our datasets with available X-ray fluorescence core scanning data, TEX_{86}-based sea-surface temperatures and plant wax-derived δD_{wax} from the same core as well as other regional and global climate records, providing the background boundary conditions for hominin evolution in SE Africa since the Pliocene. Our record reveals a dominance of savanna (including Poaceae) and fynbos-like heathland (including Cyperaceae) biomes during the past 4 Ma. The data suggest alternating vegetation states, with glacials being dominated by fynbos-like heathland and interglacials by savanna. Additionally, we record a long-term trend of decreasing savanna and increasing fynbos-like heathland pollen abundances starting at around 2.8 Ma. Pollen-independent evidence for vegetation change at 2.8 Ma is provided by the increase of high (^{13}C enriched) carbon isotope values indicating an expansion of arid-adapted C_4 plants. This ecosystem turnover is associated with a slight decrease in reconstructed annual precipitation (from ~750 to ~700 mm) and a strong sea-surface temperature decline in the SW Indian Ocean by 4°C. The timing of ecosystem change suggests a connection to the intensification of the Northern Hemisphere Glaciation during the late Pliocene. We propose that the atmospheric CO_2 decrease during the late Pliocene facilitated the expansion of C_4 plants and fynbos-like heathlands without a significant decrease in precipitation. The considerable terrestrial ecosystem change in SE Africa at around 2.8 Ma may have been crucial for the evolution of early hominin species (e.g., *Australopithecus africanus*) in southern Africa.

The role of tropical climate systems in driving humidity during the African Humid Period

Prof. William Gosling [1] ***, Dr. Manuel Chevalier*** [2] ***, Dr. Sarah Ivory*** [3] ***, Dr. Stefanie Kaboth-Bahr*** [4]

1. *University of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics, Amsterdam, The Netherlands,* ***2.*** *University of Bonn,* ***3.*** *Penn State University,* ***4.*** *University of Potsdam, Institute of Geosciences, Potsdam, Germany*

The African Humid Period (AHP; c. 14,800 to 5,500 years ago) was characterized by elevated lake levels and shift towards moisture loving vegetation across much of Africa. The pattern of increased moisture availability during the AHP is, however, spatially and temporally variable and the climate mechanism(s) and feedback driving these changes remain ambiguous. In this study, we hypothesize that changes in the Walker Circulation system, driven by shifts in tropical Pacific sea surface temperatures, modulated the delivery of moisture across Africa and drove the spatial and temporal patterns observed during the AHP. To test this hypothesis, we extracted past climate change information from 16 pollen records from across Africa spanning the last c. 20,000 years and compared these records to the patterns of moisture balance change obtained from independent sea surface temperature records. Pollen records were extracted from the African Pollen Database within the Neotoma Paleoecology Database and were plotted against time using the dating control points provided by the original authors to create new standardized chronologies. The signal of past climate change from the individual records is characterized using two approaches, through: (i) the signal of past climate change from individual records, and (ii) performing probabilistic climate reconstructions (CREST; Climate REconstruction SofTware). Comparison between the past climate change reconstructions from Africa and the sea surface temperature records was achieved by performing a Principal Components Analysis. Our analysis identified an east to west gradient in the timing of the AHP as would be anticipated from changes driven by shifts in the Walker Circulation, however, sub-regional variations in the timing and direction moisture availability change were also evident. This highlights the importance of considering local conditions, as well as global climate factors, when interpreting individual records of past climate change in Africa.

Coastal lithofacies appraisals of Quaternary sequences in Dahomey Basin, southwestern Nigeria: implications of the granulometrical, palynological and isotopic studies

Prof. Olugbenga Boboye [1]

1. *University of Ibadan*

An appraisal of the Quaternary sediments were carried out using ditch samples retrieved from drilled wells at three different locations in Lagos area. This is to evaluate the provenance, depositional environment, maturity and palaeoclimatic changes.

A total of forty two samples (sandstones) were used for the granulometric analysis, fifteen for heavy minerals and petrographic analysis, nine for palynological analysis, twelve pebbly conglomerates for morphometric studies and mollusk shells for isotopic study.

The results show medium to very coarse grained, moderately sorted to very poorly sorted (dominantly poorly sorted), strongly positive skewed to near symmetrical and very platykurtic to extremely leptokurtic indicative of river laid sediments suggesting high to low energy transporting medium. The heavy mineral assemblage is characterized by zircon(Z), tourmaline(T), rutile(R), garnet, epidote, staurolite, apatite and sillimanite suggesting igneous and metamorphic provenance. The average ZTR index is 53.9%, indicating texturally immature sediments. Petrographic results show the most abundant mineral (quartz) ranged from 90% to 95%.The QFR ternary plots suggest predominantly supermature quartz-arenites. Palynomorphs recovered from the wells show abundance of mangrove swamp forest palynomorphs including *Rhizophora* sp., *Avicennia africana* and *Acrostichum aureum* inferring marine deposit in a tidal swamp shoreline environment inhabited by mangroves community indicative of high sea level.

The occurrence of freshwater swamp forest species include *Arecidites* sp., *Mitragyna ciliata, Uapaca* sp. and *Botryococcus* sp. suggest mangrove dominated environment with high influx of freshwater. Pebble morphometric studies show littoral setting and the ratio of maximum projection sphericity and oblate prolate index suggest fluvial environment. The pebble forms are dominantly compact and compact bladed which further corroborate fluvial process. The oxygen(δ^{18}O) and carbon(δ^{13}C) isotope composition of the bivalves (gastropod) from Lekki well ranged from -4.93‰ to -2.94‰ VPDB (mean= -4.22‰) and -10.35‰ to -3.71‰ VPDB (mean= -7.43‰) respectively while Apapa well (shell fragments) revealed δ^{18}O values of -2.48‰ and -2.19‰ VPDB, δ^{13}C values of -3.27‰ and -1.96‰ VPDB. The results show positive correlation between oxygen and carbon isotopic compositions suggesting seasonal climate changes might influence carbon sources to some extent; however the estimated formational palaeotemperature was determined varying from 28.93^{o}C - 40.82^{o}C.

Keywords: Quaternary, palynomorphs, isotope, palaeoclimate, palaeotemperature

Late Holocene vegetation and climate of Wonderwerk Cave, South Africa, from charcoal

Ms. Busisiwe Hlophe [1]***, Prof. Marion Bamford*** [2]

1. *Evolutionary Studies Institute, University of the Witwatersrand, Johannesburg, South Africa,* ***2.*** *University of Witwatersrand, Johannesburg*

The Wonderwerk Cave represents one of the rare cave sites in the arid interior of southern Africa that preserve multiple palaeoclimate indicators, such as pollen, charcoal, and phytoliths. Despite the large amount of charcoal excavated from the Holocene strata, pollen has been the most used indicator for Holocene environmental conditions. Pollen is less spatially precise compared to charcoal, hence this study is aimed to reconstruct the palaeoclimate of the area around the Wonderwerk Cave during the late Holocene by studying charcoal from one of the Late Holocene strata, Stratum 2b, which records the time between 2.3- 0.5 ka cal BP. The second aim of this study is to infer the human-plant interactions that were happening at that time. To do this, a sample of 50 charcoal fragments was studied, the wood they originate from identified, and climate and human-plant interactions inferred from the woody species identified. The sample was found to be dominated by shrubs or small trees that can tolerate dry environmental conditions, such as *Ozoroa paniculosa, Searsia lancea, Brachylaena huillensis, Commiphora sp., Maytenus undata, Olea europaea* subsp. *africana* and *Ziziphus mucronata.* This indicates that the environment was mostly dry. However, the presence of taxa that tolerate wetter environments such as *Heteropyxis natalensis, Olinia ventosa,* and *Berchemia discolor* suggests that rainfall patterns may have been variable. The presence of taxa that commonly grow near river banks suggests that there may have been a water source nearby, similar to Boesmansgat found 15 km from the cave. Overall, the results indicate a semi-arid climate and an open bushveld with a grassy layer, and small woody plants that enabled the humans occupying the Wonderwerk Cave to harvest wood, fruits, and medicine from them.

The scar of migration: sourcing for material evidences

Prof. Adisa Ogunfolakan [1]

1. *AG LEVENTIS MUSEUM OF NATURAL HISTORY MUSEUM*

The nature, environment and climatic changes pushed and pushing man to migrate and change environment. In Africa and indeed in the Yorubaland of Southwestern Nigeria this migration left scars of movement in the material and non-material culture.

This paper presentation in poster identified series of evidences of migration and abandonment and concludes that at various time in the history of man, movements occurred and lefts evidences of the time and life of the people.

A pan-African spatiotemporal framework of the past one million years using advanced multi-record time-series analysis

For several decades, eastern Africa was considered the origin of*H. sapiens*, documented by the oldest fossil finds from Omo Kibish (233±22 ka BP) and Herto (160–154 ka BP), from where the species was thought to have spread across the rest of the continent and beyond. Recent finds of human fossils and related stone tools in several parts of Africa between roughly 315–75 ka ago, i.e. Jebel Irhoud, southern Africa, Arabia, and eastern Africa initiated a lively discussion of a multiregional model of the origin and development of *H. sapiens.* The chronology and diversity of human fossils and archaeological remains, associated with a pan-African cultural patchwork, are underpinned by the availability of suitable and connected environments offering enough resources for our species to survive and reproduce. As new paleoanthropological research expands into poorly understood regions of Africa, the key to understanding emerging patterns of mobility and dispersal within and out of Africa is strongly linked to accurately reconstructed climate and environmental conditions in time and space. Here, we aim to create a spatiotemporal paleoclimatic framework for testing current hypotheses about a multiregional origin of our species. To do so, we collect and review suitable climate archives that cover the time since the Mid-Pleistocene Transition, the Mid-Bruhnes Event, and the late Pleistocene. Prerequisites for site selection are: (1) an age model without major gaps, (2) proxy data with a sufficient temporal resolution, precision, and accuracy, (3) a good understanding of the mechanisms that are represented by the proxy data, and (4) together they offer good geographical coverage of Africa's most important climates. We compare records using correlation analysis, such as windowed Spearman correlation, principal component analysis, fast Fourier transformation, and wavelet-based cross-spectral analysis. Furthermore, we analyze long-term trends, shifts, and transition types, that may have provided a catalyst for evolutionary changes, cultural innovation, and expansion/ migration, using e.g. breakfit regression, running Mann-Whitney and Ansari-Bradley test, and recurrence-based transition tests, such as recurrence quantification and recurrence networks. Here, we show the first results of our experiments.

Late Holocene Palaeoecology of Rainforest Reserve Sites

Dr. Emuobosa Orijemie [1]

***1.** University of Ibadan, Nigeria*

The knowledge of environmental history of the tropical rainforests during the last Late Holocene is critical to addressing tropical biodiversity and climate change challenges. While that knowledge is increasingly becoming available in other tropical areas, such evidence of the Late Holocene environmental history of the tropical rainforests in Africa, from terrestrial sources in particular, is limited. Using palaeoecology and archaeological records from rainforest reserves (Okomu National Park and International Institute for Tropical Agriculture (IITA) forest reserve) in Nigeria, we reconstruct past climatic and environmental changes in the rainforests with attention on the response(s) of the rainforests to natural and anthropogenic impact. The pollen, sedimentology and archaeological data revealed three contrasting temporal environmental phases namely I, II and III. Phase I (*c.* 2000 BP- *c.* AD 1200) was characterised by a warm tropical rainforest that consisted of lowland rain forest, mangrove swamp and freshwater swamp forests, freshwater and fern communities; Phase II (*c.* AD 1200-*c.* AD 1700) witnessed marked decline in the rainforest in both sites, but grasslands increased at the IITA signaling the possible occurrence and severe nature of some dry climate. In the third phase III (*c.* AD 1700-Present), the rainforest became re-established; however, the appearance of the pollen of economic plants and herbaceous taxa associated with vegetation disturbance revealed the significant impact of humans. The data from the two sites documented the resilience and magnitudes of human impact on the rainforest and highlight the potentials of using palaeoecology in managing and addressing ecological restoration
Keywords: Palaeoecology, Forest reserves, Human Ecology, environmental history, West Africa

A multi-proxy paleoenvironmental reconstruction from the southeastern Ethiopian highlands during the Late Quaternary, as recorded in the sediments of Lake Haramaya

Mr. Bahru Zinaye Asegahegn [1], ***Prof. Frank Schaebitz*** [2], ***Prof. Asfawossen Asrat*** [3], ***Prof. Henry F. Lamb*** [4], ***Prof. Helen M. Roberts*** [5]

1. *Graduate School of Geosciences, University of Cologne, Germany | School of Earth Sciences, Addis Ababa University, Addis Ababa, Ethiopia,* ***2.*** *University of Cologne, Institute of Geography Education, Cologne, Germany,* ***3.*** *Department of Mining and Geological Engineering, Botswana International University of Science and Technology, Palapye, Botswana | School of Earth Sciences, Addis Ababa University, Addis Ababa, Ethiopia,* ***4.*** *Department of Geography and Earth Sciences, Aberystwyth University, Aberystwyth, UK | Botany Department, School of Natural Sciences, Trinity College Dublin, Dublin, Ireland,* ***5.*** *Department of Geography and Earth Sciences, Aberystwyth University, Aberystwyth, UK*

Eastern African paleoenvironment is highly variable and influenced by global scale phenomena (e.g., changes in solar radiation due to orbital parameters) and by local and regional topography, i.e., the East African Rift System which bisects the Ethiopian highlands. Here, we present the first multi-proxy analyses of a 27 m long sediment core from Lake Haramaya, a highly fluctuating lake located on the Southeastern Ethiopian highlands, at an altitude of ~2000 m above sea level. Based on the sedimentation rate calculated from a dated short core in the basin, we assume our sediment core might cover the last ~100,000 years an important period of human dispersal within and out of Africa.

Geochemical proxies from ITRAX XRF scans, grain size analysis and concentration of total organic and inorganic carbon and nitrogen have been used for reconstructing the palaeoenvironment of the basin. Ca/Ti ratio is used as a reliable proxy for aridity, complemented by an inverse relationship with Rb/K ratio which is an often-used proxy for chemical weathering.

Lake Haramaya shows two distinct drier periods during which a carbonate dominated sediment was deposited. These extended dry periods were preceded and succeeded by unstable, relatively wetter periods during which silicate rich, sandier silty-clay, clastic sediments were deposited. These long-term dry and wet periods were interrupted by shorter scale minor fluctuations, identified in other proxies (such as Rb/K & K/Zr) beyond that of the Ca/Ti ratio.

Our results will help provide the environmental context to the human cultural change during the Middle and Later Stone Age, which are recorded from the nearby archeological sites (e.g., Goda Buticha & Porc Epic). The highland location of Lake Haramaya at the edge of the Main Ethiopian Rift and the Afar Depression adds further significance to the lake records, making them ideally suited to testing the refugium hypothesis.

Efficient identification of cryptotephra in marine sediment cores; a non-destructive approach

Dr. Jenni L Hopkins [1], ***Ms. Madison Clarke*** [1], ***Dr. Shaun Eaves*** [1], ***Ms. Janine Bidmead*** [2], ***Ms. Charlotte Pizer*** [1], ***Dr. Jamie Howarth*** [1], ***Dr. Alan Orpin*** [3], ***Ms. Grace Frontin-Rollet*** [3], ***Dr. Richard Wysoczanski*** [3]

Volcanic eruptions have punctuated New Zealand's geologic history for millions of years. Evidence of many of these eruptions occur as distal macroscopic tephra deposits found in deep marine sediment cores, often many hundreds of kilometres from source. As such, these macroscopic tephras likely provide evidence of only the largest eruptions, potentially introducing a preservation bias in the record. The recent development of cryptotephra identification, concentration, and quantification methods are allowing an increasingly detailed picture of volcanic activity to be uncovered.

Here we present a new method for identifying cryptotephra using non-destructive techniques (XRF, magnetic susceptibility, density) coupled with statistical, machine-learning techniques. Data collected from down-core scans are modelled to quantitatively discriminate and characterise the macroscopic tephra then, unsupervised machine-learning (e.g. Principle Component Analysis, PCA) and statistical techniques are used to identify potential cryptotephra within the dataset. New results generated during this period of method development have been applied to both targeted core sections, and full cores. Previously unidentified cryptotephra deposits have been isolated, characterised and used to further refine the code (developed in R statistical language) and unsupervised machine-learning approach. With the addition of detailed chronology for the cores (through radiocarbon dating), we comment on the timing of the volcanic events identified and the longevity of elevated tephra inputs (volcanic activity) into the marine sedimentary environment.

One-year record of drift pumice from the 2021 Fukutoku-Oka-no-Ba eruption, Japan, focusing on the amount, size, shape, and attached organism

Dr. Daisuke Ishimura [1]

1. *Tokyo Metropolitan University*

On 13 August 2021 (UTC+9), an eruption occurred at Fukutoku-Oka-no-Ba, a submarine volcano in the Ogasawara Islands (Bonin Islands). The eruption lasted for three days, with an estimated volcanic explosivity index of 4 and 0.1 km^3 of drifting pumice (AIST, 2021). As noted by Bryan et al. (2012), pumice drift associated with submarine volcanic eruptions has been recorded worldwide and is suggested to contribute to the spread of marine organisms. On the other hand, large-scale pumice drift in the present could be a disaster, causing damage to ship navigation and port facilities. Monitoring of such pumice rafts is possible if the area of the pumice raft is large enough to be seen on satellite images. However, once they have spread to some extent, their amount and locations become unknown, and it is difficult to track them by the time they drift ashore. Therefore, in this study, we conducted unprecedented drift pumice tracking on an island-arc scale (Japanese Islands). We analyzed samples collected on coasts mainly in the Japanese Islands during the first year after the eruption, focusing on the amount, size, and shape of pumice clasts that drifted ashore. We found that the amount and size of drift pumice decreased rapidly with time, indicating offshore diffusion and size decrease due to breaking and abrasion. Furthermore, we could record the variety and amount of attached organisms with time. In the future, we will revisit the coasts and observe the preservation process of pumice clasts washed ashore in order to discuss whether drift pumice layers in sediments show the age of eruption or not.

Characteristics and source volcanoes of drift pumice along the Pacific coast on the central to west of the Japanese Islands based on major element composition of volcanic glass shards

Ms. Reona Hiramine [1], ***Dr. Kaori Aoki*** [1], ***Dr. Daisuke Ishimura*** [1], ***Prof. Takehiko Suzuki*** [1]

1. *Tokyo Metropolitan University*

In Japan, drift pumice clasts are found on most coasts despite no recent volcanic eruptions supplying pumice to the sea since before the 2021 Fukutoku-Oka-no-Ba (FOB) eruption. The FOB, a submarine volcano in the Ogasawara Islands (Bonin Islands), erupted on August 13, 2021, and numerous pumice clasts supplied to the sea were washed up on coasts in the Japanese Islands (Yoshida et al., 2022). Such extensive pumice drift is a low-frequency event among volcanic eruptions (Bryan et al., 2012). In this study, to clarify the source volcano and to discuss their supply and transport processes during no volcanic eruptions supplying pumice to the sea, we analyzed the major element composition of volcanic glass shards in drift pumice clasts.

We analyzed the pumice clasts (50-228 clasts per site) sampled at five coasts facing the Pacific Ocean from September 2018 to August 2019, that is to say, before being influenced by the 2021 FOB eruption and 20 tephras formed by past large terrestrial and submarine volcanic eruptions for reference. As a result, it is clarified that the source volcanoes of some drift pumice clasts are Aira caldera, Towada volcano, FOB, and submarine volcano NNE of Iriomotejima. The occurrence of the Aira-Tn tephra erupted from the Aira caldera (ca. 30 ka) formed wide pyroclastic flow plateau in the southern part of Kyushu Island (Machida and Arai, 2003). Therefore, we interpreted that reworking process of pyroclastic flow deposits is one of the major mechanisms of the continuous supply of pumice into the sea, regardless of whether volcanic activity continues or not. Besides, the presence of drift pumice from the Submarine Volcano NNE of Iriomotejima 1924 eruption (Seki, 1927) and the 1986 FOB eruption (Kato, 1988) suggests that pumice clasts from a single submarine volcanic eruption can remain on the coast for at least several tens to a hundred years. Meanwhile, the sources of many drift pumice clasts are still unknown, thus, their sources may be terrestrial volcanoes located out of the Japanese Islands and/or from unknown submarine volcanoes.

A challenge to establish a Late Pleistocene tephrostratigraphy focusing on cryptotephras within wetland sediments in Quaternary volcanic region, Central Japan

Mr. Tatsuki Watanabe [1], ***Dr. Daisuke Ishimura*** [1], ***Prof. Takehiko Suzuki*** [1]

1. *Tokyo Metropolitan University*

Establishing precise tephrostratigraphic framework is essential for reconstructing volcanic eruptive histories and crucial time-markers for geochronological studies. Recently, cryptotephra studies have developed and increased the value of tephrochronology (e.g., Lane et al., 2013). However, cryptotephra detection has difficulties caused by bioturbation, secondary deposition, etc. (e.g., Davies, 2015). Especially in volcanic regions such as the Japanese Islands, secondary deposition of tephra-derived volcanic glass shards hides primary tephra fall horizons. Although Lake Suigetsu with an ideal sedimental environment preserves cryptotephra in varve sediment, volcanic glass shards of Kikai-Akahoya tephra (K-Ah, 7.3 ka, derived by caldera forming eruption) have reworked upward several thousand years after primary deposition, causing challenge to detect other cryptotephra horizons (Mclean et al., 2018).

In this study, we focus on the mountain wetlands having small catchment area because we consider size and/or relief of catchment area influence cryptotephra detection. We selected six wetlands formed by various processes, such as deep-seated gravitational slope deformation (DSGSD), landslide, and active fault, surrounding the Kanto Plain in central Japan. Then, we conducted coring, cryptotephra detection and characterization of those by determination of refractive index and major element composition of volcanic glass shards. We also obtained radiocarbon dates to cross-check depositional age.

Peaks of glass shards concentration are distinct in wetlands formed by DSGSD comparing to other sites in smaller catchment. In Chayaike Bog (Nagano prefecture) formed by DSGSD, we detected distinct two peak horizons of K-Ah and Towada-Chuseri tephra (To-Cu, 5.9 ka) with consistent radiocarbon age, although To-Cu is small amount around study site. On the other hand, in Jaishi-Okie Moor formed by active faulting and having larger catchment, volcanic glass shards of Aira-Tn tephra (AT, 30 ka) spanned several meters upward. It shows that secondary deposition processes of volcanic glass shards continued for thousands of years after primary deposition.

From these results, the secondary deposition of volcanic glass shards strongly influences cryptotephra detection. It is clarified that secondary deposition depends on size of catchment area among our study sites. Therefore, smaller catchment area is likely to be favorable for cryptotephra detection in Quaternary volcanic regions where secondary tephric materials are continuously provided.

Sediments related to meteorite collision in the Hapcheon impact crater basin, Korea

Dr. Jin-Young LEE [1], ***Dr. Sei-sun Hong*** [2], ***Dr. Hyun Ho Yoon*** [2]

1. *Korea Institute of Geoscience and Mineral Resoiurces,* ***2.*** *Korea Institute of Geoscience and Mineral Resources (KIGAM)*

The Hapcheon impact crater basin (HB) in the southern central part of the Korean Peninsula was formed by a meteor impact. In this study, we studied HB sediments for interpreting the meteor collision process and determined the impact pressure. A 66 m long sediment core (20HCL04) was recovered from the northwest side of the HB and 20 samples from the bottom of the core were used for petrological and geochemical analyses including X-ray powder diffraction (XRD) analysis, electron probe microanalysis (EPMA), and analytical scanning electron microscopy (SEM). Sediments related to meteor impact collision were identified, including suevites, melt breccias, and impact glasses. In particular, coesite was detected through XRD analysis, and partially and completely melted porous glasses were identified among pebbles contained in the melt breccias. These results provide evidence of a shock level > 5 meteorite collision, at a pressure of ≥ 30 Ga and will form the basis for a better understanding of the HB meteor impact collision process through further sediment studies.

Refining the Middle Pleistocene (130–770 ka) tephrostratigraphy of the Eastern Mediterranean region based on glass geochemical characterization and dating of Aegean Arc tephra deposits

Dr. Polina Vakhrameeva [1]***, Prof. Olivier Bachmann*** [2]***, Prof. Axel K. Schmitt*** [1]***, Mr. Stamatios Xydous*** [3]***, Ms. Anne Sturm*** [1]***, Dr. Andreas Koutsodendris*** [1]***, Dr. Răzvan-Gabriel Popa*** [2]***, Dr. Maxim Portnyagin*** [4]***, Prof. Jörg Pross*** [1]

Tephrochronology has developed into an indispensable tool for precise correlation and dating of sedimentary sequences across different depositional settings and over distances of thousands of kilometers. However, the ability to use this approach in distal areas, where tephra deposits often occur as cryptotephra horizons, hinges critically on the availability of robust glass or mineral geochemical data as well as well-constrained ages for the respective tephra occurrences in proximal settings. Because such datasets have remained scarce for many volcanic sources in the Eastern Mediterranean region including the South Aegean Volcanic Arc (SAVA), we have aimed to extend and refine the tephrostratigraphy for this arc with a focus on the Middle Pleistocene (c. 130–770 ka). Two field campaigns were carried out in the western (Methana and Aegina), central (Milos and Kimolos) and eastern (Kos and Nisyros) parts of the SAVA, where over 50 pyroclastic units were sampled. A proximal tephra dataset is currently being generated using accessory mineral geochronology (combined U-Th/U-Pb and (U-Th)/He zircon dating) and major- and trace-element glass analyses of the collected samples. The newly obtained ages allow substantial refinement of previous age estimates for some eruptive units. For instance, five previously undated pumice lapilli tuff deposits from Methana, for which their emplacement was roughly constrained to the Early Pleistocene (c. 1.4 Ma), yielded Middle Pleistocene eruption ages (c. 340–430 ka) based on zircon dating. Ultimately, the refined tephrostratigraphy of the SAVA will assist proximal-distal tephra correlations in the Eastern Mediterranean region where many distal tephra layers, especially those older than 200 ka, have yet unknown origins. By extension, this will aid constructing robust chronologies for Eastern Mediterranean climate-proxy records and enable their precise synchronization.

Synchronization of lacustrine and marine sediment records in the Baltic realm using cryptotephra

Dr. Daniela Müller [1], *Dr. Ina Neugebauer* [2], *Dr. Rebecca Kearney* [1], *Dr. Markus J. Schwab* [2], *Mrs. Oona Appelt* [3], *Dr. Markus Czymzik* [4], *Dr. Jerome Kaiser* [4], *Prof. Helge Arz* [4], *Prof. Achim Brauer* [1]

1. GFZ - German Research Centre for Geosciences, Section Climate Dynamics and Landscape Evolution, Potsdam, Germany, 2. GFZ - German Research Centre for Geosciences, Climate Dynamics and Landscape Evolution, Potsdam, Germany, 3. GFZ - German Research Centre for Geosciences, Section Chemistry and Physics of Earth Materials, Potsdam, Germany, 4. Leibniz Institute for Baltic Sea Research Warnemünde - IOW, Marine Geology, Rostock, Germany

Robust and precise chronologies of paleoclimate records are a prerequisite for studies of past climatic changes. The identification of volcanic ash (tephra) deposits from past volcanic eruptions provides isochrones that allow the direct synchronization between different paleoenvironmental records. Novel methodological developments even allow the identification of macroscopically invisible volcanic ash (cryptotephra) that can be found in sedimentary records thousands of kilometres away from the volcanic source.

Here, we present new cryptotephra findings from Lake Tiefer See (NE Germany) and for the first time from the Baltic Sea (Western Gotland Basin) sediments. Relevant published tephra findings from Lake Tiefer See (Wulf et al. 2016) are summarized for comparison. The two sedimentary records are investigated within the frame of the BALTRAP project ('The Baltic Sea and its southern Lowlands: proxy – environment interactions in times of Rapid change'), aiming to improve the understanding of the impact of rapid climate change in the southern Baltic Sea region.

Throughout the mid- to late Holocene (~4.3 ka BP until AD1875), several cryptotephra horizons containing highly vesicular glass shards have been identified at both sites providing both, robust anchor points for the individual chronologies and for their synchronization. Major element electron probe microanalyses (EPMA) show that glass shard compositions range from rhyolitic to dacitic (Tiefer See) or andesitic (Baltic Sea) and correlate with the geochemical data of glass shards derived from eruptions of the Askja, Hekla and Torfajökull volcanoes in Iceland. The youngest and oldest tephra horizons from both sites contain glass shards from the Askja-AD1875 (see Wulf et al. (2016) for Lake Tiefer See) and Hekla-4 tephras, respectively. Glass shards in other tephra horizons correlate with the Hekla-3 (Tiefer See), Hekla-S, Askja A2000 and Grákolla (Baltic Sea) tephras. Based on these cryptotephra findings the Baltic Sea and Lake Tiefer See sediment records can be synchronized with each other and further European sites allowing the investigation of possible leads and lags in proxy responses to rapid climate changes.

Revisiting the occurrence and distribution of Quaternary marine Toba ash layers in the Indian Ocean

Dr. Steffen Kutterolf [1], *Dr. Julie Schindlbeck-Belo* [1], *Ms. Frieda Mueller* [2], *Ms. Katharina Pank* [2], *Dr. Huo-Yang Lee* [3], *Dr. Kuo-Lung Wang* [3], *Prof. Axel K. Schmitt* [4]

1. GEOMAR Helmholtz Centre for Ocean Research Kiel, 2. GEOMAR Helmholtz Centre for Ocean Research Kiel, Kiel, Germany, 3. Academia Sinica, 4. Institute of Earth Sciences, Heidelberg University, Heidelberg, Germany

The Toba Caldera on Sumatra, Indonesia is the host of the Young Toba eruption (~74 ka), globally one of the largest and most recognized eruptions during the Quaternary and regionally concentrated in the eastern Indian Ocean. Three older deposits (Middle, and Old Toba Tuff as well as Haranggaol Dacite Tuff) are also attributed to Toba caldera and distributed their eruption products over the Indian Ocean.

We present here the Quaternary marine tephra record from an array of 14 sites and 28 holes from deep ocean drilling programs complementing earlier work on distal to ultra-distal Indian Ocean sediment cores and terrestrial distribution data of Toba deposits. A unique set of major and trace element glass-shard compositions on 115 primary ash layers together with glass shard morphologies, core pictures and statistical analysis support geochemical fingerprinting between marine tephra layers and known deposits from Toba and five so far unidentified medium to large eruptions assigned to northern Sumatra. Additionally, zircon crystallization ages have been determined for the Haranggaol Dacite Tuff resulting in a new maximum eruption age of 1420±0.034 ka.

Tephra volumes and magma masses for the (co-ignimbrite) fallout are estimated based on the compiled marine tephra distribution that are complemented by published proximal ignimbrite volumes. For YTT the resulting tephra and DRE volume of 5600 km^3 and 3600 km^3 is in between the previous estimates. For MTT (253 km^3 DRE), ODT (1550 km^3DRE) and HDT (129 km^3 DRE), and the five additionally identified eruptions from Northern-Sumatran volcanoes, magma volumes have been determined. Overall, the new tephra record results in one large eruption every 200 kyr in the Quaternary that is derived from northern Sumatra.

Rain forest fragmentation in northern Madagascar during the past millennium - a result of intensified human impact and climate dynamics?

Ms. Antonia Lena Reinhardt [1], ***Dr. Thomas Kasper*** [2], ***Mr. Maximilian Lochner*** [2], ***Dr. Marcel Bliedtner*** [2], ***Dr. Kim Krahn*** [3], ***Prof. Torsten Haberzettl*** [4], ***Dr. Lyudmila Shumilovskikh*** [1], ***Dr. Jean-Jacques Rahobisoa*** [5], ***Prof. Roland Zech*** [2], ***Dr. Charly Favier*** [6], ***Prof. Hermann Behling*** [1], ***Dr. Laurent Bremond*** [6], ***Dr. Gerhard Daut*** [2], ***Dr. Vincent Montade*** [6]

With its unique flora and fauna, Madagascar is one of the earth's biologically richest ecoregions. It is known that Madagascar's ecosystems have greatly been affected by human influence during past decades, thus making it one of the most endangered ecoregions aswell. Despite the clearly visible recent changes, the exact timing of arrival of the first settlers and their impact on the environment remains a scientific debate. By analysing the sedimentary archive of Lake Amparihibe (Nosy Be Island) our research contributes to shed light on the timing of early human impact on Malagasy natural ecosystems. Several proxies i.e., pollen, fungal spore, other non-pollen palynomorphs, charcoal and diatoms combined with high-resolution sediment-physical and geochemical data were considered to reconstruct paleoenvironmental dynamics during the past three millennia. The record reveals stable environmental conditions between 3000 and 1300 cal BP. A sudden environmental change at 1300 cal BP, characterized by an increase of Poaceae pollen and charcoal particles, indicates an abrupt transformation from a highly diverse rainforest to a grassy landscape associated with fire disturbance. Increasing sedimentation rates, water turbulence and nutrient supply suggest an open landscape highly vulnerable to soil erosion. This quick shift (<10 yrs) is interpreted as a strong early human impact on the environment. After 1000 cal BP, the vegetation is dominated by a fire-disturbed forest/grassland mosaic, which is maintained until today. Since modern climatic conditions imply a potential natural vegetation dominated by rain forest, our results suggest that humans continuously shaped the vegetation during the past 1300 years. However, the scarcity of continuous records hinders a comprehensive regional synthesis. Therefore, an ongoing research effort is spent on investigating a sediment record from Lake Ravelobe (National Park Ankarafantsika) to compare both results. This might help to disentangle signals originating from human impact and/or climatic background, and ultimately detect potential (dis)similarities in climate dynamics, ecosystem responses and anthropogenic influences at the island's scale during the Holocene. This is urgently needed to understand the relationship of human influence and natural factors to current climate change and biodiversity loss, which is important to improve future conservation strategies for biodiversity hotspots such as Madagascar.

Socio-environmental interactions of the Ancient Maya in Belize from the Classic through to the colonial period: The Maya Archaeology and Palaeoecology Partnership Project

Prof. Bronwen Whitney [1]***, Prof. Sarah Metcalfe*** [2]***, Dr. Shawn O'Donnell*** [3]***, Prof. Jaime Awe*** [4]***, Dr. Sherry Gibbs*** [5]***, Dr. Joanna Tindall*** [2]***, Prof. Julie Hoggarth*** [6]

This poster describes the approach and initial results of MAPPP, a collaborative research project between archaeologists and palaeoecologists to uncover what land use change and adaptations were adopted by the ancient Maya during periods of climate instability. The ancient Maya are sometimes characterised as a society that responded inadequately to climate change, exacerbated by poor environmental stewardship, which are both hypothesized to have brought about collapse. This view is not without controversy, and although large scale forest clearances, fire and soil erosion are observed in environmental records at the beginning of the Classic period, some researchers have demonstrated rebounding arboreal resources in the Late Classic as frequent droughts began to become apparent, suggesting that the Ancient Maya adapted their management strategies to resource scarcity and/or to mitigate climate instability. Furthermore, in the post-Classic period, the socio-environmental conditions related to changing demographies and political structures have been little explored in palaeoenvironmental research. This project uses palaeoenvironmmental records that combine a full suite of proxy indicators for past environmental and landscape change complemented by well-constrained archaeological datasets. Sites are chosen from lowland Belize, where there are few multiproxy palaeoenvironmental records, but provide several decades of archaeological research into Ancient Maya social and cultural history. These paired archaeological and palaeoenvironmental datasets in lowland Belize demonstrate socio-environmental interactions through periods of change among the Ancient Maya through to the colonial period.

The Quaternary megafauna of Apa River, Mato Grosso do Sul, Brazil

Dr. Fabio Henrique Cortes Faria [1]**, *Dr. Edna Facincani*** [2]**, *Dr. Ismar de Souza Carvalho*** [3]

1. *Federal University of Rio de Janeiro,* ***2.*** *Universidade Federal de Mato Grosso do Sul,* ***3.*** *Federal University of Rio de Janeiro / Coimbra University*

The Mato Grosso do Sul State, Brazil, presents many paleontological sites of Quaternary age, containing fossils of the megafauna. They are found in cave and fluvial deposits as non-articulated specimens. In 2020, a new paleontological site named as Apa River in the region of Bela Vista county (Mato Grosso do Sul State), was recognized by isolated bones in fluvial sediments. This study aims to describe this new Quaternary paleontological site, focusing on the taxonomic identification of the fossil specimens and interpretation of the geological context where they occur. The basement area of this site are Neoproterozoic rocks from the Tamengo Formation, Corumbá Group, in which there are invertebrate fossils such as *Corumbella werneri* and *Cloudina*. The Quaternary fossils are found on gravel longitudinal bars along modern Apa river channel, identified as *Eremotherium laurillardi* and *Notiomastodon platensis*. The fossils indicate a short period of subaerial exposure, with features of bone surface modification, indicating that these were deposited primarily in floodplain deposits. Subsequently, with the reworking of the floodplain sediments, due to the fluvial erosion, these were deposited in recent longitudinal gravel bars. The fossils exhibit imbrication similarly to the pebbles on the gravel bars, indicating the same environmental processes. The megafauna species are related to the land mammal Lujanian time-interval of South America. These species extend the Intertropical Brazilian Region to the Central West Region of Brazil, as well as show relationships with the Pampean Region (South of Brazil, Uruguay and Argentina), throughout the Chaco plain. The fauna interchanges could explain the similarities between these two palezoogeographic regions during the Quaternary.

Tectonics, ecology, energetics and the security of food around the Isthmus of Panama

Dr. Aaron O'Dea [1], ***Ms. Brigida De Gracia*** [1], ***Dr. Jessica Lueders-Dumont*** [1], ***Dr. Seth Finnegan*** [2], ***Dr. Erin Dillon*** [1], ***Dr. Jeremy Jackson*** [1]

1. The Smithsonian Tropical Research Institute, 2. University of California, Berkeley

Prior to the formation of the Isthmus of Panama, the seas of the Caribbean and Eastern Pacific were connected by a single tropical biogeographic province dominated by strong upwelling and high primary productivity. By around 3Ma, formation of the Isthmus land bridge was complete. Upwelling and high primary productivity continued on the Pacific side, but the Caribbean rapidly transformed into the nutrient-poor basin we know today. Here we trace the energetic consequences of this grand geological event, from plankton to people. We find that while primary productivity is two times higher on the Pacific coast, zooplankton biomass is a remarkable seven times greater, indicating a positive trophic amplification and corroborating predictions of greater trophic transfer efficiency in upwelling regions. This pattern continues up through trophic levels: Benthic invertebrate biomass growth is 10 times greater on the Pacific side, and shark standing biomass more than 100 times greater. The impact of these oceanic differences extend into people: Pre-hispanic human population densities were more than double on the Pacific side, and isotope and midden records suggest a greater reliance on higher trophic level marine resources than their Caribbean compatriots. Even today, more people live in Pacific regions where strong upwelling supports high fish biomass, although the industrial movement of fish and other marine resources from the Pacific to the Caribbean side, starting with construction of the Panama Canal 100 years ago, diminished the interoceanic differences in human populations. Finally, we also explored the consequences of conch harvesting over millennia in both oceans. In the Caribbean, persistent size-selective harvesting of *Strombus pugilis* resulted in significant declines in size at maturity over seven millennia resulting in a 50% reduction in protein per conch. In contrast, the closely-related Pacific *Strombus granulatus* did not change in size over the same time period despite millennia of intensive harvesting. These findings support the idea that the positive trophic amplification of highly productive regions can confer ecosystem resilience. Based on these findings, we propose that the predicted decline in tropical oceanic productivity due to climate change could erode this resilience.

Chinese Pollen Database: current status and future development

Prof. Jian Ni [1], ***Mr. Borui Zhou*** [1], ***Ms. Jie Xia*** [1], ***Dr. Kai Li*** [1], ***Dr. Mengna Liao*** [1]

1. Zhejiang Normal University

The construction of the Chinese Pollen Database (CPD) was started in 1994, under the framework of the BIOME6000 core project of the International Geosphere-Biosphere Programme (IGBP). During the past three decades, several versions of regional and national pollen databases of China have been built up through unremitting efforts from domestic and international palynologists and paleobotanists over generations. Nowadays, a late Quaternary pollen database of China has been established using a unified pollen taxa and standardized, calibrated dating data, including the modern pollen dataset (> 5500 sampling sites) and fossil pollen dataset (372 sites). These two datasets are being updated continuously. A new pollen dataset of China since the Cenozoic Epoch is being setting up. All of these datasets will be united to form the official Chinese Pollen Data, which will be further made public to the palaeoworld.

Regional feature of pollen R-value in China

Ms. Jie Xia [1], ***Prof. Jian Ni*** [1]
1. Zhejiang Normal University

Understanding relationships between modern pollen, vegetation, and climate is essential for quantitatively reconstructing past vegetation and climate. The R-value, a typical and traditional indicator with easy calculation, can be used to adjust the nonlinear discrepancy between surface pollen and modern vegetation. In this study, we established a dataset of 2115 pollen R-values in China collected from 898 modern pollen sampling sites and 152 pollen taxa and from 42 publications. Syntheses of these R-values revealed that: 1) Pollen R-values in China vary greatly, with the majority being stronger under-represented and a few being weaker over-represented. 2) *Pinus*, *Picea*, *Betula*, *Ephedra*, Chenopodiaceae and *Artemisia* are mostly over-represented among the common pollen taxa, while Taxodiaceae, *Corylus*, *Nitraria*, *Tamarix*, Cyperaceae, Poaceae and Fabaceae are mostly under-represented. The representative of *Castanea*, *Quercus*, Polygonaceae and Asteraceae vary depending on vegetation types. 3) Pollen R-values in China have a clear spatial geographical pattern, changing not only with pollen taxa, but also varying in vegetation types and climatic regions. Thus, the limitation of R-value, particularly the variation of the same pollen taxon across regions, must be taken into account when using R-value to characterize pollen-vegetation relationships.

Differentiating Poaceae pollen using FTIR microspectroscopy as a chemotaxonomic tool

__Mrs. Faidra Katsi__ ***[1], Dr. Matthew Kent [1], Prof. Matthew Jones [2], Dr. Wesley Fraser [3], Dr. Phillip Jardine [4], Dr. Warren Eastwood [5], Dr. Michela Mariani [6], Prof. Collin Osborne [7], Dr. Stella Edwards [1], Prof. Barry Lomax [1]***

1. *School of Biosciences, University of Nottingham, Sutton Bonington Campus, Loughborough, United Kingdom,* ***2.*** *School of Geography, University of Nottingham, University Park, Nottingham, United Kingdom,* ***3.*** *School of Social Sciences, Oxford Brookes University,* ***4.*** *Westfälische Wilhelms-Universität Münster, Institut für Geologie und Paläontologie, Münster, Germany,* ***5.*** *University of Birmingham,* ***6.*** *University of Nottingham,* ***7.*** *School of Biosciences, University of Sheffield*

Due to the morphological similarity of pollen grains, grass (Poaceae) pollen can be difficult to classify below family level. Currently, discrimination between the pollen of domesticated cereal crops ("*Cerealia*"-type) and wild grasses is based on its morphology, i.e., the shape, size, and position of the pores, the texture of the exine wall, and importantly the size of the grains themselves. "*Cerealia*"-type pollen is generally larger than wild grass pollen, but there is frequent overlap between domesticated and wild grass pollen size which prevents not only accurate discrimination between wild and domesticated grass pollen but also identification at species level.

An alternative method for distinguishing between pollen of domesticated and wild grass species can be used to retrieve taxonomic signals from the pollen chemistry: spectra obtained by Fourier-transform infrared (FTIR) spectroscopy have been used for cluster (population) pollen samples and in a few cases single pollen grains. Our study uses the pollen wall spectra from acetolysed extant wild grass and domesticated cereal crops to explore how chemotaxonomy can be used as a tool for subfossil Poaceae pollen classification.

Pollen from 19 common wild grasses and domesticated cereals (widely cultivated in Europe and southwest Asia) were collected and acetolysed following standard palynological procedures and analysed as individual grains. K-nearest neighbour algorithms achieved a 77% classification success rate at species level with extant pollen, indicating the potential for chemotaxonomy to be applied to fossil pollen samples. Here we present our methodological approach and discuss the challenges of using chemical spectra when classifying fossil grass pollen to species level.

An extended chironomid training set for reconstructing New Zealand summer air temperatures

Dr. Valerie van-den-Bos [1], *Dr. Marcus Vandergoes* [1], *Dr. Andrew Rees* [2], *Dr. Ann Dieffenbacher-Krall* [3], *Prof. Rewi Newnham* [2]

1. GNS Science, 2. Victoria University of Wellington, 3. The University of Maine

While the number of quantitative temperature reconstructions in the Southern Hemisphere is increasing at a steady pace, many regions remain underrepresented. This is in part due to a lack of training sets to infer the relationship between proxies and climate variables. We analysed a 104-lake chironomid training set from New Zealand, an extension of an earlier 60-lake training set published in 2007 by Dieffenbacher-Krall and others.
The original model is based on the response of the lake-dwelling larvae of chironomids, or non-biting midges, to mean summer air temperatures (SmT). It has been used successfully in several studies on lake sediments to reconstruct Holocene SmT in New Zealand. However, the original model covers a relatively short SmT gradient, from ~6.5 to 15°C, and was developed primarily for use in southern New Zealand. It is therefore not appropriate to apply it in more northern parts of the country. The new training set extends the SmT gradient to 19.5°C.
We confirm that SmT is the most important variable to explain chironomid assemblage variance in the extended training set, but also find potential confounding factors, some of which correlate with SmT. We apply seven different transfer function techniques: one assemblage approach, two multivariate regression models, and four machine learning techniques. The latter are supposedly more robust in the presence of confounding variables. We discuss the differences between the seven models and apply them to a Holocene chironomid record from Lake Pupuke in northern New Zealand. We compare the performance of the original and new training set in the context of both the increased number of sites and the extension of the temperature gradient.

The updated Indo-Pacific Pollen Database (IPPD): a valuable new asset to the Neotoma Palaeoecological database

Dr. Annika Herbert [1]***, Prof. Simon Haberle*** [1]***, Dr. Suzette Flantua*** [2]***, Dr. Ondřej Mottl*** [3]

1. Centre of Excellence for Australian Biodiversity and Heritage, School of Culture, History and Language, Australian National University, Canberra ACT, Australia, 2. University of Bergen, 3. Department of Biological Sciences, University of Bergen and Bjerknes Centre for Climate Research, Bergen, Norway

The Indo-Pacific Pollen Database (IPPD) is the brainchild of the late Professor Geoffrey Hope, who gathered pollen records from across the region to ensure their preservation for future generations of palaeoecologists. This noble aim is now being fulfilled by integrating the IPPD into the online Neotoma Palaeoecological Database, making this great compilation available for public use. Here we explore the database in depth and suggest directions for future research. The IPPD comprises 226 fossil pollen records, most postdating 20 ka, but some extending as far back as 50 ka or further. However, many of the records contain few samples or have fewer than 5 chronology control points, such as radiocarbon, luminescence or Pb-210 for the younger sequences. 83.6% of the records are Australian, with a fairly even distribution between the different Australian geographical regions, with the notable exception being Western Australia, which is only represented by 3 records. The records are also well distributed in modern climate space, the largest gap being in drier regions due to preservation issues. Average sedimentation rates counted as years per cm are quite low for many sequences, meaning each cm of sediment represents a fairly low number of years, with 61% of the records having a rate of less than 50 yr/cm. However, the average rate for the whole IPPD is 60 yr/cm, with the highest rate by geographical region occurring in arid Australia. The lowest rates are from the Western Pacific and Maritime SE Asia. Overall, Australia has a higher rate than the rest of the Indo-Pacific region. This could be due to the targeting of longer records, which tend to have a higher rate, or it could be due to relatively lower precipitation leading to lower biological activity in the lakes and wetlands that represent the vast majority of sites. The IPPD offers many exciting research opportunities, with one possibility being the examination of human impact on regional vegetation, contrasting first human arrival and colonialization, and another the assessment of rates of vegetation change during the Holocene.

Using plant functional traits in paleoecology: a calibration study from Arid Central Asia.

Mr. Lucas Dugerdil [1]***, Mr. Cyrille Violle*** [2]***, Dr. Odile Peyron*** [3]***, Dr. Sébastien Joannin*** [4]***, Mr. Holger Kreft*** [5]***, Mr. Patrick Weigelt*** [5]***, Mr. Pierre Denelle*** [5]***, Mr. Eric Garnier*** [2]

__1.__ ISEM, Univ Montpellier, CNRS, IRD, Montpellier, __2.__ CEFE (UMR5175), CNRS – Univ. Montpellier – Univ. Paul-Valéry Montpellier – EPHE, Montpellier, France, __3.__ Institut des Sciences de l'Évolution de Montpellier, __4.__ ISEM, University of Montpellier, CNRS, EPHE, IRD, Montpellier, France, __5.__ Biodiversity, Macroecology & Biogeography, University of Goettingen, Büsgenweg 1, 37077 Göttingen, Germany

The necessity of accurate past climate reconstructions for climate modelling is a key issue in (paleo)ecology. Especially, dryland such as Arid Central Asian deserts may spread in the next decades in surrounding steppes due to aridification. Several methods already exist to convert pollen in quantitative climate (transfer functions) and biome (biomization). However, these methods are impeded by numerous biases, which could be overcome by current breakthrough in plant functional response to climate understanding.

Few past pollen studies attempt to merge plant functional traits with pollen samples in order to reconstruct paleo-trait cover and functional vegetation dynamics. However, this approach has not been tested using modern samples. Especially, since the taxonomic resolution used in ecology is not the same as the one used in pollen studies (usually family or genus pollen identification), whether the phenotypic space of extant vegetation is consistent with that derived from pollen modern samples remains an open question.

Here, we tested the performance of combining paleoecology and plant functional ecology to validate the use of pollen to infer the phenotypic space of past vegetation. The pollen surface sites from Arid Central Asia (n = 2393) have been extracted and the pollen-types have been used to aggregate traits (height, leaf area, leaf nitrogen, seed mass, specific leaf area and stem specific density from TRY, BIEN and GIFT databases). Then, the community-weighted mean (CWM) traits have been calculated using the pollen fractional abundances. These pollen-CWM traits have been compared with the vegetation-CWM (n = 21347). Finally, both have been related to current climate parameters.

The preliminary results of this study show that the trait values aggregated by pollen-types respect the same plant economic spectrum than observed in botanical taxonomic resolution. Moreover, it validates the use of pollen as equivalent of vegetation plots to calculate the CWM. It also appears that the scheme of aggregation between the pollen-type and botanical species is not strongly impacting the CWM trait response to climate. These results open a new avenue to use plant traits in paleoecological study in order to reduce climate reconstruction biases and to improve pollen-biomization scheme for past vegetation reconstructions.

Automated pollen analysis: the state of play

Dr. Katherine Holt [1]
1. *Massey University*

Since the 1960's, partial or complete automation of pollen microscopy has provided a tantalising prospect for the labour-intensive discipline of palynology. Since then, progress has occurred in fits and starts, typically occurring in step with advances in computing power, which have facilitated developments in the fields of machine learning and image processing. Until recently, most attempts at automated palynology, or at least those captured in the literature, could only really be regarded as proof- of-concept, in that they demonstrated that it was possible to successfully identify pollen, or indeed other microfossils using the chosen methods. But few studies were working with problems at a 'real world' scale. For example, the majority of studies involved a limited number of taxa, which were not representative of the likely diversity expected in paleoecology samples.

In recent years, we have arguably entered a new phase of automated pollen analysis, again driven by advances in computing capability and digital image technology. Specifically, the ability to produce very large sets of digital images, quickly and cheaply, has paved the way for Deep Learning Convolutional Neural Networks (DLCNNs) to come to the fore. DLCNNs differ from earlier artificial neural networks mainly in the number of hidden layers they use and the way they represent features in images. So far, they have shown considerable promise, in that they have been applied to classification problems of a much greater diversity than previous attempts, AND have delivered strong results. Automated systems also show considerable promise in discriminating morphologically cryptic taxa which have so far been too challenging for human analysts to distinguish through purely visual methods alone.

But despite these advances, we are still not at the point where we are actually realising the dream of using an automated system to significantly reduce the amount of time spent on the microscope in order to generate data for palaeoecology. What limitations, then, remain? Arguably, the most significant challenges lie in dealing with non-pollen objects, broken/deformed pollen, clumped pollen, and pollen that is not yet known by the trained system. These issues, and more, will be explored in this presentation.

pastclim: an R package to easily access and use paleoclimatic reconstructions

Dr. Michela Leonardi [1], ***Dr. Emily Hallett*** [2], ***Dr. Robert Beyer*** [1], ***Dr. Mario Krapp*** [1], ***Prof. Andrea Manica*** [1]

1. Department of Zoology, University of Cambridge, 2. Department of Anthropology, Loyola University Chicago

The recent development of continuous paleoclimatic reconstructions covering hundreds of thousands of years paved the way for a large number of studies from disciplines ranging from paleoecology to conservation, archaeology to population genetics, macroevolution to anthropology, and human evolution to linguistics. The downside to this process is that (paleo)climatic data are stored in large and complex file formats, and they can be challenging to handle for scholars unfamiliar with them.

Here we present pastclim, an R package facilitating the access and use of paleoclimatic reconstructions (https://evolecolgroup.github.io/pastclim/index.html).

It currently gives direct access to two such datasets, covering respectively the last 120,000 and 800,000 years, and a vignette provides instructions on how to include additional ones. We are expecting the number of datasets available to increase in the following months.

The package contains a set of R functions to quickly and easily recover the climate for time periods of interest either for the whole world or specific areas, extract data from locations scattered in space and/or time, retrieve time series from individual sites, and manage the ice or land coverage, offering a handy platform to include the climate of the past into existing or new analyses and pipelines.

Making spatial pollen modelling FAIR: Multiple Scenario Approach in QGIS

Ms. Thya van den Berg **[1], *Dr. M. Jane Bunting*** **[1]**

1. *School of Environmental Sciences, University of Hull*

Spatial reconstruction of vegetation has been one of the main goals of pollen analysts since the dawn of the discipline. Approaches centred around algebraic models of the pollen-vegetation relationship have made considerable progress in recent decades, resulting in reconstruction methods such as the Landscape Reconstruction Algorithm (LRA) and Multiple Scenario Approach (MSA). Spatial pollen modelling is currently a niche activity within the wider discipline of pollen analysis, due to the complex nature of the models and the closed, available-on-request approach to software and code. This approach is understandable, since complex models can be subject to misuse due to the user not completely understanding the model assumptions and input requirements (treating the model like a "magic black box").

In order to realise the potential of spatial modelling within the field of pollen analysis, pollen modelling software packages need to be available for wider use. As an educational tool they would allow students to experimentally explore connections between landscape and pollen assemblages, which is essential to learning to interpret pollen data. As a research tool the models can be used not just for a full reconstruction of past landcover, but also to explore thought experiments or inform site selection. Reconstruction outputs, especially in the form of maps, also have a wider outreach value, as maps convey information in a more intuitive way compared to traditional pollen diagrams, which makes them suitable for communication with non-specialist audiences.

I therefore present a new software package for the Multiple Scenario Approach, written in Python for QGIS, that adheres to the FAIR (Findable, Accessible, Interoperable and Reusable) principles. Keeping the data and software FAIR allows spatial pollen modelling specialists to check the work of the users and allows users to look inside the "magic black box", while also making spatial pollen modelling more widely available, which will be beneficial for underfunded research facilities, commercial and independent researchers, and students and teachers.

Expanding capacity and support for Quaternary vertebrate data curation and analyses

Prof. Jessica Blois [1], ***Dr. Val Syverson*** [1], ***Dr. Simon Goring*** [2], ***Ms. Socorro Dominguez Vidana*** [3], ***Ms. Nicola Cullen*** [1], ***Dr. Marta Jarzyna*** [4], ***Dr. Shanan Peters*** [2], ***Dr. Russell Graham*** [5], ***Dr. Edward Davis*** [6]

1. *University of California, Merced,* **2.** *University of Wisconsin-Madison,* **3.** *HT-Data Consulting,* **4.** *The Ohio State University,* **5.** *Colorado School of Mines,* **6.** *University of Oregon*

Reliable inference of the drivers of and impacts from biotic responses to climate change require high-quality data. The FAUNMAP database was the result of a multi-institution vertebrate data curation effort that catalyzed a generation of impactful research focused on North American Quaternary mammals. Key early findings stemming from this database included the widespread occurrence of no-analog species associations, the influence of climate on small mammal communities across the Quaternary, and substantially reduced Holocene mammal diversity relative to previous time periods. In 2008, FAUNMAP data along with the North American Pollen Database were joined to form the core of the Neotoma Paleoecology Database. The Neotoma-FAUNMAP constituent database is a living rather than static repository: originally contributed data are preserved with a stable DOI, but datasets can also be refined and updated as new information becomes available. The Neotoma framework and common data format has provided researchers with the ability to update taxonomies and nomenclature, and to link records to other data types such as pollen, plant macrofossils, ostracodes, diatoms, coleoptera and isotopic data from bones and teeth in a seamless way, facilitating analyses of whole-ecosystem responses to climate over the Quaternary.

Here, we describe new updates to both the vertebrate data in the Neotoma Paleoecology Database and to the underlying Neotoma data model. Data model changes include the ability to curate specimen-level data, linked to repository IDs, which facilitates associations between specimens, radiocarbon dates, isotopes, ancient DNA, and the broader site context. These data model changes have spurred updates to site-level data and improved data coverage. We also describe progress towards automatically capturing new radiocarbon dates, new specimens, and new sites using the automated text and data mining tool xDD. We use these new and refined data to undertake a comprehensive update to the age models for North American vertebrate sites, and provide the foundation for a new generation of analyses targeted at understanding community assembly processes through time.

FOSSILPOL: The workflow to process global palaeoecological data of fossil pollen for large-scale synthesis

Dr. Ondřej Mottl [1]***, Dr. Suzette Flantua*** [1]***, Dr. Vivian Astrup Felde*** [1]***, Dr. Kuber Bhatta*** [2]***, Prof. Hilary Birks*** [1]***, Prof. John-Arvid Grytnes*** [2]***, Dr. Alistair Seddon*** [1]***, Prof. John Birks*** [1]

1. *Department of Biological Sciences, University of Bergen and Bjerknes Centre for Climate Research, Bergen, Norway,* **2.** *Department of Biological Sciences, University of Bergen, Bergen, Norway*

The study of biodiversity and ecosystem patterns through time and space requires large-scale syntheses of palaeoecological datasets. The data preparation for such syntheses must be transparent and reproducible. Until now, a guide for interdisciplinary data analysts on how to standardise large data compilation of palaeoecological records is missing. Without guidelines on the explicit assumptions that underlie palaeoecological data and their analyses, appropriate use of the data is jeopardised and follow-up analysis can be undermined.

We present FOSSILPOL as a workflow to efficiently process global fossil pollen data to create a standardised project-specific dataset compilation. The goal of the FOSSILPOL workflow and corresponding R-package called R-fossilpol is to facilitate such compilation in a comprehensive and reproducible way, ready for multi-record and multi-proxy analyses at macroecological scales. With our workflow documentation and website, we outline the most crucial decisions needed to standardise palaeoecological data, specifically using fossil pollen data. User-defined criteria are project-, and research-question dependent and are condensed into one overview file for easy reviewing and reproducibility purposes. Such criteria will maximise the quality of the dataset compilation and facilitate discussions among interdisciplinary experts.

Using palaeoecological data with solid knowledge of the data's strengths and weaknesses – and how to overcome them – is a great tool for researchers in any field to address research questions that can ultimately help decision-makers, conservation organisations, and governments understand biodiversity and ecological processes

Given the increasing amount of open-access data across large spatial and temporal scales, our workflow offers an easy way to prepare reproducible palaeoecological compilations for synthetic and cross-disciplinary analyses with macroecological, biogeographical, and palaeoecological perspectives.

Forecasting Fossils: Combining Paleontological and Contextual Attributes for Predictive Models in the Eastern Narmada Basin, India.

Ms. Aarya Joshi [1], Dr. Matthew Sisk [2], Ms. Bharti Jangra [3], Dr. Tosabanta Padhan [3], Dr. Parth Chauhan [3]

1. Department of Biological Sciences, IISER Mohali, 2. Lucy Family institute for Data & Society, University of Notre Dame, USA, 3. Department of Humanities and Social Sciences, IISER-Mohali, Punjab

Narsinghpur district, Madhya Pradesh, situated in the Narmada valley is known to be one of the most fossiliferous areas in this region. Since initial discoveries this area has been known as the home of fossils of multiple vertebrate species such as Antilope cervicapra, Boselaphus tragocamelus, Proboscideans, Trionyx gangeticus, Hexaprotodon sp, and Equus namadicus, etc. many of which have now become extinct. The discovery of microvertebrate species has also been made in this region. While the preserved fossils are not rare, most of the fossil occurrences are represented by individual elements having varied extents of preservation. Narsinghpur district holds the unique position of being between the Satpura and the Vindhya mountain range and along with Narmada, is home to many of its tributaries. Interestingly, field surveys and newly built predictive models both suggest that obtaining fossils from areas near the rivers such as river beds, river banks, and terraces hold a high probability. Localities near these areas such as Barmaan Ghat, Devakachar, Umeriya, Gawari, etc. have yielded multiple fossils, and the geological contexts of the discovered fossils have been studied in detail. The geological contexts at Narsinghpur district contain combinations of boulder conglomerate, cemented sandy gravel, yellow or pinkish cross-bedded sand, breccia gravel, and reddish silty clay. A predictive model of potential fossil locations was initially created using a weighted combination of environmental and geological variables (slope, vegetation, soil type and character), This was combined with a MaxEnt model trained using known fossil locations to predict likelihood using the same variables but without biasing the model towards investigated areas. In this paper, we would like to explore the possible correlations between concentration of fossils and their extent of preservation, and geological factors such as: proximity towards specific geological features, the AMSL height of the locality, and the lithostratigraphy present at the site. We posit that finding such patterns will expose a quantitative effect of geological phenomena on fossil preservation and eventual discovery. With the help of the predictive model, we hope to predict fossil occurrences in currently unexplored regions of the world, directing on-ground human effort more efficiently.

Selecting sites for pollen analysis

Dr. M. Jane Bunting [1], ***Dr. Michelle Farrell*** [2], ***Prof. Nicki Whitehouse*** [3]

***1.** School of Environmental Sciences, University of Hull, **2.** Coventry University, **3.** Department of Archaeology, University of Glasgow, UK*

Pollen analysis is a very widely used technique for reconstructing past land cover, and thus inferring human activity, climate change and a range of other ecological and environmental processes. The power of pollen analysis comes in part from the importance of plants in ecosystem formation and in part from the wide dispersal of pollen grains, which enables sedimentary systems to record not just local environments but also traces of the wider environment. Interpretation of the pollen record is challenging due to taxonomic limitations (multiple related plant species can produce indistinguishable pollen grains), variations in the amount of pollen produced by different plants, and variations in dispersal mechanisms? relating to plant growth habits and reproductive strategies. Model-based approaches have improved our understanding of the spatial signal reflected by pollen assemblages and provided means of extracting quantitative estimates of past landcover from pollen data, using approaches such as the Landscape Reconstruction Algorithm or the Multiple Scenario Approach, and have considerable scope for improving communication and collaboration between palaeoecologists, archaeologists and ecologists, vital for addressing major societal challenges.

In order to take full advantage of the new understanding offered by models of the pollen-vegetation relationship, modelling should be fully integrated into the pollen analyst's work flow, rather than something reached for once the data collection is complete. Simulation based on the landscape of interest can be used to make an informed choice of sediment core location, by exploring the sensitivity of different possible sampling points to the hypothesised changes of interest, and to inform the size of pollen count needed to be able to detect a specific change, should it have occurred, with confidence. This paper presents a recommended workflow for using simulation to maximise the relevance of data retrieved from months or years of laboratory work both through informing site selection and through contributing to interpretation and reconstruction of past landcover.

SIG in Palaeontology: Biome dynamics through the Pleistocene

Facultad CC. Geológicas, Universidad Complutense de Madrid, c/José Antonio Novais 12, 28040 Madrid, Spain*

Biomes are the ecological and evolutionary units in which we can divide the Earth attending to their biological community and physical environment. Large-scale properties and distribution of terrestrial biomes depend primarily on climatic factors, along with soil type, water availability and environmental disturbances, among others. These factors have affected biomes in the past and keep doing so nowadays. Thus, shifts in climatic factors drive changes in the distribution of biomes, which fluctuated through geologic time. Nevertheless, our knowledge of past biomes configuration is scarce. Understanding the fluctuation of biomes' distribution through time is important to frame palaeontological and evolutionary studies of species in relation to their environment. One way to assess the distribution of these biomes in the past is through geographic information system (GIS) tools, which together with the recent availability of fine-scale climate data allow us to model climate at both temporal and spatial scales.

In this work, we modelled past biomes' distributions to explore how climatic changes affected them during the Pleistocene, a period of marked climatic fluctuations. We compared glacial and interglacial periods, typical of the Quaternary climatic cycles. In particular, we modelled biomes distribution during the Last Glacial Maximum (LGM) and the Last Interglacial (LIG). This allowed us to see how the world biomes geographic areas expanded or fragmented according to the climatic fluctuations. We found that glaciations contracted and fragmented tropical biomes, whereas colder biomes expanded. In the interglacial phases, however, tropical biomes were favoured whilst colder and arid biomes were contracted and fragmented.

Reconstructing the past: 14C dating and stable isotopes of archaeological mollusc shells from Vale Boi (Portugal).

Ms. Dragana Paleček [1], ***Prof. Giuseppe Falini*** [1], ***Dr. Lukas Wacker*** [2], ***Prof. Nuno Bicho*** [3], ***Dr. Stefania Milano*** [4], ***Prof. Sahra Talamo*** [1]

1. *University of Bologna,* ***2.*** *ETH Zurich, Ion Beam Physics, Otto-Stern-Weg 5, 8093,* ***3.*** *ICArEHB - Interdisciplinary Center for Archaeology and the Evolution of Human Behaviour, University of Algarve,* ***4.*** *Leibniz Institute for Zoo and Wildlife Research - IZW, Berlin*

Mollusc shells are often found in archaeological sites, given their great preservation potential and high value as a multipurpose resource. The site of Vale Boi (Algarve, Portugal) is a well-known Upper Paleolithic site representing the earliest recorded modern human occupation in southwestern Iberia, as attested by the Early Gravettian remains dated to c. 32 ka cal BP. This site has a long stratigraphic sequence spanning from the early Gravettian to the Proto-Solutrean, Solutrean, and Magdalenian. Previous studies found evidence of multiple human occupations at this site, proving that it was most likely a seasonal residential camp with a combination of exogenous and regional cultural traits and intense and diversified use and processing of available resources, including mollusc shells. Furthermore, there was an intense presence of inland and coastal foraging, hunting, and processing of various types and sizes of prey, possible processing of edible plants, as well as the production of various lithic and bone tools, ornaments and art, including abundant shell beads. The presence of numerous mollusc species spans the site's different layers, proving the continued use and importance of mollusc shells as a resource throughout the stratigraphic sequence of Vale Boi. Being situated between two different environments: the Mediterranean and Atlantic coasts, this site could give us insight into the ecological and socio-cultural dynamics of different populations that inhabited the Southwestern part of the Iberian Peninsula during the transition from Middle to Upper Paleolithic. This underlines the importance of creating a secure chronological determination, which, combined with paleoclimatic and archaeological data, can give us a better understanding of the socio-cultural, technological, and ecological behaviour at the site.

To do this, we tested and applied four different pre-treatment methods for ^{14}C dating of mollusc shells and performed stable isotope measurements for climate reconstruction. Determining which of these methods is the most reliable for ^{14}C dating and combining it with isotope measurements will result in the possibility of constructing precise chronologies and paleoclimate scenarios, allowing for a better interpretation of the ecological and cultural variability at the Middle to Upper Paleolithic transition at Vale Boi.

Single-grain OSL dating of the Neanderthal site of Axlor (Biscay, Spain): cultural and environmental change in southwestern Europe from MIS 5 to MIS 3

Dr. Martina Demuro [1]***, Prof. Lee Arnold*** [1]***, Dr. Jesús González-Urquijo*** [2]***, Dr. Manuel Frochoso*** [2]***, Dr. Talía Lazuen*** [2]

1. *University of Adelaide,* ***2.*** *Universidad de Cantabria*

The cave site of Axlor (Biscay, Spain) preserves one of the most informative Middle Palaeolithic (MP) records for the North Atlantic Iberian region, though its age remains poorly known. Key findings at the site include Neanderthal remains, marked faunal changes through time, micro-Levallois assemblages overlain by typical Quina, and original osseous tools and hearth structures. Here we use single-grain optically stimulated luminescence (OSL) and single-grain thermally-transferred OSL (TT-OSL) dating of sediments to improve the age constraint of Axlor's MP succession (levels N–B). Our new ages are consistent with (i.e., older than) the previously published terminus ante quem 14C ages for the site (>42.9 cal ka BP), and suggest the sequence accumulated between ~100 ka and ~50 ka, during a critical period in Neanderthal history. Our results indicate that major faunal and technological turnovers occurred towards the end of MIS 5, potentially correlative with broader environmental and climatic changes. Additionally, our new ages indicate that the Axlor's Quina record is one of the oldest in Spain. Comparisons with neighbouring sites point to complex regional chronologies and development for this particular behaviour, though detailed correlations with other MP sequences remain difficult due to their poor chronological attributes. The present study highlights the important role that single-grain optical dating can play in elucidating the broader evolution of the MP across the region.

Cividate Camuno (Brescia – north-west Italy) – hunter gatherers between the Late Glacial era and the beginning of the Holocene

In the Alpine area, during the last glaciation, in the large valleys such as that of the Adige the glaciers filled the valleys reaching a thickness of up to a thousand metres. These areas were, during the coldest times, completely uninhabited, most recently around 24-20,000 years ago. After the Last Glacial Maximum, the environmental and climatic conditions began to change and humans returned to the valleys. North-eastern Italy – east of Lake Garda – has provided numerous traces of these early recolonisations, but the same cannot be said for the areas to the west of Lake Garda (Lombardy and Piedmont) where only a few faint traces of early Holocene human presence are known.

The site at Cividate Camuno (Valcamonica – Brescia), on the valley floor at an altitude of 275 m asl, with multiple occupation levels datable to the Late Glacial and early Holocene, is unique in north-western Italy. At the site were found an inhabited area with a Palaeolithic "hut" and an Early Mesolithic level.

The archaeozoological analyses of the Late Palaeolithic levels (18,066-15,576 years cal BP) show different hunting strategies from those of the Mesolithic level (10,180-9590 years cal BP), reflecting environmental variation and, hence, changes in locally available prey.

The Late Palaeolithic occupation thus represents the first trace of a human presence in the western Alps since the glaciers reached the Po Plain, at least 15,000 years earlier. The members of these human groups were pioneers in an uninhabited and hostile environment who, thanks to their technical knowledge, were able to adapt to such difficult environmental conditions. They hunted ibex, which lived on the valley floor, and the deer that returned to the areas from which the glaciers receded.

The Mesolithic occupation provides evidence of the subsequent adaptation of human groups to an environment that had changed thanks to the retreat of the glaciers to higher elevations and, on the valley floors, had left room for the spread of wooded areas that hosted deer, roe deer and wild boar – the favoured prey of these Mesolithic hunters.

Organic Material from the Ancient Great Wall of China as a Climate Archive: Environmental Change and Archaeological Conservation

Dr. Robert Patalano [1], ***Dr. Jing Hu*** [2], ***Dr. Qin Leng*** [3], ***Dr. Weiguo Liu*** [2], ***Dr. Patrick Roberts*** [4], ***Dr. Michael Storozum*** [5], ***Dr. Lin Yang*** [6], ***Dr. Hong Yang*** [3]

***1.** isoTROPIC Research Group, Max Planck Institute for Geoanthropology, Germany, **2.** State key laboratory of Loess and Quaternary Geology, Institute of Earth Environment, Chinese Academy of Sciences, **3.** Department of Biological and Biomedical Sciences, Bryant University, **4.** isoTROPIC Research Group, Max Planck Institute for Geoanthropology, **5.** School of History, Classics and Archaeology, Newcastle University, Newcastle upon Tyne, **6.** National Museum of China*

The Great Wall of China is one of the most recognizable world heritage sites. What is perhaps less well known, is that the iconic brick walls built during the Ming Dynasty in the 15th Century AD are only a small part of an extensive system composed of fascine and rammed-earth walls, beacon towers, and fortifications that expanded to the western imperial frontier as early as the Han Dynasty in the 2nd Century BC. Plant materials used in the construction of these wall segments and beacon towers contain untapped potential for revealing paleoclimatic and paleoenvironmental changes of northwestern China over the last two millennia. For the first time, we characterize the molecular preservation and stable carbon and nitrogen isotope compositions of AMS-dated common reeds (*Phragmites*) collected from ancient Great Wall fascines in today's Gansu and Xinjiang using a combination of chromatographic techniques and isotope analyses.

Using these novel archaeological samples, we quantitatively demonstrate that ancient Great Wall reeds retain excellent molecular preservation and illustrate the potential of using this common construction material as an archive for paleoclimatic and archaeological proxies. Both the molecular distribution of plant waxes and bulk carbon isotope compositions indicate that the ancient reeds were harvested from local sources and illuminate site-specific environmental records and differential rates of environmental change across northwestern China. Meanwhile, extremely heavy nitrogen isotope values show variability in the use of fertilizers around large population centers. Overall, our study represents the first attempt to reconstruct the source and local habitats of Great Wall building materials that contain information on the impact of climate change on local environmental settings. Additionally, this work demonstrates the potential for paleoenvironmental reconstructions applying molecular and stable isotope methodologies to any ancient structure that was built, at least partially, using locally-sourced organic materials.

Investigating the effect of UV radiation on Pinus spp. pollen-chemistry in field conditions

Dr. Florian Muthreich [1]***, Dr. Boris Zimmermann*** [2]***, Prof. Matthew Robson*** [3]***, Dr. Alistair Seddon*** [1]

1. *University of Bergen,* ***2.*** *Norwegian University of Life Sciences,* ***3.*** *Viiki Plant Science Centre*

Ultraviolet radiation has effects on the biosphere at the level of genes, species and ecosystems. Despite the significance of UV-B for ecosystems functioning and individual plant fitness, the response of plants to UV radiation remains poorly understood. One of these responses is the production of *para*-coumaric acid to protect cell contents from the adverse effects of UV. *Para*-coumaric acid is an important compound in the pollen grain wall and is theorized to act as a "sunscreen" for pollen grains and the genetic material within. Nevertheless, the relationship between dose and response of para-coumaric acid to UV in pollen grains is not fully understood. Plant responses to UV radiation are mediated by environmental factors and by interacting regulatory and stress-induced pathways in the plant. UV exposure experiments have shown contradictory results from dose-responses and stress responses to UV damage, which indicate that multiple mechanisms are involved in regulating a plants response to UV exposure. For pollen chemistry it is important to untangle the response of para-coumaric acid production to not just UV-B, but also in combination with UV-A and PAR.

We present the first results from field experiments to help understand the chemical response in pollen to UV-radiation. In the field experiment three filters were attached to branches of *Pinus* uncinata trees to shield the pollen from i. only UV-A radiation, ii. both UV-A and UV-B radiation, and iii. permit all UV radiation. After maturation of the pollen, chemical methods are used to identify the composition of the pollen (IR/Raman spectroscopy, and mass spectrometry). This field experiment aims to identify the effects of natural UV-B radiation on pollen-chemical composition in general and on *para*-coumaric acid in particular. Our results are the first systematic field experiment which manipulates incoming solar radiation and its effect on pollen chemistry. These results will further our understanding of chemical responses to UV radiation and represent an important contribution to the ongoing effort to develop a UV-proxy based on pollen chemistry.

The role of the Moonmilk speleothem in hypogeal archaeological sites

The moonmilk is a speleothem of microbial origin, usually formed by nanofibers of calcium carbonate, and found in karst caves. We discovered the presence of the moonmilk in the Etruscan hypogeal tombs of Tarquinia, a unique case of a biogenic activity resulting in protective rather than damaging a cultural heritage site. In fact, after 2,500 years, the Etruscan mural paintings in these hypogeal tombs were found well preserved under the white patina of the moonmilk. To study this phenomenon, we previous analyzed the calcite nanofibers of 5 tombs, together with their microbial communities. A deep investigation of the geology of this site was also conducted to unravel how the co-evolution of microorganisms and the rock contributes to this calcium carbonate deposition.

The Etruscan tombs were carved in a yellow calcarenite, called *macco*, rich in calcium, produced 5 million of years ago, during the Pliocene. In Italy, a similar calcarenite rock is found in Puglia, in the south of Italy. This region is rich in karst caves and many of them harboring important archaeological remains. One of the most famous sites is the Lamalunga cave, near Altamura, Puglia, where a complete Neanderthal skeleton was discovered in 1993. We had the opportunity to take samples from this cave and we will present a comparative analysis of the calcarenite rocks and the microbial communities of the moonmilk from Tarquinia and Lamalunga archaeological sites, to investigate the geomicrobiological situation, as a part of a preservation project of archeological karst caves, to be ready, in the near future, to identify criticisms due to climate changes.

Genetic structure of the population reflect the Pleistocene glaciations: the case of the humid- and cold-tolerant root vole Alexandromys oeconomus (Rodentia, Cricetidae) in Poland (Central Europe)

Prof. Ewa Falkowska [1], *Prof. Elżbieta Jancewicz* [2]

1. University of Warsaw, Faculty of Geology, Warsaw, 2. Warsaw University of Life Sciences - SGGW, Institute of Forest Sciences, Department of Forest Zoology and Wildlife Management, Warsaw

Contemporary distribution of species in many areas of the globe is the result of phenomena occurring in the Pleistocene. During this period there were significant changes in the climate and extensive areas were occupied by ice sheets. Their presence not only limited the range of species, but also influenced the shape of the landscape, and thus the contemporary habitat system that determines biodiversity pattern. The purpose of the presented research was to find out how the landscape of eastern Poland, formed as a result of subsequent Pleistocene glaciations: Sanian 1, Sanian 2, Odranian, Wartanian and Vistulian, affects genetic differentiation of a species. The hypothesis was tested by analyzing the DNA of the root vole *Alexandromys* (*Microtus*) *oeconomus* (Arvicolinae, Rodentia) - boreal and hygrophilous species. Samples of tissue were collected from 439 vole individuals at 33 locations in different post-glacial landscape zones. Based on analysis of 12 microsatellite loci and the 908 bp of cytochrome b sequences (mtDNA), the genetic structure of M. oeconomus in the landscape zones of Polish Lowlands was determined. The results of the study showed that longitudinal variability of the relief in the area of eastern Poland (resulting from different limits of Pleistocene glaciations) and the related specific configuration of hydrogenic habitats are reflected in the genetic differentiation of the root vole. It was found that the best living conditions for this species persist in large habitats with a high degree of connectivity - in swampy river valley systems of central eastern Poland, shaped mainly during the Wartanian Glaciation. The lowest genetic variability was found in the most mature, southern zone, the original relief of which was formed during the oldest glaciations (Sanian 1 and Sanian 2). It indicates that the most difficult conditions of life for the root vole occur there. And this is due to a completely different arrangement of habitats preferred by this species. The relationships found may also become an indicator useful in explaining the geological history of the region.

A needle in the haystack: Tracing and quantifying the sea ice diatom and IP25-producer Haslea spicula in environmental DNA samples

Dr. Sara Harðardóttir [1], Mr. Joshua Roland Evans [2], Dr. Jessica Louise Ray [3], Dr. Remi Amiraux [4], Dr. Guillaume Massé [4], Prof. Connie Lovejoy [5], Dr. Audrey Limoges [6], Dr. Sofia Ribeiro [7]

One of the most striking effects of climate change is the continuing loss of Arctic sea ice in the last decades. Past sea-ice conditions are poorly understood particularly prior to the satellite era, and there is a significant gap in our understanding of sea-ice variability on geological timescales. Therefore, there is a need to develop new reliable proxies that can capture sea ice variability. Sea ice harbors a vast biodiversity of unicellular microorganisms with fine-tuned evolutionary traits. Sedimentary ancient DNA has recently been shown to be a promising tool for reconstructing past marine biodiversity. However, most of the species that are truly specific to sea ice only account for a small fraction of the biota, are understudied, and for DNA approaches references are largely missing in existing DNA databases. A few species of the diatom genus *Haslea* produce a source-specific molecular compound (a lipid biomarker named IP_{25}) that can be preserved in the seabed for millions of years. However, the environmental and physiological conditions controlling the production of IP_{25} are not well understood and thus detecting the species itself might provide more robust reconstructions. In classical diatom microfossil assemblages and in DNA metabarcoding studies, the IP_{25} producers are usually not detected. Here, we explore the potential to detect and quantify past occurrences of *Haslea spicula* in sedimentary ancient DNA records. Several strains of diatoms from Hudson Bay in the Canadian sub-arctic were isolated into monocultures, among them three strains of *H. spicula*. The strains were confirmed to produce $IP_{25.}$ We isolated a molecular signal from the *rbc*L gene and designed a beacon specific to *H. spicula* that can be used to trace and quantify this species in marine sediments using a droplet digital PCR approach. DNA was isolated from ~ 100 surface sediment samples in Baffin Bay and Northeast Greenland, as well as from locations outside the seasonal sea-ice regime to compare with sea-ice concentrations and biomarker profiles. We validated the approach by applying it to a dated sediment core record from Northeast Greenland.

The main periods and environment factors of coastal sand dunes developments in the East Asia during the mid to late Holocene

Dr. Min Han [1], ***Dr. Jin Cheul Kim*** [1], ***Dr. Dong-Yoon Yang*** [1], ***Dr. Jaesoo Lim*** [1], ***Dr. Sangheon Yi*** [2]

1. Korea Institute of Geoscience and Mineral Resources, 2. Korea Institute of Geoscience and Mineral Resoiurces

To confirm coastal sand dune development processes and periods in the west coast of the Korean Peninsula, this research examined the depositional age using optically stimulated luminescence (OSL) dating for three dunes including Taean Chollipo, Seocheon Dasari, and Gochang Sabanri dunes. The results were then compared with those of previous research. Sedimentation rates were calculated for the three dunes, and their development periods were classified through statistical analysis that included data from previous studies. According to the results, the coastal dune development during mid to late Holocene was divided into five main periods: <0.1, 0.2−0.5, 1.2−2.0, 2.5−3.2, and 5.5−6.5 ka. These periods correlate with the periods global cooling of the Holocene by ice rafted debris (IRD) records. The development of coastal dunes is mainly affected by the global cooling events and the enhanced East Asian winter monsoon. In addition, human activity increases also contributed to the development of the dunes recently.

Unravelling the evolution of a complex strandplain (Western Port, Australia)

Dr. Daniela Mueller [1]***, Prof. Ruth Reef*** [2]***, Dr. Rafael Carvalho*** [2]

1. *University of Freiburg, Faculty of Environment and Natural Resources, Institute of Earth and Environmental Science,* ***2.*** *School of Earth, Atmosphere and Environment, Monash University, Clayton, Victoria, Australia*

Strandplains, or prograded barriers are worldwide distributed, coastal landforms that provide a palaeoenvironmental record within a sequence of successive, mostly linear ridges and intervening swales. While many of these landforms have been studied intensely, those with variable terrestrial morphologies are often poorly understood due to their complexities and uniqueness. One complex strandplain stretches along the main entrance of Western Port on the southeastern coast of Australia. This morphologically complex barrier was formed as a function of its somewhat sheltered position and orientation in relation to sporadic swells and tidal circulation. LiDAR-derived topography shows highly truncated and asymmetrical ridges both across and along the plain. These uncommon morphologies are associated with an intricate hydrodynamic circulation subject to sporadic storms approaching at a sharp angle to the shoreline that eliminate a significant part of the sedimentary record but also redistribute vast quantities of sand to the downdrift shoreline, and a large and variable sandy bank that undergoes intense sediment movement. Using optically stimulated luminescence (OSL) dating of quartz, it was possible to unravel the rather unique and entangled development of this strandplain. An age of around 2,600 years for the innermost dated ridge, located about halfway across the plain. Significant erosion of the ridges' record occurred on the western side of the barrier between 2,600 and 700 years ago and between 600 and 240 years ago while ridges on the eastern side were preserved. Sediment characteristics suggest that the type of material provided for barrier accretion remained the same throughout the late-Holocene. An evolutionary model is proposed to decipher this barrier's formation and contribute to the sediment budget of Western Port.

Boulder barricades in northern Finnmark, Norway

Dr. Chantel Nixon [1]

1. *Norwegian University of Science and Technology*

Spectacular boulder barricades are widespread along the Barents Sea coast of Finnmark, Norway, similar to those found along other parts of the Norwegian coast, the Baltic Sea and in eastern and Arctic Canada. Not particularly well studied in terms of their formation, boulder barricades are nonetheless important Arctic coastal landforms that play an important role in arctic pond and wetland development. The spatial distribution of the northern Finnmark boulder barricades, classified into distinct types, will be presented alongside an analysis of the processes and conditions responsible for their formation, including sea ice, currents, wind, waves, coastal physiography, and changes in relative sea-level, past and present.

Misremembered natural heritage: a case for integrated ecologies

Dr. Rebecca Hamilton [1], ***Prof. Dan Penny*** [2], ***Prof. Josephine Gillespie*** [2]

1. Max Planck Institute for Geoanthropology, 2. University of Sydney

The significance of geohistory, including oral history, is commonly overlooked in the practical management of today's natural landscapes. In Australia, conservation policy is largely embedded in the physical sciences, with targets directed at the preservation or restoration of Indigenous or early-European ecological benchmarks. For example, federal and state environmental legislation strives to protect "Endangered Ecological Communities" (EECs). These purportedly represent remnants of naturally occurring groups of plants, animals and other organisms. In many cases, however, classifications of EECs are made in the absence of any long-term data, making it unclear as to whether the "natural" community that is being protected is indeed "natural". Further, it precludes an understanding of past Indigenous land-use practices, making it challenging to manage landscapes appropriately to account for the range of past disturbances that are crucial for shaping ecosystem expression and resilience dynamics. We use multidisciplinary geohistorical data to map the long-term socio-ecological history of freshwater wetlands that were once a key landscape feature of Australia's biggest city, Sydney, and today provide habitat for EECs protected under State and Commonwealth legislation. Our results clearly demonstrate that what is being conserved today is remarkably different from the pre- and early- European landscape, highlighting how quickly we can come to "misremember" landscapes of the past. This showcases the importance of long-term, multidisciplinary data from both the social and physical sciences for developing evidence-based conservation policy. More broadly, it highlights flaws in post-colonial approaches to environmental management.

Combining palaeoecology and system dynamics modelling to inform management and restoration in the Cape Floristic Region, South Africa

Dr. Cherié Dirk [1], ***Prof. Lindsey Gillson*** [2], ***Prof. M. Timm Hoffman*** [1]

__1.__ Plant Conservation Unit, University of Cape Town, South Africa., __2.__ Plant Conservation Unit, University of Cape Town South Africa.

Effective restoration and sustainable management of ecosystems requires knowledge of the extent of anthropogenic impact over recent decades and centuries, and identification of management options that can restore ecosystem services. Combining palaeoecological reconstructions of past changes with modelling techniques allows stakeholders to understand landscape history and explore the effects of different management interventions and future scenarios.

This transdisciplinary study investigates the variability plant biodiversity and drivers of change by combining palaeoecology, stakeholder engagement and system dynamics modelling. Palaeoecological data (fossil pollen, spores, charcoal) were used to define the historical range of variability in vegetation, herbivory and fire. Stakeholder collaboration was used to identify feedbacks between environmental (climate) and anthropogenic (fire, herbivory) drivers, a process that underpinned the development of causal loop diagrams and a system dynamics model that was used to explore the implications for restoration and management.

The 1300-year-old palaeoecological record from Elandsberg Private Nature Reserve, in the Cape Floristic Region of South Africa shows a decrease in plant biodiversity driven by increasing grazing and exacerbated by increased fire during agricultural and conservation activities. Specifically, intensive grazing and burning from the 1950s led to an increase in *Elytropappus* (renosterbos) that persisted after the area was declared a nature reserve, with continued high levels of grazing and burning. The associated system dynamics model successfully simulated this transition. Running the mode with various combinations of fire and herbivory suggest that it will be difficult to restore the ecosystem to its former state, even if fire and grazing are reduced.

The study shows the potential of integrating palaeoecological work with system dynamics modelling to engage with stakeholders and guide effective restoration and sustainable management of social-ecological systems.

Towards integrating palaeoecological and traditional knowledge to preserve the Ethiopian Ericaceous belt.

***Dr. Graciela Gil-Romera* [1], Mr. Mekbib Fekadu [2], Mr. Lucas Bittner [3]**

***1.** ARAID Researcher - Pyrenean Institute of Ecology - CSIC, **2.** Plant Ecology and Geobotany, Faculty of Biology, Philipps University of Marburg, Germany | Department of Plant Biology and Biodiversity Management, College of Natural and Computational Sciences, Addis Ababa University, Ethiopia, **3.** Heisenberg Chair of Physical Geography with Focus on Paleoenvironmental Research, Institute of Geography, Technische Universität Dresden*

The Afromontane biome is a globally important biodiversity hotspot, supporting the livelihoods of more than 200 million people by providing essential natural resources and ecosystem services. The biome occurs between ca. 2000 to 4000 m asl including the Ericaceous belt (EB) above 3200 m asl, The EB is one of the most fragile Afromontane communities, dominated by *Erica arborea* and *E. trimera* stands. It is especially and critically endangered by rising temperatures and unpredictable rains, rapid population growth, and agricultural expansion. Conservation efforts in the EB have traditionally aimed to limit burning practices in protected areas, despite evidence that fire has been used as an agropastoral tool on the African continent for tens of thousands of years and current research suggesting that elimination of burning may result in high-severity fires.

The EB is one of the ecosystems where fire has long been used by people and local knowledge and paleoecology therefore need to be considered in conservation planning. Here we show how information on long-term ecosystem dynamics from the Ethiopian Ericaceous belt in the Bale Mountains National Park (BMNP) can be combined with interviews to pastoral communities of the Arsi Mountains National Park (AMNP). Both protected areas present similar vegetation and human activities, but AMNP receives less tourism, and traditional cattle and farming management is more widespread. Combining both perspectives will produce an integrated scenario on past vegetation change, as well as a better understanding of local attitudes about the environment in the Ericaceous Belt.

The evidence from paleoecology and local community knowledge suggests that past burning patterns in the Ethiopian highlands occurred under fire-conducive climates and seasonal biomass accumulations. We also inferred that intermediate fire return intervals, between 4 to 30 years, may have sustained a continuous Erica cover. The results suggest that a total fire ban will lead to important changes in EB structure and high-severity fires, given current increasing temperatures and population. As still many questions remain, we plan to continue our paleoecological research in the Arsi Mountains by examining other lake-sediment records as well as starting new calibration studies including the local knowledge and communities perspectives.

Response, resilience, and recovery of Tasmania's endangered Pencil Pine using a multi-archive palaeoenvironmental record

Ms. Sarah Cooley [1], ***Prof. Michael Fletcher*** [2], ***Prof. Russell Drysdale*** [2], ***Dr. John Hellstrom*** [1], ***Dr. Patricia Gadd*** [3], ***Dr. Quan Hua*** [3]

1. *School of Geography, Earth and Atmospheric Sciences, The University of Melbourne,* **2.** *University of Melbourne,* **3.** *ANSTO*

The Tasmanian Wilderness World Heritage Area (TWWHA) in Australia is home to globally significant and highly valued flora, with ancestries in the Gondwanan supercontinent. Anthropogenic climate change is shifting baseline conditions and increasing pressures on long-lived palaeoendemic tree species directly via increasing temperatures and aridity across southeast Australia and indirectly via increased lightning-ignited wildfires. During the summer of 2016 over 80 wildfires were ignited across the Central Plateau (Tasmania/Lutruwita) decimating stands of Gondwanan taxa in TWWHA severely threatening core refugia of extremely fire-sensitive palaeoendemic conifer *Athrotaxis cupressoides* (Pencil Pine).

In the Northern Hemisphere, fire-sensitive species with demographic traits similar to Pencil Pine (i.e., long-lived (>1000 years), slow-growing and poorly dispersed) are becoming increasingly climatically stranded as envelopes of optimal climate conditions rapidly migrate with altitude and latitude. This increases their vulnerability to loss or extirpation when left exposed in areas where climate is unfavourable for post-fire regeneration.

Despite efforts to manage threatened Tasmanian ecosystems, the long-term impact of climate change (and other factors) on the resilience of these systems remains poorly understood. Thus, there is a lack of understanding of how to apply the most efficient, impactful and cost-effective management strategy. Here, there is a need to develop a deep, long-term understanding of these long-lived ecosystems to execute well-informed land-management strategies for their future preservation.

This project applies palaeoecological and geochemical analyses on organic sediments extracted from lake and bog sites across the Central Plateau (Lutruwita) coupled with high-resolution palaeoclimatological speleothem analysis performed on a stalagmite collected from a proximal cave site. This research will provide a detailed multifaceted understanding of how historical species composition, fire regime and moisture variability has influenced the response, resilience and post-fire recovery of Pencil Pine dominated systems across the Central Plateau throughout the Holocene (ca ~11.7 kyrs to present). Such findings aim to facilitate a holistic understanding of how best to target management efforts to preserve highly threatened Pencil Pine, and other long-lived fire-sensitive ecosystems in the wake of the climate crisis.

Ostracod shell chemistry as an independent measure of shallow lake eutrophication?

Dr. Lucy Roberts [1], ***Dr. Thomas Davidson*** [1]

1. *Department of Ecoscience, Aarhus University, C. F. Møllers Allé 4-6, 8000 Aarhus, Denmark*

Shallow lakes provide extensive ecosystem services and are ecologically important non-marine resources, supporting a diverse flora and fauna. However, worldwide lakes are threatened by environmental degradation (e.g. nutrient pollution from agricultural fertilizers). The restoration of these environments is critical for future biodiversity, resilience to climate change, the provision of ecosystem services, and is legally binding under the EU Water Framework Directive (WFD). To meet the requirements of ‘good ecological status’, lakes must not be significantly altered from pre-defined ‘reference conditions’, which are the conditions expected in the absence of anthropogenic impacts. Palaeolimnology offers a method to define reference conditions for effective restoration. However, existing approaches (e.g. diatom transfer functions) for reconstructing nutrient enrichment are problematic due to their indirect approach that involves major assumptions. Multi-proxy studies attempt to disentangle drivers but fail due to circular reasoning and a lack of an independent measure of phosphate (P). Ostracod (small bivalved crustaceans) shells, however, calcify using elements taken from the lake water, providing a direct reflection of lake-water concentrations. Here, we present results of ostracod shell chemistry (P/Ca) calibrations from natural and controlled environments to reconstruct palaeo-P concentrations. Robust independent palaeo-P concentrations are a potentially significant advancement in the ability to 1) set reference condition P concentrations for shallow lake restoration targets under the WFD and 2) to predict the effects of future climate change on freshwater biodiversity.

Climate and human impacts on montane forests in the Simmental near Boltigen, Northern Swiss Alps

Ms. Sina Aregger [1], Ms. Lieveke van Vugt [1], Dr. Erika Gobet [1], Prof. Willy Tinner [1]

1. Institute of Plant Sciences & Oeschger Centre for Climate Change Research, University of Bern

Global change significantly impacted life on Earth over the last few decades and negative effects such as species losses or community collapses are anticipated to increase in the future. One of the most pressing challenges associated with global change is assessing potential ecosystem responses to global warming as well as land-use. Mountain ecosystems, such as the European Alps, are particularly vulnerable to global change due to the presence of endemic and highly specialized species along steep climatic and ecological gradients. Understanding long-term vegetation responses to past climate change and anthropogenic disturbance is critical for assessing future community and ecosystem responses to global change. In the Alps, fundamental uncertainties about former vegetation dynamics and human impact still exist. Novel well dated, multi-proxy reconstructions are needed to better understand the interactions between climate, vegetation, fire and land use.

We cored two neighbouring montane mires in the Simmental, Northern Swiss Alps, Chutti (941 m a.s.l.) and Chrome (995 m a.s.l.), which will be analysed for pollen, spores, stomata, microscopic charcoal and plant macro-fossils. The Late Glacial vegetation history of these mires was studied by the palaeoecology pioneer Max Welten since the 1930's, but the Holocene vegetation history remains unexplored. A recently discovered Bronze Age hilltop settlement in very close proximity to the mire Chutti shows the potential of the sites in studying the impacts of land use on local vegetation. Moreover, not much is known about the ecosystem history of the intermediate elevations in the Simmental and generally the Swiss Alps. Here, we will use different statistical techniques, like ordination analyses, cross-correlations and biodiversity estimations to analyse our data and quantify the impacts of climate, land use, fire and browsing on vegetation dynamics. The results will be crucial in contextualising recent ecosystem changes and are needed to plan appropriate restoration strategies under global change conditions in order to avoid biodiversity and ecosystem service losses.

Understanding ecological change at popular inshore reef settings in the Whitsundays, Great Barrier Reef, Australia

Dr. Tara Clark [1], ***Dr. Nicole Leonard*** [2], ***Dr. Hannah Markham Summers*** [3], ***Ms. Ellen Hall*** [3], ***Ms. Jasmine Hunter*** [1], ***Ms. Ariella Arzey*** [1], ***Mr. Josh Melleuish*** [1], ***Mr. Hugo Fahey*** [1], ***Prof. John Pandolfi*** [3], ***Prof. Jian-xin Zhao*** [3], ***Prof. Helen McGregor*** [1]

1. *School of Earth, Atmospheric and Life Sciences, The University of Wollongong, Wollongong, NSW 2522, Australia,* **2.** *Radiogenic Isotope Facility, School of Earth and Environmental Sciences, The University of Queensland, Brisbane, QLD 4072, Australia,* **3.** *The University of Queensland*

Historical photographs of reef environments have been contentiously used in recent years to highlight the decline of the Great Barrier Reef since European settlement. Yet the presence of low levels of living coral and high macroalgal cover may represent natural senescence or a transitional stage following recent disturbance, rather than a degraded state. By taking a multidisciplinary approach that combines geomorphology, palaeoecology, geochronology and palaeoclimatology, our aim is to provide a comprehensive understanding of coral community change for inshore reef flat environments from the popular Whitsundays region, a major tourist destination that has been repeatedly photographed since c.1890. Elevation surveys of Bramston Reef, Stone, Hayman, Daydream and Saddleback Island conducted during periods of lowest astronomical tide in 2012, 2021 and 2022, reveal all reef crest environments depicted in the historical photographs to lie well below the upper limit for coral growth [i.e. ±20 cm mean low water spring tide level], suggesting vertical accommodation space is not a limiting factor for reef health. Uranium-thorium dating of surficial dead coral assemblages collected from these locations revealed mortality to have occurred before modern ecological surveys began (with the exception of Hayman Island), with ^{230}Th ages bracketing the timing of historic acute disturbance events such as major flooding and cyclones. Modern benthic photographic surveys suggest coral recovery is taking place at all locations except Stone and Daydream Island, with both remaining at <5% coral cover for the entire survey period. We attribute this to be a result of low structural complexity and long-term chronic disturbance, respectively. These results provide a preliminary baseline understanding of coral community change over the past several centuries with which to appropriately assess the current and future health of Whitsunday reef systems.

What is ‘natural’? Stand-scale pollen and plant macrofossil analyses of remnant broadleaved woodlands in Scotland offer insight for restoration

Ms. Annabel Everard [1]***, Dr. James Schofield*** [1]***, Dr. Tim Mighall*** [1]***, Dr. Gill Plunkett*** [2]***, Dr. Scott Timpany*** [3]

Extending the timescales over which we understand the scale and drivers of change is vital in efforts to restore more naturally functioning and resilient ecosystems. Our research focuses on remnant ‘ancient’ semi-natural broadleaved woodlands in Scotland which have been designated for conservation. With woodland cover considerably lower than the European Union average (18.5% versus 38% of land area), Scotland has ambitious plans to expand woodland cover and restore more favourable ecological conditions. Ancient woodlands are often considered to be the natural ecosystem ‘baseline’ against which woodland management strategies are conducted. However, plot-based long-term woodland monitoring is typically limited to timespans shorter than single generations of long-lived tree species – meaning management and restoration efforts may be based on inappropriate reference conditions.

In this paper, we demonstrate that palaeoecological data can provide records of woodland dynamics on a spatial and temporal scale that is highly relevant to ecologists and site managers. Pollen and plant macrofossil analyses of peat deposits from forest hollows are used to provide highly localised records of vegetation change over the last c.1500 years, thus spanning multiple woodland generations. ‘Stand-scale’ insights into compositional and structural changes, and their drivers, are more closely comparable to long-term woodland monitoring than more traditional landscape-scale palynology. Our approach also focuses on sub-canopy layers which are often masked by the canopy forming trees. Plant macrofossil analysis is used to compliment pollen analysis and heighten taxonomic resolution. Micro and macro-charcoal analyses and coprophilous fungi are utilised to assess disturbance from fire and herbivory. Robust chronologies are provided by radiocarbon (^{14}C) based Bayesian age-depth models.

Collectively, these techniques are used to explore the effects of grazing, burning and management on woodland composition, species diversity, function and resilience. We critique associations between woodland continuity and conservation value and investigate whether woodland biodiversity has changed over time. Potential shifts in baselines are identified and we highlight the importance of human activities as agents of woodland change and survival.

From early Medieval forest fires and livestock foraging to the current phase of global warming (Valmalenco, Italian Alps): hints for rewilding and nature conservation

Dr. Giulia Furlanetto [1]***, Dr. Renata Perego*** [2]***, Dr. Davide Abu El Khair*** [3]***, Dr. Federica Badino*** [4]***, Dr. Paolo Bertuletti*** [2]***, Prof. Roberto Comolli*** [3]***, Prof. Giovanni Vezzoli*** [3]***, Prof. Valter Maggi*** [3]***, Dr. Cesare Ravazzi*** [2]

An increasing array of observations shows that European mountains are experiencing a period of intensified environmental transformation. However, the timing, rate and amplitude of these changes are only partly detectable by monitoring contemporary ecosystem dynamics. Too many ecological alterations occurred since Medieval permanent settlements, overriding part of the pristine (i.e., pre-Neolithic) ecosystem structure. More recent trajectories in land use promoted by industrial revolution were ultimately redirected, due to a fast abandonment since the Second World War and the last forty years of amplification in Global Warming. We suggest that land use changes observed since the mid- to late-19th century may provide one of the tipping points connecting earlier baselines with the contemporary active pressures on mountain ecosystems. This requires focusing on the timing, the rate of change, and the mutual interaction between climate and land-use variation with a decadal to centennial scale resolution.

We discuss the contribution of paleoecology and historical ecology to assess contemporary dynamics through a case study on the last 1750 years of forest fires and livestock foraging in Valmalenco that combines co-registered microbotanical data, charcoal analyses, sediment lithology, mineral nutrients, modern pollen deposition, dendrochronological information, and documentary written records. The following ecological processes concern future strategies of nature conservation and rewilding: (i) slope denudation connected to fire events in the late Roman age; (ii) early medieval forest fires in pristine mixed conifer forest with *Abies alba*, nowadays eradicated; (iii) Late Medieval expansion of the foraging area for pastoralism, timberline depression and expansion of larch parklands, and preservation of old-growth larch individuals; (iv) Industrial Age and the post- World War II abandonment of traditional land uses and (v) the last forty years of increasing trend in Global Warming.

Disturbances mediated European mountain forest diversity and stability

Recent studies have shown that latitude is responsible for Europe's primary long-term diversity gradient, controlled by climate and human impact combined, the latter being more prominent in recent millennia. The diversity trends may also vary regionally depending on the biogeographical regions. The disturbance is essential for maintaining or even increasing ecosystem diversity in many systems, therefore it is crucial to reconstruct its past dynamics. The European mountain forests dominated by spruce and beech have been affected by many threats in recent decades, increasing their vulnerability of loosing biodiversity and stability. These ecosystems may serve as a long-term laboratory to study these threats.

We reconstruct long-term diversity trends on the longitudinal gradient in central-eastern Europe across several biogeographical regions. We use data from multiple proxies (pollen, plant, and insect remains). Primarily, we use richness in fossil taxa as an index of their alpha diversity. To uncover ecosystem diversity's complex mechanism, we also reconstruct beta diversity for standardized time slices. To better understand the diversity dynamics, we reconstruct disturbance regimes using charcoal data, pollen-based disturbance indicators and insects. Moreover, we also calculated the stability index of the ecosystem based on change point analysis of dominant taxa and their variability assessment.

Our results support the previous findings of increasing diversity gradient throughout the middle and late Holocene and reaching higher values at the gradient towards the east. We observe much higher fire activity and overall disturbance in the east than in the west despite increasing trends in beech representation in the forests in both regions and relative forest stability. Climate may be one of the reasons behind such a trend, and the trend itself could also help maintain the higher diversity in the east. Beta diversity shows first the homogenizing trends in ecosystem development shifting to more diversification of ecosystems amplified by intensifying human impact. We conclude that moderate human activities may be beneficial in maintaining forest stability and diversity, but the observed accelerating trend in disturbance and deforestation during the Anthropocene may imply enormous threats to mountain forest diversity in the near future.

Peatland restoration based on a landscape (palaeo)ecological system analysis (LESA): the case of Aamsveen, eastern Netherlands

Dr. Marjolein van der Linden [1]***, Prof. Jan Sevink*** [2]***, Dr. André Jansen*** [3]

1. *BIAX Consult Biological Archaeology & Environmental Reconstruction,* ***2.*** *University of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics, Amsterdam, The Netherlands,* ***3.*** *Stichting Bargerveen/Unie van Bosgroepen*

This study illustrates the relevance of a spatiotemporal landscape ecological system analysis (LESA) for the recovery and sustainable management of a complex, dynamic rare wetland ecosystem. The Dutch Aamsveen lies in a glacial basin in the Dutch-German border area. It consists of remnants of a cross-border raised bog and a lagg with degrading species-rich basiphilous plant communities. Farther west, the Glanerbeek drains the footslope at the edge of the basin and adjacent lagg. For the Netherlands, this is a rare wetland ecosystem and an important Natura 2000 area, but it is threatened by ongoing degradation. A spatiotemporal LESA, including extensive palaeoecological research, showed the fundamental role of the interplay between infiltrating acid bog water that gradually acquires basic cations from the underlying base rich sediments as it flows laterally towards the lagg, where it seeps up, and the (lesser) influx of base rich surficial groundwater from the ice-pushed ridge in the west. Anthropogenic disturbance of this interplay has led to serious system degradation. The results of this LESA, in which palaeoecological, geophysical, hydrological and ecological data were combined, served to develop an integrated management plan at landscape level, instead of habitat level plans as is usual in the context of Natura 2000. This research is therefore a great example of integrating paleoecology in nature conservation and restoration ecology.

Validating future land use change scenarios using long-term perspectives from lake sediment records: approaches to restoring freshwater total phosphorus conditions

Dr. Madeleine Moyle [1]***, Dr. John Boyle*** [1]***, Prof. Richard Chiverrell*** [1]***, Dr. Victoria Janes-Bassett*** [1]***, Ms. Daisy Burris*** [2]

__1.__ Department of Geography and Planning, University of Liverpool, ***2.*** *Natural England*

Phosphorus (P) supply to freshwater systems has accelerated over the last few centuries due to land use intensification and exacerbated landscape degradation, causing a global deterioration in water quality and ecosystem health. Reversing this trend requires management decisions that prioritise stabilising the landscape and re-establishing natural ecosystem functioning via land use change, that will ultimately work towards restoring 'pre-disturbance' lake water total P (TP) conditions.

Export coefficient and process models can be used to estimate how such changes will impact on catchment P cycling. However, it is not possible to determine whether the modelled scenarios represent realistic responses of P dynamics to land use change without comparison to suitable analogues. Lake sediment geochemical records of historical catchment P export can provide an empirical framework for validating past (and thus future) model predictions.

Here we present a critical comparison these methods using case studies from the Shropshire-Cheshire Meres, a collection of lakes with a long history of human activity; clear impacts on P cycling are visible from the Neolithic and there is evidence that cultural eutrophication occurred as early as the Iron Age. We compare outputs from export coefficient and processes model outputs with lake sediment records of Holocene landscape P export and land use change. Using this combined approach, we find that it may not be possible for lake water TP to return to 'pre-disturbance' levels, as present-day atmospheric loadings, including lateral contributions from adjacent catchments, are too high. However, the modelling suggests that it may be possible to achiever 'good' TP concentrations if the direct contribution from cattle and the human contribution via septic systems are removed. The modelling approach combined with the long-term perspective from the sediment record provides a robust basis for exploring management options for reducing lake water TP concentrations.

Geoarchaeology of the Younger Dryas in the Northern Great Basin, USA: The View from the Paisley and Connley Caves

Dr. Justin Holcomb [1], ***Dr. Lisa-Marie Shillito*** [2]

1. *University of Kansas,* ***2.*** *Newcastle University*

In the northern Great Basin, the Younger Dryas Cold Event (YDCE) occurred between 12,900–11,600 years ago (cal yr BP) and is marked by cold temperatures and wetter conditions which resulted in pluvial basins being filled with shallow but permanent lakes or well-watered marshes or meadows. Consequently, the region experienced rapid changes in plant and animal communities that subsequently affected late Pleistocene and early Holocene human population organization and settlement dynamics in the region. The abrupt shift to cold and wet climates appears to have positively affected Paleoindian foragers, but a lack of well-dated and stratified archaeological sites hinders our ability to adequately test this hypothesis and place early foragers into broader discussions of human-environment dynamics. Thus, there is a need for high-resolution studies of deposits containing evidence of occupation spanning this key late Pleistocene to early Holocene transition, especially those aimed at shedding light on the types of deposits, characteristics, and features that define the YDCE. Research at the Paisley and Connley Caves since 2015 has revealed stratified deposits with rich cultural assemblages spanning the LP/EH transition, providing a unique opportunity to study Paleoindian lifeways during this key climate transition. Our results suggest that YD-aged deposits at the Connley and Paisley Caves were altered under periglacial conditions, consequently exhibiting weakly and moderately developed cryogenic structures. Soil micromorphology revealed cryogenic fabrics and features, including banded and lenticular fabrics, silt caps, vesicular pores, and ice blades. Coupled with high-resolution mapping of cultural materials and radiocarbon dating, this paper incorporates geoarchaeological data and outlines one approach for disentangling human-environment dynamics occurring at the end of the Pleistocene, thereby providing a framework for understanding similarly-aged sites in the northern Great Basin.

Late Pleistocene and Holocene climate variability in inland Iberia. Stalagmites from Los Casares cave (Guadalajara, Spain).

Dr. Virginia Martínez-Pillado [1], ***Dr. Eneko Iriarte*** [2], ***Prof. Hai Cheng*** [3], ***Dr. Luis Luque*** [4], ***Dr. Manuel Alcaraz-Castaño*** [4], ***Dr. José Javier Alcolea-González*** [4], ***Dr. Adrián Pablos*** [5], ***Dr. Nohemi Sala*** [6]

In the central area of the Iberian Peninsula there is a great general void in the study of speleothems, being limited to Castilla y León the vast majority of works carried out. In this paper we present a paleoclimatic reconstruction during the Late Pleistocene and Holocene, comprising part of the Marine Isotope Stages (MIS) 3-1, from two stalagmites from Los Casares cave (Guadalajara, Spain) based on U/Th dating and stable isotopes. The Cueva de los Casares is the most important site with Palaeolithic rock art in the centre of the Castilian Plateau and contains a key archaeological deposit for the understanding of the human occupation of the last Neanderthals in the interior of the peninsula. Due to the presence of this important site in the cave, it has been possible to correlate the regional paleoclimatic variations recorded in the stalagmites with the anthropic activities in the cave during the Middle and Upper Palaeolithic in inland Iberia.

Multiproxy evidence for the Late Pleistocene environmental stability in the Lesser Caucasus

Dr. Mariya Antonosyan [1], ***Ms. Armine Davtyan*** [2], ***Ms. Satenik Mkrtchyan*** [2], ***Dr. Ricardo Fernandes*** [1], ***Prof. Michael Petraglia*** [3], ***Dr. Patrick Roberts*** [4], ***Prof. Nicole Boivin*** [1], ***Prof. Levon Yepiskoposyan*** [2], ***Dr. Noel Amano*** [1]

Located at the crossroads of out-of-Africa migration routes, the Lesser Caucasus served as a natural passage, the so-called Trans-Caucasian corridor, that enabled hominin dispersal out of the Levant and into the rest of Eurasia during the Pleistocene. Additionally, it has been long debated whether the region persisted stable environment throughout the last glaciation and served as a refuge for ancient human groups and temperate biota.

To deepen our knowledge of the Late Pleistocene environmental conditions and test the refugium hypotheses we endeavoured a multidisciplinary exploration of Karin Tak cave, Lesser Caucasus. In particular, we examined biostratigraphic changes in the site by looking at the taxonomic composition of acquired samples using traditional paleontological/zooarchaeological approaches and novel molecular methods of faunal identification including the use of collagen fingerprinting and aDNA metabarcoding. Father, to zoom into the region's environmental conditions, we applied stable carbon and oxygen isotope analyses to faunal tooth enamel dated between ca. 48,000 and 22,000 cal BP.

The obtained results allow us to suggest that cold and arid MIS 2 conditions did not cause a dramatic change in the regional environment, and during the Late Pleistocene the cave was close to the boundary between arid subtropical and humid climate regions (with the latter supporting forests), a pattern similar to the current environment of the site.

Let it burn! A micromorphological investigation of the Kropfsberg mine (Tyrol, Austria) and its history of use from the late Roman period until modern times

Dr. Susanna Cereda [1], ***Prof. Gert Goldenberg*** [1], ***Mr. Markus Staudt*** [1]
1. *Institute of Archaeologies, University of Innsbruck*

The Kropfsberg hill is a dolomite outcrop located next to the confluence of the Inn Valley and the Ziller Valley, in North Tyrol (Austria). The mound is dominated by a castle built from 1280 CE onwards, which destroyed most of the prehistoric traces of occupation on its summit. Indeed, Kropfsberg was inhabited from at least the Early Iron Age and favoured for its advantageous position within the rich fahlore mining district of Schwaz-Brixlegg. Starting from this period, the mound itself was exploited for its copper minerals, while during the Middle Ages and the Early Modern period mining activities shifted primarily towards the extraction of silver. Over time, the prehistoric use of the fire-setting technique to quarry the hill led to the formation of impressive domed cavities in this hard dolomitic rock.
Excavations conducted in 2020 exposed for the first time the stratigraphic sequence of this man-made cave and led to a surprising discovery. Indeed, what was thought to be exclusively a mining site revealed the existence of a phase of use—dated to the late Roman period—with ritual connotations. The deposits of this phase are strikingly different from the other mining sediments, not only because of the abundant charcoals and animal bones, but especially because of the deposition of hundreds of votive coins.
In this talk we will focus on the results of the micromorphological study conducted on sediment blocks collected from the stratigraphic sequence of the cave. Aim of the investigation was not only to define the nature, temporal scale and possible cyclicity of the firing episodes that occurred in occasion of ritual ceremonies, but also to characterise the complex history of use of the Kropfsberg mine over time. For this purpose, of primary importance was the reconstruction of the many natural and anthropogenic processes that led to the formation of the sequence and to the preservation of this extraordinary infill, which would have hardly survived in an unsheltered context.

Early evidence of human presence in Western Europe beyond 1 Ma: new dating results from Alto de las Picarazas site (Valencia, Spain)

Our understanding of early human dispersals in western Europe sits on a very fragmented archaeo-palaeoanthropological record based on a limited number of Early Pleistocene localities widely scattered throughout the continent. Evidence older than 1 Ma is even more scarce and restricted to a few sites, mainly located on the northern Mediterranean margin.

In this context, the Alto de las Picarazas site (Valencia, Spain), discovered in 2007 during the construction of wind turbines, can bring additional key information about these little-known early human occupations, as far as timing, palaeoenvironmental conditions or behavioural/cultural aspects. The site is made of a series of fissures and cavities in a limestone formation filled with fossil-bearing brecciated sediment. Successive excavation campaigns performed at Cavity 1 revealed a ca. 6 m thick sedimentary infill in which four stratigraphic layers were identified (named I to IV from top to bottom). In particular, the stratigraphically lowermost layer (IVb) yielded fossil remains from large and small mammals in association with a few lithic artefacts.

A magnetostratigraphic pilot study showed a dominantly reversed polarity for the bottom part of the sequence, correlating the deposits to the Matuyama Chron (> 0.77 Ma). The study of the rodent assemblage, and especially the presence of *Allophaiomys ruffoi*, suggests that unit IVb is biochronologically older than Barranco León and Fuente Nueva-3 (Spain) and coeval with the fauna from Venta Micena (Spain) and Pirro Nord (Italy).

In order to refine this first chronological estimation, several fossil teeth were collected from the lower layers and dated by means of Electron Spin Resonance in combination with Uranium-series (U-Th). The samples were processed following the most advanced analytical procedures: various enamel samples were collected from each tooth, while several laser ablation ICP-MS U-series profiles were carried out across dental tissues. The environmental dose rate was evaluated through laboratory and *in situ* measurements. Our numerical dating results, in combination with additional magnetostratigraphic data, confirm not only the Early Pleistocene antiquity of the lowermost unit IV, but also an age > 1 Ma, making Alto de las Picarazas one of the oldest dated archaeological site in W Europe.

Spatial and temporal distribution of major tree and shrub taxa during the Cantabrian Magdalenian

Dr. Josu Aranbarri [1], ***Dr. Paloma Uzquiano*** [2], ***Dr. Mónica Ruiz-Alonso*** [3], ***Dr. María José Iriarte-Chiapusso*** [4], ***Ms. Ainhoa Aranburu-Mendizabal*** [1], ***Dr. María Ángeles Medina-Alcaide*** [5], ***Ms. Miren Ayerdi*** [1]

1. *Departamento de Geografía, Prehistoria y Arqueología, Universidad del País Vasco/Euskal Herriko Unibertsitatea (UPV/EHU), Francisco Tomás y Valiente s/n., 01006 Vitoria-Gasteiz, Spain,* ***2.*** *Departamento de Prehistoria, Universidad Nacional de Educación a Distancia (UNED), Mediodía Grande 17, 28005 Madrid, Spain,* ***3.*** *Departamento de Botánica, Universidad de Granada, Avenida Fuente Nueva s/n, 18071 Granada, Spain,* ***4.*** *IKERBASQUE, Basque Foundation for Science, 48011 Bilbao, Spain,* ***5.*** *Université de Bordeaux, UMR CNRS 5199 PACEA, F-33615 Pessac, France*

Recent excavations ascribed chronologically to the Cantabrian Magdalenian cultural complex have provided a huge number of well-dated palynological and anthracological records, allowing to reconstruct, not only the main climate features and the human-vegetation interactions, but also the spatial distribution of tree and shrub taxa. Overall, the Lower Magdalenian (20000-17000 cal yr BP) sites are defined by an steppe landscape with scattered conifers like *Juniperus* sp. or *Pinus* sp., xerophilous shrubs like *Prunus* or *Hippophae rhamnoides* and heaths (*Erica* sp.), whereas western Cantabrian Range coastal archaeological records denote high amount of Fabaceae (*Cytisus* sp., and *Ulex* sp.) and *Betula* sp., probably linked to particular substrate affinities. During the Middle Magdalenian (17000-15500 cal yr BP) charcoal and pollen assemblages include diverse mesic taxa, especially *Salix* sp., *Quercus* subg. *Quercus* and *Sorbus aria*, although steppe elements and conifer trees/shrubs continue being the main landscape elements. This pattern, however, is reversed during the Late Magdalenian (15500-12700 cal yr BP) when palaeobotanical assemblages reveal a sharp increase in broadleaved tree taxa (*Quercus* subg. *Quercus*, *Corylus avellana*, *Alnus* sp., *Sorbus aria*, *Fraxinus* sp.) in response to the increase in humid and milder climate conditions. It is worth noting that some records have also addressed the survival of Mediterranean trees and shrubs (e.g., *Quercus ilex/coccifera* type, *Laurus nobilis*, *Arbutus unedo*, *Rhamnus/Phillyrea* or *Pistacia* sp.) in topographically favorable coastal and mid-altitude shelters, which long-term presence is explained by complex adaptations to edaphic, topographic and microclimatic factors.

Examining sediment infill dynamics at Naracoorte Cave megafauna sites using multiple luminescence dating approaches

The Naracoorte Cave Complex (NCC) represents Australia's richest Pleistocene megafaunal fossil locality, preserving extensive palaeontological and palaeoenvironmental sediment records spanning the last 550 thousand years (ka). Relatively little is known about the long-term sediment accumulation dynamics of NCC solution pipe cavities, and many of the megafauna-bearing infill deposits remain undated as they lie beyond radiocarbon and OSL age ranges. In this study, we assess the suitability of using 'extended-range' luminescence dating signals (single-grain TT-OSL, multi-grain pIR-IRSL) for improving existing chronologies at six Late and Middle Pleistocene NCC sites. We additionally undertake multi-site examinations of NCC sediment infill dynamics using published chronological datasets.

Replicate luminescence dating comparisons performed on 22 sediment infill samples reveal consistent OSL, TT-OSL and pIR-IRSL ages over the last 300 ka, and broader agreement with independent and semi-independent age control (U–Th and ESR ages). Modern analogue samples collected from above and beneath active solution pipe entrances confirm adequate OSL, TT-OSL and pIR-IRSL signal resetting down to sufficiently low residual levels. Collectively, the results of the modern analogue and (semi-) independent dating comparisons demonstrate the potential usefulness of extended-range luminescence techniques for dating NCC deposits that exceed conventional OSL dating limits.

A detailed luminescence dating examination of solution pipe dynamics is performed at Smoke Tortoise Cave (SMT), which reveals a complex accumulation history focused on the marine isotope stage (MIS) 9 and MIS 7 interglacial complexes, as well as the MIS 8e interstadial. The SMT case study highlights that NCC solution pipes are not simply associated with short-lived opening and sediment accumulation events, but may involve multiple, discontinuous deposition episodes and reactivation events.

An initial multi-site examination of all published NCC infill chronologies (n=70) appears to suggest statistically significant, preferential solution pipe development during relatively wet parts of interglacial or interstadial cycles. This non-uniform infill age distribution implies that NCC solution pipe dynamics may have exerted taphonomic biases on fossil accumulation, which should be taken into consideration when reconstructing long-term palaeoecological histories from NCC solution pipe cavities.

Pyrotechnologies of Middle and Later Stone Age foragers in Malawi – a micro-contextual approach with controlled heating experiments

The use and control of fire has shaped who we are today, and virtually all human populations depend on fire both biologically and culturally. While much research has focused on biological aspects and on when or where humans first started to use fire, less is known about how the use of fire evolved as a technology in early hunter-gatherers. Excavations in the rockshelter sites of Hora-1, Mazinga-1, and Kadawonda Complex in the Kasitu Valley of northern Malawi have exposed late Pleistocene and Holocene anthropogenic deposits containing MSA and LSA archaeological assemblages. Human remains have been retrieved from all three sites, with the apparent use of fire for ritual interment practices during the LSA. Thin section analysis of the archaeological deposits has revealed abundant soil aggregates and combustion-derived materials, including well-preserved plant ashes. In our EU-funded project, MicroAsh, we investigate this rich combustion-record to obtain a better understanding of pyrotechnological practices, which will enable us to make more detailed interpretations about the types of activities carried out at these locations.

We use micromorphology and μFTIR to study (1) site formation processes, (2) the relationship between fire use and palaeoenvironments, (3) variability in the use of fire for ritual and subsistence practices through time, and (4) site-use intensity. The production of reference samples of ash and heated soil through controlled burning experiments plays an important role in our approach and is aimed at reconstructing fuel sources and burning temperatures. Preliminary results indicate that wood ashes likely make up bulk of the combustion materials, rather than sedges or grasses from the nearby riverbanks. By exploring different microarchaeological techniques to study these human-made fire residues, we hope to contribute to a better understanding of pyrotechnologies during the MSA and LSA, and related aspects of human behavior such as rituals and foraging strategies.

Exceptionally Rich Late Neanderthal Occupation of Sesselfelsgrotte in the Franconian Jura: Different Behaviour or Different Preservation?

A large body of research from the Swabian Jura (SW Germany) has resulted in the interpretation that Neanderthals in this area were outplaced by H. sapiens ca. 43 ka ago and that they used caves and rock shelters less intensively than their successors. These interpretations are in contrast with findings from Sesselfelsgrotte in the nearby Altmühl Valley (Franconian Jura, SE Germany). This rock shelter site, excavated in the 1960s-80s, contains multiple Neanderthal hearths, suggestive of a use of the shelter different from the Swabian sites. Sesselfelsgrotte also exhibits a rich fossil record of 14 Neanderthal remains, belonging to at least three different individuals, including a potential infant burial, while Swabia so far yielded only one, poorly contextualized, Neanderthal bone. Do these dissimilarities reflect differences in late Neanderthal forager behaviour, or are they the result of differential site preservation? These questions cannot be answered with the data available from the excavations, as detailed geoarchaeological studies at the site were not carried out.

In this poster, we present preliminary results of "SHARP - Testing hypotheses on the transition from Neanderthals to H. sapiens at the Palaeolithic site of Sesselfelsgrotte", funded by the National Geographic Society (NGS-96087R-22). In this project, we aim to (1) determine whether the Altmühl Valley served as a refugium for late Neanderthals, (2) investigate the cause of their rich record in this valley, (3) reconstruct late Neanderthal fire use, (4) explore the morphological and genetic similarities with other late Neanderthals and possible admixture with early European modern humans, and (5) test previous hypotheses on the arrival of H. sapiens in Central Europe.

Cutting-edge geoarchaeological methods are the backbone of this project and will address key taphonomic issues to clear up potential analytical biases and ambiguities in the reconstruction of late Neanderthal and early sapiens behaviours in SW Germany. Geoarchaeological investigations within SHARP will provide a multi-scale framework (from microscopic to regional) to help integrate new geochronological data and results from lithic, faunal, microfaunal, archaeobotanical, paleoanthropological, paleogenetic, and stable isotopic analyses.

Tackling site formation at the archaeofaunal assemblage of Level 3 from Cueva Des-Cubierta site (Pinilla del Valle, Madrid) using spatial taphonomic approaches

Paleolithic assemblages preserved in cave deposits are taphonomically complex due to the effect of alternating hominin and carnivore occupations and the impact of post-depositional processes. Quantifying the effect of post-depositional disturbance, identifying the factors operating in these cave deposits, and defining individual depositional events is, however, essential in order to make accurate interpretations of hominin behavior.

Cueva Des-Cubierta cave is a site located in the upper valley of the Lozoya River, in the Spanish Central System. It is an 80 m long roofless cave with a zig-zag-shaped narrow gallery (2-4 m wide) in which several archaeopalaeontological levels were deposited. Level 3 is a 2 m thick clast-supported gravel deposit formed over a speleothem dated in the MIS6a, and deposited over a cold period according to the pollen and micromammal record (probably MIS4 or the earlier MIS3). This level contains a Mousterian lithic assemblage, an archaeofaunal record dominated by cranial remains of large horned ungulates, and abundant fire-affected materials, and it has been interpreted as a symbolic place.

In this study, we use spatial taphonomy to examine whether the cave deposit exhibits any spatial variation in its vertical section regarding post-depositional disturbance caused by typical karstic processes, such as water flows or gravitational processes. Spatial statistical approaches are applied to a number of taphonomic variables, including specimen size, taxon, anatomical part, bone shape, and bone composition.

Overall, the archaeological deposit shows a low degree of disturbance. Bone shape and composition types are uniformly distributed, suggesting a similar low degree of post-depositional impact caused by water flows throughout the deposit. There is a marked contrast in the spatial distribution of cranial and postcranial remains, which could be suggesting a differential treatment of cranial and postcranial elements by Neanderthals.

Further spatial statistical examination of other taphonomic attributes, such as fire-affected remains, as well as

the analysis of spatial associations between bone and lithic remains, will shed further light on the role played by Neanderthals in this faunal accumulation. This study also shows that spatial taphonomy constitutes a powerful tool that can be used to unravel palimpsests in cave deposits with complex depositional histories.

Quaternary paleontological records in Sardinia caves

Dr. Laura Sanna [1]

1. *CNR-IGAG*

Within the Mediterranean realm, Sardinia is one of the most important sites for paleontological studies, with an international scientific value. The fossiliferous heritage of this island was early recognised since the first zooarcheological investigations. This paleobiodiversity is related to its geological history that records over 500 million years of sedimentary successions. Separated from Southern Europe in the Tertiary, its insularity has determined significant evolutionary changes of its fauna with respect to the mainland. For this reason, Quaternary fossils in Sardinia are characterised by a few taxa with an high endemic faunistic content. Many of these paleontological archives have been preserved in cave deposits. In fact, about 10% of the Sardinia area is composed of karst rocks (most of which are limestones, dolostones, and small spots with marbles outcrops) and over 4,500 caves have been explored. The main morphological feature of these karst systems is an horizontal arrangement of its underground cave passages that makes possible to preserve relatively thick sedimentary deposits. As poorly affected by recent tectonic deformation and erosive processes, Sardinian caves are excellent continental archives of Past Global Changes and document an extremely interesting evidence of Quaternary fauna records. Several paleontological studies have been addressed to the description of these cave faunistic remains and to establish their evolution over time. In this study an extensive literature review of the taphonomic researches on Quaternary fossil vertebrates in Sardinia caves is proposed, focusing on their chronological constrain with the aim of a better characterisation of the paleoclimatic and paleoenvironmental conditions of Western Mediterranean climate during the Quaternary.

What can marine shells tell us about climate change and human behaviour? A contribution to the SPHeritage Project

Dr. Silvia Gazzo* [1], Prof. Luca Ragaini [2], Dr. Deirdre Ryan [3], Dr. Elena Rossoni-Notter [4], Dr. Olivier Notter [4], Prof. Marta Pappalardo [5], Prof. Fabio Negrino [1]

***1.** Department of Antiquities, Philosophy, History, University of Genova, **2.** Dipartimento di Scienze della Terra, Università di Pisa, **3.** Department of Earth Science, University of Pisa, Italy, **4.** Musée d'Anthropologie Préhistorique de Monaco, **5.** DST, Department for Earth Sciences, University of Pisa*

The SPHeritage Project (MUR grant: FIRS2019_00040, P.I.: M. Pappalardo) investigates how human population have responded to major sea-level variations and climatic changes that affected the Liguro-Provençal Mediterranean coast over the last 400,000 years.

This project proposes a multidisciplinary approach that includes geomorphology, geology, stratigraphy, palaeontology, and archaeology. Both non-invasive and microinvasive methods were applied to materials of geo-archaeological relevance.

Here, we provide a preliminary review of the mollusc remains from both marine and archaeological deposits recovered at Barma Grande and Prince of Monaco caves (Ventimiglia, Italy).

The present study represents a major contribution to the SPHeritage project, providing information on the biodiversity of coastal marine ecosystems and its evolution due to environmental and ecological processes, and how human presence have influenced these processes.

As most of the local deposits were removed by former archaeological excavations since the end of the nineteenth century, we combined analyses of materials preserved at museums and specimens still preserved in situ.

A methodology combining taxonomy and taphonomy was applied to better understand the nature of the deposits. A systematic review of the old nomenclature was conducted, allowing a re-reading of the assemblages from a modern perspective.

Interglacial MIS5e is well documented in the studied marine natural deposits due to the presence of typical warm water "Senegalese" fauna (e.g., *Thetystrombus latus*) along with a heterogeneous malacological assemblage including small gastropods and very worn beach shells. The characterization of this malacofauna as a whole will enable a reconstruction of the original paleoenvironmental and paleoclimatic conditions.

Otherwise, the above anthropic layers are dominated by human selected species, mainly *Patella rustica* and *Patella ferruginea*. Although nowadays its range is restricted to few Mediterranean areas, Neanderthal populations largely exploited *P. ferruginea* for dietary purposes.

Preliminary analysis of cave features and archaeological evidence at Grotta dei Pipistrelli (Matera, southern Italy)

Prof. Luca Antonio Dimuccio [1], ***Dr. Felice Larocca*** [2], ***Dr. Maurizio Zambaldi*** [3], ***Dr. Vincenzo Iurilli*** [4]

Dipartimento di Scienze della Terra e Geoambientali, Università degli Studi di Bari, Via Orabona 4, 70124 Bari, Italy

In karst settings, the study of stratigraphy and the interpretation of the site formation processes are the keys to understanding the diachronic changes and long-term patterns of human evolution, but also a matter of discussion concerning culture and behaviour in the past, especially when considering archaeological deposits whose accumulation is mainly the result of natural processes. At Grotta dei Pipistrelli cave (Matera, southern Italy), where a Middle Palaeolithic to Bronze Age human occupation was attested, an integrated multidisciplinary approach combining geological, geomorphological, and geoarchaeological analyses of cave features and deposits was applied to tackle these issues. The cave opens on the western side of a deeply incised fluviokarst canyon, at the contact between the Upper Cretaceous Apulia carbonate units and the Plio-Pleistocene Calcarenite of Gravina Formation. A recent topographic survey indicates that the cave plan reaches a total extension of 225 m, including a main sub-horizontal wide conduit, a smaller branch towards its end, and two secondary passages which form an orthogonal network of galleries. A collapsed doline, obstructed by siliciclastic sediments from the top surface, overlays the end of the main conduit. A significant amount of guano covers the cave floor. In the main conduct, an archaeological deposit with carbonaceous levels and fine-grained siliciclastic sediments is currently the object of petrographic and microstratigraphic characterisation (micromorphology) and luminescence dating. The topographic survey allowed us to measure and map several types of cave-rocky features, including ceiling pockets and cupolas, condensation-corrosion channels, pendants, wall convection niches, smooth walls, and replacement pockets. Secondary cave minerals and weathering products were sampled on the cave walls and floor for mineralogical identification by X-ray diffraction – calcite, gypsum, quartz, arsenopyrite and brushite are the minerals found. A few samples of gypsum were also analysed for sulphur isotopes ($d^{34}S$) – the obtained $d^{34}S_{V\text{-}CDT}$ values range from -3.10 to 4.47 ‰. These preliminary results indicate that the maze pattern of Grotta dei Pipistrelli cave follows a local fracture network, showing evidence of a polygenic speleogenesis that includes a hypogenic origin and subsequent epigenic overprinting, with the latter conditioning the preservation of the archaeological record in specific cave sectors.

The Holocene neotectonic diversion of the Cotovelo River

***Prof. Mario Teixeira Rodrigues Bragança* [1], *Prof. Luiz Fernando de Paula Barros* [2], *Prof. Déborah de Oliveira* [3]**

***1.** Programa de Pós-Graduação em Geografia Física, Faculdade de Filosofia, Letras e Ciências Humanas, Universidade de São Paulo, **2.** Departamento de Geografia, Programa de Pós-Graduação em Geografia, Instituto de Geociências, Universidade Federal de Minas Gerais, **3.** Programa de Pós-Graduação em Geografia Física (FFLCH/USP); Programa de Pós-Graduação em Rede Nacional para Ensino das Ciências Ambientais (EESC/USP)*

This research aims to investigate the diversion of the Cotovelo River channel as a probable tectonically-controlled feature in an intraplate environment. The Cotovelo River catchment drains 788 km² of the Western São Francisco Craton foreland basin, in the Western Brazilian Atlantic Shield. Although it flows to the Southeast upper stream, the river is sharply diverted to the Southwest in the middle valley, in an almost right angle bend, a feature that nominated the river, *Cotovelo* (elbow in Portuguese). Thus, the elbow denotes the point where the Cotovelo River was deflected to Southwest. However, there is a 7 km-long wind gap, geometrically aligned to that upper channel, crossing the low and diffuse meridional watershed, where alluvial sands and pebbles pave extensively the landscape. Matching this wind gap direction, run a water gap, presently drained by the Pedras Creek, straightforward toward the South, to the Paracatu River. During the summer rainy season, the wind gap is filled up by rainwater, arranged in a straight N-S line of ephemeral lakes and flatter hydromorphic bodies. The water confinement in these lakes is due to topographic lows, conforming a dry channel, delimited for 5 to 10-m high levees. Three alluvial sediment samples collected in the watershed at 0.85 and 1.30 m-deep, and dated by OSL, yielded absolute ages between 3,300 (±350) ka and 13,065 (±1,295) ka, pointing to Upper Pleistocene to Holocene deposition. Other samples gathered in terraces inside the current floodplain, gave younger ages, between 1,100 (±175) ka and 3,880 (±180) ka. Therefore, diversion occurred entirely in the Holocene, resulting from very recent and astonishingly rapid tectonic lowering, processed westward, which become headward erosion operative, probably in small ravines or first order creeks. This subsiding block led to the capture and diversion of the Cotovelo River to Southwest, toward the Paracatu River, upstream the older mouth, with a very marked Northeast-Southwest oriented drainage, controlled by impressive dissected sedimentary walls; the current floodplain stands 30 m lower than the paleo-valley. Structural evidences of the subsidence are hidden under sandy, pebbles, and gravelly thick coverages, waiting to be disclosed. This diversion reinforce intraplate neotectonic reactivation hypothesis.

Coastal switching of dominant depositional process according to the decreasing rates of Holocene sea-level rise in the macrotidal coast of Gochang, SW Korea

Prof. Woo Hun Ryang [1], ***Dr. Hyun Ho Yoon*** [2], ***Prof. Seung Soo Chun*** [3], ***Prof. Alexander Simms*** [4], ***Dr. Jin Cheul Kim*** [5]

1. *Jeonbuk National University,* ***2.*** *Korea Institute of Geoscience and Mineral Resources (KIGAM),* ***3.*** *Chonnam National University,* ***4.*** *University of California, Santa Barbara,* ***5.*** *Korea Institute of Geoscience and Mineral Resoiurces*

Decreasing rates of eustatic sea-level rise during the Holocene accompanied the deposition of transgressive coastal deposits worldwide. However, unraveling how transgressive deposition varies in response to different rates of relative sea-level (RSL) rise is limited by the scarcity of long (10+ m) well-dated cores spanning the entire middle to late Holocene record along macro-tidal coasts. To investigate the sedimentary response of this macro-tidal coast to decreasing rates of RSL rise, we acquired four cores up to 32 m in length and Chirp seismic profiles along the west coast of Korea. Core sediments were analyzed in terms of sedimentary texture, structure, and facies. Nineteen optically stimulated luminescence (OSL) and fourteen ^{14}C accelerated mass spectrometry (AMS) ages constrain the timing of deposition within the sandy sediments. This relatively dense distribution of ages was used to determine how depositional rates changed through time. We also used a compilation of previously published RSL indices for the southwestern Korean coast in order to better constrain RSL changes through time. Results show that the evolution of the Gochang coastline switched from a tide-dominated environment to a wave-dominated environment during the latter stage of transgression as the rate of the sea-level rise decreased. Rugged antecedent topography likely led to the development of tidal currents and the formation of a tide-dominated tidal flat during rapid RSL rise from 10 to 6 ka. As the tidal channels filled with fine-grained sediments from 6 to 1 ka, tidal-amplification likely waned leading to a greater role of wave energy in shaping the formation of the sandy open-coast tidal flat. Since 1 ka, wave-dominated environments formed sand-rich tidal beaches and flats. Decreasing changes in rates of the RSL rise resulted in changes in depositional environments from a tide-dominated intertidal flat to an open-coast tidal flat and finally a wave-dominated tidal beach. This study highlights the important role that rates of RSL rise play on not only sedimentation rates within a shelf setting but also playing a role in the switch from a tide to a wave-dominated setting.

Incised-valley filling sedimentation of the wave-dominated embayed coast in response to Holocene sea-level rise, Yeongil Bay in SE Korea

Dr. Hyun Ho Yoon [1]***, Dr. Jin-Young LEE*** [2]***, Dr. Jin Cheul Kim*** [2]***, Prof. Chang-Pyo Jun*** [3]***, Dr. Han Woo Choi*** [2]

1. *Korea Institute of Geoscience and Mineral Resources (KIGAM),* ***2.*** *Korea Institute of Geoscience and Mineral Resoiurces,* ***3.*** *Chonnam National University*

The Yeongil Bay is on the southwestern part of the East Sea (Sea of Japan), and is a semi-enclosed, funnel-shaped morphological feature in the land direction on the east coast of Korean peninsula. The Hyeongsan River incised valley lies east of the bounding fault zone and runs seaward, approximately parallel to it. The incised valley deepens to more than 160 m below mean sea level near the coast, deeper than sea-level fall during the Last Glacial Maximum, because of subsidence governed by the fault zone. In this study, we examined the sediment stacking patterns of the incised-valley fill by analyzing sedimentary facies and OSL and radiocarbon ages from three sediment cores from the Pohang city. The latest Pleistocene to Holocene Hyeongsan River incised-valley fill sediments unconformably overlie a basement of semi-consolidated Tertiary deposits. The infilling sequence comprises sediments of fluvial lag and meander (>12 cal kyr BP), estuarine (12–8 cal kyr BP), and deltaic (8–0 cal kyr BP) systems, in ascending order. Thousand-year isochrons based on OSL and radiocarbon ages show that the fluvial and estuarine systems were deposited retrogradationally and the deltaic system was deposited progradationally stacking patterns. These sediment stacking patterns resemble those of other incised-valley fill sequences indicates that the last deglacial eustasy was a major factor controlling sediment stacking patterns of incised-valley fill sequence.

The Role of Sub-daily Weather Variability on Rock Cracking across Arid to Semi-arid California throughout the Quaternary

Mrs. Monica Rasmussen [1], ***Dr. Martha Cary Eppes*** [1], ***Dr. Brian Magi*** [1]

1. *University of North Carolina Charlotte*

Geomorphologists and soil scientists commonly leverage mean annual temperature and precipitation to construct climosequences of field data. Yet many surface processes are driven by extreme conditions associated with daily or even hourly weather. Thus, longer-term climate means cannot reflect the full range of conditions the rocks are subjected to at different sites. Here, as part of a broader study to interrogate how climate impacts rock weathering, we estimate the influence of short-term weather variability on longer-term mechanical weathering.

Acoustic emissions field data have shown that, outside of freeze-thaw environments, rock cracking occurs during periods of high stress associated with diurnal heating cycles (Eppes et al., 2016), and that cracking rates for any given stress are exponentially larger during periods of high atmospheric vapor pressure (Eppes et al., 2020). While the daily stress from solar cycles is relatively constant across decades, the field data suggest that instances of high vapor pressure on timescales of hours to days could disproportionately influence the overall cracking rates. Our preliminary analysis suggests that hourly environmental conditions may contribute to cracking rates as much as the variations in longer-term seasonal to decadal climate variability.

In this study, we utilize sub-hourly weather data from three Eastern California field sites and determine that hourly resolution captures the fluctuating weather conditions that influence cracking, and this variability is broadly underestimated when utilizing mean annual values. For example, >10 years of hourly data show that vapor pressure extremes in the arid site are 47% higher than the semi-arid site, while mean annual vapor pressure at the arid site is only 28% higher than the semi-arid site. Utilizing mean annual conditions to understand the influence of climate at these sites would significantly underestimate the difference in vapor pressure extremes.

Due to the importance of hourly-resolution data, we apply perfect prognosis modeling to estimate the magnitude of paleoclimate weather events over the last ~30 ka, leveraging paleoclimate predictions and overprinting modern weather trends. Our goal is to estimate the importance of high-resolution weather variability for paleoclimate analysis of mechanical weathering, and we welcome suggestions and criticisms.

Back-barrier evolution and along-strike variations in infilling of the Kosi Bay lake system, South Africa

***Dr. Nonkululeko Dladla* [1], *Prof. Andrew Green* [1], *Prof. Marc Humphries* [2], *Prof. Andrew Cooper* [3], *Mr. Matthew Godfrey* [1], *Dr. Ian Wright* [4]**

1. University of KwaZulu-Natal, 2. University of the Witwatersrand, 3. University of Ulster, 4. TERRAMARE LIMITED

The Kosi Bay system comprises four interconnected lakes with varying degrees of marine influence. Their location behind a continuous coastal barrier predisposes them as excellent archives of environmental change related to changing sea levels and sediment supply. In this context, two cores were extracted from the system, together with over 150 km of seismic reflection profiling. A major unconformity surface (SB) was identified that incised the underlying unconsolidated sandy basement, in which multiple slumps filled the early valley form. The slumps are coeval with a Holocene-age muddy fill indicative of quiet water conditions in the back-barrier. These intercalate with thick prograding spits that comprise the dominant infill of the lakes. Two forms are evident, C1 progrades from the palaeo-highs of the valley interfluves into the nearest available accommodation space. Unit C2, progrades from the margins of the system into the basin. The two separated by an erosional surface formed by migrating tidal channels as sea levels rose and marine waters entered the system during the Holocene. These are in turn associated with younger slump deposits formed on the steepest part of the margins which post date ~3000 yr BP. Unit E caps the stratigraphy and is interpreted as lacustrine fines with a thin layer of acoustically transparent material (gyttja) at the top. This kind of stratigraphic arrangement is not yet reported from the global estuarine and incised valley literature. Future work entails an examination of the fines in the context of the changing hydroclimate of SE Africa.

Role of aeolian sedimentation and mass movements in the evolution of kettle-holes of glacial flood origin

Dr. Joanna Ewa Szafraniec [1], *Ms. Aleksandra Osika* [1]

1. University of Silesia in Katowice, Faculty of Natural Sciences, Institute of Earth Sciences

Sandur kettle-holes of flood origin are landforms formed after melting buried blocks of glacial ice. They undergo intensive transformations at the initial stage and become stabilised by the plants' colonisation. The main aim was to determine the quantity of aeolian sedimentation and assess the role of mass movement processes in transforming fresh landforms and those covered by vegetation. The fieldwork was carried out in the Skeiðarárjökull forefield (S Iceland) in VI.2021 – VI.2022. Material deposited in young kettle-holes – not colonized or poorly covered by vegetation (25 years) and in overgrown, older landforms (80–90 years) was obtained. The amount of deposition was, on average, 5 kg per m^2 in the younger depressions and was six times higher than in the corresponding older landforms and almost 15 times higher than on the vicinity of older kettle-holes. It was found that within the older depressions, the weight of the aeolian material is more than twice as high when it is deposited on mosses than on stones, grass, and heathers. These preliminary results show that kettle-holes are important sedimentation traps for wind-blown dust-sand material. The mechanism of retaining grains and incorporating them into the soil-forming process is closely dependent on vegetation and its ability to retain moisture. In the case of younger landforms, the dominant role is played mainly by mass movements and surface runoff. Up to 80–90 years after the depression is formed, approx. 70–85% of the mineral mass supply to the bottom comes from solifluction, debris flow and landslides. This share is much higher in fresh landforms and decreases with their progressive overgrowing. In the broader context of studies, Iceland's sandur areas will be used as an analogy for reconstructing palaeoenvironment sedimentation conditions for N Poland at the end of the Pleistocene.
Fieldwork was carried out thanks to funding from: the National Science Centre project "Development of a high-resolution digital elevation model (DEM) of kettle-holes of flood origin at Skeiðarársandur (S Iceland)", no. 2021/05/X/ST10/00710, the Director of the Institute of Earth Sciences of the University of Silesia in Katowice and Centre for Polar Studies in the University of Silesia in Katowice.

Tectonic Uplift, Subsidence and Erosion from Integrated Stratigraphy and Geomorphic Signatures in a Source-to-Sink System: the Case Study of Pagliara Basin, Northeastern Sicily, Italy

Dr. Francesco Pavano [1], ***Prof. Frank Pazzaglia*** [1], ***Prof. Tammy Rittenour*** [2], ***Prof. Stefano Catalano*** [3], ***Dr. Lee Corbett*** [4], ***Prof. Paul Bierman*** [4]

1. Lehigh University, 2. Utah State University, 3. Catania University, 4. University of Vermont

How exogenic (e.g. tectonic) forces are encoded in coupled stratigraphic and geomorphic records in source-to-sink systems is still uncertain. Using sedimentological, geochronological, and geomorphic approaches, our work sheds light on the relationships between transient topography and delta environment deposition within an actively-deformed region. We present new luminescence ages and paleo-erosion rates for the late Pleistocene Pagliara fluvio-deltaic system and model the uplift and erosion of the source catchment located on the Ionian flank of the Peloritani Mountains of northeastern Sicily, Italy. The catchment feeding the deltas is characterized by steep channels incised into lower-relief interfluves with iso-elevation knickpoints, and shallow and bedrock-cored landsides on hillslopes. The Pagliara delta system is part of the broader Messina Sands and Gravel lithostratigraphic unit; these deposits outcrop along the coast due to recent basin inversion driven by the increase in uplift rate related to normal faulting along the Messina Straits. The deltas exposed at the mouth of the Pagliara River are ~100-200m thick, with constructional tops at ~300m a.s.l., and onlap steeply-dipping bedrock along the coast. Six infrared-stimulated luminescence (IRSL) ages collected from the delta range in age from ~180ka to ~125ka, indicating a vertical long-term sediment accumulation rate of ~1-2cm/yr over the latter half of the MIS 6 and MIS 5 glacio-eustatic cycle. Two cosmogenic 10Be concentrations measured in samples of delta sediment indicate paleo-erosion rates during the MIS 6-MIS 5 deglaciation similar to, or slightly higher than, modern rates of ~1mm/yr. Linear inversion of Pagliara fluvial topography indicates an unsteady uplift history that doubled in rate from ~0.9 to ~2.0mm/yr in the past 200ky. This increase in uplift rate at the footwall of normal faults implicate the further creation of accommodation space necessary to initially host the delta deposits in the basin, later uplifted and now exposed hundreds of meters above sea level. Given the location of the Pagliara delta system near the center of the footwall of a deforming normal fault embedded in an uplifting, translating, and fragmented forearc, our data contribute to define the role of major lineaments in the frame of the late Quaternary tectonic evolution of Central Mediterranean.

Event geochronology at the edge of the last glaciation

Dr. Nataliya Zaretskaya [1], Mr. Dmitrii Baranov [2], Ms. Anna Utkina [2], Prof. Andrey Panin [2], Dr. Svetlana Trofimova [3], Dr. Alexandra Simakova [4]

1. The Middle of NoWhere, 2. Institute of Geography, Russian Academy of Sciences, 3. Institute of Plant and Animal Ecology, Uralian Division of the Russian Academy of Sciences (RAS), 4. Geological Institute, Russian Academy of Sciences (RAS)

We present the results of parallel and consecutive ^{14}C, OSL and ^{230}Th/U dating together with plant macrofossil and pollen analyses applied to the Upper Quaternary composite sedimentary succession located at the edge of the last Scandinavian ice sheet (SIS) southeastern flank. The sedimentary succession is comprised of a 65 km long series of the middle Severnaya Dvina River valley terrace sections named Tolokonka, previously studied in the early 2000s. Our studies conducted in 2012-2022 included lithostratigraphic and geomorphological survey, dating and palaeocological analyses that aimed to reconstruct the Upper Quaternary sedimentary setting in extra-glacial environment, the chronology of landforms' evolution and any abrupt/slow landscape changes.

The composite section contains a full record of the Late Pleistocene starting with Eemian (MIS 5e) organic-bearing oxbow lake sediments ^{230}Th/U dated to 120-104 ka BP which probably accumulated in the vicinity of the Boreal Sea. Palaeoecological record shows that climatic conditions changed from moderately cool and humid to warm and slightly dry and then again to moderately cool and humid. At the end of Early Weichselian and in the beginning of Middle Weichselian (MIS 5/4) alluvial beds of high-velocity stream (OSL-dated to 78-68 ka) with permafrost traces later during MIS 3 changed to the gentle floodplain and oxbow-lake sedimentation in the moderate climatic conditions, ^{14}C and ^{230}Th/U dated to 42-39 ka BP. A short warming at the beginning of MIS 2 ^{14}C-dated to 27.4-25.9 ka BP was followed by extreme cooling, and then the 100 km long proglacial lake was formed at the edge of the SIS glacial tongue. The hydrodynamic regime of this lake was unstable, and it was controlled by the glacial lobe oscillation and magnitude of glacioisostatic subsidence near the trimline. We reconstruct at least three episodes of proglacial lake drainage during the LGM (OSL-dated to 19-17 ka) in the extremely cold conditions and deep river incision in the Late Glacial (ca 16 ka). At the end of MIS 2 (16-11 ka), river terrace was formed and aeolian impact in the landscape formation became notable.

This research was supported with RSF grant 22-17-00259.

Paleodischarge reconstruction of historical flood events in the Copiapó river (southern Atacama Desert, Chile). Implications for flood hazard assessment in arid basins

Dr. Tatiana Izquierdo [1], ***Ms. Ai-ling Rivera*** [2], ***Ms. Ángela Giovanna Galeano*** [2], ***Ms. Verónica Salas*** [2], ***Dr. Jan Pieter Buylaert*** [3], ***Dr. MANUEL ABAD*** [1]

1. Department of Biology and Geology, Physics and Inorganic Chemistry, Universidad Rey Juan Carlos, 2. Research Group in Earth Dynamics and Landscape Evolution (DYNAMICAL), Universidad Rey Juan Carlos, 3. Technical University of Denmark

The understanding of extreme event patterns in the context of global change is critical, particularly in arid fluvial basins where extremes are an inherent feature of their hydrological regime. However, long-term changes of rare events are difficult to identify due to short gauge records, of only a few decades in some cases. These need to be lengthened by reconstructing discharges of past floods using paleoflood evidence and/or historical descriptions. For this reason, we have studied an outcrop located in the Lower Copiapó basin (southern Atacama Desert, Chile) downstream the Angostura sector, where the valley narrows and incises the Palaeozoic bedrock forming a 10.5 km long canyon. In this sector, measured mean annual discharge is 0.43 m^3/s although extraordinary floods with peak discharges of 240 m^3/s have been recently recorded (March 2015 flood event). Downstream the Angostura canyon, where changes in the valley geometry result in a reduction of the flow velocity, 14 flood events have been identified in a terrace where slackwater deposits alternate with shale, peat and paleosoils, ranging from 541 BC at its base to the 19th century near the top. Quartz OSL dating of the 5 upper flood deposits has revealed a complex three-dimensional architecture of this bench as the highest flood unit gave an age of 377 ± 40 years and the other four below resulted in an average date of 146 ± 13 years. These dates were correlated with the historical flood record of the Copiapó river to identify the flood events that produced these deposits: AD 1655, AD 1877, AD 1882, AD 1888 and AD 1890. Finally, we used the software HECRAS to estimate the discharges associated with the slackwater deposits obtaining values ranging between 118 and 250 m^3/s. The 1655 event had a similar discharge to that of 2015 catastrophic flood. The flood frequency analysis of systematic and non-systematic data will increase our knowledge of future hydrologic and flood hazard scenarios in the southern Atacama Desert. Ultimately, we hope that this information will improve flood resilience in local communities in the context of present dramatic climate and hydrologic changes.

Changing flood dynamics on the large, flood-prone River Tweed (Scotland/England border) inferred from a luminescence-dated lake palaeoflood record

Dr. Daniel Schillereff [1], ***Dr. Rachel Smedley*** [2], ***Mrs. Jenny Bradley*** [3], ***Prof. Neil Macdonald*** [3], ***Ms. Emma Cowell*** [3], ***Ms. Amy Facer*** [4], ***Ms. Madeleine Woods*** [1], ***Prof. Richard Chiverrell*** [3]

River flooding is a costly and deadly hazard. Whether flood frequency and magnitude are changing due to climate change is a growing concern for communities, cities and countries. However, conventional time series of gauged river flow are usually a few decades in length or shorter, so capture only a snapshot of a river's flood regime and associated climate drivers. More comprehensive assessments require longer-term and often palaeo-hydrological data.

The River Tweed, one of the largest drainage basins in the UK, is notable for its biodiversity, fish stocks, drinking water provision and history of intense flooding. Historical records and alluvial sequences spanning the last 250 years have produced useful re-assessments of flood risk but lake sediment archives from the catchment are underused.

We report the first luminescence-dated lacustrine palaeoflood sequence, overcoming pervasive challenges with radiocarbon dating at temperate lakes dominated by eroded catchment soils. The sequence provides a 1000-year particle size record of flooding for the River Tweed. We apply a suite of complementary analytical techniques to high-resolution grain size measurements to disentangle event-scale flood signatures from the long-term variability in climate and anthropogenic landscape change. Integrating the event-scale sedimentary data with the historical flood record developed for the Tweed, one of the longest in the UK, confirms the reliability of our palaeoflood reconstruction.

We find the late-Holocene flood regime of the Tweed is dominated by multi-decadal clustering, with frequent flooding during the mid-1300s, late-1500s, 1650-1740, mid-1800s and since Common Era 1900. This dataset expands our understanding of spatially and temporally congruent flood-rich and flood-poor phases across the UK. We find some association between flood-rich phases and the negative winter NAO mode as well as the intensity of solar irradiance, in keeping with literature from elsewhere in the UK and northern Europe, but geochemical markers of land-use change also correlate with patterns in flood frequency over recent centuries. We apply a process-based approach to isolate climate and anthropogenic drivers, which produces insight into contemporary flood dynamics and facilitates the re-evaluation of flood risk for this nationally important river.

Outburst floods strongly influence valley evolution in the Tsangpo Gorge, Eastern Himalaya

Regular flows and infrequent outburst floods shape many mountain landscapes, but the relative contributions from these gradual processes and infrequent high-magnitude events have been widely debated, in part due to a paucity of reliable data from historical outburst floods. Here we quantify erosion and deposition from a catastrophic outburst flood in June 2000, caused by a landslide-dam failure on the Yigong River in a rapidly exhumed region of the Eastern Himalaya. The flood, with a peak discharge of 10^5 m^3/s, lasted for only ~10 hours, but its geomorphic effects were equivalent to the cumulative effect of $1\text{-}2\times10^3$ years of long-term fluvial processes in the region. Ubiquitous boulder bars deposited in the channel by the flood promoted extensive lateral erosion through increased bed roughness. As a result, the valley floor widened threefold, triggering many additional secondary landslides, which contributed boulders to the riverbed. The resultant widespread bank erosion and concurrent landslides will continue to influence fluvial dynamics until the next catastrophic flood remobilizes the boulders. Our quantitative findings highlight the importance of recurrent outburst floods for gorge development and landscape evolution in southern Asia and in rapidly uplifting mountain belts worldwide.

Spatiotemporal pattern of flood episodes and climatic variability in southern New Zealand from 1862 to 2020

Mr. Alexander Schulte [1], ***Prof. Lothar Schulte*** [2], ***Dr. Juan Carlos Peña*** [3], ***Prof. Ian Fuller*** [4], ***Dr. Filipe Carvalho*** [2]

1. PaleoRisk-FluvAlps Research Group, Department of Geography, University of Barcelona, Spain, 2. Department of Geography, University of Barcelona. Physical Geography Group, School of Agriculture & Environment, Massey University, New Zealand

In the Northern Hemisphere, more than 345 paleofloods studies have been published according to the PAGES Floods Working Group meta-database. In the humid temperate climate zones of the Southern Hemisphere, the number of studies is modest (approx. 21), thus the assessment of SH regional flood trends is a major goal in light of Global Change.

Our study focuses on the spatial-temporal reconstruction and climatic characterization of flood episodes in three southern regions of New Zealand from 1862 to 2020. We reconstructed three regional qualitative indices of flood severity and spatial incidence from documentary data provided by NIWA. The flood severity matrix integrates numbers of fatalities, witness description of peak flows, flooded area and geomorphological impact, losses of livestock, properties and infrastructure, evacuation and mitigation measures. Synoptic Sea Level Pressure maps were reconstructed from the 20CR Project to explore the influence of climatic variability

The three regional flood series (295 floods) show synchronous flood pulses around 1878, 1905, 1913, 1957, 1968, 1978, 1999 y 2008. However, other flood pulses are out of phase because of different physiographic settings, catchment size, location on the western or eastern slope of the Southern Alps, and exposure to oceans and paths of weather systems. In the West Coast Region seven of ten flood pulses recorded from 1862 to 2020 correlate with positive Southern Annular Mode, higher SST, blocking weather types in summer and lows over the Tasman Sea producing increased humid airflows from the north and northwest. In the larger Otago catchments, ten of fourteen pulses occurred during the positive phase of the Southern Oscillation Index with higher SST, blocking types in summer and autumn, and an increase in northeasterly winds. By contrast in Southland ten of fourteen pulses correlate with negative phases of the Southern Oscillation Index characterized by lower sea surface temperatures, more zonal flow, and troughs with stronger and more frequent winds from the west (summer) and the south (winter).

Finally, we will discuss the possible reasons (and limitations) why the trends of reconstructed flood indices show no increase during the last 158 years despite, the possible effect of Climate Change.

Modeling wetlands of tectonic origin in a representative upstream basin of the Pampas plain (Argentina) during present hydro-climatic extreme events: Geomorphologic thresholds controlling hydrodynamics.

During the last few decades, the more frequent high-intensity storm events in the Pampa plain have generated a steady increase in the water table elevation near the surface limiting soil infiltration. The flat landscape alters the surface runoff and develops temporary water bodies (non-floodplain wetlands), enhancing the flood hazards in the upstream fluvial basins. This work aims at deepening the knowledge of the mechanisms that govern the response of small temporary wetlands of neotectonic origin. The study focuses on the Vila-Cululú sub-basin, a tributary of the Salado river (Paraná river basin) in the North Pampa plain. Structural depressions with rectangular patterns and a network of Pleistocene parallel ENE-trending palaeochannels characterize the area. These palaeochannels are deactivated by neotectonics and conditioned by a homogenous lithology (loess) and very gentle slopes. In some sectors of the study area, the palaeochannels intercept those depressions and significantly restrict the drainage network (low-order streams and artificial channels).
The research involved an integrated approach, including geomorphic and morphometric analyses based on remotely sensed satellite imagery in a GIS platform coupled with field and hydrometeorological data. A two-dimensional hydrological-hydraulic mathematical model of the Vila-Cululú system using the HydroBID Flood tool was set up to capture the system behavior for an extraordinary rainfall event (December 2016-March 2017). Model calibration was carried out using satellite images and the head-discharge curve in the outlet of the sub-basin. Spatial-temporal evolution of flow velocity and water depth maps obtained from the simulation at different time steps were evaluated in a geomorphological frame. Results show that some landforms act as control thresholds to surface runoff and isolate zones with a general dendritic flow pattern towards the neotectonic depressions. It leads to a more relevant surface water storage process. This flow pattern also highlights the poor capacity of both the natural and the artificial drainage network to conduct excess water to the sub-basin outlet. This work is one the first studies in the North Pampa that combine hydrological and Quaternary geomorphological data to explain hydrodynamics. Identifying critical thresholds adds to the knowledge of different levels of hydrology connectivity and risk of flooding.

Microbial community shift appears synchronous with the collapse of mammoth-steppe in subarctic Yukon during the Pleistocene-Holocene transition

Dr. Tyler Murchie [1], ***Prof. Hendrik Poinar*** [1]

1. *McMaster University*

We analyzed the microbial constituents of previously published sedimentary ancient DNA (sedaDNA) sequence data recovered from subarctic permafrost sediments dating between 30,000–4,000 years ago. These samples were originally studied for macro-ecological shifts associated with the Pleistocene-Holocene transition. Our goal was to explore whether there were changes in microbial communities paralleling the transition from grazing megafauna (woolly mammoths, steppe-bison, and horses), forbs (herbaceous plants), and graminoids (grasses), which together formed the mammoth-steppe ecosystem, towards the expansion woody shrubs, extirpation of grazing megafauna, and development of the boreal forest. We observe a clear shift in the taxonomic composition of microbial taxa through this ecological transition irrespective of sampling site. We observe consistency in microbial communities between replicate core samples, including between two different extraction methods as well as shotgun sequencing and targeted capture. These data highlight that the ‘off-target’ fraction from studies using sedaDNA to study macro-ecosystems can also be used to more holistically investigate shifts in microbial communities that are coeval with major ecological transitions.

The taphonomy and taxonomic value of sedaDNA for animal community reconstruction

Ms. Zoë Kleijwegt [1]

1. *Netherlands Center for Luminescence Dating & Soil Geography and Landscape group, Wageningen University, Wageningen*

As biodiversity is threathened globally, the reconstruction of past vegetation and animal communities is becoming an increasingly relevant tool in conservation efforts. Landscape history can provide benchmarks for landscape restoration and optimization. Vegetation can be reconstructed at a high taxonomic resolution through phytoliths and pollen, but the reconstruction of animal communities is still challenging and largely limited to coprophilous fungal spore analysis. This method is reliable, but provides a low taxonomic value of herbivores only. Sedimentary ancient DNA, however, is a new, experimental, paleoecological proxy with potential to uncover past animal communities at a high taxonomic resolution. Much is unknown about the taphonomic processes and taxonomic value that this method yields. As DNA degradation is accelerated by high temperatures, climate is often suggested to play a key role in whether or not sedaDNA can be extracted and interpreted from sediments. I compiled the research on taphonomic processes and the taxonomic value of sedaDNA over a range of climates, and found that water quality and lake morphology play a greater role than climate in the preservation of sedaDNA. The detection of sedaDNA of a particular species appears to be density dependent, making abundant or heard animals more easily identifiable than rare, solitary species. Careful consideration of both sampling site and sedaDNA methodology can optimize the taxonomic value of sedaDNA in past wildlife reconstructions. Therefore, I provide a framework for choosing the methodology and the sampling site based on the research question, the targeted species and desired spatial scale.

A needle in the haystack: Evaluating the potential of ancient DNA from conifer macrofossils preserved in lake sediments from the Swiss Alps.

Mx. Laura Dziomber [1], ***Dr. Maria Leunda*** [2], ***Ms. Ursula Huonder*** [1], ***Ms. Lisa Gurtner*** [3], ***Prof. Christoph Sperisen*** [4], ***Dr. Nadir Alvarez*** [5], ***Dr. Christoph Schwörer*** [1]

Over the last years, the analysis of ancient DNA (aDNA) has expanded in many fields, including palaeoecology. Thanks to the development of new sequencing techniques, palaeogenomic data allow observing demographic and evolutionary processes over time. While most of the studies still focus on animal remains and on material preserved in archaeological sites, only a few emphasize past plant communities. This scientific gap is relevant because studying genetic variation of plant populations through time and space is essential to understand ecological processes, such as postglacial range expansion or adaptation to climatic changes.

Lake sediments host ideal conditions for the preservation of plant remains for millennia and potentially for the conservation of endogenous aDNA therein. However, the preservation of biological remains also depends on different physical, chemical and biological processes, which may affect the DNA quality. Thus, it is not possible to predict the suitability of the samples for aDNA analysis based on appearance alone. Therefore, it is recommended to screen samples, e.g. using a PCR-based assay, to select the most promising material.

We analyzed the aDNA quality of subfossil plant material preserved in lake sediments of six localities over the Swiss Alps. These lakes are situated in key locations in the Eastern, Central and Southern Alps, along an East-West and a North-South transect. We are analyzing Lateglacial and Holocene subfossil conifer needles from *Larix decidua*, *Abies alba* and *Picea abies*, which are keystone species of the mountain forests in the Alps. We isolated the DNA in a dedicated aDNA facility and assessed the DNA quality by amplifying the chloroplast *trn*L P6 loop, a short universal plant barcode. The results of this study show different levels of DNA preservation in the lakes and will provide the basis to design a genome-scale aDNA analysis.

Our study has the potential to provide unprecedented data to track microevolutionary and demographic processes through time and identify possible adaptations to climatic and anthropogenic factors. Such data may refine regional assessments of post-glacial range expansions and recolonization routes of important conifer species in the Alps.

Pollen, macrofossils and sedaDNA reveal climate and land use impacts on Holocene mountain vegetation of the Italian Lepontine Alps

1. *Institute of Plant Sciences & Oeschger Centre for Climate Change Research, University of Bern,* ***2.*** *The Arctic University Museum of Norway, Tromsø & Department of Evolutionary Biology, Ecology and Environmental Sciences, University of Barcelona,* ***3.*** *Institute of Plant Sciences, University of Bern,* ***4.*** *Institute of Plant Sciences, University of Bern & University College Cork,* ***5.*** *The Arctic University Museum of Norway, Tromsø*

Mountain ecosystems, and specifically the treeline ecotone, are very sensitive to changes in climate. However, climate change is not the only factor driving vegetation change over time; human land use also plays a major role. A better understanding of past vegetation dynamics is necessary to disentangle the influence of climate and land use and to assess future vegetation change. Here, we present the first multi-proxy palaeoecological study combining sedimentary ancient DNA (*sed*aDNA), pollen, spores, stomata, charcoal and plant macrofossils from the Alps. We reconstructed the Holocene vegetation dynamics and fire history at Lago Inferiore del Sangiatto (1980 m asl), a small lake in the subalpine belt of the Ossola region, Italian Lepontine Alps.

The sediment record of Lago Sangiatto starts during the Younger Dryas and spans the entire Holocene. Our results show that afforestation in response to climate warming started at 10,700 cal yr BP with *Larix decidua* and tree *Betula*, which formed open forests together with *Pinus cembra* from 10,500 cal yr BP onwards. Human impact on regional vegetation started at 5100 cal yr BP, resulting in expansions of *Picea abies* and *Alnus viridis* and the collapse of *Abies alba*. Species response models and ordination analysis show that livestock grazing and fire were major drivers of vegetation change at Lago Sangiatto during the late Holocene. Finally, increasing human impact during the Bronze Age and Iron Age led to the formation of species-rich larch meadows and alpine pastures that are still dominant today. The palaeoecological data suggest that under projected climate change and land abandonment, the treeline ecotone will likely shift to higher altitudes, leading to important changes in species composition and increasing the risk of biodiversity loss.

The strength of our study is the multi-proxy approach, combining classical palaeoecological methods with *sed*aDNA analysis. A major advantage of *sed*aDNA is the high taxonomic resolution for herbaceous plants, whereas pollen and macrofossils can quantitatively reconstruct biomass and vegetation dynamics. Our study shows how this combination can provide novel insights into the reconstruction of past ecosystems and their response to palaeoenvironmental change.

Linking Holocene and extant Mediterranean lowland Abies alba populations using population genetics and ancient DNA

As a keystone conifer of European mountain forests, silver fir (*Abies alba*) has been the focus of many ecological, physiological, paleoecological, and genetic studies. Based on its extant distribution, *A.alba* is commonly assumed to prefer cool (<18°C July means) and moist habitats with abundant summer precipitation. However, paleoecological studies document high abundance of *A.alba* under Mediterranean climates (July means ca. 25-26°C) with moderate to severe summer drought, such as in coastal Tuscany (Italy). The widespread occurrence of *A.alba* populations during the last interglacial (Eemian) under higher temperatures further indicates a much wider climatic niche than anticipated. Besides, dynamic process-based modeling shows discrepancies between the realized and potential spatial range of *A.alba* during the late Holocene until today, corroborating paleoecological evidence that *A.alba* became regionally extinct due to anthropogenic disturbance (logging, browsing, slash-and-burning) at its warmest edge of the niche. Furthermore, some cryptic stands within the submediterranean and mesomediterranean lowland vegetation support the palaeoecological notion that *A.alba* can thrive under warmer and drier conditions.

Here, we perform population genetic analyses combining extant populations, including cryptic *A.alba* stands under warmer and drier climates, and ancient populations using ancient DNA (aDNA) analyses. We will genotype several *A.alba* populations across Switzerland and Italy with selected neutral single-nucleotide polymorphisms (SNPs) to link them to well-known (cool-temperate) populations in central Europe via Bayesian population structure analysis. This will allow us to check whether these cryptic stands are specific or of local origin and might thus be direct descendants from warm-adapted Holocene *A.alba* populations, or if they are deriving from other origins. Central-marginal hypothesis and isolation by distance scenarios will be tested, considering several proposed primary Last Glacial Maximum and secondary Late-Glacial refugia, as well as Holocene expansion of *A.alba*. Additionally, we will link extant populations to Holocene extinct populations known to have grown under warm conditions (approximately 23-24°C July means) via hybridization capture of these SNPs in aDNA from needles preserved in the lake sediment of Lago d'Origlio (Ticino). Our results will allow a detailed understanding of the current population structure, reconstructing their history, and help identifying populations that may be adapted to future climate conditions.

Palynology and sedaDNA metabarcoding as complementary tools to reconstruct vegetation history at Lago di Mezzano in central Italy

Ms. Giorgia Beffa [1], ***Dr. Erika Gobet*** [2], ***Prof. Inger Alsos*** [3], ***Ms. Marie Kristine Føreid Merkel*** [3], ***Prof. Laura Sadori*** [4], ***Prof. Willy Tinner*** [2]

1. *University of Bern*, ***2.*** *Institute of Plant Sciences & Oeschger Centre for Climate Change Research, University of Bern*, ***3.*** *The Arctic University Museum of Norway, Tromsø*, ***4.*** *University La Sapienza*

Understanding the linkage between past vegetation dynamics, climate, and human impact can be critical to coping with ongoing climate change. The reconstruction of past vegetation history by means of palynological studies has been carried out at many sites in Europe and elsewhere. However, the determination of plant species through pollen identification shows some limitations, for instance pollen determination may sometimes reach only the plant genus or family level. Moreover, the pollen of some important insect-pollinated species might not be well dispersed or in extreme cases, when the exine is missing or thin, not preserved.

Metabarcoding of lake sediments ancient DNA (*sed*aDNA) has proven to be a powerful tool for the identification of rare plant species. The combination of palynological data with *sed*aDNA provides the opportunity to discover more details on the composition and diversity of specific plant communities. However, in the Mediterranean region this palaeoecological approach is still poorly implemented, and more studies are needed.

Here, we present the first results of our study on the sediments of Lago Mezzano (a maar lake located at 452 m a.s.l. in central Italy), which combines pollen, spores, charcoal and *sed*aDNA analyses. High-resolution Neolithic vegetation history is reconstructed using pollen and *sed*aDNA from the same sediment depths to investigate complementarity. Preliminary results on 26 tandem samples show 107 plant taxa (43 arboreal and 64 herbaceous) based on palynology vs. 75 (28 arboreal and 47 herbaceous) based on *sed*aDNA. The detection of dissimilar taxa and vegetation dynamics in palynology and *sed*aDNA suggests complementarity in both, taxonomic resolution and spatial origin between the two palaeoecological proxies (e.g. extralocal vs. local). Moreover, although the two records only partially share statistically significant changing vegetation zones, they show similarities in richness variation, which in both cases increases slightly over time. This study is intended to provide novel insights on the composition of specific plant communities, and their relationship with human activities, fire, and climate. Given that assessments of future community changes require a thorough understanding of long-term vegetation dynamics, our data may contribute to improve projections of ecosystem responses to global change conditions.

Sedimentary ancient DNA reveals local vegetation changes driven by glacial activity and climate

Mr. Lucas Elliott [1]***, Dr. Dilli Prasad Rijal*** [2]***, Prof. Antony Brown*** [3]***, Prof. Jostein Bakke*** [4]***, Mr. Lasse Topstad*** [1]***, Dr. Peter Heintzman*** [5]***, Prof. Inger Alsos*** [2]

Disentangling the effects of glaciers and climate on vegetation is complicated by the confounding role that climate plays in both systems. We reconstructed changes in vegetation occurring over the Holocene at Jøkelvatnet, a lake located directly downstream from the Langfjordjøkel glacier in northern Norway. We used a sedimentary ancient DNA (*seda*DNA) metabarcoding dataset of 38 samples from a lake sediment core spanning 10,400 years using primers targeting the trnL P6 loop region. A total of 193 plant taxa were identified revealing a pattern of continually increasing richness over the time period. Vegetation surveys conducted around Jøkelvatnet show a high concordance with the taxa identified through *seda*DNA metabarcoding. We identified four distinct vegetation assemblage zones with transition periods at ca. 9.7 and 4.3 ka mirroring climatic shifts recorded by the Langfjordjøkel glacier. Soil disturbance trait values of the vegetation increased with glacial activity, suggesting that the glacier had a direct impact on plants growing in the catchment. Both temperature optimum and moisture trait values correlated with glacial activity and reconstructed climatic variables showing direct/indirect effects of climate change on the vegetation. In contrast to other catchments without an active glacier, the vegetation at Jøkelvatnet has displayed an increased sensitivity to climate change throughout the Middle and Late Holocene. Beyond the direct impact of climate change on arctic vegetation, our results suggest the ongoing disappearance of glaciers will have an additional effect on plant communities.

Extraction of modern and ancient RNA from single pollen grains

Dr. Christoph Schwörer [1], ***Dr. Maria Leunda*** [2], ***Prof. Christoph Sperisen*** [3]

1. Institute of Plant Sciences & Oeschger Centre for Climate Change Research, University of Bern, 2. Institute of Plant Sciences & Oeschger Centre for Climate Change Research, University of Bern & Swiss Federal Institute for Forest, Snow and Landscape Research, 3. Swiss Federal Institute for Forest, Snow and Landscape Research

Pollen deposited in natural archives such as lake sediment is a well-established proxy in paleoecology to study vegetation responses to past environmental changes. However, only a handful of studies have tried to use the full potential of this proxy by additionally analyzing genetic information preserved in subfossil pollen grains. Until now, these studies have been limited to traditional PCR-based Sanger sequencing techniques focusing on specific marker regions on the chloroplast or mitochondrial genome. Due to large expenditures in single pollen preparation and handling as well as low PCR recovery rates, this approach has not been developed further. Particularly since recovering the same information directly from the sediment matrix has proven to be more efficient and effective, leading to the establishment of the field of sedimentary ancient DNA (*sed*aDNA) analysis. Here, we applied novel single cell sequencing techniques to pollen grains from a variety of environments and time periods. Specifically, we tested if we can reliably recover modern and ancient transcriptomes from a large number of pollen grains using the Chromium Single Cell Gene Expression application from 10x Genomics. The analysed pollen come from fresh (modern) plant material, herbarium collection (museomics) and lake sediment archives. This novel approach has the potential to significantly improve the taxonomic resolution of pollen analysis and track postglacial range shifts in response to past climatic changes in unprecedented detail. If successful, this pilot study will pave the way for larger research projects that have the potential to revolutionize the fields of paleoecology and population genetics, by opening a window into the past and provide a glimpse of the future.

Ancient sediment DNA shows biodiversity change in the Anthropocene

Prof. Miklos Balint [1]

1. *Senckenberg Research Institute Frankfurt*

Human impact on the Earth System exponentially grew during the last centuries, with marked increase during the Great Acceleration of the Anthropocene in the 20th century. Biodiversity rapidly changes as a result, with climate change, pollution, overexploitation, species invasions being recognised as major drivers. These drivers are largely collinear during the Great Acceleration and existing biomonitoring data is not sufficiently long-term to separate their effects. Here I combine sedimentary DNA-based lake biodiversity data with proxies (heavy metals, organohalogen pesticide and nutrient pollution) and global records and models of human impact (temperature, CO2, nitrogen enrichment), and parametrise a structural equation model to disentangle drivers of biodiversity change during the last two centuries. The results suggest that different aspects of lake biodiversity are driven by different drivers: CO2 and phosphorus enrichment is linked to a departure of community composition compared to baseline conditions, temperature is linked to increased species richness, CO2 is linked to general biomass increase. Surprisingly, the models found no direct effects of heavy metal and pesticide pollution on any investigated aspects of lake biodiversity, but suggest a large and unexpected early effect of CO2 on freshwater lake ecosystems. The study is a blueprint of how sedaDNA time series can be integrated with proxies, records and models of human impact into a theoretical community ecology framework, and how this may differentiate collinear drivers of Anthropocene biodiversity change.

Optimizing DNA isolation from small ancient plant remains

Dr. Maria Leunda [1]***, Dr. Niklaus Zemp*** [2]***, Ms. Julia Bilat*** [3]***, Dr. Pamela Nicholson*** [4]***, Dr. Nadir Alvarez*** [5]***, Prof. Christoph Sperisen*** [6]***, Dr. Christoph Schwörer*** [7]

Ancient DNA (aDNA) provides a unique opportunity to track genetic variation over time and observe demographic and evolutionary processes. Driven by recent advances in DNA isolation, library preparation, and next-generation sequencing, ancient whole-genome sequence data are becoming available at a rapid pace. Because DNA preserved in ancient biological material is present in only minute amounts and degraded to short fragments, DNA isolation remains a critical step in paleogenomic studies. The methods most widely used to purify and concentrate DNA from ancient material are based on absorption of the DNA to silica particles by supplementing the extraction buffer, used to release the DNA from the sample powder, with a buffer containing chaotropic salt. Refinement of this method for ancient bones and teeth allowed efficient recovery of DNA fragments as short as 25 bp. Currently, different protocols for aDNA isolation from a variety of tissues exist, but they have not been stringently compared for their efficiency in recovering ultrashort aDNA fragments.
In an attempt to optimize DNA isolation from small ancient plant remains, we applied a two-step approach. First, we compared four silica-based DNA purification methods by digesting plasmid DNA with a restriction enzyme to obtain equimolar amounts of short DNA fragments (9 to 622 bp). We show that all four purification methods allow for recovery of DNA fragments as short as 15 bp but that the addition of a widely used plant aDNA extraction buffer shifted the size distribution to DNA fragments of > 67 bp in one of the methods. Because the size distribution of the sequences is also influenced by the library preparation method, we prepared single stranded libraries using a method developed for degraded DNA and assessed incorporation of the restriction fragments by sequencing. In step 2, we used the two best-performing DNA purification methods to isolate DNA from individual 12,700–5,000 years old *Larix decidua* needles and prepared libraries. Finally, we evaluated the performance of the two purification methods based on fragment size distribution of chloroplast DNA. Our optimized protocol will greatly facilitate the extraction of aDNA from ancient plant remains and open macrofossils to the paleogenomic era.

Paleo-ecological changes in Danube river palaeo-channels and diadromous fish taxa

Mrs. Giulia Zampirolo [1]***, Prof. Mikkel Winther Pedersen*** [2]***, Dr. Ivana Živaljević*** [3]***, Mrs. Kristina Penezic*** [4]

1. *The Globe Institute, University of Copenhagen, Denmark; Marie Skłodowska-Curie, Horizon 2020.,* ***2.*** *The Globe Institute, Section for GeoGenetics, University of Copenhagen,* ***3.*** *Department of History, Faculty of Philosophy, University of Novi Sad,* ***4.*** *BioSense Institute, University of Novi Sad*

Preliminary results from eDNA analyses of sedimentary archives taken from pale-channels of Danube river (Serbia) complemented with aDNA from sturgeon archaeological specimens. The sampling was performed at three different site locations selected for their vicinity to archaeological sites: Starčevo, Donja Branjevina and Magareći Mlin (Vojvodina Region). We performed metagenomics analysis of the old fluvial system to track human-environment interactions from the Early Neolithic to Middle Ages and in particular with the purpose of detecting the presence of extinct fish species in the sedimentary record. We integrated our study with population genetics analysis on archaeological specimens from sites along the river. This poster aims at presenting preliminary results and the potential of paleo-channels for future studies of past ecosystems.

Long-term ecosystem impacts of distal ashfall from a large volcanic eruption in eastern Beringia.

1. *University of California Santa Cruz, Santa Cruz, USA,* ***2.*** *University of Alberta,* ***3.*** *University of California Santa Cruz, Santa Cruz,* ***4.*** *McMaster University*

Natural disasters can have profound long and short-term ecological impacts, both locally and regionally. Volcanic eruptions can deposit tephra across the landscape hundreds to thousands of kms from the source volcano, burying entire landscapes with devastating impacts on plants and animals. The ecological effects of these ashfall events have been studied in the context of modern eruptions but are only known sparsely from the geological record. About 30,000 years ago, a massive volcanic eruption in the Aleutian archipelago deposited tephra across eastern Beringia, resulting in deposition of the Dawson tephra with thicknesses ranging from 10 to 80 cm more than 1500 km from its source. This tephra is in loess deposits in Yukon and Alaska, including perennially frozen silt deposits in the Klondike area. These frozen silt deposits are ideal conditions for recovering ancient environmental DNA preserved in sediment (*sedaDNA*). We will use taxonomically sensitive *seda*DNA data to characterize the long-term impact of the Dawson tephra using multiple exposures from the Klondike area. Using a bait-based hybridization capture approach, we reconstruct ecosystems before and after the eruption and subsequent ashfall to observe how plant and animal communities responded to the disturbance. The results of this study can be used to understand the resilience of Arctic communities in response to ecological disturbances.

Residual soil sequence (MIS 5 – MIS1) on a thin loess mantle at the Upper Palaeolithic site Dzbańce 21 (northern edge of the Moravian Gate, SW Poland)

Prof. Przemysław Mroczek [1]***, Prof. Maria Łanczont*** [2]***, Prof. Marta Połtowicz-Bobak*** [3]***, Mr. Dariusz Bobak*** [4]***, Mr. Karol Standzikowski*** [2]

Thin loess covers (<2 m) are commonly found in southern Poland at the transition from thick loess to clastic sediments with a slight contribution of aeolian dust. Many papers show that the formation of this thin loess mantles was a short-lived event that occurred during and just after the Last Glacial Maximum (LGM). Investigations of the archaeological site Dzbańce 21 located on the plateau of the Głubczyce Upland showed the possibility of a different scenario of the formation of thin aeolian silt cover and its pedogenic alteration. The sediment sequence documented in the trenches overlies Pleistocene deposits with fluvioglacial characteristics and/or pre-Quaternary age. The sequence has a generalised structure Ap-Bt and represents sediment which involved a long-term and multi-stage pedogenic transformation. There are no pedogenically unaltered loess layers. The key features of soil profiles are the multiplicity of Bt horizons (up to 5 subhorizons) and the truncation. The different Bt subhorizons are clearly distinguishable from each other in lithology, morphology and colour; the boundaries between them are clearly erosional in nature. The results of OSL dating confirm the complex genesis of the soil horizons. The youngest date (21.1±1.4 ka) sampled from the Bt2 indicates the Upper Pleistocene (MIS 2) age of the loess material. This is also an archaeological layer (Gravettian or Epigravettian complex) in which flint artefacts, charcoal fragments and bone remains were found *in situ*, approximately 30 cm above the youngest dated sample, suggesting an age of the site younger than the cited date. Bt3 horizon has an OSL age of 60-57.3 ka, which correlates with the older part of MIS 3; this is a reduced interstadial soil. The lowermost horizons (Bt4-Bt5) with an OSL age of 161-183 ka represents a bipartite horizon of mature soil (Eemian Interglacial) developed on loess of the penultimate glaciation. The investigated site is the proof that we need to take a wider view at the specific environment for the formation and preservation of Late Pleistocene soils in a high topographic location exposed to a strong influence of periglacial erosion processes, with a probable lack of supply of fresh aeolian material.

Palaeoenvironmental significance of the sandy-palaeosol sequences in the central part of the European Sand Belt

1. University of Wrocław, 2. Maria Curie Skłodowska University, Institute of Earth and Environmental Sciences, Lublin, 3. Silesian University of Technology, 4. University of Gdańsk, 5. Polish Geological Institute – National Research Institute, 6. Maria Curie-Skłodowska University in Lublin

Knowledge of the distribution, types and properties of fossil soils is essential in understanding landscapes and their variability occurring over time. It's also an indispensable requirement for assessing short- and long-term human impact, considering soil erosion and land cover change dynamics. In the central part of the European Sand Belt (Central Poland) 21 key sites with palaeosol-aeolian successions have been documented and analysed. The study employed a multidisciplinary approach using geochemical, spectrophotometric analysis and radiometric dating measurements. Considering the study, most of the documented fossil soils have a simple A-C or at most A-B-C structure. The best developed are Podzols. The results of 14C dating of the charcoals preserved in the structure of the palaeosols, while controlling for the OSL age of the sandy sediments, indicate that the soils described were formed during the warm periods of the Late Glacial and can be correlated with the "warm" units recorded on the Greenlandic climate change curve. Therefore, they are therefore initial, simple interphase soils or at most of interstadial rank. A surprising fact is quite commonly recorded in sandy-palaeosol sequences is the presence of well-preserved charcoals forming continuous layers and resembling well-developed A soil horizons. Observations of the morphology of the soil profiles, extended by the results of paleobotanical analyses, allow us to associate these layers with the vegetation of zones of more fertile habitats and overgrown by woody vegetation located on the periphery of the dune fields. So, their presence indicates the local redeposition of burned plant remains into the periphery of currently formed dunes. In turn, the layers with charcoals allow us to consider these sequences as unique archives recording environmental changes occurring in the surroundings of the analysed dune fields. The origin of the charcoals layers needs to be clarified - are they evidence of natural or human-induced fires?

The research was performed under the National Science Centre, Poland project No. 2018/30/E/ST10/00616 entitled "Multi-proxy investigations and advanced methods of determining numerical time scales in the reconstruction of the evolution of inland dunes in Poland during the end of the last glaciation".

Sediment-paleosol successions in the Mongolian forest-steppe as archives of Late-Pleistocene to Holocene geomorphological processes, including hints for the onset of human impact

Prof. Daniela Sauer [1]***, Dr. Michael Klinge*** [1]***, Prof. Manfred Frechen*** [2]

1. *Georg-August-University Göttingen, Department of Physical Geography,* ***2.*** *Leibniz Institute for Applied Geophysics (LIAG), Section Geochronology, Hanover*

The central-Asian forest-steppe forms the transition between the Gobi Desert in the south and the Siberian taiga in the north. In this sensitive landscape, even slight climatic shifts and minor human influence may lead to changes in vegetation patterns and geomorphological processes. Numerous alluvial and colluvial geoarchives, including successions of paleosols and periglacial, eolian, alluvial and colluvial sediments, indicate that diverse geomorphological processes have been active with varying intensity in different periods over the Holocene, shaping this landscape. Characteristic dark sediment layers, including soil material, charcoal and plant remains, are often embedded within the sediment-paleosol successions. They suggest that very often fires were the triggers that disturbed the vegetation cover and induced soil erosion.

Against this background, the aim of our work was to identify periods of enhanced geomorphological dynamics and relative stability with dominating soil formation, and to identify potential links with fire frequency. We focused on the forest-steppe in the northern Khangai Mountains, central Mongolia. Our approach included field observation and sedimentological analyses in combination with OSL and ^{14}C dating.

During the period between 9.5 and 4.5 ka before present, the region was largely covered by Siberian larch forests. Minor charcoal occurrence in the sediments of this time points to negligible fire activity. This phase of relative geomorphological stability is documented by a well-developed paleosol in several sediment-paleosol records. Geomorphological processes substantially intensified around 4.5 ka, as indicated by rapid accumulation of colluvial, eolian and alluvial sediments, including dark layers that are rich in charcoal and soil organic matter. Although the climate became more humid, forest fires became more frequent than during the previous warmer and drier periods. With the development of pastoralism since the early Bronze Age and associated population growth, the grazing pressure in the region increased. Its expression in the sedimentological records is very similar to that of aridification.

Late Quaternary aridification in central Iran: Signals from high-resolution distribution of stable isotopes in a palaeosol

Mr. Omid Bayat [1], ***Prof. Alireza Karimi*** [2], ***Dr. Jan-Hendrik May*** [3], ***Dr. Guido Wiesenberg*** [4], ***Prof. Markus Egli*** [5]

***1.** University of Zurich,* ***2.** Ferdowsi University of Mashhad, Mashhad,* ***3.** School of Geography, Earth and Atmospheric Sciences, The University of Melbourne,* ***4.** University of Zurich, Zurich,* ***5.** Department of Geography, University of Zurich, Zurich, Switzerland*

Aridification during the late Quaternary is recorded in subtropical deserts around the world but the onset of this process varies in different regions. Here, we report the first data on timing and trend of aridification in an arid region of central Iran based on stable carbon and oxygen isotopic composition of pedogenic carbonates. A relict, gravely and non-calcareous palaeosol in alluvium materials of a stable landform in eastern Isfahan was selected to study. High-resolution sampling strategy (10cm intervals) was used for soil samples and stable carbon and oxygen values were measured using mass spectrometry. Radiocarbon chronology of calcite coatings on the gravels showed that calcite deposition began around 32ka B.P. and deep carbonates were formed between 32-26ka B.P. It seems that aridity in the region started around 26ka B.P. and intensified gradually during the Last glacial maximum (LGM) and the Holocene as reflected in both leaching depth and the distribution of oxygen isotopic composition of matrix carbonates. Stable carbon isotopes of matrix carbonates revealed an increase in $\delta^{13}C$ values around 20ka B.P. which is likely related to a decrease in vegetation cover and influx of atmospheric CO_2 in response to cool and arid conditions during the LGM. Significant enrichment of both $\delta^{18}O$ and $\delta^{13}C$ values of matrix carbonates in the late Holocene (~4ka B.P.) proves the establishment of arid conditions with minimal leaching conditions, high rates of atmospheric CO_2 and calcareous dust influx with extreme evaporation rates in the region. This study highlights the efficiency of high-resolution analysis of soil matrix carbonates in paleoenvironmental reconstructions.

Influence of Long-term straw returning and manure application on soil erosion resistance

Prof. Qianjin Liu [1]***, Prof. Min Zhao*** [1]***, Prof. Bao Li*** [1]

1. *Linyi University*

Organic materials addition is considered an effective practice to prevent soil erosion by changing the soil physiochemical properties. However, the potential effects of long-term application of organic materials to soil on rill erosion is unclear. In this study, the effect of organic amendments on soil erosion resistance in non-calcareous fluvo-aquic soil under five fertilization treatment were interpreted. The treatments included: (1) CK (no fertilizer), (2) □ (wheat straw +276 kg N ha^{-1}), (3) □ (wheat + maize straw), (4) □ (wheat + maize straw+276 kg N ha^{-1}), (5) □ (pig manure 60000 kg ha^{-1}). The results showed that compared to CK, □ and □ significantly increased the soil critical shear stress by 83% and 40%, and reduced rill erodibility by 25% and 57 %, respectively. The optimal partial least squares regression model showed that <0.053 mm soil aggregates were positively correlated with soil critical shear stress because of the large surface area of silt and clay, which can lead to a strong chemical binding and adsorption capacity and subsequently a high soil stabilization. The optical density ratio at wavelength of 465nm and 665nm (E4/E6 ratio) of humic acid had a negative effect on rill erodibility maybe due to the increase of alkyl carbon, a hydrophobic matter preventing the soil aggregates from water disperse. The <0.053 mm soil aggregates in the □ treatment was 45% lower than that in CK. Compared to CK, treatments of □, □, □, and □ significantly increased the E4/E6 ratio of humic acid by 11%, 6%, 19%, and 39%, respectively. The results indicated that the application of pig manure alone and combination of wheat straw and nitrogen fertilizer could improve the soil physicochemical properties, which was beneficial to the improvement of rill erosion resistance.

Modelling the effect of climate, dust deposition and climatic precession on paleosol development on the Chinese Loess Plateau

Dr. keerthikanirmani ranathunga [1], Prof. Peter Finke [2], Dr. Qiuzhen Yin [3], Mr. Zhipeng Wu [4]

***1.** Department of Environment, Research group of soilscape genesis,Ghent University, **2.** Department of Environment, Research group of soilscape genesis, Ghent University, **3.** Earth and Life Institute, Georges Lemaître Centre for Earth and Climate Research, Université catholique de Louvain, Belgium, **4.** Georges Lemaître Center for Earth and Climate Research, Earth and Life Institute, Université catholique de Louvain, Louvain-la-Neuve, Belgium*

The loess-paleosols sequences in the Chinese Loess Plateau (CLP) are the most comprehensive terrestrial palaeoenvironmental records for paleoclimates, reflecting global scale climatic oscillations, glacial-interglacial phases. Environmental conditions over the Quaternary period have resulted in continuous loess deposits during glacials (cold-dry), which nevertheless interrupted by paleosols during interglacials (warm-humid) in the CLP. However, paleosols in there are least well understood in response to relative contributions of various soil forming factors, including climate conditions during interglacials (e.g. precipitation, evapotranspiration), duration of soil formation, dust deposition etc. One of the objective of this research is to better understand paleosol formation in the CLP, particularly through quantitatively assessing paleosol responses to interglacial climates. As far as climate is concerned, astronomical forcing play an important role in regulating glacial-interglacial cycles during the Quaternary period and have been found to be indirectly linked with paleosol development in the CLP. However, how astronomically-induced climate change has affected paleosol development is still unclear through changes in climatic variables. We use SoilGen2-LOVECLIM process-based soil-climate models to simulate paleosol development using time series of climate data (e.g. precipitation, temperature, dust input). Our results show that the simulated soil properties (mass of calcite and clay) are sensitive to precipitation, dust addition and potential evapotranspiration in a different order of sensitivity. Interestingly, results shows an indirect link between the simulated soil properties (calcite and clay content) and precession through its control on precipitation in the last five interglacials.

Superposed karstic and fluvial drainage networks in the Zadorra River Catchment (Northern Iberian Peninsula)

Mr. Iván Martín-Martín [1]***, Dr. Fernando Sarrionandia*** [2]***, Prof. Pablo G. Silva*** [3]***, Dr. Antonio Tarriño*** [1]

__1.__ Department of Geography, Prehistory and Archaeology, Faculty of Letters, University of the Basque Country (UPV/EHU), Tomás y Valiente s/n, 01006 Vitoria-Gasteiz., __2.__ Department of Geology, Faculty of Pharmacy, University of the Basque Country (UPV-EHU), Paseo de las Universidades, 7, 01006 Vitoria-Gasteiz., __3.__ Department of Geology, Escuela Politécnica Superior de Ávila, University of Salamanca (USAL), Hornos Caleros 50, 05003 Ávila.

The Zadorra River is one of the main tributaries of the upper catchment of the Ebro River, which represents the main river of the Northern Iberian Peninsula flowing to the Mediterranean Sea. The middle zone of the drainage basin, carved on a thick Upper Cretaceous calcareous sedimentary sequence of the Ganboa Mountains (Northern Álava province), displays interesting elements and landforms indicating fluviokarstic origin. The dissected materials comprise a WNW-ESE trending alternance of marls, marly limestones and locally thick limestone-calcarenite beds of Coniacian to Santonian age affected by to large fracture systems of NE-SW and NW-SE orientation controlling the drainage pattern.

The geomorphological analysis of the area identifies two contrasted types of fluvial incision (a) purely fluvial, and (b) fluviokarstic. In this last type, the drainage network follows mainly the bedding direction displaying a typical subsequent parallel pattern, but locally transverse streams following the NE-SW fracture-system generate small-scale gorging consequent to the bedding suggesting a case of drainage superposition. Noteworthy, these valleys appear exclusively constricted to the location of the interbedded thick limestone-calcarenite lenses. Contrary to the v-shaped fluvial valleys, the fluviokarstic valleys are relatively short (< 1 km length), with wide and flat bottoms directly carved on the bedrock (no infilling deposits) of u-shaped morphology. Purely fluvial valleys are controlled by the bedding of the Cretaceous bedrock with a minor fracture control in their pattern. Considering the overall landform assemblage in the studied area, fluvial valleys seems to be in an apparent younger stage of development than the fluviokarstic ones. Initially, karstic processes were constricted to the limestone-calcarenite beds, but dissolution processes propagated along the two main fracture-systems affecting the area (NE-SW and NW-SE), generating a primary fluviokarstic network in embryonic stage connecting surface and subsurface drainage. Further base-level driven fluvial incision connected subsequent drainage parallel to the bedding with the slightly oblique transverse fluviokarstic valleys. We suggest that the transition from the karstic modelling to the more recent fluvial modelling was in response to a change towards a more temperate-cold climate, maybe linked to the end of the Mid-Pleistocene Transition, around 700 ka ago.

New ice margin chronology for the North American Ice Sheet Complex based on a comprehensive database of chronological data: NADI-1

Dr. Martin Margold [1]***, Dr. April S. Dalton*** [1]***, Ms. Helen Dulfer*** [1]***, Dr. Jakob Heyman*** [2]***, Prof. John J. Clague*** [3]***, Dr. Duane Froese*** [4]***, Dr. Michelle S. Gauthier*** [5]***, Dr. Anna L.C. Hughes*** [6]***, Dr. Carrie E. Jennings*** [7]***, Dr. Sophie L. Norris*** [8]

The last North American Ice Sheet Complex (comprising the Innuitian, Cordilleran and Laurentide ice sheets) was in its extent and volume comparable to the present-day glaciation of Antarctica. Its ice margin chronology is important for a variety of research fields, from numerical ice sheet modelling to archaeology. Several previous generations of ice margin chronology relied exclusively on a database of radiocarbon ages. Here we present a new ice margin chronology from an updated set of radiocarbon ages (n=4916), cosmogenic exposure ages (n=2165 ^{10}Be and n=459 ^{26}Al), and optically stimulated luminescence ages (n=354). These data were screened for their quality and applicability in line with procedures introduced in recent reconstructions for other Pleistocene ice sheets. The newly-built isochrones capture the uncertainty in the ice margin position, with a minimum, maximum, and best-estimate ice margin position for each time step. We reconstruct a diachronous Last Glacial Maximum for the ice sheet complex occurring between 27 ka and 17 ka. In terms of the ice extent, the maximum occurred at 22 ka. The complete NADI-1 deglaciation chronology will be available in multiple formats and will include the underlying chronological data and extensive justification texts explaining the choices taken when constructing each of the isochrones.

Innovation at the beginning of the last glacial cycle in the neandertal populations of southwestern Europe. Quina strategies from level D of Axlor cave (noratlantic Iberia)

Dr. Talía Lazuen [1], ***Dr. Pedro Castaños*** [2], ***Dr. Manuel Frochoso*** [1], ***Dr. Andoni Tarriño*** [3], ***Dr. Jesus Gonzalez-Urquijo*** [4]

1. *Universidad de Cantabria,* ***2.*** *Sociedad de Ciencias Aranzadi,* ***3.*** *Departamento de Geografía, Prehistoria y Arqueología, Universidad del País Vasco/Euskal Herriko Unibertsitatea (UPV/EHU), Francisco Tomás y Valiente s/n., 01006 Vitoria-Gasteiz, Spain.,* ***4.*** *Instituto Internacional de Investigaciones Prehistóricas de Cantabria-IIIPC (UC, Santander, Gobierno de Cantabria), Universidad de Cantabria, Santander, Spain*

The installation of cold environmental conditions in Europe at the beginning of the last glacial cycle (circa 70 ka) encouraged innovations in the technical and economic organization of the Neanderthal populations of southwestern Europe.

The origin and development of these innovations are documented at the Axlor site (noratlantic Iberia) where the Middle Paleolithic sequence extends over the period circa 100 to 50 ka. Level D, dated between the end of OIS 5a and the beginning of OIS 4, contains very characteristic Quina-type occupations. These occupations show changes in the mobility patterns and in the territorial ranges covered, with wider radii and very marked seasonal cycles. These strategies are based on the frequent exploitation of migratory ungulates and the use of raw materials for lithic tools collected over long distances. The technical innovations are oriented towards the emerging systems of production and management of stone tools that define the Quina type industries. Central to these strategies are standardized tools designed to be employed in particularly long cycles of use and resharpening. The massive use of bone tools for the processing of stone tools and some animal materials is also part of this strategy.

The occupations of Axlor level D constitute some of the oldest evidence of these Quinean innovations and therefore help to understand the genesis and structuring of these original strategies.

Soil formation on loess along a climatic gradient in Tajikistan

***Mr. Saman Valizadeh* [1], *Ms. Ramona Schneider* [2], *Dr. Redzhep Kurbanov* [3], *Dr. Petr Sosin* [4], *Dr. Farhad Khormali* [1]**

***1.** Gorgan University of Agricultural Sciences and Natural Resources, Gorgan, Islamic Republic of Iran, **2.** Department of Earth Sciences, Uppsala University, **3.** Institute geography RAS, Moscow; Institute of water problems, hydropower and ecology, TNAS, Dushanbe, **4.** Institute of water problems, hydropower and ecology, TNAS, Dushanbe*

Loess deposits are the major parent materials in Tajikistan and modern soil development studies and understanding the formation processes especially in different climate regions could provide an insight to the paleosols which are important archives of environmental changes of Late Pleistocene in Central Asia.

Ten soil profiles were investigated in a climate gradient with the mean annual precipitation and temperature range of 200-900 mm and 10-20 °C, respectively. The studied soils formed in the order of increasing precipitation were classified as Entisols, Aridisols, Inceptisols, Mollisols and Alfisols based on the American Soil Taxonomy and Regosols, Cambisols, Calcisols, Kastanozems and Luvisols based on the World Reference Base for Soil Classification (WRB). The dominant soil forming processes in the more arid regions of Tajikistan were calcium carbonate accumulation and redistribution, gypsum dissolution and salinization and alkalization. In the steppe regions organic matter accumulation on the surface horizons were the dominant process. With increasing water availability in more humid regions, carbonate dissolution and precipitation in the deeper horizons and subsequent clay dispersion and illuviation were dominant.

Thin sections were prepared from each horizon and studied using polarizing microscope. The parent material loess has a massive microstructure with very little marks of biologic activity. The microstructure in the soils varied from massive and weakly separated subangular blocky in the arid regions to moderately to well separated blocky in the steppe and more humid regions. The b-fabric is calcitic crystallitic in the regions with lower precipitation and changes to speckled in the soils with higher moisture availability. This provides conditions for the formation of depletion pedofeatures of calcite and clay coatings in the moister areas. The features related to the biologic activity such as excrements, needle shaped calcite and cytomorphic calcite are also dominant in the soils with higher organic carbon in the steppe regions. Pedogenic features in the studied modern soils well correlate with the present climate and could be applied for the interpretations of the existing paleosols in the region. This study was supported by of INSF (Iran National Science Foundation Project № 99006758) and NordForsk (THOCA project № 96926).

Soil piping – the key driver of landscape transformation in Yucatan, Mexico during the Late Holocene: implications for the Classic Maya collapse.

Prof. Sergey Sedov [1], ***Dr. Elizabeth Solleiro-Rebolledo*** [2]

***1.** Instituto de Geología, Universidad Nacional Autónoma de México, Mexico City*, ***2.** National Autonomous University of Mexico*

Interaction of the Maya civilization with its environment and in particular the possible ecological reasons for the cultural collapse at the end of the Classic period have drawn major interest during the last years. The hypothesis of climate change impact ("the Mayan drought") was supported by various lacustrine, marine and speleological records; on the other hand, simultaneously the scenario of human-induced landscape degradation as an important factor of cultural decay was developed. In particular, soil erosion and loss of the soil mantle were considered to be the main mechanism of this degradation. Our research pretends to answer the following fundamental question: how could large-scale soil erosion develop in the Maya Lowlands – the Platform of Yucatan? This territory has even low-contrast relief with few pronounced slopes and besides lateral surface water flow does not develop because of vertical drainage through karstic cavities. Our research during 20 years demonstrated that vertical karstic erosion ("soil piping") could be responsible for the degradation of soil mantle. This process consists in the transport of soil material from the surface through the karstic sinkholes to the underground reservoirs: pockets, galleries and caves. Study of the underground pedosediments confirmed this process and revealed the soil materials deriver from surface profiles. Radiocarbon datings of charcoal, humus and terrestrial mollusk shells from these pedosediments produced ages corresponding to Formative and Classic periods (4000 – 1000 yr BP). In the light of these findings the origin of shallow soils – Rendzinas widely spread in Yucatan is revised. They could be not incipient young soils (as thought traditionally) but rather the relicts – minor residues of the pre-existing much more developed but then eroded profiles. Mineralogical and micromorphological results which show high weathering status of Rendzina groundmass agree with this conclusion. Ancient Maya cultivation was adapted to thin and discontinuous soil cover. However, the lack of soil thickness could have dramatic consequences for agriculture during the droughts because of decreased water storage in the soil.

Behavioral stability and ecological diversity in west African Middle Stone Age : a case study from Bargny, Senegal

Dr. Khady Niang [1], ***Dr. James Blinkhorn*** [1], ***Prof. Mark Bateman*** [2], ***Dr. Christopher Kiahtipes*** [3]

1. Max Planck Institute for Geoanthropology, 2. Sheffield University, 3. University of south florida

The Middle Stone Age is a crucial period in human evolution, during which numerous forms of ecological, socio-cognitive and techno-cultural adaptations are apparent. Discussions of these key issues typically exclude West Africa as archaeological data from this cultural stage has been scarce and archaeological sites characterized by poor chronological control. This paper presents the results of new investigations at Bargny, a quarry located approximately 2 km from the Atlantic coast of Senegal. Preliminary results make it possible to place human occupation in the Middle Pleistocene within a habitat associated withlow-levels of water stress and proximity to a mangrove environmental system. From a technological point of view, the classical elements of the MSA persisting in the region until the Holocene are represented. Notwithstanding the proximity to the ocean, no form of exploitation of marine resources has been revealed. This situation raises question about the diversity of trajectories in terms of environmental engagement and the relevance of the factors identified so far as drivers of cultural evolution.

Poster - sessions 21, 31, 59, 83, 101

Northward expansion of the westerlies and an extended LGM over southeastern Australia

Prof. Kathryn Fitzsimmons [1], ***Dr. Sergey Gromov*** [2]

1. Department of Geosciences, University of Tübingen, 2. Department of Atmospheric Chemistry, Max Planck Institute for Chemistry

It has long been hypothesized that the last glacial maximum (LGM) oversaw cold, arid, windy climates across southern Australia, and that these were driven by intensification and northward expansion of mid-latitude westerly circulation. Additionally, it has been suggested (by Lynda Petherick, among others) that Australia experienced an extended LGM which began several millennia before the global peak. Aeolian sedimentary deposits provide key evidence for these hypotheses, and climate modelling an alternative means to test them. As yet, however, few studies combine modelling and sedimentology in order to reconstruct glacial-age environments on the Australian continent.

Here we provide new evidence for westerly wind regimes across glacial southeastern Australia. We confirm active transverse lunette deposition at c. 29 ka and c. 23-19 ka in the semi-arid Willandra Lakes, and identify aeolian sand incursions to Spring Creek on the temperate Western Victorian Volcanic Plains from c. 29 ka onward. The Spring Creek deposits contain a surprising quantity of sand-sized quartz given the basalt setting, which we propose to be allochthonous and likely transported some distance. The site lies more than 50 km east and south of dunefields which were active at the same time; we suggest that these contributed sediment via long distance transport.

We investigate the hypothesis for northward glacial expansion of westerly winds by combining our sediment records with aeolian particle transport simulations. We find that LGM near-surface winds were dominated by stronger, more focussed westerly air flow across southeastern Australia, compared with the more diffuse wind regimes of the present day. Our results suggest stronger potential for LGM eastward distal sand transport onto the basalt plains, coeval with enhanced aeolian activity in the semi-arid Australian dunefields. Our combined reconstruction of aeolian deposition and trajectory modelling confirms the extended LGM hypothesis, and indicates a northward migration of westerly winds over southeastern Australia during this period.

Late Quaternary glacial maxima at Lake Tennyson, New Zealand, and their climatic implications

***Dr. Shaun Eaves* [1], *Dr. Andrew Lorrey* [2], *Ms. Greta Stuthridge* [1], *Mr. John-Mark Woolley* [2], *Dr. Tim Barrows* [3], *Dr. Levan Tielidze* [1], *Ms. Angela Perks* [2], *Prof. Peter Almond* [4], *Dr. Brian Anderson* [1], *Dr. Jochen Bind* [2], *Dr. Paul Augustinus* [5], *Dr. David Barrell* [6], *Dr. Alan Hidy* [7], *Dr. Christian Hyde* [2], *Dr. Kevin Norton* [1], *Dr. Petra Pearce* [2], *Dr. Hamish Sutton* [2]**

Mountain glacier extent is primarily determined by regional climate. Geomorphological evidence of past changes in glacier extent preserved in the landscape thus affords insight to past climate change. Here we present new constraints on the extent, timing, and climatic implications of glacial maxima at Lake Tennyson, New Zealand. High-resolution geomorphological mapping from a bespoke Light Detection And Ranging (LiDAR) survey, coupled with field-based investigations, reveals a well-preserved terminal moraine sequence extending c. 2 km from the southern lake shoreline. We constrain the timing of glacier retreat using cosmogenic ^{10}Be surface exposure dating applied to boulders on moraine crests. Preliminary results indicate the moraine sequence records the culmination of two glacial maxima of similar extent, first in oxygen isotope stage 4, and then at the end of the Last Glacial Maximum. Supported by numerical glacier model simulations, we provide quantitative constraints of the climatic conditions under which these former glaciers existed and commentary on the proposed drivers of late Quaternary glacial maxima.

Early glacier advance in New Zealand during the Antarctic Cold Reversal

***Dr. Levan Tielidze* [1], *Dr. Shaun Eaves* [2], *Dr. Kevin Norton* [2], *Prof. Andrew Mackintosh* [3], *Dr. Joel Pedro* [4], *Dr. Alan Hidy* [5]**

***1.** Victoria University of Wellington/Monash University, **2.** Victoria University of Wellington, **3.** Monash University, **4.** Australian Antarctic Division, **5.** Lawrence Livermore National Laboratory*

Glacial landscapes preserve records of past climate change. Investigating the glacier-climate system over the Late Quaternary provides information about past climate change and context for present day glacier response to climate warming. Using twenty-eight beryllium-10 (^{10}Be) surface exposure dates and snowline reconstructions, we present glacier fluctuations and climate changes for the Antarctic Cold Reversal in the Ahuriri River catchment, Southern Alps of New Zealand (44°7'50"S, 169°38'29"E). Prominent terminal and lateral moraine features from the upper right tributary of the Ahuriri River valley have exposure ages of 14.5±0.3 ka, 13.6±0.3 ka, and 12.6±0.2 ka, suggesting retreat of the glacier during the Antarctic Cold Reversal. Maximum elevation of lateral moraines (MELM) and accumulation area ratio (AAR) suggest snowline elevations at these ages were ≤700 m, ≤630 m, and ~360 m lower than today, respectively. This equates to air temperatures of ≤3.9, ≤3.5 °C, and 2.3±0.7 °C colder than today (1981–2010), assuming no changes in past precipitation. Ice-sculpted bedrock surfaces bound by a lateral moraine at nearby Canyon Creek have an age of 13.1±0.3 ka, indicating the moraine correlates with those in the Ahuriri upper right tributary. MELM and AAR reconstructions from the Canyon Creek suggest that snowline elevations at 14.5–13.6 ka were ≤500 or ~380 m lower than today, corresponding to air temperatures of ≤2.8 or 2.4±0.7 °C cooler than the present-day (1981–2010). Our results provide insight into the structure of the Antarctic Cold Reversal in the Southern Alps, showing that the largest glacier advance occurred at the start of this interval at c. 14.5±0.3 ka and was followed by gradual retreat. We hypothesize that the early cooling and glacier readvance in New Zealand at the onset of Antarctic Cold Reversal were triggered by a latitudinal shift of the Southern Hemisphere westerly wind belt.

Southern Hemisphere Glacier fluctuations during the past 70 kyr : Insights from offshore New Zealand

1. *IFREMER*, **2.** *AWI*, **3.** *CRPG*, **4.** *IUEM*, **5.** *The University of Queensland*

Landforms produced by mountain glaciers are fundamental paleo-records of quaternary climate changes. However, the reconstruction of a full, and continuous paleo-records of glacier fluctuations based on glacigenic landforms is complex due to their random preservation because of erosion or overprinting issues. Here, we circumvent this limitation through producing a 70 kyr-long record of glacier fluctuations at the southern tip of the New Zealand's Southern Alps (44.5-46.2°S) from the study of deep-sea core TAN1106-28 (Solander Trough ; 48.4°S). High-resolution (≤500 years) geochemical (neodymium radiogenic isotopes, XRF) and mineralogical (including clay) investigations, coupled to a set of 52 radiocarbon dates, makes it possible to fingerprint the changes in source area (Fiordland versus Southland) of the sediment deposited at core site. We relate the changes in the sediment source to i) the long-term growth and decay of the Fiordland Icefield and, ii) to millennial-scale glacier fluctuations from MIS 4 to the Late glacial. Our Southern Alps glacier record reveals at least four periods of extension of the Fiordland Icefield well beyond the Te Anau, Manapouri and Monowaï proglacial lakes from ca. 70 to 30-28 ka. The largest ice advance is dated to ca. 44 ka and could represent the Local Last Glacial Maximum. From ca. 30-28 ka onward, the Fiordland Icefield significantly receded, likely forced by the rising obliquity, with the last fluctuations being recorded at around 17-15 ka at core site. This marine-based chronology for Southern Alps glaciers will be compared to cosmogenic surface-exposure moraines chronologies from New Zealand Central South Island (44°S), Kerguelen (49°S), Patagonia (42°S), and the Northern Hemispere records of glaciation. Finally, forcing factors, including latitudinal shifts of the austral westerlies and the Subtropical Front, will be discussed in the light of foraminifera-based paleoceanographic reconstructions at site TAN1106-28.

Vertebrate records, paleoclimatic and environmental features in MIS-3 and MIS-2 continental sedimentary beds of Uruguay, South America.

Dr. Martin Ubilla [1], ***Dr. Andrea Corona*** [2], ***Dr. Aldo Manzuetti*** [3], ***Mr. Felipe Montenegro*** [4], ***Dr. Elizabeth Morosi*** [3], ***Dr. Daniel Perea*** [3], ***Dr. Andres Rinderknecht*** [4]

1. *Facultad de Ciencias,* ***2.*** *Facultad de Ciencias Montevideo,* ***3.*** *Facultad de Ciencias, Montevideo,* ***4.*** *Facultad de Ciencias, Montevideo, Museo de Historia Natural*

The vertebrate record in continental sedimentary beds correlated to MIS-3 and MIS-2 at mid-latitudes of South America (SA) is analyzed in order to infer biotic responses to the climatic conditions. Concomitantly, the information provided by the fauna itself is useful to characterize both intervals (in particular the less known MIS-3 in terrestrial contexts of SA). Fossiliferous sedimentary beds (Sopas Formation) outcropping in northern Uruguay (30°08'16''S, 57°00'33''W to 32°13'16''S, 56°00'46"W), mostly originated under fluvial environments, are dated with several ^{14}C AMS (36,089 – 39,426 cal BP to 42,025 - 45,389 cal BP) and OSL ages included in the 45-28 ka interval. Vertebrates include migratory and aquatic avian taxa suggesting seasonal climate and mammal taxa (extant and extinct) related to open habitats, savannahs, woodlands, and gallery forests. It is emphasized the record of tropical to temperate mammals (such the tapir *Tapirus*, the marsh-rat *Lundomys molitor*, the capybara *Hydrochoerus hydrochaeris*, the ocelote *Leopardus pardalis*, the peccary *Parachoerus wagneri,* among others) into the MIS-3, which should have been more benign enough than the LGM, when different environments were able to house this fauna. Isotopic studies support C3/C4 grasslands, savannahs, open canopy wooded areas and gallery forests. A contrasting context is verified in late Pleistocene/early Holocene beds (Dolores Formation) outcropping in southern Uruguay (32°13'16''S, 56°00' 45"W), with gravitational and alluvial origin, including small lakes and ponds. Several ^{14}C AMS (28,565-27,930 cal BP to 11,117–11,121 cal BP) and OSL (30 to 8 ka) ages are available. This unit including MIS-2 allows analyzing its effect at biotic level. The prevailing cold and arid contexts are substantiated by the presence at this latitude of taxa living nowadays in arid to semiarid environments. The record in the southern Uruguayan Pampean area of some mammals currently inhabiting Patagonia, northwest and central Argentina, and even Andean highlands (such *Dolichotis*, *Galea*, *Microcavia*, *Chaetophractus*, *Lagostomus*, and *Vicugna*) could be explained by the predominance of open areas and cold climates favoured by the LGM. In both units, the mammalian assemblage provides evidence of not only local extinctions but also shifting range at genus and specific level highly related to climatic and habitats changes.

Paleoenvironmental and climatic inferences for the Late Pleistocene of Uruguay based on the native ungulate Neolicaphrium recens

Dr. Andrea Corona [1], ***Ms. Ana Clara Badin*** [1], ***Dr. Daniel Perea*** [2], ***Dr. Martin Ubilla*** [3]

1. Departamento de Paleontología, Facultad de Ciencias, Universidad de la República, 2. Dpto. de Paleontología, Instituto de Ciencias Geológicas, Facultad de Ciencias, Iguá 4225, 11400 Montevideo, perea@fcien.edu.uy, 3. Facultad de Ciencias

The knowledge of deposits belonging to MIS 3 in northern Uruguay (Sopas Formation), have been dramatically increased over the last decades. Different sources of information have provide evidences of warm, humid and seasonal climate, including open habitats, savannahs and woodlands. One of the species recently studied in order to acquire and compare environmental information is the proterotheriid (Mammalia, Litopterna) *Neolicaphrium recens*. This species is recorded in several localities from the Late Pleistocene of northern Uruguay as well in center and north of Argentina and southern Brazil. Specifically, we studied the dental microwear pattern and performed some estimations of body mass as a way to know its niche preferences. The results, obtained from specimens from different localities, showed a higher relative percentage of pits over scratches on the enamel surface, indicating a browser feeding habit. This kind of diet allow us to assume that the analyzed specimens consumed mostly leaves, shoots, buds and soft portions of trees and shrubs. These results are in agreement with those from isotopic analyses and support the prevalence of an open environment similar to a savannah. In addition, another important issue is the estimation of the body size (body mass) of this species, which is related to several ecological aspects, particularly type of physical environment and niche size. Calculations have been made by applying classical equations (based on several extant ungulates) on teeth and appendicular elements of *N. recens*. The last one are the most appropriate as they are directly linked to the support of the body and the relationship with the type of substrate (environment). Body masses ranging from 28 to 32 kg were obtained, which is similar to the Pampas deer *Ozotoceros bezoarticus*. *N. recens* has been also recorded in sediments from the Dolores Formation, outcropping in the South of Uruguay and deposited under LGM-related weather conditions (MIS 2). Exploring different ways to know the biology of this proterotheriid is important to understand its role in the communities, its niche preferences and its potential usefulness in the reconstruction of environments and their distribution during MIS 3-2.

Southern African dryland environments within SHeMAX: towards a terrestrial regional chronostratigraphic frameworks during the last global glacial.

Dr. Abi Stone [1]

1. *Department of Geography, The University of Manchester*

Subdivision of Quaternary environmental change in Southern Hemisphere drylands is usually arranged using Marine Oxygen Isotope Stages (MIS) as a framework. This overlooks the importance of terrestrial-based stratigraphic correlations and the opportunity to identify environmental shifts that were diachronous from global ice volume and/or subdued, or amplified responses to the forcing from global ice volume change. The Kalahari and the Namib Desert are the two key dryland areas of southern Africa, and these did not have ice cover during the last global glaciation. There is a range of archives and proxies in drylands from geomorphological proxies, such as sand dunes, former lake basins and former fluvial systems, through hydrological and hydrogeological precipitates and chemical signatures, to biological evidence within hyrax middens. This study aims to integrate these records to see if a (or a number of) terrestrial regional chronostratigraphic framework(s) can be identified. A lack of long near-continuous terrestrial sequences in drylands makes this a significant challenge, and an attempt to produce parasequences from the correspondence between nearby records is explored. In addition, recognising the modern climate diversity of southern Africa, a subdivision of four broad areas, the Namib Desert, the northern Kalahari, the southern Kalahari and the eastern fringes of the southern Kalahari, is used to explore potential sub-regional parasequences. A recent review of dunes and other geoproxies in dryland southern Africa suggests there have been seven broadly wetter intervals over the last ~190 ka, separated by relatively drier conditions, are seen, and their onset and cessation does not align with MIS. In this presentation, I focus on the character and extent of four identified wetter intervals ~64-43 ka, 34-25 ka, 32 to 16 ka and ~15 ka, during the period leading up to, and including the global Last Glacial Maximum, and discuss a range of hypothesised mechanisms for these hydroclimate shifts that have previously been identified.

Synchronous onset of the last glacial termination in the southern mid-latitudes

1. *School of Geography, Earth and Atmospheric Sciences, The University of Melbourne,* ***2.*** *University of Melbourne,* ***3.*** *Victoria University of Wellington,* ***4.*** *University of Newcastle,* ***5.*** *Department of Ecological Sciences, Universidad de Chile*

Detailed comparisons of Antarctic and Greenland ice core records suggest an inter-hemispheric asynchrony of climate change at the end of the last glaciation. The extent to which this climate variability, its timing and regional synchrony affected the southern mid-latitudes remains uncertain. Here we present a compilation of multiples selected terrestrial proxy paleoclimate data from key mid-latitude Southern Hemisphere landmasses spanning the last glacial-interglacial transition, focusing on the onset of the last termination (T1). Our results show that synchronous deglacial climate conditions induced terrestrial environmental shifts in Tasmania, New Zealand's southern Island and western Patagonia at the beginning of T1, consistent with the commencement of the deglacial warming revealed by Antarctic ice records following the Last Glacial Maximum (LGM).

Pacific Island palaeovegetation change across the South Pacific Convergence Zone during the last glacial period

Dr. Matiu Prebble [1]***, Mr. Ronald Lloren*** [2]***, Prof. Nathalie Dubois*** [3]***, Dr. Paul Augustinus*** [4]***, Dr. Nick Porch*** [5]***, Dr. Seth Quintus*** [6]***, Prof. Ethan Cochrane*** [4]

1. University of Canterbury, 2. ETH Zurich, Department of Earth Science and Eawag, Department of Surface Waters - Research & Management, 3. EAWAG, 4. University of Auckland, 5. Deakin University, 6. University of Hawaii

The South Pacific Convergence Zone (SPCZ) is the most extensive rain band in the southern hemisphere and is a major driver of the prevailing climate of the South Pacific Region. Changes to the SPCZ at annual to millennial time scales have been measured from historical and palaeoclimatic proxies, respectively. While geochemical evidence has shown rapid shifts in the SPCZ during the last glacial period, evidence for ecological responses is limited. In order to address the role of MIS 3 climates in shaping the terrestrial ecosystems of the tropical oceanic Pacific islands, in periods unaffected by human activity, we present rare 'snapshots' of ecological changes on Tahiti (French Polynesia) and Upolu (Sāmoa). Fossil pollen, spores, and other fossil remains are examined from algal-rich sediments from both islands and are compared with geochemical measures of climatic change (e.g. XRF). Vegetation associations no longer present on these islands are observed, including the dominance of palm and sub-shrub vegetation more characteristic of some of the sub-tropical Pacific Islands. The ecological responses identified from these Pacific Islands provide evidence counter to the prevailing view that the tropical oceans buffered the ecological effects of abrupt climate changes during the last glacial period.

Millennial scale surface and deep water changes in the Benguela upwelling system during the last 45 ky

Dr. Natalia VAZQUEZ RIVEIROS [1], ***Dr. Claire WAELBROECK*** [2], ***Ms. Angelique ROUBI*** [1], ***Mr. Joao BALLALAI*** [1]

1. Ifremer, Geo-Ocean, Plouzané, France, 2. LOCEAN, CNRS, Sorbonne Université, Campus Pierre et Marie Curie

The intensity and extension of the Benguela upwelling, along the southwestern coast of Africa, have been shown to vary on a millennial time scale during the last deglaciation. The changes in sea surface temperature in this region have been associated either with changes in the position of the ocean fronts in the SE Atlantic Ocean, themselves related to cold episodes in the North Atlantic, or to variations in the intensity of the upwelling, related to the intensity of the dominant winds.
Marine sediment cores from the Namibian margin, a region characterized by the upwelling of waters from 150-500 m depth, contain climate records showing these surface water variations. In particular, core MD08-3167, retrieved at 23°S and 1950 m of water depth on the Namibian margin during the 2008 RETRO cruise, has been shown to present high-resolution time series covering the last 40 ky. Stable isotopes ($d^{18}O$ and $d^{13}C$) and Mg/Ca have been measured in the planktonic foraminifer *Globigerina bulloides*, which may be assumed to thrive in upwelled waters. The records show a very marked, rapid warming of more than 4°C at the start of the last deglaciation, coinciding with the beginning of Heinrich Stadial (HS) 1 in the North Atlantic. However, the previous three HS show a different pattern, with subdued variability and evidences of cooling and freshening during some of them. Planktic foraminiferal counts and $d^{18}O$ measured in the deeper-dwelling foraminifera *Globorotalia inflata* rather suggest enhanced upwelling driving augmented productivity between 28 – 19 ky BP, that may have been driven by enhanced trade winds and obscured glacial millennial scale variability.

Neolicaphrium recens in the Late Pleistocene of Uruguay, new records and use of CAT in the study of young specimens

Mrs. Ana Clara Badin [1], ***Dr. Andrea Corona*** [2], ***Dr. Martín Ghizzoni*** [3], ***Mr. Renzo Loggio*** [4], ***Dr. Daniel Perea*** [5], ***Dr. Martin Ubilla*** [5]

***1.** Paleontology Department, Facultad de Ciencias (UdelaR), Montevideo, Uruguay., **2.** Departamento de Paleontología, Facultad de Ciencias, Universidad de la República, **3.** Escuela Tecnológica Superior de Administración y Servicios, DGETP, Salto., **4.** Museo Nacional de Historia Natural, Montevideo., **5.** Facultad de Ciencias*

South America evolved as an isolated system for a long time during the Cenozoic, allowing the radiation of very diverse groups of native ungulates (SANUs). The Family Proterotheriidae (Litopterna, Panameriungulata) is one of those SANUs, recording the only single species Neolicaphrium recens in the Late Pleistocene. This taxon has shown a wide latitudinal distribution, from the center-north of Argentina, South of Brazil until southern Uruguay. In this contribution, we present new specimens of N. recens recently found in deposits of the Sopas Formation (Late Pleistocene, northern Uruguay) and discuss the usefulness of the computed tomography (CAT) as a powerful tool, helping in the descriptions and study of juvenile specimens. The new records consist of a an almost complete mandible with left dp2-dp4 and m1 erupting and right p1, dp2-dp4, and m1 erupting (MNHN 3186); right calcaneus and astragalus, and two mandible fragments with right p3-m2 and left m1-m3 (m3 erupting) (FC-DPV 3427); a right mandible fragment with p3-m2 (CPG 93-2); a left M2 (CPG 24-2) and a right astragalus (CPG 122-1). The tomographies performed on the specimen FC-DPV 3427 revealed that it did not have any unerupted tooth inside the bone, but the remains are too fragmentary and have a really poor preservation. On the other hand, for the specimen MNHN 3186, studied under the same conditions, the tomography revealed that the m2 on both right and left sides are present inside the alveolus, very close to the surface, near eruption, and with no evidence of the presence of the m3, even having little space for its development. The obtained images are very convincing, allowing to determine the sequence and time (quite long) of dental eruption. Moreover, these specimens and techniques allow us to improve the morphological knowledge of N. recens at a craniomandibular (specially dental) and postcranial level, being very important the understanding of the ontogeny. N. recens is currently the native subject of several approaches in order to assess a complete set of information for the reconstruction of environments and climates during the Late Pleistocene at middle latitudes in South America.

Paleoceanography of the Southern Ocean during the last glacial period

Dr. Helen Bostock [1]***, Dr. Harris Anderson*** [2]***, Prof. Zanna Chase*** [3]***, Dr. Taryn Noble*** [4]***, Dr. Joel Pedro*** [5]

1. *The University of Queensland,* ***2.*** *Institute of Marine and Antarctic Science,* ***3.*** *Institute for Marine and Antarctic Studies, University of Tasmania,* ***4.*** *Institue of Marine and Antarctic Science,* ***5.*** *Australian Antarctic Division*

We have compiled published Sea Surface Temperature (SST) records from 30-60°S to understand the paleoceanographic changes in the Southern Ocean (SO) over the last 75 ka (Anderson et al., 2021). Here we will focus on the Last Glacial period from 35-15 ka, in line with the objectives of the SHeMAX project.

We included SST from a range of proxies including alkenones, microfossil assemblages and transfer functions, and Mg/Ca foraminifera. We only used records with sedimentation rates >2.5 cm/kyr and recalibrated the radiocarbon dates from each of these sites and synchronised the sea surface temperature (SST) records using a range of tie points with the Antarctic Ice Core Chronology 2012. SST anomalies were determined by subtracting the average SST for each individual core from the period of 59-27 ka (MIS3 average) in order to focus on relative temperature changes. The records were then combined to form a SO stack of SST anomalies as well as Atlantic and Indo-Pacific basin stacks of SST anomalies.

The normalised SST anomaly stacks from the Atlantic and Indo-Pacific show strong similarities in amplitudes of SST changes across the SO. While there is a general cooling trend from MIS5a through to the last glacial period, there is a slightly anomalous cool period during 50-40 ka immediately prior to a 35 ka. Between 35-18 ka the SST display temperature anomalies of 0 to +1°C. On millennial scale, the SO SST stacks show similar temperature variability with the ice cores, with warmer periods of SST aligned with Antarctic Isotope Maxima (AIM), for example between 30-28 ka aligned with AIM4 (Heinrich Stadial 3). At the end of the glacial period the deglacial in the SO is characterised by abrupt warming, synchronous with the timing of Antarctic temperature changes.

Transient response of the ocean carbon cycle during the last deglaciation

Dr. Hidetaka Kobayashi [1], **Dr. Akira Oka** [2], **Dr. Takashi Obase** [2], **Prof. Ayako Abe-Ouchi** [2]

1. The University of Toyama, 2. The University of Tokyo

We used an ocean carbon cycle model that was imposed on the output of the climate model MIROC 4m to explore the mechanisms of transient changes in the ocean carbon cycle during the last deglaciation. The model experiment showed that atmospheric partial pressure of carbon dioxide (pCO2) increased during the Heinrich Stadial 1 (HS1) and the Younger Dryas (YD) and decreased during the Bølling-Allerød (BA). In other words, the ocean becomes a source of carbon during the HS1 and YD and a sink during the BA. The atmospheric pCO2 rise during the HS1 was found to be largely attributable to an increase in sea surface temperature (SST), especially in the Southern Hemisphere. During the BA, an increase in surface alkalinity associated with the recovery of the Atlantic meridional overturning circulation (AMOC) contributed to the decrease in surface ocean pCO2. On the other hand, a decrease in CO2 solubility due to temperature changes partially compensated for the pCO2 decrease. During the YD, an increase in SST again contributed to the increase in surface ocean pCO2. The model experiments showed that changes in the oceanic carbon cycle associated with changes in AMOC may explain about a quarter of the real atmospheric CO2 during deglaciation. It has remained difficult for us to simulate the rapid centennial-scale changes in atmospheric pCO2 indicated by ice core data. Previous studies have suggested that changes in the strength of mixing in the Southern Ocean due to changes in westerly winds and stratification may have contributed to the rise in atmospheric pCO2 during the deglaciation. Therefore, reproducing environmental changes in the Southern Ocean under paleoceanographic data constraints may contribute to accurately simulating the rapid increase in atmospheric pCO2 during the deglaciation.

Carbonate Counter Pump and upwelling strengths in the Indian sector of the Southern Ocean during TV-MIS 11 and their impacts on the carbon cycle

***Dr. Margaux Brandon* [1], *Dr. Stephanie Duchamp-Alphonse* [2], *Dr. Elisabeth Michel* [3], *Dr. Amaelle Landais* [3], *Mrs. Gulay Isguder* [3], *Mrs. Patricia Richard* [3], *Mr. Nicolas Pige* [4], *Dr. Franck Bassinot* [3], *Dr. Samuel Jaccard* [5], *Dr. Annachiara Bartolini* [6]**

1. LOCEAN, 2. Paris Saclay University - GEOPS Laboratory, 3. LSCE, 4. LGL-TPE, 5. UNIL, 6. MNHN

During the glacial-interglacial cycles of the past 800 000 years (800 ka), atmospheric CO_2 concentrations (pCO_2) have changed with amplitudes of 50-100 ppm, the fastest increases being registered during glacial terminations (T). Biological productivity in the Southern Ocean plays an important role in such pCO_2 variations, impacting the ocean-atmosphere exchanges of CO_2 through changes in Biological Carbon Pump strength that includes the Soft Tissue Pump (i.e., the net downward flux of phytoplanktonic carbon that draws down pCO_2) and the Carbonate Counter Pump (CCP - i.e., the export of planktonic carbonate that influences the surface-to-depth alkalinity gradient and increases pCO_2).

Existing paleoclimate studies usually focus on the Soft Tissue Pump and demonstrate that its weakening may contribute to the increase in pCO_2 during Terminations. Not much is known about the CCP due to the lack of high-resolution studies in the SO based on both, micropaleontological and geochemical approaches.

Among the last 9 interglacials, Marine Isotope Stage (MIS) 11, that follows TV, is the longest and is characterized by an exceptional 30 ka-plateau of pCO_2. It registers the strongest global productivity signal and the highest marine carbonate export production.

Here, we present micropaleontological (coccolith, planktonic foraminifera) and geochemical ($CaCO_3$, Ca_{XRF}, $d^{13}C_{N.\ pachyderma}$) data from sediment core MD04-2718 retrieved in the Polar Front Zone of the Indian Ocean, covering MIS 12-10. We compare our results with published records from sediment and ice cores, to reconstruct past changes in CCP and upwelling strength, and understand their leverage on the ocean-atmosphere portioning of CO_2.

We demonstrate that the sharp increase in pCO_2 during TV is associated with enhanced deep-water ventilation. Strengthened CCP is observed later, during MIS 11, and is probably the consequence of higher sea surface temperature and nutrient availability due to the reinvigoration of Southern Ocean upwelling, leading to increased coccolith export production. The low eccentricity signal recorded during MIS 11 might have additionally strengthened the CCP, exerting a specific control on *Gephyrocapsa* morphotypes. Together with a strong global biological productivity these synergistic mechanisms may have permitted to shape the long pCO_2plateau characteristic of MIS 11.

Chronostratigraphy of the Late Pleistocene fluvio-aeolian succession in the Polish part of the European Sand Belt

Prof. Piotr Moska [1], *Dr. Robert Sokołowski* [2], *Prof. Zdzisław Jary* [3], *Prof. Paweł Zieliński* [4], *Dr. Jerzy Raczyk* [3], *Prof. Przemysław Mroczek* [4], *Ms. Agnieszka Szymak* [1], *Prof. Grzegorz Poręba* [1], *Mr. Michał Łopuch* [3], *Prof. Natalia Piotrowska* [1], *Dr. Jacek Skurzyński* [3], *Mr. Marcin Krawczyk* [3], *Dr. Konrad Tudyka* [1], *Prof. Anna Hrynowiecka* [5]

1. Silesian University of Technology, 2. University of Gdańsk, 3. University of Wrocław, 4. Maria Curie-Skłodowska University in Lublin, 5. Polish Geological Institute – National Research Institute

The Polish part of the European Sand Belt (ESB) is a remarkably interesting remnant of the Late Glacial aeolian accumulation. It is covered with extensive dune fields as well as individual dunes related to numerous river valleys. In the last few years has been carrying out multi-proxy studies of phases of aeolian activity in the ESB at over 50 profiles including fluvio-aeolian succession with palaeosols. The research results obtained so far indicate, first of all, the high sensitivity of the aeolian environment to environmental changes, including climatic changes and oscillations.

The currently collected results, which consist over than 300 OSL dates and about 70 ^{14}C results as part of the implemented project allow for verification the existing models of aeolian deposition development which they assumed that dune-forming processes took place mainly during the late-glacial cooling of the climate (the Oldest, Older and Younger Dryas). These dune-forming periods were assigned a different rank (the formation of dunes or their transformation). These phases were interrupted by the Bølling and Allerød interstadials, during which soil-forming processes took place.

A comparison of the existing models with new research results from marine sediments and ice cores from Greenland and the results from the western part of ESB reveals large discrepancies, which are probably not only due to a different position in within the ESB. Their causes can be found in stratigraphic models, which are mostly based on a few, often uncalibrated, results of radiocarbon dating obtained from individual sites, or too few samples taken from opencasts without checking them with other methods. Also, new research results obtained from the Polish part of ESB indicate that both in reservoir sediments and in the fluvio-aeolian succession, it is possible to identify climatic oscillations known from the Greenland ice cores.

Atmospheric dynamics, surface Pacific conditions and the North American ice sheet at the Last Glacial Maximum

Dr. William Dow [1], ***Dr. Ruza Ivanovic*** [1], ***Dr. Sam Sherriff-Tadano*** [1], ***Dr. Lauren J. Gregoire*** [1]

Surface ocean conditions and atmospheric dynamics can affect the surface mass balance of remote ice sheets via their influence on heat and moisture transport. Here, we use the FAMOUS-ice coupled climate-ice sheet model to simulate the Last Glacial Maximum. The model was run hundreds of times to produce a large ensemble that captures a range of uncertain model inputs (parameter values). We investigate the range of simulated atmospheric circulation patterns, their relationship to sea surface conditions in the North Pacific and the interactions with the North American ice sheet (e.g. through the effects on ice sheet surface mass balance).

The hydrological variability from the Last Glacial Maximum to Holocene transition in the central Mediterranean from speleothem stable isotopes

The last deglaciation (Termination I) saw rapid northern latitude temperature changes and ice-sheet loss, coupled with changes in the Atlantic Meridional Overturning Circulation. However, the modes, timing and sustaining mechanisms that propagated these changes to the Mediterranean region are far from well understood. Here, we compare two high-resolution stalagmite $\delta^{18}O$ time series from Southern Italy: one from Sicily (new data) and one from Puglia (Columbu et al., 2022). Both records show a substantial agreement in the main changes and steps in $\delta^{18}O$ patterns (within uncertainties of the two age models), which indicates synchronous changes in local hydrology. However, between 14.2 and 13.2 ka the two records show prominent antiphasing, with drying in Sicily occurring at a time of wetter conditions in Puglia. This suggests the presence of a thus-far-undetected strong atmospheric gradient at a specific phase of the glacial-to-interglacial transition. This requires further investigations using other highly resolved proxy data to confirm these data and evaluate the regional extent of this pattern.

Parameter ensemble simulations of the North American ice sheet and climate at the Last Glacial Maximum with Famous-BISICLES

Testing the ability of coupled climate-ice sheet models to simulate past ice sheet can provide a way to evaluate the models and ground truth projections. One example is the Last Glacial Maximum (LGM), when huge ice sheets covered the Northern Hemisphere, especially over North America. Here, we performed ensemble simulations of the North American ice sheet and climate of the LGM with an ice sheet-atmosphere-slab ocean coupled model Famous-BISICLES. The model consists of an atmospheric general circulation model Famous (Smith et al. 2008) and an ice sheet model BISICLES (Cornford et al. 2013). The atmospheric model reproduces the surface mass balance of the modern Greenland ice sheet reasonably well (Smith et al. 2021). We conducted more than 200 members of ensemble experiments varying 17 parameters associated with climate, ice albedo, ocean and ice dynamics. The simulated results are first evaluated against LGM global temperature. These simulation results are then used to explore effects of individual uncertain parameter as well as to evaluate parameter spaces that reproduce the ice sheet and climate reasonably well. We will show the role of individual parameter on the performance of the North American ice sheet. In addition, we discuss how the uncertainties in the LGM global temperature can affect the maintenance of an ice sheet. Ensemble simulations of modern Greenland and climate are also performed with the same model (Lang et al. in prep) and the results will be compared to our LGM simulations together with some simulations of the last deglaciation.

The last deglaciation in the SW Iberian margin: changes in the Atlantic surface and Mediterranean bottom waters.

The transition from the Last Glacial Maximum to the Holocene interglacial period is marked by abrupt global changes in which ocean thermohaline circulation, ice sheets and atmosphere interacted. Mediterranean overturning circulation and thus Mediterranean outflow were strongly influenced by these changes and might even have played a role by exporting heat and salt to the North Atlantic. The gulf of Cádiz Contourite Depositional System is characterized by the presence of two sandy contourite layers, corresponding to periods of reduced Atlantic Overturning Circulation (AMOC) during late Heinrich stadial 1 and Younger Dryas. In this work we present new multiproxy record for last 30ka from a sediment core located in the main branch of Mediterranean overflow. Planktic foraminifera assemblages have been used to reconstruct North Atlantic-influenced sea surface temperatures (SST), and Mg/Ca in benthic foraminifera to reconstruct Mediterranean overflow-influenced seawater bottom temperature (SBT).

Results from planktic foraminifera are well correlated with what is recorded in nearby sites, marked by an abrupt SST drop during Heinrich event 1 and relatively high SST during LGM. Sea bottom temperatures raised gradually from Greenland stadial 3, as observed in Greenland ice temperature records, showing relatively warm values during LGM as noticed in SST. We suggest that this synchronism between Mediterranean deep water and Greenland air temperatures trends can be explained by the atmospheric teleconnection between both regions. Cool air temperatures in Greenland are transferred to the Mediterranean through winter winds that caused surface water cooling and sinking to the deep Mediterranean. This long-term warming trend that reflects the average temperature of Mediterranean deep water was punctuated by by two events of higher temperatures at times of Sandy Contourite layers deposition (Late Heinrich stadial and late Younger Dryas). These pulses of heat and salt export to the North Atlantic just before the onset of AMOC restoration are consistent with the hypothesized Mediterranean Outflow contribution during Terminations.

Late Pleistocene deglaciation and Scandinavian Ice Sheet dynamics in NE-Germany and NW-Poland: new results from surface exposure dating

Dr. Henrik Rother [1]***, Dr. Vincent Rinterknecht*** [2]***, Dr. Andreas Boerner*** [3]***, Ms. Regina Kindermann*** [4]***, Mr. Norbert Hermsdorf (deceased)*** [5]***, Dr. Alf Grube*** [6]

1. *Landesamt für Geologie und Bergwesen Sachsen-Anhalt,* ***2.*** *CEREGE, CNRS, UMR 7330 Europole Méditerranéen de l'Arbois BP80,* ***3.*** *State Agency for Environment, Nature Conservation and Geology Mecklenburg-Vorpommern,* ***4.*** *Wilhelm-Potenberg-Straße 22, 17454 Zinnowitz, Germany,* ***5.*** *Landesamt für Bergbau, Geologie und Rohstoffe Brandenburg,* ***6.*** *Behörde für Umwelt und Energie - Geologisches Landesamt, Freie und Hansestadt Hamburg*

Age compilations documenting the late Quaternary dynamics of the Scandinavian Ice Sheet (SIS) have highlighted that last glaciation advance and retreat timings varied significantly across different SIS sectors. Resolving these issues has been difficult as there are still some key areas with contradictory evidence and/or gaps in the record due to a lack of absolute age information. Among the regions where significant uncertainties persist is the North-German Plain, in spite of representing one of the classical landscapes for glacial research since the mid-19th century. As a consequence, there is an ongoing lively debate around a series of SIS research questions including: (a) if and how far a potential mid-Weichselian ice advance extended into northern Germany; (b) whether or not the local maximum of the Odra ice stream pre-dates or coincides with the overall SIS maximum at c. 21 ka; and (c) at what time did the LGM retreat commence and when was the deglaciation of the German mainland completed? Here we present new information on the regional deglaciation history of the SIS based on a total of 72 CRN surface-exposure-ages (^{10}Be) from glacial landforms between the main LGM ice margin and the Baltic Sea coast. We find that stagnation and initial ice retreat from the main LGM limit commenced as early as 23.0 ± 1.4 ka, while the Frankfurt ice limit further to the north was abandoned around 19.9 ± 3.8 ka. Following a major re-advance to the Pomeranian ice margin yielded a mean age of 17.0 ± 1.7 ka, while glacial boulders from the Islands of Rügen, Usedom and Wollin, deposited just before the SIS retreated into the Basltic Sea Basin, returned a mean age of 15.9 ± 1.5 ka. Our record indicates that the post-LGM deglaciation of the North German Plain, referring to the final SIS retreat from the Pomeranian moraine to the present-day coast, and covering a recession of c. 130 km, occurred relatively rapidly and was probably accelerated by widespread glacier calving into large proglacial lakes.

A multi-model assessment of the onset of the last deglaciation

Ms. Brooke Snoll [1], Dr. Ruza Ivanovic [1], Dr. Lauren J. Gregoire [1], Dr. Sam Sherriff-Tadano [1]

1. School of Earth and Environment, University of Leeds

At the onset of the last deglaciation, beginning ~19 thousand years ago, ice sheets that covered the Northern Hemisphere at the Last Glacial Maximum started to melt, Earth began to warm, and sea levels rose. This time period is defined by major long-term, millennial-scale, climate transitions from the cold glacial to warm interglacial state, as well as many short-term, centennial- to decadal-scale warmings and coolings of more than 5 °C, sudden reorganisations of basin-wide circulations, and jumps in sea level of tons of meters. Long transient simulations of the deglaciation have been increasingly performed to better understand the long and short term processes, examine different possible scenarios, and compare model output to observable records. The Paleoclimate Modelling Intercomparison Project (PMIP) has provided a framework for an international coordinated effort in simulating the last deglaciation whilst encompassing a broad range of models and model complexities. This study is a multi-model intercomparison of 17 simulations of the last deglaciation from nine different climate models. Unlike other multi-model intercomparison projects, these simulations do not follow one particular experimental design but follow an intentionally flexible protocol suitable for all participants. The design of the PMIP protocol provides the opportunity to compare results from models using different forcings and examine a variety of scenarios, hence, representing the range of uncertainty in climate predictions of the time period. One particularly challenging choice to make in the experimental design is how to incorporate the resultant freshwater flux from the melting ice sheets. This research focuses on the divergence between climate trajectories in the simulations as a result of the meltwater scenario preferred by the modelling groups as well as other experimental design choices and their impact on the onset of the deglaciation. These results provide a better understanding of modelling this time period as well as model biases and uncertainty with respect to deglacial forcings and the observable proxy records.

A fast slow model for glacial interglacial cycles since the Mid-Pleistocene Transition

Ms. Jade Ajagun-Brauns [1], **Prof. Peter Ditlevsen** [1]

1. Physics of Ice, Climate and Earth, Niels Bohr Institute, University of Copenhagen

A new simple approach inspired by MacAyeal (1979) is used to explain the time asymmetric saw tooth shape of glacial interglacial cycles. A simple model with slow fast dynamics, where the global ice volume is taken to be a function of two independently varying parameters, the solar insolation and 'alpha', a secondary control parameter, is used. The study investigates how dynamics of the system are altered due to the addition of the second control parameter, which changes the geometry of the slow manifold to a partially folded surface. The pleated cusp geometry allows the system to exhibit both smooth changes and sudden discontinuous transitions from one stable solution to another, producing the gradual increase and sudden decrease in ice volume observed in the paleoclimate record. The control parameter alpha is suggested to be related to the internal dynamics of the climate system, proposed to be a measure of the glacial oceanic interaction, which varies due to glacial isostatic adjustments of the bedrock. The Mid-Pleistocene transition is suggested to occur as a result of northern hemisphere glaciers exceeding a critical threshold, which allows alpha to become larger, causing 100kyr glacial interglacial cycles of higher amplitude than prior to the MPT.

High precision δ13C of atmospheric CO2 record for the penultimate deglaciation and last interglacial

Ms. Julia Marks Peterson [1]***, Dr. Edward Brook*** [1]***, Dr. Jeffrey Severinghaus*** [2]***, Dr. Thomas Bauska*** [3]***, Dr. Andy Menking*** [4]

The stable isotopic ratio of CO_2 ($\delta^{13}C$-CO_2) measured in ice cores can be a useful tool for deciphering which of the carbon sources and sinks are responsible for past changes in atmospheric CO_2. A record of $\delta^{13}C$-CO_2 across the penultimate deglaciation and last interglacial period was constructed by Schneider et al. 2013 and presented novel insight into the potential carbon cycle fluxes affecting CO_2
across Termination II. We are reconstructing $\delta^{13}C$-CO_2 from a large diameter ice core from the Allan Hills, Antarctica. The core provides an opportunity to construct a more detailed record, roughly doubling the resolution, as well as increasing the precision to ~0.03 ‰. With this detailed record, we will be able to investigate outstanding questions about Termination II, such as: 1) What is the $\delta^{13}C$ during the penultimate glacial maximum, and can we better understand the long-term carbon cycle processes influencing atmospheric CO_2? 2) Do we see a change in $\delta^{13}C$ associated with centennial-scale CO_2 events that have been observed during the penultimate deglaciation? 3) Can a higher resolution $\delta^{13}C$ dataset provide further information about the 5000-year lag between CO_2 and temperature inferred from the EPICA Dome C ice core? Finally, a detailed $\delta^{13}C$-CO_2 record can inform our understanding of the interplay between millennial- and orbital-scale climate variability and how they interact to produce a termination.

Catchment vegetation and erosion controls soil carbon cycling in SE Australia during two Glacial-Interglacial transitions

Soil Organic Carbon (SOC) represents up to 80% of the terrestrial carbon pool. However, it is highly debated if soil carbon is a net atmospheric carbon source or sink. This is mainly due to a paucity of information on the fate of SOC during soil erosion, which affects oxidation during the storage, transportation, and final deposition of SOC. The Southern Hemisphere may play a dominant role in the global SOC - atmosphere carbon cycle, since changing climates can cause the expansion or contraction of terrestrial biomass across vast continental areas, for example in temperate to semi-arid Australia.

Here, we investigate the interplay between catchment erosion (quantified by means of uranium isotopes), vegetation cover (pollen), the wetland response (diatoms), and lake carbon accumulation on glacial/interglacial time scales in south-eastern Australia. The analyses are applied to the sediments of Lake Couridjah (Thirlmere Lakes) SW of Sydney. The recovered lake sediments cover the time interval between ~135 ka and 107 ka, and between ~17.6 ka and present day. This offers an outstanding opportunity to study SOC cycling across different glacial/interglacial boundary conditions.

Partial Least-Square Regression (PLSR) analyses reveal robust phase-relationships between catchment erosion, vegetation density, and carbon and nitrogen cycling during both glacial-interglacial complexes. The data imply that the density of the catchment's sclerophyll mid- to understorey vegetation, and not the amount of rainfall, has the dominant effect over catchment erosion, and over SOC storage in the catchment. Wetter and warmer conditions promote the expansion of dense sclerophyll vegetation, reducing (increasing) catchment erosion while simultaneously increasing (decreasing) SOC storage as well as lake productivity and lake carbon storage. This would imply a positive relationship between warmer and wetter climates and atmospheric CO_2 sequestration in the Thirlmere catchment.

A Bayesian Multiproxy Approach to Regional Age Models

Dr. Lorraine Lisiecki [1]***, Dr. Taehee Lee*** [2]***, Mr. Devin Rand*** [3]***, Dr. Geoffrey Gebbie*** [4]***, Dr. Charles Lawrence*** [5]

***1.** Department of Earth Science, University of California, Santa Barbara, CA 93106, USA,* ***2.** Harvard University,* ***3.** University of California, Santa Barbara,* ***4.** Woods Hole Oceanographic Institution, Falmouth, MA,* ***5.** Brown University*

Previously developed software packages that generate probabilistic age models for sediment cores are designed to use either age proxies (e.g., radiocarbon or tephra layers) or stratigraphic alignment (e.g., of benthic δ^{18}O) and cannot combine age inferences from both techniques. Furthermore, many radiocarbon dating packages are not specifically designed for marine sediment cores and default settings may not accurately reflect sedimentation rate variability in the deep ocean, requiring subjective tuning of parameter settings. Here we present a new technique for generating Bayesian age models and stacks of ocean sediment core data, implemented in a software package named BIGMACS (Bayesian Inference Gaussian Process regression and Multiproxy Alignment of Continuous Signals). BIGMACS constructs multiproxy age models by combining age inferences from both radiocarbon ages and δ^{18}O stratigraphic alignment and constrains sedimentation rates using an empirically derived prior model based on 37 ^{14}C-dated ocean sediment cores (Lin et al., 2014). BIGMACS also constructs continuous benthic δ^{18}O stacks via a Gaussian process regression, which requires a smaller number of cores than previous stacking methods. This feature allows users to construct stacks for a small hydrographic region that shares a homogeneous deep water δ^{18}O signal, while leveraging radiocarbon dates across multiple cores. Thus, BIGMACS efficiently generates local or regional stacks with smaller uncertainties in both age and δ^{18}O than previously available techniques.

Global and regional effects of Hudson Bay closure during deglaciation periods

Mr. Zhipeng Wu [1], *Dr. Qiuzhen Yin* [2], *Prof. Andrey Ganopolski* [3], *Prof. André Berger* [1], *Prof. Zhengtang Guo* [4]

1. *Georges Lemaître Center for Earth and Climate Research, Earth and Life Institute, Université catholique de Louvain, Louvain-la-Neuve, Belgium,* **2.** *Earth and Life Institute, Georges Lemaître Centre for Earth and Climate Research, Université catholique de Louvain, Belgium,* **3.** *Potsdam Institute for Climate Impact Research, Potsdam, Germany,* **4.** *Institute of Geology and Geophysics, Chinese Academy of Sciences, Key Laboratory of Cenozoic Geology and Environment*

During the Quaternary, the Hudson Bay switched between closed (covered by ice sheet) and open (ice sheet-free) condition due to large variations of ice sheets. However, how the closure and opening of the Hudson Bay have affected the local and global climates is still poorly understood. Using the LOVECLIM1.3 model, here we investigate the global and regional effects of Hudson Bay closure at the beginning of each deglaciation period of the last 800 ka. Sensitivity experiments are performed at nine selected dates at the early stage of the deglaciation periods which are characterized by large Northern Hemisphere (NH) ice sheets, relatively low CO2 and different combinations of astronomical parameters. Two experiments are performed at each date, one with the Hudson Bay open and another with the Hudson Bay closed. Our model results show that the closure of the Hudson Bay could lead to a strengthening of the Atlantic Meridional Overturning Circulation (AMOC), which in turn leads to a warming in the Northern Hemisphere with notable warming in the Labrador Sea and northeast North Atlantic, a cooling in the Southern Hemisphere and a northward shift of the Inter-tropical Convergence Zone (ITCZ). In addition to the large-scale climate changes related to the modification of AMOC, the closure of Hudson Bay also has a great effect on regional climate. For example, there is a cooling over the Hudson Bay and over the southeast of Greenland. Our results also show that the effect of the Hudson Bay closure depends on background climate conditions, and it could weaken or slightly reinforce the effect of the ice sheets for different astronomical configurations.

Simulating the chain of events of the last deglaciation using its ice sheet meltwater history

Mr. Yvan Romé [1], ***Dr. Ruza Ivanovic*** [1], ***Dr. Lauren J. Gregoire*** [1], ***Ms. Brooke Snoll*** [2]

1. School of Earth and Environment, University of Leeds, 2. University of Leeds

Despite being one of the most thoroughly studied periods in our planet's history, the last deglaciation remains an active topic of study. In the early phase of deglaciation, Heinrich stadial 1, increasing greenhouse gases and mid-high latitude Northern Hemisphere orbital forcing did not lead to a significant warming and it took another six to seven thousand years before this cold period ended. A sequence of abrupt transitions followed with the Bølling–Allerød warming, the Younger Dryas cooling and the Holocene warming. Changes of Atlantic Meridional Overturning Circulation (AMOC) regimes are widely thought to be the origin of such climate disruptions, but exactly what role they play remains unclear.

Reproducing the complex chain of rapid climate-ocean events in a general circulation model has proven to be particularly challenging. Abrupt climate changes may only be obtained in a small window of opportunity, and such delicate balance is hard to strike considering the uncertainty inherent within reconstructions of the palaeo-environment. In particular, the ice sheets 'reconstructions' have a strong influence on the North Atlantic climate but are amongst the least well constrained. Different geometry and meltwater discharge histories from ice melting/calving produce widely varying wind patterns (including the position of the atmospheric jets) and ocean currents.

To investigate the sensitivity of a climate model to the ice sheet layout and meltwater flux, we produced a series of transient deglacial simulations using different combinations of ice sheets and transient freshwater forcing. The simulations manage to catch significant disruptions of the climate, but the timing of the events remains variable depending on the input. We identify the main drivers of changes in our model to be the geometry of the Laurentide ice sheet and the meltwater from the Eurasian ice sheet. The uncertainty surrounding the history of the Eurasian ice sheet and its meltwater discharge is a real limitation for any last deglaciation experiment.

Biomarker analysis of a marine sediment core (Northern Svalbard) reveals new insights into post-glacial permafrost carbon release

During the last post-glacial warming, the Arctic region experienced a major reorganization of the entire cryosphere. In particular, the Bølling-Allerød interstadial (B-A; ca. 14.7-12.8ky BP) was characterized by a significant ice loss from the Eurasian Ice Sheet, associated with a period of rapid sea level rise (Meltwater Pulse 1A, MWP-1A; ca. 14.7-14.3ky BP). However, how the land-ocean connection and in particular the fate of the terrestrial cryosphere were ultimately affected by this rapid climatic change remains poorly understood.

We present the multiproxy analysis of a marine sediment core (HH11-09GC) from the upper slope of Nordaustlandet (Svalbard archipelago), encompassing the last 30ky. Our results reveal that, after a phase influenced by the release of clastic material eroded by the Svalbard Barents Sea Ice Sheet (SBIS) during the Last Glacial Maximum and the early deglaciation, biospheric terrestrial carbon became the dominant component of the organic material deposited along the margin, in phase with MWP-1A and with a corresponding peak in the sedimentation rate, exceeding 1 mm/y.

We initially narrowed the possible origin of this atypical deposit down to four different hypotheses: (1) local Arctic material from Svalbard supplied via glaciers, (2) an unprecedented flooding event from the Baltic/Kara continental shelf, (3) the subglacial transport of land-derived material beneath the SBIS and (4) the advection and melting of sediment-laden sea ice via the Transpolar Drift. Collectively, the age of the terrestrial compounds, the biomarkers fingerprint and the sedimentological characteristics suggest sea ice transport of terrigenous material. We envision that during MWP-1A the intensified erosion of coastal Pleistocene Ice Complex Deposit from an unidentified source along the Siberian margin yielded massive amounts of sediment-laden sea ice; in addition, the strengthening of the Atlantic Water inflow through the Fram Strait during the B-A likely sustained a high melting rate of sea ice in the region.

Our findings provide a novel understanding of deglacial permafrost release in a rapid warming and sea level rise scenario. Furthermore, we provide evidence of how long-range transport and thawing of sediment-laden sea ice from coastal regions can impact the depositional characteristics at the gate of the Arctic Ocean.

Deglacial climate changes as forced by ice sheet reconstructions

Dr. Nathaelle Bouttes [1], Dr. Fanny Lhardy [2], Dr. Aurelien Quiquet [3], Dr. Didier Paillard [1], Prof. Hugues Goosse [4], Dr. Didier Roche [1]

1. LSCE-IPSL, Laboratoire des Sciences du Climat et de l'Environnement (CEA-CNRS-UVSQ), Paris-Saclay, 2. Max Planck Institute for Meteorology, Hamburg, Germany, 3. Laboratoire des Sciences du Climat et de l'Environnement, 4. Earth and Life Institute, Université catholique de Louvain, Louvain-la-Neuve, Belgium

During the Last Deglaciation, the climate evolves from a cold state at the Last Glacial Maximum at 21 ka with large ice sheets, to the warm Holocene at ~9 ka with reduced ice sheets. The deglacial ice sheet melt can impact the climate through multiple ways: changes of topography and albedo, bathymetry and coastlines, as well as fresh water fluxes. In the PMIP4 protocol for deglacial simulations, these changes can be accounted or not depending on the modelling group choices. In addition, two ice sheet reconstructions are available (ICE-6G_C and GLAC-1D).

Using the iLOVECLIM model of intermediate complexity, we evaluate the impact on climate of these boundary changes related to ice sheet evolution. We show that the two reconstructions yield the same warming to a first order, but with a different amplitude (3.9°C with ICE-6G_C and 3.8°C with GLAC-1D) and evolution. We obtain a stalling of temperature rise during the Antarctic Cold Reversal (from ~14 ka to ~12 ka) similar to proxy data only with the GLAC-1D ice sheet reconstruction. Accounting for changes in bathymetry in the simulations results in a cooling due to a larger sea ice extent and higher surface albedo. Finally, fresh water fluxes result in AMOC drawdown, but the timing in the simulations disagrees with proxy data of ocean circulation changes. This questions the links between reconstructed fresh water fluxes from ice sheet melt and recorded AMOC weakening and their representation in models.

Deglacial oceanic CO2 outgassing in MPI-ESM

Dr. Bo Liu [1], ***Dr. Fanny Lhardy*** [2], ***Dr. Tatiana Ilyina*** [1]

1. *Max Planck Institute for Meteorology,* ***2.*** *Max Planck Institute for Meteorology, Hamburg, Germany*

Ocean-atmosphere CO2 exchange plays an essential role in the atmospheric CO2 variations at the glacial-interglacial time scale. Extensive studies have suggested that during the last deglaciation, the oceanic CO2 outgassing results from the interplay between physical (e.g. ventilation, sea-ice cover) and biogeochemical (e.g. biological pump, carbonate pump) processes. To quantify their contributions to ocean-atmosphere CO2 flux, modelling studies have been conducted for the Last Glacial Maximum (LGM) and/or the last deglaciation using Earth System Models of different complexity. Given the complex nature of the interplay of Earth system processes driving the global carbon cycle, as well as the limitations of the models, it is still challenging to simulate the LGM and deglacial ocean states that capture the major features of proxy data. A particular example is that most models in the Paleoclimate Modelling Intercomparison Project 4 (PMIP4) feature an Atlantic Meridional Overturning Circulation (AMOC) with a deeper upper cell during LGM than the pre-industrial, the opposite of the proxy data, and therefore hinder the storage of carbon in the deep ocean.

To address this challenge, we conduct two types of simulations with the Max Planck Institute Earth System Model (MPI-ESM) using a ‘prognostic CO2’ set-up; that is, the global carbon cycle prognostically computes atmospheric CO2, while the radiation calculation uses prescribed CO2 from ice core measurements. First, to examine the impact of ocean circulation on the LGM ocean carbon sequestration, we simulate two LGM AMOC states by model tuning: one with a deeper upper cell and the other with a shallower upper cell than the pre-industrial state. We evaluate the LGM simulations with a comparison to sea surface temperature, benthic CO_3^{2-}, $\delta^{13}C$ and $\Delta^{14}C$. Next, we conduct transient deglaciation simulations, forced by reconstructions of orbital parameters, ice sheet and dust deposition. We present results from the deglaciation simulation and focus our analysis on the above-mentioned oceanic CO2 outgassing mechanisms. We also compare the model results of the prognostic CO2 set-up to a previous simulation where CO2 is prescribed for both radiation calculation and the global carbon cycle to reveal the different model behaviours linked to the modelling strategy.

Polar and Arctic Fronts movement and attendant water masses changes in the North Atlantic during the last glacial cycle

Ms. Min Zeng [1]***, Dr. Harunur Rashid*** [2]

1. College of Marine Sciences, Shanghai Ocean University, 201306, Shanghai, China, 2. Shanghai Ocean University

Past studies using planktonic foraminiferal assemblages in the North Atlantic were mainly focused on narrow regions. As a result, such data are scarce, especially from the North Atlantic transition region (NATZ) and the western subpolar gyre (SPG) during the last glacial cycle. Here, we report planktonic foraminiferal assemblages in conjunction with oxygen isotope and ice-rafted detritus (IRD) data from three sediment cores (i.e., Hu90-08, Hu71-377, and IODP Site U1313) covering a latitudinal transect between the SPG and subtropical gyre (STG). These data suggest that the Polar front (PF) and Arctic front (AF) were located south of the cores Hu90-08 and Hu71-377, while the subarctic front (SAF) was situated south of site U1313 during last deglaciation. An increase in the transitional water mass species (i.e., Globigerina bulloides and Globigerinoides inflata) suggests that the core Hu71-377 was mainly affected by the North Atlantic Current (NAC), and the SAF was located north of Hu71-377 during the MIS3. Simultaneously, cores Hu90-08 and U1313 recorded cold (40-27 ka) and warm (60-40 ka) periods. During the last glacial maximum (LGM), the PF moved southward to 45°N, and the heat transported by the NAC accumulated south of the IRD-belt south of the PF, resulting in a relatively warmer sea-surface surrounding the site U1313. Consequently, a significant hydrological difference appeared between the STG and SPG during the LGM. Compared with the eastern SPG, the western SPG (near Newfoundland Basin) and STG were generally warmer during the MIS5. However, the abundance of planktonic foraminifers in the Newfoundland Basin core Hu90-08 shows that the western SPG was affected by seasonal subpolar water masses during the MIS5e (~124-120 ka) indicating a transient southward movement of the PF and AF. Contemporaneously, a stable warm climate prevailed at Site U1313, which was affected by warm subtropical water mass throughout the MIS5e. Moreover, our data shows that the western SPG was influenced by polar water but the STG was influenced by subpolar water during termination II. Therefore, our data suggest an identical transformation and movement of the surface water masses in the western SPG and NATZ during terminations I and II.

Coccolithophores responses during Termination II: perspectives on their potential within the ocean carbon cycle

Mrs. Stefania Bianco [1], ***Dr. Claudia Lupi*** [2], ***Dr. Manuela Bordiga*** [3], ***Prof. Andrea Di Giulio*** [2]

1. University School for Advanced Studies - IUSS, 2. University of Pavia, 3. National Institute of Oceanography and Applied Geophysics OGS

Coccolithophores are single-celled eukaryotic algae capable of capturing carbon dioxide (CO_2) through photosynthesis, and fixing carbon in their calcite exoskeleton (coccosphere). Through their vital processes, they can significantly impact the atmosphere-ocean CO_2 exchanges and the global carbon cycle, influencing Earth's climate system since geological time.

The aim of this project is to deepen on coccolithophores' role within the ocean carbon cycle during Termination II (i.e., Marine isotope stage 6/5e transition), and to investigate their responses to the deglaciation phase. To do so, the coccolithophore fossil remains (i.e., nannofossils) from the International Ocean Discovery Program (IODP) Site U1501C (South China Sea) have been analyzed along an interval spanning from 155 to 70 kyrs, thus encompassing the Termination II. These data were compared with 6 sites distributed in the Pacific, Atlantic, and Indian oceans in order to observe at global level the study of coccolithophore response to climate variations in terms of diversity, primary productivity and carbonate production.

At Site U1501C, the data on calcareous nannofossil absolute and relative abundances, primary productivity, and coccolith-derived calcium carbonate production allowed reconstructing both the biological and carbonate pumps efficiencies at a local scale. We document an increase in abundance of the heavily-calcified species (*Helicosphaera* spp., *Syracosphaera* spp., *Calcidiscus leptoporus*) together with increased primary productivity and calcite production at MIS 6/5 boundary suggesting that coccolithophores accelerated both the biological and carbonate pumps in response to the glacial/interglacial transition in South China Sea.

The data derived from other sites highlighted similar results in most of the areas, documenting an increase in the nannofossil absolute abundances and coccolith-derived calcium carbonate production during the glacial/interglacial transition, indicative of a global acceleration of the carbonate pump during this interval. We suggest that the higher calcite production during the Termination II may have resulted in an increased carbon sequestration, possibly acting as a negative feedback towards CO_2, contributing partly to the mitigation of the Late Pleistocene global warming.

New constraints on reservoir ages and deglacial climate events in the North Atlantic

Dr. James Rae [1], *Dr. Andrea Burke* [2], *Dr. Rosanna Greenop* [2], *Dr. Rhian Rees-Owen* [2], *Dr. Tim Heaton* [3], *Prof. Paula Reimer* [4]

1. University of St Andrews, 2. University of St. Andrews, 3. Sheffield University, 4. Centre for Climate, The Environment and Chronology (14CHRONO), School of Natural and Built Environment, Queen's University, Belfast

Paleoclimate records from the North Atlantic show some of the most iconic signals of abrupt climate change during the ice ages, but variable reservoir ages and regionally distinct paleoclimate signals complicate chronologies. Here we present a stack of North Atlantic surface radiocarbon reservoir ages over the past 40,000 years, using new synchronized age models from over 25 sediment cores refined with thorium normalization between tie-points. This stack shows consistent and large changes in reservoir age, with rise from the last glacial period into the LGM, climb further into early HS1, and then drop abruptly prior to the onset of the Bolling-Allerod. We use the intermediate complexity earth system model cGENIE to investigate the potential drivers of these reservoir age changes. We find that sea ice, circulation and CO_2 all play important roles in setting the reservoir age. We use these coherently dated records to revisit the sequence and timing of climatic events during HS1 and the last deglaciation, and show that Laurentide Heinrich Events are a response to stadial conditions, rather than their root cause.

Modeling of glaciers in Cerro Chirripó National Park, Costa Rica, during the last glacial-interglacial transition

Ms. Liesel Robbins [1], ***Prof. Meredith Kelly*** [2], ***Dr. Alice Doughty*** [3], ***Mr. Caleb Okpala*** [1], ***Dr. Maxwell Cunningham*** [1], ***Dr. Michael Kaplan*** [4], ***Dr. Adolfo Quesada-Román*** [5]

1. Department of Earth Sciences, Dartmouth College, 2. Dartmouth College, 3. School of Earth and Climate Sciences, University of Maine, 4. Lamont-Doherty Earth Observatory, Columbia University, 5. School of Geography, University of Costa Rica

Reconstructing past mountain glacial extents in the tropics provides insight into the climatic conditions in a geographic region where the influence of temperature forcings needs better temporal and spatial resolution. Here we focus on simulating past extents of mountain glaciers in the humid inner tropics (~10N-10S latitude), where glacial mass balance is sensitive to temperature. We present simulated glacial extents in Cerro Chirripó National Park in the Cordillera de Talamanca Range of Costa Rica during the Last Glacial Maximum (LGM; ~26-19 ka) and Termination 1 (19-11.7 ka). We aim to reconstruct combinations of temperature, precipitation, and lapse-rate values relative to modern values needed to simulate glaciers to the mapped and dated glacial extents. We are using a two-dimensional numerical model that incorporates surface energy balance and ice-flow models and modern climatic input variables including temperature, precipitation, lapse rate, short-wave radiation and wind speed. We adjust the modern climatic variables to the past based on prior work and other proxy records (e.g., pollen records that provide estimates on precipitation change relative to modern). We will compare the climate conditions determined for the LGM and Termination 1 in Costa Rica with prior reconstructions for the site as well as for other sites including the Rwenzori Mountains of East Africa and mountain ranges in New Guinea to assess climate variability throughout the tropics during the last glacial-interglacial transition.

Variations of marine primary productivity in the southeastern Arabian sea during the last two glacial terminations

Mr. Rahul Pawar [1], ***Dr. Dharmendra Pratap Singh*** [1]

1. *Department of Earth Sciences, Indian Institute of Technology Roorkee, Uttarakhand*

Carbon dioxide outgassing during the glacial terminations is one of the main mechanisms for onsets to pull earth out from its cold periods. Marine primary productivity holds large of this CO_2 Outgassing where marine phytoplankton accounts for nearly half of global net primary production. As they die and sink, the organic matter gets preserved in the ocean bottom and gets cut out from the global carbon cycle. This sequestering of atmospheric CO_2 plays a crucial role as a feedback system in glacial-interglacial cycles. Tropical Oceans witness both open ocean and coastal upwelling-induced primary productivity. Here, we present a new paleo-proxy dataset from the tropical Indian Ocean to demonstrate how the primary production has changed during these tipping events. The tropical southeastern Arabian Sea experiences intense upwelling during the Indian summer monsoon season triggering the phytoplankton bloom and is an ideal region to observe these changes. We made use of a marine sedimentary core SSD004 GC11 collected at a depth of 2901m, in total 584 samples covering the span of last 175 kyrs were analyzed for the $\delta^{13}C_{org}$ and Total Organic Carbon (TOC) to reconstruct the variation in primary productivity. We report severe decrease in marine primary productivity during the glacial termination events. The plausible reasons for the decline in primary production include rapid rise in sea level and weakening of AMOC, both triggered by the melting of continental ice sheets. We suggest that the low primary production in the tropical Indian Ocean has assisted in the rapid global CO_2 rise, which worked as positive feedback along with insolation during termination I and II.

Multi-model assessment of the climatic evolution of the last deglaciation at high southern latitudes

The quaternary climate is characterized by glacial-interglacial cycles, with the most recent transition from the last glacial maximum to the present interglacial (the last deglaciation) occurring between ~ 21 and 9 ka. Paleo-proxy records from high southern latitudes suggest that the deglacial warming was not constant, as indicated by the onset of warming, rapid warming, or response to AMOC due to the bipolar seesaw mechanism. A few transient simulations of the last deglaciation have been used to examine the processes leading to the deglacial high southern latitude temperature evolution. To enhance our understanding of deglacial processes, the 4th phase of the Paleoclimate Modelling Intercomparison Project (PMIP4) working group proposed a common framework to perform transient simulations of the last deglaciation.

In this study, we analyze results from six climate models that have carried out transient simulations of the last deglaciation under the PMIP4 protocol. We analyze 21 to 11 ka focusing on climatic changes in the high southern latitudes and their inter-model differences. We find that one model exhibits a significant annual mean warming trend between 21 and 18 ka (1 degree / 3000 years) without significant AMOC change. Some other models exhibit similar warming trends during that time period, which could be due to a bipolar seesaw response to the AMOC reduction. The subsequent period (18 to 15 ka) shows significant warming related to increased atmospheric greenhouse gases and an AMOC weakening in some models. The subsequent cooling (15 to 13 ka) occurs in some models with an abrupt increase in the AMOC, while the models that simulate an AMOC shutdown at that time simulate a high southern latitude temperature increase. We note that the different time evolution of AMOC changes arises from the different approaches used to estimate glacial meltwater input in the Northern Hemisphere. Overall, we find that the deglacial increase in atmospheric CO_2 concentration and the AMOC weakening are the main controls on surface air and ocean temperature during the deglaciation.

Phase relationships between paleoclimate records during glacial inception and termination periods

Prof. Kyung Eun Lee [1], ***Mr. Tae Wook Ko*** [1], ***Ms. Ryoung Ah Kim*** [1], ***Prof. Steven Clemens*** [2], ***Dr. Yoshimi Kubota*** [3], ***Dr. Ann Holbourn*** [4]

To understand climate changes and associated driving forcing (insolation, CO_2 concentrations, and ice sheets) for glacial inceptions and terminations, we investigated the timing of changes in multiple proxy records including seasonal and annual mean sea surface temperatures (SSTs) and benthic foraminiferal $\delta^{18}O$ that were reconstructed from the same materials of IODP Site U1429 in the northwestern Pacific margin. Investigation of multiple proxy records in a single core can be an advantageous approach to achieve this research goal. Regarding U1429 SST records, we used high-resolution records of alkenone-based annual mean and *Globigerinoides ruber* Mg/Ca-based summer SSTs over the past four interglacial-glacial cycles (~400 kyrs). Our proxy records have an average resolution of approximately 100 years for the inception and glacial periods. According to our records, despite being SST proxies, different proxies present different temperature variations in the same core materials. Phase relationships between the proxy records and climate forcing demonstrate that the temperature variations were associated with different climate forcing. Our records reveal that, during the glacial termination period, the CO_2 concentration began to increase first, and annual mean SST increased simultaneously responding to CO_2 changes. After then, summer insolation increased, and in response to this, summer SST increased during the late termination period. Followed this change, U1429 benthic foraminiferal oxygen isotopic ratios decreased, indicating a decrease in ice sheet volume. During the glacial inception period, summer SST changes initiated to decrease first by responding to summer insolation decrease. By following this, benthic foraminiferal $\delta^{18}O$ increased, indicating the initiation of building of ice sheets. After then, CO_2 and annual mean SSTs decreased during the late glacial inception period.

How coupled were the benthic and planktic oceanic environments off Oman, over the last Glacial-Interglacial Cycle?

Dr. Rajani Panchang [1]***, Ms. Khushi Gorakh*** [2]***, Mr. Omkar Janrao*** [2]***, Dr. Naveen Gandhi*** [3]***, Dr. Pankaj Baghel*** [4]***, Ms. Mugdha Ambokar*** [2]

1. *savitribai phule pune university,* ***2.*** *1. Marine Bio-geo Research lab for Climate & Environment (MBReCE), Department of Environmental Science, Savitribai Phule Pune University,* ***3.*** *Indian Institute of tropical Meteorology,* ***4.*** *Inter University Accelerator Centre, New Delhi*

The Oman margin plays a vital role in bringing monsoon to India and thus has been of interest to many climatologists as well as palaeoclimatologists worldwide. From the work done so far it is clear that most of the work along the Oman Margin either covers long durations, low resolution palaeoclimatic data or are focused on understanding monsoon dynamics, upwelling, productivity and SST in the region using planktonic foraminifera. No significant attempts have been made to understand the hydrographic changes in the area and its impact of the benthic environment or its connections with the Eastern Arabian Sea (EAS). A few attempts with benthic foraminifera have been able to detect the Oxygen Minimum Zone and its relationship with productivity. However, benthic assemblages have not been described and no attempts have been made to understand changes in the environment of deposition. There are a few stable isotopic studies done to understand the hydrodynamics and the influence of Persian Gulf waters and the Red Sea waters on the study area. No work has been carried out using comparative studies of benthic and planktic foraminiferal assemblage and / or coupled benthic-planktic isotopic signatures.

The present study presents high resolution multi proxy records on a sediment core collected on the upper slope of the Oman Margin. It is the first multiproxy approach to decode the benthic and planktic hydrography in the region over the last glacial-interglacial cycle. Sediment textures, benthic foraminiferal assemblages, planktic and benthic oxygen and carbon isotopic signatures provide crucial insights into how the benthic ocean responded to the warming of the surface ocean when the glacial ice-sheets started melting during the Late Glacial Warming and the Holocene Sea Level rise.

Key words: Foraminifera, Stable isotopes, benthic assemblages, Oman margin, coupled responses

Modeling the retreat of the North American ice sheet

Ms. Meike Scherrenberg [1]***, Dr. Constantijn Berends*** [1]***, Prof. Roderik van de Wal*** [2]

1. *Institute for Marine and Atmospheric Research Utrecht, Utrecht University, Netherlands,* ***2.*** *Dept. of Physical Geography, Faculty of Geosciences, Utrecht University*

Due to the current rise in global temperatures the Antarctic and Greenland ice sheets are at risk to melt in the future. Ice sheets have fully melted in the past. Large parts of Eurasia and North America were covered by ice 21 thousand years ago, which have since fully melted. Understanding the mechanisms that lead to this deglaciation may help us to understand what will happen to Antarctica and Greenland in the future.
Mass loss of ice sheets can be attributed to three processes: surface melt, basal melt and calving. During the deglaciation of the North American ice sheet, a proglacial lake was formed at the southern margin allowing for ice-water interactions. In this study we simulate the deglaciation of the Northern Hemisphere ice sheets using an ice-sheet model to investigate which mechanisms are responsible for deglaciation.
We found that by excluding either or both calving and basal melt North America can still deglaciate fully by present day, suggesting that solely surface melt is sufficient for melting the ice sheet. At the southern margin of the North American ice sheet a proglacial lake allows for floating ice. Floating ice has negligible basal friction and therefore has increased ice velocities compared to grounded ice. This decreases ice thickness and surface topography, and increases surface temperature. As a result, this floating ice has high melt rates and accelerates the deglaciation of the North American ice sheet. By applying the basal friction of land to floating ice, the North American ice sheet retains an ice volume of 13.3 meters of sea level equivalent by present day.

Hydrological variability in the Agulhas current across Terminations I and II as inferred from geochemical multi-foraminiferal species in the Mozambique Channel: link with transient simulations

Dr. Laurence Vidal [1], Dr. Kazuyo Tachikawa [1], Mrs. Linda Rossignol [2], Dr. Jose Pérez-Asensio [3], Dr. Thibaut Caley [2], Mr. Olivier Gerbaud [1], Dr. Corinne Sonzogni [1], Dr. Stephan Jorry [4], Dr. Natalia VAZQUEZ RIVEIROS [5], Dr. Laurie Menviel [6]

1. Aix Marseille University, CNRS, IRD, INRAE, College de France, CEREGE, Aix-en-Provence, France, 2. University of Bordeaux, 3. CEREGE, 4. Ifremer, Geo-Ocean, Plouzané, France, 5. IFREMER, 6. Climate Change Research Centre/ESSRC, The University of New South Wales

The Mozambique Channel is an important region for ocean circulation, as it is the source of the Agulhas Current, which contributes to the Agulhas leakage. The Agulhas leakage acts as a climate modulator by transferring warm, salty waters to the Atlantic and thus contributing to the efficiency of the thermohaline circulation. This work investigates the hydrological variability of the Agulhas current (spatial and temporal) at different depths in the water column of the Mozambique Channel during Terminations I and II. A multi-proxy approach (O and C stable isotopes, Mg/Ca paleothermometer, foraminiferal U/Ca, and planktic foraminiferal assemblages) is applied to two cores in order to reconstruct a latitudinal gradient and characterise the water column structure from the surface to the ocean floor. Several foraminiferal (planktic and benthic) species were selected according to calcification depths: *G. ruber s.s*, *N. dutertrei* for surface and subsurface waters and *C. wuellerstorfi* for deep waters. The main results indicate a decoupling between surface and subsurface waters, which suggests an earlier warming for subsurface waters associated with an increase in salinity during both Terminations. On the other hand, bottom waters show a decrease in ventilation synchronous with the slowing down of the thermohaline circulation at the beginning of Terminations. These results will be discussed in the light of the latitudinal migration of the subtropical front during TI and TII and the related intensity/effectiveness of the "Agulhas leakage" and transient simulations performed with Earth system models.

Proposal IODP 985-Full2: Eastern Fram Strait Paleoarchive (FRAME): Science and research opportunities during and after Exp-403 (June-August 2024)

Dr. Renata Lucchi [1], ***Dr. Stefan Buenz*** [2]

1. National Institute of Oceanography and Applied Geophysics OGS, 2. Centre for Arctic Gas Hydrates, Environment and Climate (CAGE), Department of Geosciences, UiT

The research proposal IODP 985-Full was motivated by the necessity of retrieving continuous, high-resolution, and datable depositional sequences containing the record of the palaeoceanographic characteristics and cryosphere evolution during the past key climatic transitions that followed the opening of the Fram Strait in the Arctic. Such data are greatly needed to better constrain global climate connections, forcing mechanisms and climate models.

High-resolution, continuous depositional archives were identified in the contourite drifts (Bellsund, Isfjorden, Svyatogor and Vestnesa) developed on the mid-upper slope of the western continental margin of Svalbard (eastern Fram Strait) under the effect of the West Spitsbergen Current (WSC) transporting sediments and warm Atlantic Waters to the Arctic Ocean, exerting a strong control on climate variability.

The general objective of FRAME is the reconstruction of the variability of the WSC and its influence on climate changes particularly during key Quaternary climate transitions and beyond (the late Miocene–Pliocene transition, late Pliocene–Pleistocene Transition, Mid-Pleistocene Transition, Mid-Brunhes Transition, and sub-orbital Heinrich-like events), its impact on the Arctic glaciations, ice shelves development and stability, and sea ice distribution over last 5.3 Ma.

The proposal was submitted in April 2020 as outcome of the Magellan+ Workshop EFRAM-ARC, held in Trieste (Italy) in January 2020. IODP 985-Full was approved in May 2022 and scheduled as IODP Exp. 403 of the JOIDES Resolution that will take place from June 4th to August 2nd, 2024 (http://iodp.tamu.edu/scienceops/expeditions/eastern_fram_strait_paleo_archive.html). Scientists and PhD students can take part in FRAME research by applying to become shipboard scientist or by submitting sample requests after a moratorium period of one year.

The Holocene marine benthic ostracod record of the Alkyonides Gulf (Corinth Basin, Greece) in a Mediterranean perspective

Dr. Roberta Parisi [1], ***Dr. Ilaria Mazzini*** [1], ***Dr. Thomas M Cronin*** [2]

1. Consiglio Nazionale delle Ricerche, Istituto di Geologia Ambientale e Geoingegneria (IGAG), 2. U.S. Geological Survey

The Gulf of Corinth is a narrow arm of the Mediterranean, currently connected to the Ionian Sea and the wider Mediterranean Sea by the Rion Sill and Acheloos-Cape Pappas Sill in the west (at 60 m and 55 m below sea level, respectively). In the east, the artificial 22m-wide, 8 m-deep Corinth Canal connects the Gulf with the Aegean Sea. The aim of IODP Expedition 381 was to sample sediments deposited in the Corinth Basin formed during the earliest stage of continental rifting. Details of the Corinth Basin's environmental change from glacial to interglacial states are poorly known. For example, the precise timing of transition from lacustrine to marine conditions is unconfirmed in addition to the interacting controls of basin subsidence, sill elevation and eustatic sea level. Benthic ostracods (microcrustaceans) inhabit virtually all aquatic environments on Earth, and they are the only micropaleontological proxy that can live in all the paleo-environments that this study spans. As such they provide a unique and continuous record of paleoenvironmental evolution of the area. Previous studies on core M0080 revealed that when the Mediterranean Sea level dropped below the sill height and separated the Gulf of Corinth from the Mediterranean, major faunal transitions occurred from lacustrine (Ponto-Caspian, Lake Corinth) glacial-age assemblages to fully marine (Mediterranean) during the last 20 kyr. During deglacial periods, the Corinth Gulf [GL1] [CTM2] was characterized by fully marine conditions, and Mediterranean waters breached the shallow sills. A detailed study of the benthic ostracod assemblages from two cores, M0080 and M0078, provides useful insights about the timing and evolution of the salination of the water body as well as suggests water mixings due to hyperpycnal flows down from the sill.

Glacial-interglacial ice-rafted debris variability in the western Indian sector of the Southern Ocean: Palaeoceanographic implications

Dr. M C Manoj [1]***, Mr. K Ajay Krishna*** [2]***, Dr. Xavier Crosta*** [3]***, Dr. Sunil Kumar Shukla*** [4]***, Mr. Masud Kawsar*** [1]

***1.** Birbal Sahni Institute of Palaeosciences, 53-University Road, Lucknow-226007, India, **2.** Christ College (Autonomous), Kerala, India, **3.** Univ. Bordeaux, CNRS, Bordeaux INP, EPOC, UMR 5805, F-33600 Pessac, France, **4.** Birbal Sahni Institute of Palaeosciences, Lucknow, India*

Little is known about the ice-rafted debris (IRD) inputs to the Indian sector of the Southern Ocean (ISO) during the middle to late Pleistocene. In this study, we present first combined data of morphological and geochemical investigations on IRD grains obtained from sediment core MD19-3576, collected from Del Caño Rise in the ISO during MD218 CROTALE cruise. The sediment core chronology was developed by tuning its blue reflectance with the benthic stable oxygen isotope record (LR04). Our data show a higher fractional abundance of biogenic fragments and lesser IRD in the coarse fraction (>250 µm) of sediments during the major glacial-Interglacial transitions (Terminations V, IV, III, and II) and during the interglacial periods. On the other hand, glacial periods are characterised by lesser biogenic fragments and higher IRD concentrations (<15 and up to 35 %). High blue reflectance along with the higher fractional abundance of biogenic fragments, whereas negligible IRD concentration during the interglacial periods and major terminations indicate that the warmth significantly reduced ice capping and possibly provided favourable conditions for marine productivity bloom in the ISO. The IRD principally consist of quartz, volcanogenic lithic fragments and crystalline rock fragments. The presence of volcanogenic lithic fragments (300 to 500 µm) within the IRD bearing sections of the core reiterates Sub-Antarctic origin of IRD. Additionally, the SiO_2 and Na_2O+K_2O percentages of the volcanic and crystalline grains agree well with the geochemical characteristics of rocks from the nearby volcanic islands, e.g., the South Sandwich and Marion Islands. On the other hand, the presence of garnet and quartz bearing lithic grains within IRD flux especially during the Terminations V and IV suggest that Antarctic ice mass loss might be a possible factor that contributed to the IRD flux to the core site. Therefore, it indicates a northern boundary of Antarctic iceberg variability during the Pleistocene glaciation in the ISO. Our study opens up a new possibility to investigate long term variability of Antarctic continental ice sheet stability as well as sub-Antarctic IRD variability, which will provide vital information to reconstruct iceberg trajectories and the northern extent of iceberg transport during Pleistocene glaciation.

Were Patagonian glaciers smaller than today during past extreme warm periods?

Dr. Esteban Sagredo [1], ***Dr. Rodrigo Soteres*** [2], ***Mr. Fabian Riquelme*** [1], ***Mr. Rodrigo Hevia*** [1], ***Ms. Catalina Guglielmetti*** [1], ***Dr. Michael Kaplan*** [3], ***Ms. Roseanne Schwartz*** [3], ***Dr. Joerg M. Schaefer*** [3]

1. *Pontificia Universidad Católica de Chile,* ***2.*** *Universidad de Magallanes,* ***3.*** *Lamont-Doherty Earth Observatory, Columbia University*

Present-day warming is triggering a *global-scale glacier crisis*. Glaciers worldwide have undergone rapid melting, at rates that have surpassed our most extreme predictions and that have never been recorded before in the instrumental or geologic record. Global changes in mountain glaciers are causing dramatic impacts on both physical (e.g., landslides, flooding) and ecological systems (e.g., ecosystem shifts). The livelihoods of hundreds of millions of people downstream from melting glaciers is under threat. Unfortunately, due the nature of the geologic record, most of our understanding of past glacier-climate interaction comes from the study of cold periods. Thus, predictions as to possible glacier changes in the near-future and their potential impact are hampered by limited knowledge on prior glacial response during warm periods. This is particularly relevant for the extra tropical Andes, a region that contains the two largest icefields in the Southern Hemisphere, which exhibit some of the highest melting rates on the planet. Here, we explore the response of Patagonian glaciers to past, extreme warm conditions. We will combine surface measurements of multiple cosmogenic nuclides (^{10}Be, *in situ* ^{14}C and ^{36}Cl) to quantify the cumulative duration of periods when selected Patagonian glaciers were smaller than today during the last 450,000 years of Earth's history. This information is crucial to understand whether the magnitude of present-day deglaciation is unique and unprecedented within the recent geologic history, and to put the response of glaciers to present-day climate change into context. The application of this cutting-edge cosmogenic nuclide technique ushers in a new era of glacier-climate science, allowing for the systematic investigation of glacier behavior during warm periods.

Solving the paradox of conflicting glacial chronologies: reconstructing the Cordillera Darwin ice sheet (53°-55°S) during the last glacial – interglacial transition.

Dr. Robert McCulloch [1]***, Dr. Juan L. García*** [2]***, Dr. Andy Hein*** [3]***, Ms. Carla Huynh*** [3]***, Dr. Derek Fabel*** [4]***, Mr. Hans Fernandez*** [5]***, Dr. Eileen Tisdall*** [6]

During ice ages, cooler climate coupled with high precipitation fed by the southern westerly winds and orographic processes caused the Patagonian ice fields to expand and glaciers to flow to the edge of the continental shelf in the west and through the major valleys and ice-scoured troughs in the east. Successive glacier advances have left a suite of glacial landforms and glacial deposits, including glacial lacustrine sediments from ice dammed lakes, that allows us to reconstruct the extent and timing of former glacier fluctuations. However, the evidence we have at present from southern Patagonia and the Cordillera Darwin (54°S) is contradictory. There is evidence (glacial lacustrine sediments, raised shorelines) for the formation of large (approx. 9,000 km^2) pro-glacial lake in the Strait of Magellan (estrecho de Magallanes) between c. 15.0 and 12.0 cal yr BP; broadly coeval with the Antarctic Cold Reversal. This necessitates a more extended ice cap damming meltwater routes to the Southern Ocean during the Late glacial. However, there are cosmogenic and ^{14}C ages from the north-eastern margins of the Cordillera Darwin for earlier (> c.16.0 cal yr BP) glacier retreat which suggests a smaller Late glacial ice cap that appears less likely to have supported a large Magellan pro-glacial lake. Here we present new cosmogenic, ^{14}C and OSL ages, supported by tephrochronology, from the southern Strait of Magellan and the Cordillera Darwin. These new ages help constrain the timing of glacier retreat from the southern Strait of Magellan and into the fjords and channels around the western flanks of the Cordillera Darwin. We suggest that significant westerly ice divide migration (i.e. towards the source of precipitation) of the Cordillera Darwin ice cap would have enabled the persistence of ice dams supporting the Magellan pro-glacial lakes, while being consistent with earlier deglaciation to the north and east of the ice cap.

Reconstructing glacier change between 31°S and 40°S in the Chilean Andes since the Last Glacial Maximum

Ms. Charlotte S. Curry [1], ***Dr. Ann V. Rowan*** [2], ***Dr. Stephen J. Livingstone*** [1], ***Dr. Robert G. Bryant*** [1], ***Dr. Duncan J. Quincey*** [3], ***Dr. Claudio Bravo*** [4], ***Dr. Jose Luis Antinao*** [5]

Local geochronological studies in the Chilean Andes suggest that glaciers were sensitive to changes in temperature and precipitation during the Last Glacial Maximum (LGM) and Holocene. Glacial histories are latitudinally asynchronous and the timing of glacial maxima vary sub-regionally. Whilst extensive glacial geomorphological mapping has been completed across much of the Chilean Andes, there is a large gap in the Southern Andes between 31°S and 40°S where the timing and pattern of glacier change has not been constrained.
Here, we present a synthesis of existing literature and a compilation of moraine geochronological data representative of glacier change between 31°S and 40°S. We also present the results of geomorphological mapping to determine ice marginal extents during and since the last glaciation, to enable interpretations of palaeo-glacial behaviour and dynamics. This analysis was based on high-resolution PlanetLab and Google Earth satellite imagery to remotely map terminal and lateral moraines following standard identification criteria. In addition, we plan to sample boulders from moraines in the Olivares Basin in the Maipo Valley, ~52 km northeast of Santiago, for cosmogenic nuclide exposure-age dating to produce a geochronology for this valley. These results will be used to produce a comprehensive reconstruction of glacier change in the semi-arid Andes since the LGM and through the Holocene to understand the timing of maximum glacier extent in a largely understudied and unconstrained region of the Chilean Andes.

Post-Glacial dynamics of the Patagonian Ice Sheet across the Southern Volcanic Zone

Mr. Matías Romero [1] ***, Dr. Joshua K. Cuzzone*** [2] ***, Mr. Andrew Jones*** [1] ***, Mr. Simon Bushmaker*** [1] ***, Dr. Shaun Marcott*** [1]

1. University of Wisconsin Madison, 2. Joint Institute for Regional Earth System Science and Engineering, University of California Los Angeles, Los Angeles, CA, USA

During the Last Glacial Maximum (LGM), the Patagonian Ice Sheet (PIS) formed a contiguous cap over the southern Andes from 38° to 55° S, with an ice mass loss that accounts for 1.2 m of post-glacial sea level equivalent. While glaciological observations and remotely-sensed data allowed for a comprehensive understanding of glacier mass changes during the last century, detailed deglacial reconstructions of the PIS are needed for contextualizing such changes. Despite recent progress in investigating regional post-glacial ice sheet configurations, constraints on the climatic drivers of the last glacial to interglacial transition remain elusive in the Southern Volcanic Zone, and present a possibility to evaluate ice sheet sensitivity to such forcings. In order to precisely determine the timing and rate of ice sheet retreat, as well as to account for volumetric changes, we employ cosmogenic nuclide surface exposure dating with 10Be from exposed bedrock surfaces at elevations ranging from 1000-3000 meters across the Southern Volcanic Zone. Using these data as constraints, we then perform transient simulations of the PIS during the last deglaciation with the Ice Sheet and Sea-level System Model (ISSM) to test the sensitivity of the northern PIS to changing climatological inputs driven by the Community Climate System Model (CCSM3) Trace-21ka experiment. Our new data and model simulations provide a comprehensive data-model comparison to investigate both the timing and drivers of post-glacial ice sheet change following the last glacial period.

Revisiting the history of the Río Cisnes Glacier, Patagonian Ice Sheet (44°S) - new insights from luminescence and surface exposure dating

Prof. Christopher Lüthgens [1]***, Dr. Juan L. García*** [2]***, Dr. Andy Hein*** [3]***, Dr. Steven Binnie*** [4]***, Dr. César Méndez*** [5]***, Ms. Emma Cooper*** [6]

The glacial geomorphology of Patagonia comprises one of the most complete records of glacier fluctuations during the Quaternary. Recent progress in mapping, interpretation and dating enabled the reconstruction of the last glaciation and deglaciation, providing insight into paleoclimatic and paleoenvironmental conditions of the region. In the Cisnes river valley in the Aysén region, Chile, a complex geomorphological and sedimentological record of the last glacial cycle has been preserved, including moraines, glaciolacustrine and glaciofluvial sediments, allowing for the reconstruction of the LGM ice extent, the retreat of the ice front during termination 1, the formation of proglacial lakes and the subsequent reversal of the general flow direction to today's conditions with Río Cisnes draining the valley westward towards the Pacific.
Results of Garcia et al. (2019) provided a first robust chronological and geomorphological framework especially for the process dynamics in the Late Glacial, however, new questions were raised with respect to the timing of the maximum ice extent during the last glacial cycle and the process dynamics throughout the Late Glacial and into the Holocene. Here we present new results from luminescence dating (using a pIRIR225 (post infrared, infrared stimulated luminescence @225°C) protocol for single grains of potassium-rich feldspar), surface exposure dating using cosmogenic nuclides (^{10}Be and ^{36}Cl), and radiocarbon dating to refine the geochronological record especially for the LGM and the Late Glacial to Holocene times. The new age constraints allow insights into the LGM ice dynamics and the paleoenvironmental development during the Late Glacial to a phase of prevailing fluvial erosion in Holocene times. The results have paleoclimatic and paleogeographical implications, thus helping to understand glaciation and deglaciation in Patagonia, its chronology and associated geomorphological processes. Our results show that the glacial maximum of the Cisnes lobe occurred during the global LGM, whereas advances during MIS 4 or MIS 3 as observed in other areas of the Patagonian Andes are lacking. The deglaciation period was characterized by erosional processes and incision of previously deposited glacial sediments, with the Cisnes River forming fluvial terrace systems starting during the Late Glacial to Holocene transition phase and lasting well into the Holocene.

A 3He based Holocene glacial chronology from Villarrica volcano, Chile

Ms. Yasmeen Orellana Salazar [1], ***Mrs. Emily E. Mixon*** [1], ***Mr. Pablo Moreno-Yaeger*** [1], ***Mr. Matías Romero*** [1], ***Dr. Marissa Tremblay*** [2], ***Dr. Shaun Marcott*** [1]

Understanding how glaciers have changed in the past lends important information about prior climate variations and provides insight on the glacial driving mechanisms on decadal to millennial timescales. In turn, understanding past glacial conditions provides insight into how the cryosphere might respond to future climate change. Here we address the timing of Holocene glaciation at Villarrica volcano (39°S) – a composite volcano located in the Southern Volcanic Zone (SVZ) of central Chile that was encased by the Patagonian Ice Sheet during the Last Glacial Maximum (LGM) and continues to support glaciers today. Moraines along the flanks of the volcano demarcate past glacial positions during the latest Pleistocene to Holocene when ice extent was greater than today. The eruptive products of Villarrica are composed of olivine rich basalts to basaltic-andesites presenting an ideal opportunity to perform cosmogenic surface exposure dating with ^{3}He on moraine boulders. To date, the post-LGM glacial history of the SVZ is poorly constrained, limiting our understanding of how glaciers in the Southern Hemisphere behaved during the last deglaciation and Holocene when climate conditions were drastically changing.

To characterize Holocene glacial extent in the SVZ, we collected ~25 samples for surface exposure dating with ^{3}He from boulders obtained along the crests of several moraines at Villarrica volcano. Initial results from moraine boulders from a right lateral moraine deposited by Pichillancahue-Turbio glacier on the eastern flank of Villarrica indicate moraine abandonment between 500-1,000 years b.p. (n= 3). We will present additional ^{3}He ages from several other moraines deposited by Pichillancahue-Turbio and Voipir glaciers to fill spatial gaps and complete the glacial chronology around Villarrica volcano. Our new Holocene glacier chronologies will provide improved constraints of ice retreat in this sector of the SVZ and fill critical gaps in chronologic control on recent glacial changes in northern Patagonia.

The Eltanin 27-21 magnetic record of deep sea sediments in the Ross Sea area over the last 2.2 Myrs

ABSTRACT:

The Eltanin 27-21 Core provides a unique opportunity to study environmental magnetic variability in a continuous Pleistocene deep-sea sedimentary record, retrieved from the lower continental slope in front of Ross Sea, Antarctica (Cape Adare). The high-resolution magnetostratigraphy of the Eltanin 27-21 Core demonstrates the cyclical nature of the environmental magnetic record, directly linked to orbital periodicities of short-term eccentricity (100-kyr) and obliquity (41-kyr) over the last 2.2 Myrs. Magnetic minerals concentrations influenced by terrestrially derived materials driven by glacier dynamics and biological material related to blooms during the early interglacials, are related to Ice Rafted Debris and, consequently, Ross Sea Ice Sheet (RSIS) dynamic. Eltanin 27-21 magnetic mineral concentration testify advances and retreats of the grounding line of the RSIS, which are linked to global climate change. Magnetic minerals concentrations show same amplitude fluctuations during maximum extensions in the '41-kyr world' and in the '100-kyr world' also if glacials were shorter and sea-level drop was smaller (35 and 65 m) before the Mid Pleistocene Transition (MPT) and was larger (75 and 115 m) after the MPT, providing a new perspective on climate sensitivity.

Application of novel methods of estimating relative pollen productivity: a key for reconstruction of past land cover from pollen records from Patagonia

Dr. Valentina Álvarez-Barra [1], ***Dr. Robert McCulloch*** [1], ***Dr. M. Jane Bunting*** [2]

1. Centro de Investigación en Ecosistemas de la Patagonia (CIEP), 2. School of Environmental Sciences, University of Hull

Pollen analysis has been the principal tool to reconstruct past vegetation patterns to understand plant dynamics and the response to natural and anthropogenic disturbances. Most palynological studies emphasize the role of climate in driving vegetation patterns. In Patagonia, many studies have focused on glacial and postglacial vegetation changes and shifts in the position and strength of the southern westerlies. However, the interpretation of the palaeo record depends on understanding the relationship between pollen production and dispersal and the land cover at the time, which is poorly understood. The evaluation of quantitative methods in vegetation reconstructions at a local scale is needed to improve the reconstruction of past vegetation cover in Patagonia. Models such as REVEAL and LOVE have been applied in the northern hemisphere resulting in more accurate estimates of the regional/local vegetation by incorporating parameters such as pollen productivity, pollen dispersal, basin size, and background pollen input. To apply the REVEAL and LOVE models, the first step is to estimate the relative pollen productivity (RPPs) for relevant plant taxa, a key input parameter for regional and local vegetation estimates. In this study, we aim to obtain quantitative estimates of pollen productivity for different vegetation types in the Aysén region (43°-49°S) and apply them to reconstruct vegetation cover of past landscapes to inform conservation strategies. Initial results show that the plant diversity recorded in the area around a pollen sample is not reflected in the pollen assemblage. Moreover, introduced taxa such as *Pinus* sp, the most abundant alien species in the region, override most of the local vegetation signal. Within open *Nothofagus* forest, dense understory of shrubs species (e.g. *Gaultheria*) represent <1% on modern pollen samples. Given these results, paleo pollen records do not closely represent actual plant diversity. Therefore, the calibration and testing of landcover reconstruction models is key to effectively reconstruct quaternary landcover from pollen records in this region.

Late Holocene riparian vegetation dynamics, environmental changes, and anthropogenic impact in the Harapan forest of Sumatra, Indonesia

***Mr. Chung Nguyen Hoai* [1], *Dr. Kartika Anggi Hapsari* [2], *Dr. Asmadi Saad* [3], *Prof. Supiandi Sabiham* [4], *Prof. Hermann Behling* [1]**

***1.** University of Göttingen, Department of Palynology and Climate Dynamics, Albrecht-von-Haller-Institute for Plant Sciences, Göttingen, Germany, **2.** College of Life and Environmental Sciences, University of Exeter, Exeter, United Kingdom, **3.** University of Jambi (UNJA), Department of Soil Science, Jambi, Indonesia, **4.** Bogor Agriculture University (IPB), Department of Soil Science and Land Resource, Bogor, Indonesia*

Wetlands are important ecosystems for carbon sink but are vulnerable due to climate change and human activities. For the past few decades, wetlands in Sumatra are under transformed and converted into arable lands. Aiming to understand the effects of natural factors (e.g. climate change, flooding, drought) and human activities (e.g. agriculture, socioeconomically local communities) on wetlands is vital for development of management strategies. For that, we conducted a multi-proxy palaeoecological analysis, including pollen and spore, macro-charcoal and radiocarbon dating, on a sediment core taken at a riparian area in the Harapan forest, Sumatra. The results show an ecosystem evolution from riparian forest to freshwater swamp during the last 1000 years. Three periods are highlighted: i) AD 1100 - 1400: the sandy layers associated with the frequent pollen of riparian and swamp vegetation (e.g. *Calamus*, *Elaeocarpus, Pandanus*, Dipterocarpaceae, *Mallotus/Macaranga*, Poaceae) indicate the presence of freshwater swamps of *Pandanus, Elaeocarpus*, grasses and herbaceous mashes nearby the study site, that was possibly abandoned channels or oxbow lake; ii) AD 1400 – 1820: a high frequency of swamp vegetation (e.g. *Calamus, Tristaniopsis*, Dipterocarpaceae) suggests that the freshwater swamps started either expanding to the study site or the study site itself evolved into freshwater swamps after being cut off from the river; iii) later, from AD 1820 to present, this ecosystem became a closed canopy of freshwater swamp mixed lowland forest with the dominant Dipterocarpaceae, Icacinaceae, *Elaeocarpus, Lithocarpus/Castanopsis*. The presence of oil palm (*Elaeis guineensis*) at the end of this period indicates the presence of small-scale agriculture in the Harapan catchments. For the first time, the detail of riparian vegetation dynamics and environmental changes in the Harapan forest of Sumatra has been studied, showing the evolution of the freshwater swamp under the impact of climate change and human activities. The insight of this study allows us to predict and explore the response of wetland vegetation in Sumatra to climate change and human impacts in the future.

Investigating and refining the use of oxygen isotopes from chironomid head capsule chitin to reconstruct past climatic changes

Dr. Christopher Francis [1], *Dr. Angela Lamb* [2], *Dr. Stefan Engels* [3]

1. Department of Geography, Royal Holloway University of London, London, United Kingdom, 2. British Geological Survey, Keyworth, Nottingham, NG12 5GG, UK., 3. Birkbeck, University of London

Oxygen-isotope records derived from authigenic lacustrine carbonate allow for detailed quantitative reconstructions of past climate change and have been vital in improving our understanding of LGIT climate dynamics. However, their application is restricted to carbonate lakes. Even for lake which do contain carbonate-rich sediments, there are several limitations including: (i) carbonate precipitation is subject to temperature fractionation effects during formation; (ii) detrital allogenic material can contaminate the isotopic signal; and (iii) carbonate precipitation may not be continuous through the sequence leading to discontinuous isotope records. Chironomid head capsules are available in high concentrations in most lakes around the world, even non-carbonate lakes, and analysis of their oxygen isotope composition can overcome some of these issues. Laboratory studies have demonstrated that the isotopic composition of ambient lake water has a strong influence on the $\delta^{18}O$ of the larval head capsule chitin. However, the application of $\delta^{18}O_{chitin}$ for climate reconstruction is still in its infancy, with many aspects still to be explored. Due to the technical capabilities of the time, previous $\delta^{18}O_{chitin}$ studies required large samples (>50 μg) to determine past climate variations. As a result, the analysed samples contained multiple chironomid morphotypes which may fractionate isotopes differently. The latest GCIRMS-elemental analysers now allow the measurement of much smaller sample sizes, potentially circumventing the issue of having to measure multiple taxa as part of a single sample. Here, we first explore the minimum number of head capsules needed to produce a coherent isotopic signal from a sample using Thermo-Finnigan IsoLink EA. Preliminary results suggest samples as small as 25 μg can be measured robustly. Secondly, we investigate whether different chironomid genera fractionate oxygen isotopes differently. Eleven different morphotypes were analysed for isotopic off-sets from the Lateglacial sediment record of Crudale Meadow. Our results show that isotopic differences as large as 2.5 ‰ are apparent between different chironomid morphotypes, which is of similar or even greater magnitude than the isotope shifts between the Lateglacial Interstadial (GI-1) and the Loch Lomond Stadial (GS-1).

Lateglacial vegetation dynamics of the central Pyrenees: the Bassa Nera record

Dr. Valentí Rull [1]***, Mr. Arnau Blasco*** [2]***, Mr. Miguel Ángel Calero*** [3]***, Dr. Teresa Vegas-Vilarrúbia*** [2]

1. *Botanic Institute of Barcelona (CSIC), Barcelona,* ***2.*** *Department of Evolutionary Biology, Ecology and Environmental Sciences, University of Barcelona, Barcelona,* ***3.*** *Department of Geography, University of Barcelona, Barcelona*

The ecological dynamics of mountain vegetation from the Pyrenees as a response to Late Glacial environmental dynamics is poorly known due to the paucity of past records encompassing this time interval. This work uses palynology to reconstruct the development of high-mountain ecosystems as a response to climatic changes that occurred between 15 and 10 cal ka BP, at multidecadal resolution, which is unprecedented in the few available studies. Paleoclimatic and paleoenvironmental trends are deduced from independent physicochemical records developed on the same sediments, along with detailed studies on glacial deposits and landforms, which are available for the study area during the period of interest. The sediments of the Bassa Nera pond are especially well suited for this type of analysis because its elevation, slightly below the present treeline, makes the site highly sensitive to altitudinal oscillations of montane vegetation belts. Emphasis is placed on treeline altitudinal shifts during the Bølling/Allerød-Younger Dryas interstadial/stadial succession, and the existence of potential microrefugia for high-elevation conifer forests. Another point of interest is the analysis of community versus individual species' response to environmental change, aimed at identifying the most suitable indicator taxa. In the study area, the Late Glacial time interval was free from human disturbance and is therefore an excellent past analog to assess the effect of climatic shifts alone on high-mountain Pyrenean ecosystems. The results obtained in this study are placed within the context of the conspicuous spatiotemporal anthropization gradient that has been defined for the central Pyrenees, which will be useful to disentangle the effects of natural and anthropogenic drivers of ecological change. The Bassa Nera pond is located in a National Park (PNAESM) and the results obtained in this study will be useful to inform conservation practices in the face of the ongoing climatic change. Research funded by project LACEN OAPN 24505 (Sentinel Lakes of Global Change in National Parks).

Disentangling the influence of climate and lake-basin evolution on GDGT-based proxies: the 250-ka Lake Chala record

Ms. Allix Baxter [1], ***Dr. Francien Peterse*** [1], ***Prof. Dirk Verschuren*** [2], ***Prof. Jaap Sinninghe Damsté*** [3]

1. Utrecht University, 2. Ghent University, 3. NIOZ Royal Netherlands Institute for Sea Research

High-resolution paleoclimate records from equatorial continental settings are needed to deepen the current understanding of global climate dynamics. Biomarker studies on the sediment archives from long-lived lakes can provide records of past climate variability from such underrepresented regions. However, the degree to which biomarker proxies are impacted by aspects of long-term lake-basin development is rarely discussed, even though it may critically influence their ability to consistently reflect a particular climate variable through time. The International Continental Scientific Drilling Program (ICDP) project DeepCHALLA recovered a continuous sequence of diatom and organic-rich sediments from Lake Chala, a permanently stratified crater lake in equatorial East Africa, spanning the last c. 250,000 years (250 kyr) likely reaching the initial lake infilling. A series of modern system studies in Lake Chala have revealed crucial information about the mechanisms unpinning biomarker proxy-climate relationships, but the permanence of these relationships in deep time remains unclear. To assess the reliability of the climate signal recorded by isoprenoid (iso-) and branched (br-) glycerol dialkyl glycerol tetraethers (GDGTs) in these sediments, we compared downcore variations in GDGT distributions at ~200 year resolution with major phases in basin evolution, mixing regime, and nutrient dynamics as indicated by independent proxies (seismic reflection data, lithology and diatom assemblages). Together, these records suggest that during the early phases of the lake's development the clearly defined mixing zones to which specific GDGT producers are presently associated were not yet established, due to the lack water column stratification. As a consequence, before ~150 ka many of the GDGT-based proxies show irregular trends, and periodicities reflecting expected orbital insolation forcing of the local climate are mostly absent. Therefore, we conclude that GDGT proxies in Lake Chala primarily reflect climatic changes in equatorial East Africa from ~150 ka onwards, i.e., covering the complete last glacial-interglacial cycle. This work demonstrates the potential of lacustrine GDGTs for elucidating tropical climate history at Quaternary timescales provided the availability of suitable high-quality sediment archives, and, furthermore, sets a new standard for lacustrine biomarker studies to incorporate a broader understanding of lake basin evolution or else risk misclassifying past climate conditions.

Untangling climate-driven changes in pollen signals from external drivers; a study of pollen in deep marine deposits on the active Hikurangi Subduction Margin, New Zealand.

Pollen is a valuable and reputable tool for reconstructing paleoclimate and is often preserved within marine sedimentary records, capturing the onshore vegetation response to changing climate states. A benefit of using marine sedimentary records for reconstructions is that they span longer timeframes than are typically available from terrestrial sites. However, reconstructing climate and vegetation from marine records can often be more complicated than reconstructions from terrestrial records. Furthermore, active sedimentary systems adjacent to tectonically active margins pose additional challenges, as the sedimentary sequence can be heavily influenced by extreme events, including volcanic eruptions, earthquakes, and submarine density flows. Therefore, to harness records from these environments for paleovegetation and paleoclimate reconstruction, the distribution of palynomorphs above and within tephra from volcanic eruptions, turbidite event beds from earthquakes, and hyperpycnites from major storms must be understood.

To investigate this relationship, we use the Hikurangi Subduction Margin (HSM) as a case study as it is an active sedimentary margin, influenced by volcanic eruptions from the adjacent Taupō Volcanic Zone, frequent earthquakes and major storms due to New Zealand's maritime climate. We present preliminary results from short sediment cores collected from the HSM, comparing palynomorph assemblages and sedimentary facies from Holocene turbidites, hyperpycnites and primary and secondary tephras. Pollen spectra, CT imaging, magnetic susceptibility measurements, density measurements, laser grain-size analysis and carbonate analysis are used to investigate the relationships between sedimentary facies and palynomorph assemblages. In turbidite and hyperpycnite beds, we hypothesise that results will show evidence of palynomorph sorting according to size, morphology and exine thickness. Within and above tephras deposited in the HSM from major volcanic eruptions, we hypothesise a potential decrease in the overall pollen species diversity and a subsequent increase in pollen from seral species.

The characterisation of pollen profiles that represent extreme events will make it possible to disentangle the external influence of these events on the pollen assemblage from the true paleovegetation and paleoclimate signal. The findings from this preliminary study will facilitate paleovegetation, paleoclimate and extreme event reconstruction for a Late Quaternary (~1.85 Ma) sediment record from the HSM.

Towards an improved understanding of the Late Pleistocene and Early Holocene eco-climatic context of human activities in the Northern Apennines, Italy.

Prof. Nicholas Branch [1]***, Dr. Carlo Montanari*** [2]***, Dr. Mike Simmonds*** [1]***, Dr. Roberto Maggi*** [3]***, Prof. Fabio Negrino*** [4]

1. *School of Archaeology, Geography & Environmental Science, University of Reading, Whiteknights, Reading, RG6 6AH, UK,* ***2.*** *Department of Earth, Environment and Life Sciences (DISTAV), University of Genova,* ***3.*** *LASA (Laboratory of Environmental Archaeology and History), University of Genova,* ***4.*** *Department of Antiquities, Philosophy, History, University of Genova*

Two well-dated palaeoenvironmental records from Liguria (Pian del Lago and Rovegno) in the northern Apennines (NW Italy) were used to reconstruct the timing and nature of sedimentary changes and vegetation succession during the upper Late Pleistocene and Early Holocene. The results from Pian del Lago and Rovegno have provided clear signals for multiple abrupt climatic events: Interstadials at *~43,440-41,950* cal. BP, *~37,130-36,650* cal. BP, *~36,050-35,160* cal. BP, *~33,860-32,650 cal.* BP, *~26,880-26,400* cal. BP, *~23,030 to 22,800* cal. BP, *~14,660-12,480* cal. BP (Lateglacial Interstadial); Stadials at *~22,540-19,300* cal. BP, *~19,300-17,480* cal. BP, *~17,480-14,660* cal. BP and *~12,480-11,560* cal. BP (Lateglacial Stadial - 'Younger Dryas' chronozone). The event stratigraphy proposed represents an enhanced version of that proposed by the authors previously and critically it confirms the presence of further stadial events in the northern Apennines during the upper Late Pleistocene. During the Early Holocene, there is no pollen-stratigraphic evidence to support the presence of the ~11,400 cal. BP rapid climate change event, although the changes in vegetation succession at a number of northern Apennine sites indicate possible signatures for the ~9300 cal. BP and ~8200 cal. BP events. The records from Pian del Lago and Rovegno are supported by other terrestrial sequences in Italy, although there are notable spatial and temporal differences in taxa recorded that may reflect latitude, location of glacial refugia and local site-specific characteristics including elevation, aspect and soil development. Importantly, the presence of these climate events suggests that the northern Apennines were probably sensitive to many of the changes recorded in other parts of Europe and the Mediterranean. The data have provided important new information on the climatic and environmental context of human activities in the Italian Maritime Alps and northern Apennines especially at the transition between the Middle to Upper Palaeolithic, and during subsequent socio-economic and cultural developments during the Late Mousterian, Proto-Aurignacian, Aurignacian, Gravettian, Epigravettian, Mesolithic and Early Neolithic.

5500 years of ecosystem change in the Tana River Delta (Kenya) in response to sea-level fluctuation, hydrological dynamics and human impact

Mr. PETER GITAU [1]***, Dr. Stéphanie Duvail*** [2]***, Prof. Dirk Verschuren*** [3]***, Dr. Stephen Rucina*** [4]

1. *Muséum National d'Histoire Naturelle-Alliance Sorbonne Université,* **2.** *UMR PALOC, French Institute for Sustainable Development (IRD),* **3.** *Ghent University,* **4.** *National Museums of Kenya*

Coastal deltas worldwide are under risk of degradation due to the increasing impacts of sea-level rise and alterations of river hydrology. This double threat also applies to the Tana River Delta in Kenya, which forms a lifeline for local communities almost entirely dependent on its ecosystem services, while also providing very attractive habitat to a wide variety of flora and fauna that make this area a biodiversity hotspot in the Eastern African coastal region. However, past and historical dynamics that have influenced the current status of the Tana River Delta ecosystem are not sufficiently understood to construct a proper baseline to evaluate the uniqueness and magnitude of the delta's current environmental challenges.

In order to gain such understanding of long-term ecosystem dynamics in the Tana River Delta, we developed a multi-proxy paleo-environmental study involving the analysis of sediment cores recovered from floodplain and mangrove forest areas within the delta. We performed a detailed lithological description and geochemical analyses to determine changes in the depositional environment, and analyses of fossil pollen and aquatic invertebrate assemblages to determine past changes in delta vegetation and aquatic habitat features in response to natural and anthropogenic environmental drivers.

Our results indicate that since the mid-Holocene sea-level maximum *ca* 5500 cal yr BP, the central Tana River Delta evolved from a marine ecosystem dominated by mangrove vegetation to the present-day wooded freshwater floodplain, in response to late-Holocene sea-level decline and subsequent changes in river hydrology. The timing of salinity changes, as registered by aquatic invertebrates, differed between various locations in the delta. In addition, we find that sediment composition and delivery to the delta have been impacted by human hydrological alterations at the basin and local scale over the past two centuries. With continued sediment starvation and hydrological alterations under the current trend of rising sea level, we foresee increased sea intrusion and submergence of the Tana River Delta.

Confocal Raman Spectroscopy Montaging: An open sesame to visualize sub-daily growth lines in short-lived marine gastropod shells

Ms. Mahsa Alidoostsalimi [1]***, Dr. Amy Prendergast*** [1]***, Prof. Russell Drysdale*** [1]***, Prof. Ian J. McNiven*** [2]***,***
Prof. Sean Ulm [3]

1. *School of Geography, Earth and Atmospheric Sciences, University of Melbourne, Victoria, Australia,* ***2.*** *ARC Center of Excellence for Australian Biodiversity and Heritage, Monash Indigenous Studies Center, Monash University, Clayton, Victoria, Australia,* ***3.*** *ARC Center of Excellence for Australian Biodiversity and Heritage, College of Arts, Society and Education, James Cook University, Cairns, Queensland, Australia*

Confocal Raman Spectroscopy (CRS) is a common, powerful, rapid, and non-destructive technique which is well–established in the field of sclerochronology – the study on the accretionary hard parts of animals such as corals and mollusc shells and the temporal context in which they were formed. CRS has predominantly been used in sclerochronology to determine the crystalline structure (e.g. calcite, aragonite) of mollusc shells and corals. However, this research employs CRM to investigate growth patterns of the short-lived marine gastropod shells, *Rochia nilotica* and *Conomurex luhuanus*, collected from the Great Barrier Reef. Our results show that CRS is a powerful and reliable tool, to visualise daily to sub-daily growth patterns in short-lived marine gastropods, often performing better than other commonly utilised techniques including light microscopy on stained and un-stained sections, and cathodoluminescence (CL). This technique can therefore be used to better understand daily to sub-daily growth patterns in marine gastropod shells and their relationship to tidal cycles, and as a primer for high-resolution biogeochemical analyses of modern and archeological gastropod shells to better characterize the temporal resolution of sampling when obtaining paleoenvironmental records of climate modes such as ENSO at ultra-high resolution.

Integrating palaeoecological and dendrochronological data to explore the past impact of climate and land-use changes on Sphagnum peatlands in the temperate climate of Central and Eastern Europe

Mr. Mariusz Bak [1]***, Prof. Mariusz Lamentowicz*** [2]***, Prof. Piotr Kołaczek*** [2]***, Ms. Daria Wochal*** [1]***, Dr. Paweł Matulewski*** [3]***, Prof. Katarzyna Marcisz*** [2]

Understanding climate change's extent, rate and effects is one of modern science's most critical challenges. These changes, manifested by increasingly higher average air temperatures and changes in precipitation, are affecting ecosystems globally. *Pinus* sylvestris monocultures, because of their homogeneous structure and simplified ecosystem structure, are particularly vulnerable to extreme events, including insect outbreaks, drought, fire and strong wind. As air temperatures rise and precipitation patterns change, the risk of fires in forests increases. In the context of global warming, forest fires are hazardous. The situation is even more dangerous when, along with a forest fire, a fire occurs in a peatland located in its area. Peatlands are effectively store carbon accumulated over hundreds or thousands of years. The main objective of this study is to reconstruct the history of peatland development over the past 300 years. We chose the Okoniny peatland in the Tuchola Pinewoods (N Poland). We looked at the period associated with the transition from mixed forest/open area to pine monoculture. We also studied the past impact of the change in forest management on the local vegetation and peatland hydrology. In addition, we wanted to answer the question of how the peatland ecosystem responded to extreme events, including natural and anthropogenic fires. Our reconstructions are based on a multi-proxy approach, including pollen, plant macrofossils, charcoal and testate amoebae. We also use dendrochronological data to compare the peatland record with *Pinus* sylvestris record. Our preliminary results showed that a change in forest management and progressing climate warming affected the development of the peatland. Pollen data revealed that transition from lacustrine to peatland environ took place before the 1930s and progressed along the strongest agriculture activity in the site vicinity. However, 20th century, especially its second part, was a period of constant decline of agriculture and increase in Scots pine dominance in the landscape. Considering the context of forest management and the protection of valuable ecosystems in the monoculture forest area, the study's conclusions are essential for peatland and forest ecology, paleoecology and forestry.

Study financed by the National Science Centre, Poland, grant no. 2020/39/D/ST10/00641.

Multi-proxy paleoceanographic reconstruction of the Mediterranean Sea during sapropel S6 deposition (~172 ka)

Mrs. Savannah Myers [1]***, Ms. Laura Aiudi*** [2]***, Dr. Francesca Caridi*** [1]***, Ms. Michelle de Groot*** [3]***, Dr. Timme Donders*** [4]***, Dr. Katharine Grant*** [5]***, Prof. Eelco Rohling*** [5]***, Prof. Anna Sabbatini*** [1]***, Prof. Francesca Sangiorgi*** [3]***, Prof. Alessandra Negri*** [1]

1. *Dipartimento di Scienze della Vita e dell'Ambiente, Università Politecnica delle Marche,* ***2.*** *Independent Researcher,* ***3.*** *Department of Earth Sciences, Utrecht University,* ***4.*** *Department of Physical Geography, Utrecht University,* ***5.*** *Research School of Earth Science, Australian National University, Canberra, Australia*

The formation of Mediterranean sapropels (dark-colored, organic-rich sedimentation layers) is not fully understood, but it has been found to be deposited at times of high-amplitude precession minima, which cause changes in the basins' freshwater and heat budgets, limiting bottom water ventilation, and leading to basin-wide anoxia. For this reason, the majority of sapropels are recorded during warm interglacial periods. However, glacial sapropels do exist, such as sapropel S6, which was deposited during the penultimate glaciation (Marine Isotopic Stage 6). During MIS 6 (□132−185 ka), millennial-scale climate variability is suggested to have been present in the North Atlantic and Mediterranean Sea, evidenced by marine, speleothem, and pollen climate record studies, and, more recently, evidenced in more detail by a high-resolution foraminiferal stable isotope record. With this data, we are provided with more insight into the paleoclimatological and paleoceanographic mechanisms behind the deposition of sapropel S6. But, because there are several sources of freshwater input that could be involved during the sapropel formation, more evidence is needed to pinpoint the exact conditions. Here, we present a multiproxy paleoecological study of the sapropel S6 sedimentation layer found in piston core M25/4-12 retrieved from the Ionian Sea of the Eastern Mediterranean basin (EMED). We compiled the data from analyses of planktonic foraminifers, calcareous nannofossils, pollen, dinocysts, and foraminiferal d18O, and compared our findings to the previously mentioned published literature on MIS 6 and sapropel S6. Our multiproxy data agrees with the previously published data indicating that glacial meltwater input from the Alpine glaciers was responsible for preconditioning the EMED for stratification being the result of an interstadial warm period during MIS 6. However, with this additional paleoecological data, we also propose that, immediately after the glacial meltwater, Nile River discharge from enhanced monsoonal activity was the mechanism for sustaining the stratification and bottom water anoxia.

Congo Basin Vegetation Sensitivity to Hydroclimate Shifts During the Pleistocene

Ms. Andrea Mason [1]***, Prof. James Russell*** [1]

1. *Department of Earth, Environmental, and Planetary Sciences, Brown University*

The Congo Basin is the world's second largest rainforest and plays an important role in global convection and carbon cycling. Despite its enormous impact, the Congo is vastly understudied due to political and economic instability. The lack of observational records from the Congo has greatly impacted our ability to predict future climate change in the region. For example, the IPCC 6th Assessment cites low confidence in the current projections of mean precipitation change and drought frequency in Central Africa, resulting in a high level of uncertainty for future rainfall in the region. Rainfall is particularly important in the Congo because it already exists at relatively low levels for a tropical rainforest. Modern satellite data from the Congo has shown an increase in dry season length coinciding with a decrease in forest greenness. With few observational records, and an inability to predict if these trends will continue, paleoclimate studies provide an opportunity to study climate variability and ecological sensitivity in the Congo under past climate conditions. Using dD and d^{13}C of leaf wax n-alkanes, we evaluate the sensitivity of vegetation type to changes in precipitation. Additionally, using alkenone unsaturation ratios (U^{k}_{37}') we reconstruct Atlantic sea surface temperature to investigate the role of the Atlantic in driving Congo Basin hydroclimate patterns. We focus our efforts on the late Pleistocene, which includes MIS 11, one of the warmest and longest interglacials of the last 5 million years and an analogue for future climate change.

Pliocene-Pleistocene environments in the Dacian Basin (S Romania): a stable isotope study of land and freshwater fauna

Fluvial and lacustrine deposits in southern Romania yielded mammal and fresh water fossil fauna that can contribute to understanding both long and short term regional environmental changes during the Pliocene and Pleistocene.

We present here oxygen and carbon stable isotope data from ostracod and mollusk shells, as well as from mammalian tooth enamel from three main sites: Măru (3.0 Ma), the Olteț River Valley complex (ORV, spanning the 2.2 Ma to 1.1 Ma period), and Copăceni (1.0 Ma).

Moreover, we provide a first radiometric age estimate for Fântâna lui Mitilan site within the ORV complex, based on the LA-MC-ICPMS U-Pb dating of an artiodactyl tooth fragment.

Pollen analysis reveals a typical mesothermic riparian plant association at Măru, while at Irimești (part of the ORV complex) a temperate steppe was present.

Although sparse oxygen isotope data have been previously published from this region, high resolution records that could help understand climate seasonality are needed. We aim to address this issue by studying tooth enamel and mollusk shells at monthly resolution, while also adding data from seasonally molted ostracod valves. Extracting local oxygen isotopic information from freshwater fauna allows us to infer the isotopic composition of precipitation and its sources. Such local information combined with carbon isotope results, will further help us constrain mammalian behaviors regarding migration or feeding.

The open-cast lignite pits of central Poland present an outstanding opportunity to investigate the Quaternary sedimentary record. Those in the Bełchatów area have been studied by numerous workers since the 1970s, and in 2004 a new pit was opened in the neighbouring Szczerców area. Here we present the results of a range of investigations conducted (2017-22) on the fluvial and lacustrine sediments exposed at Szczerców. These include lithostratigraphy, fossil biota (diatoms, pollen, macroflora, seeds, Cladocera, molluscs), and geochemistry (elemental and isotopic composition) partly constrained with carbon-14 dating. The sedimentary sequence at Szczerców ranges from lacustrine deposits of the Odranian (Early Saalian) marine isotope stage 6 (MIS 6), through lacustrine-peat deposits of the Eemian (MIS 5e) to lacustrine and fluvial deposits of the Early Vistulian (MIS 5d–a) and Plenivistulian (MIS 4–2). Pleistocene glacial tills are also observed together with remnants of an associated Middle Pleistocene(?) proglacial lake. The tills were studied in terms of gravel lithology and rare earth elements in the matrix. We also focus upon the mineral and organic sedimentary infills of palaeolakes formed during three interglacial periods that we postulate represent MIS 15, MIS 11, and MIS 5e.

Granulometric analysis of recent Saharan dust with insight into bioaerosol content analysis

Ms. Fruzsina Gresina [1], ***Dr. Zoltán Szalai*** [1], ***Dr. György Varga*** [2]

1. Geographical Institute, Research Centre for Astronomy and Earth Sciences, Budapest, Hungary; Institute of Geography and Earth Sciences, Eötvös Loránd University, Budapest, Hungary, 2. Geographical Institute, Research Centre for Astronomy and Earth Sciences, Budapest, Hungary; Department of Meteorology, Eötvös Loránd University, Budapest, Hungary

The arid-semiarid regions of the Earth release billions of tons of mineral dust into the atmosphere and the lifted dust is transported even over vast distances by winds of the global atmospheric systems. Extensive measurement networks and remote sensing methods can determine the main source areas and their geological and geomorphological environments. Although, the potential applications of the individual grain properties obtained from the grain size and shape analysis lie in a deeper understanding of dust transport and deposition processes since the transport mode, distance and deposition mechanisms affect the transported particles. Thus, by knowledge of unique granulometric marks we could also track changes in the environmental conditions for the transported particulate matter by monitoring their morphological parameters. Bioaerosol (diatom, pollen) particles are mixed with the mineral dust, which can also be used to refine the delineation of source areas.
The analysis was carried out on samples from the Saharan source areas (e.g., the Atlas foreland chotts) and from recent years' intense European depositional events from Pyrenees, Alps, Carpathian Basin. Granulometric analyses based on automated static image analysis (Malvern Morphologi G3SE-ID) can be used to obtain direct data on the size, shape and optical properties of the particles, while the built-in Raman spectroscope of the instrument also allows the determination of the qualitative properties (mineral phase) of any individual grains. Particle size of mineral grains from some intense deposition episodes was very coarse with a significant volume fraction of particles >20 µm. The dust grains are generally characterised as atmospheric cooling factors, but once larger particle sizes appear in the calculations, the whole issue turns around. These giant dust particles play a heating role, essentially influencing the radiation equations. By automated image analysis, the pollen and diatom particles of the sediments can also be detected in some source materials and deposited sediments. Using automated image analysis, it is possible to distinguish between the mineral and bioaerosol components of the different sediments based on their shape parameters.

Pollen productivity estimates for past land cover reconstruction in mountain regions

Mr. Ugo Bisson [1], *Mrs. Esra Ergin Erdogmus* [2], *Dr. Florence Mazier* [3], *Dr. Laurent Marquer* [1]

1. Department of Botany, University of Innsbruck, 2. ITU, Eurasia Institute of Earth Sciences, Istanbul, Turkey, 3. GEODE, UMR 5602 CNRS, Toulouse

Pollen-based land cover modelling have been applied at local, sub-continental and continental scales with a major aim to evaluate the performance of past land use scenarios and to study the vegetation, climate and human interactions through time. However, the application of such modelling in mountain regions is more complex than for lowland ecosystems, in particular because of the challenge to model the dispersal mechanisms of pollen in complex topographic contexts.

A key parameter to use pollen-based land cover modelling schemes such as the REVEALS model and the Landscape Reconstruction Algorithm is the relative pollen productivity estimates (RPPs) for the major plant taxa present in the region. Most RPP studies have been done in lowlands and further researches are required to develop these approaches in mountain. In particular, different pollen dispersal models are now available to calculate alternative sets of RPPs that can be used specifically in mountains.

This study aims at investigating pollen production and dispersal mechanisms for the most abundant plant taxa in the Eastern part of the Alps, i.e. southern Germany, Austria and northernmost Italy. The performance of two approaches in pollen dispersal modelling are here evaluated, namely the Lagrangian stochastic model and the Gaussian plume model. The objective is to create a set of RPPs including spruce, pine, larch, fir, Ericaceae, Poaceae, alder, birch, beech and hazel, as examples. For this purpose, the pollen-plant abundance relationships are assessed in an area covering different valleys and altitudes. Thirty sites were randomly selected within a radius of 50km. For each site, a modern pollen sample (moss polsters) was collected in the center of the site and vegetation surveys were carried out to estimate plant abundance for incremental distances, i.e. incremental rings of 1m from the center to 5km. Vegetation maps were created based on GPS mapping during fieldwork for the 0-100m and then by using satellite images and regional vegetation maps for the distances from 100m to 5km. The extended *R*-value (ERV) model is used for the calculations. The first results are presented in this poster.

Aquatic insects' responses to rapid climate change: a high-resolution chironomid analysis in Lake Mezzano (Italy) sediments during the Last Glacial termination

Dr. Julieta Massaferro [1]***, Ms. Giorgia Beffa*** [2]***, Prof. Willy Tinner*** [3]***, Dr. Andrea Lami*** [4]***, Prof. Martin Grosjean*** [5]

1. *CENAC/CONICET,* ***2.*** *University of Bern,* ***3.*** *Institute of Plant Sciences & Oeschger Centre for Climate Change Research, University of Bern,* ***4.*** *National Research Council of Italy, Water Research Institute (CNR-IRSA), Largo Tonolli 50, 28922 Verbania, Italy,* ***5.*** *Institute of Geography & Oeschger Centre for Climate Change Research, University of Bern, Bern, Switzerland*

The Lateglacial period is characterized by a series of rapid and abrupt shifts in climate that are recognisable in numerous records worldwide, but specially in Central and Northern Europe. Lake sediments are an important source of climate information and may be used for reconstructing past environmental conditions as they are particularly sensitive to the combined effect of climate change and anthropogenic pressures. Indeed, they contain proxies that can provide quantitative, highly resolved temperature data to reconstruct climate dynamics. In this study, a high-resolution Lateglacial chironomid record from lake Mezzano (central Italy) will be analysed. This small deep maar lake is partly varved, allowing a high-resolution reconstruction of environmental changes during the interval of time proposed. Using an existent chironomid-based quantitative inference model developed from two combined calibration datasets from Norway and the Swiss Alps, we aim to quantitatively reconstruct the summer temperatures in Central Italy, during the interval of 15,000 to 12,000 BP which broadly correspond to the Bölling/Alleröd climate event. This study combines bioproxy information with already available information derived from X-ray fluorescence, geochemical and palynological data. Up to date, no chironomid-inferred temperature reconstructions are available from Central Italy. The model will be compared with other regional climatic records to evaluate the coherence of climate patterns during the Lateglacial in the Mediterranean region. Previous results in a stratified lake from northern Italy showed that during the B/A the disappearance of the cold-adapted chironomids together with the presence of low-oxygen -tolerant *Chironomus* is indicating warmer conditions and low oxygen concentrations.

This study underpins previous information about lake productivity, lake bottom anoxia and postglacial climate change especially during these rapid climate changes observed during the warming B/A interval. Therefore, it contributes to our understanding of climatic patterns and of biotic responses to temperature and other environmental changes throughout Europe and the Mediterranean region

Lake system response to annual hydroclimate variability in the East African Rift System between 150 and 100 kyr

Ms. Cécile Porchier [1], ***Prof. Mark Maslin*** [1], ***Dr. David Williams*** [2], ***Dr. Tom Hill*** [2], ***Dr. Eileen Cox*** [2], ***Prof. Anson Mackay*** [1], ***Prof. George Swann*** [3], ***Prof. Melanie Leng*** [4], ***Prof. Martin H. Trauth*** [5]

1. *University College London,* ***2.*** *Natural History Museum,* ***3.*** *University of Nottingham,* ***4.*** *British Geological Survey,* ***5.*** *University of Potsdam, Institute of Geosciences, Potsdam, Germany*

Lake sediments provide useful insight into environmental responses to climate variability over a wide range of timescales from seasons to millennia. Paleoclimate records, including lacustrine records, in the East African Rift Valley show rapid changes from humid to hyper-arid climates during the late Quaternary. Records of such events at annual to decadal timescales are however currently scarce in this region.

This study applies a multi-proxy approach to reconstruct hydroclimate variability at annual to decadal timescales in the East African Rift System (EARS). Diatom assemblages, oxygen isotopes in diatom biogenic silica ($\delta^{18}O_{diatom}$) and bulk X-Ray Fluorescence (XRF) records are used to understand past changes in moisture and precipitation patterns over East Africa as well as changes in lake water chemistry and lake levels. An age model at annual timescales was also developed using high-resolution XRF measurements and layer counts which allow us to study the cyclicities present in the moisture and precipitation patterns over the EARS.

In the current climate change context, understanding how a lake system responds to rapid climatic fluctuations is critical to help mitigate the impacts of a warming planet, which include phenomenon such as droughts and floods.

Understanding changes in plant paleocommunities in the southern Baltic region during postglacial global climatic and human expansion events

Dr. Laura Gedminienė [1], ***Prof. Andrej Spiridonov*** [2], ***Dr. Miglė Stančikaitė*** [1], ***Dr. Žana Skuratovič*** [3], ***Dr. Giedrė Vaikutienė*** [2], ***Dr. Kathleen Stoof-Leichsenring*** [4]

__1.__ Nature Research Centre, Akademijos Str. 2, LT-08412 Vilnius, __2.__ Department of Geology and Mineralogy, Faculty of Chemistry and Geosciences, Vilnius University, M. K. Čiurlionio 21/27, LT-03101, Vilnius, __3.__ Nature Research Centre, Akademijos Str. 2, LT-08412, Vilnius, __4.__ 1. Polar Terrestrial Environmental Systems Research Group, Alfred Wegener Institute Helmholtz Centre for Polar and MarineResearch, Potsdam, Germany

Post-glacial history of the local catchment and surrounding morphology have been analysed taking into account the results of the multiproxy studies of the Dūkštelis Lake sediment sequences. Seven cores were analysed as a result, and their records were synchronized using lithological boundaries as well as magnetic susceptibility data, and consequently, cross-sections of the palaeolake were modeled. The multiproxy investigations of the deepest sediment core (1300 cm) consist of palaeobotanical (spore-pollen, diatom analysis), lithological (grain-size and loss-on-ignition survey), magnetic susceptibility (MS), isotopic (^{14}C, AMS, δ^{18}O and δ^{13}C) studies and geochemical analyses. A detail radiocarbon dating of the section revealed that the area deglaciated much earlier than it was thought before at about 15000 cal yr BP. At the beginning of the Early Holocene, the local climate stabilized. Formation of the dense plant cover inhibited erosional processes. Alongside the closing of the basin more and more nutrients concentrated in the lake which led to its eutrophication while the decrease in oxygen content slowed down the mineralization of organics. At the end of the Middle Holocene, the investigated part of the lake transitioned into the bog state. During the last 1000 years, human settlement strongly affected all near-lake environments. Heavy metals on the top of the sediments show significant pollution levels. An additional study is planned, and it will focus on the quantitative temperature reconstructions based on fossil pollen data and plant sedimentary ancient DNA (sedaDNA). Recent advances in the analyses of plant DNA from fossil samples enabled the molecular reconstruction of palaeofloras and suggest that sedaDNA from lake sediments is a powerful tool. The application of this tool will help us to detect if some species persisted near the lake during time intervals when they are not detected as macrofossils, thus filling the gaps in the macrofossil record. Independent long-term climate variability estimators will help us to understand the mechanisms of changes in terrestrial environments in the epoch of human expansion.

Acknowledgment: this project has received funding from the Research Council of Lithuania (LMTLT), agreement No [S-PD-22-77].

Polar marine environments and ecosystems under a warming climate: recent deglacial records from the Antarctic Peninsula

1. *Institute of Geology, Adam Mickiewicz University, Poznań,* ***2.*** *University of Plymouth,* ***3.*** *Institute of Human Biology and Evolution, Adam Mickiewicz University,* ***4.*** *University of Exeter,* ***5.*** *Geohazards Research Unit, Institute of Geology, Adam Mickiewicz University in Poznan*

High-latitude regions such as Antarctica have seen unprecedented environmental shifts over the last few decades due to anthropogenically-driven climate warming. Such shifts, perhaps most visibly expressed in the decline of the cryosphere, impact marine ecosystems. Here, we present emerging results from 'CHARME' (Changing AntaRctic Marine Environments), a project funded by the POLS program (National Science Centre Poland & Norwegian Grants; No. 2020/37/K/ST10/04127) focused on characterizing the biogenic proxy signature of recent deglaciation (retreating tidewater margins). Three fjords along the Antarctic Peninsula have been sampled systematically in transects from fjord head to mouth for both surface and short (multicore) sediments; multiproxy analyses include micropalaeontological, biogeochemical, and molecular approaches. In surface sediments, highly-branched isoprenoid (HBI) biomarkers concentrations ($IPSO_{25}$, HBI III, HBI IV) increase with distance from the tidewater glacier. The sea-ice biomarker $IPSO_{25}$, whose surface sediment abundances rise with increasing latitude, shows good correlation with the proportion of sedimentary DNA (sedDNA) of the cyst-producing sea-ice dinoflagellate *Polarella glacialis*. The open-water phytoplankton biomarkers HBI III and HBI IV are most abundant towards fjord mouths, whereas concentrations of sterols such as dinosterol and desmosterol are higher towards the fjord head, closer to the tidewater margin. Benthic foraminifera are abundant and diverse throughout surface sediments, with *Cribroelphidium webbi* confirming its indicator potential for ice-proximal environments. Multicores taken at fjord mouths cover the last ~70-200 years (depending on location), allowing a detailed glimpse into deglacial dynamics. HBI biomarkers show comparable downcore trends, concentrations of the sea-ice biomarker $IPSO_{25}$ increasing over the last few decades in tandem with the sedDNA of *P. glacialis*, in correspondence to retreating tidewater margins.

The Holocene climate changes, fire history and palsa peatland dynamics: case study from Yenisei Siberia

Prof. Elena Novenko [1]

1. Lomonosov Moscow State University

Our paleoecological study is focused on one of the palsa mires located at the eastern edge of the West Siberian Lowlands (Yenisei Siberia) in the forest-tundra ecotone. Perennial frost mounds, often called as palsas and peat plateaus, are the dominant landscape type in this region. The paleoecological reconstruction is based on high resolution pollen, plant macrofossils, stable isotope and loss on ignition data macroscopic charcoal records and detailed AMS radiocarbon dating from a 8 m long peat sequence, obtained from the palsa mire situated near the town of Igarka (N 67°31'53.77' E 86°38'05.65').

The obtained data show that peat inception in the studied mire occurred at about 6200 cal yr BP during the Holocene Thermal Maximum. The time interval between 6500 and 5360 cal yr BP was characterized by warm and dry climate conditions and the highest charcoal accumulation rate throughout the Mid and late Holocene. The fire return period was 70-120 years that is shorter then at present. The main stages of palsa uplift occurred at about 5360 cal yr BP and 2250 cal yr BP and coincided with the periods of climatic cooling and moistening and permafrost aggradation in the Russian Arctic region. Since 5360 cal yr BP charcoal accumulation in the palsa decreased significantly and in some time interval ceased. The fire return period extended to 1500-1800 years. The increase of the charcoal accumulation rate in the peatland under study occurred at the end of 14th – beginning 15th centuries and then charcoal input declined. We supposed that human induced fires led to the biomass burning. According to historical data the Russian colonization of this part of Siberia began in the 17th century, but the first Russian settlers already found a local hunter population in the area of Igarka. The settlement lies on the banks of the Yenisei River, historically one of the main trading routes in Siberia. During the 20th century wood-using industry and a river harbor were developed in Igarka, was obviously accompanied by active deforestation that led to some reducing the forest fire occurrence.

Mineral magnetic properties of loess–paleosol couplets of northern Serbia over the last 1.0 Ma and paleoclimatic implications

Ms. Namier Namier [1], ***Prof. Qingzhen Hao*** [1], ***Mr. Xinbo Gao*** [2], ***Prof. Slobodan Marković*** [3], ***Prof. Zhengtang Guo*** [1]

1. *Institute of Geology and Geophysics, Chinese Academy of Sciences, Key Laboratory of Cenozoic Geology and Environment,* ***2.*** *Institute of Geology and Geophysics, Chinese Academy of Sciences,* ***3.*** *Department of Geography, Tourism and Hotel Management, Faculty of Sciences, University of Novi Sad, Trg Dositeja Obradovića 3, 21000 Novi Sad, Serbia*

A systematic rock magnetic measurement is conducted on composite Titel-Stari Slankamen loess section in Serbia, representing one of the most continuous and representative European loess–paleosol sequences spanning the last 1.0 Ma. Magnetic enhancement of Serbian loess follows the pedogenetic model, and is attributed mainly to the SP and SD maghemite. The ferrimagnetic grain size (X_{fd}/X_{ARM} ratio) of the paleosols is roughly constant over the past 1.0 Ma, which suggests that, with the possible exception of S5, magnetic dissolution model is not applicable. Therefore, environmental magnetic parameters of these loess deposits can reliably be used for paleoclimatic reconstruction.

Two new proxies, normalized $dJ/dT_{@120K}$ and normalized $\chi_{heating@530°C}$ was first time applied in Serbian loess. They are more sensitive to pedogenesis or low-temperature oxidation in more arid conditions compared with other commonly used magnetic proxies related to the concentration of pedogenic magnetic minerals. The long-term upward-increasing trend in normalized $dJ/dT_{@120K}$ and normalized $\chi_{heating@530°C}$ indicates a stepwise aridity trend during the past 1.0 Ma, with a major step at ∼0.6–0.5 Ma, which is consistent with records from Central and East Asia. The expansion of Northern Hemisphere ice sheets was possibly the primary forcing factor of the aridification trend over the past ∼1.0 Ma.

Dinoflagellate cyst assemblages as a paleoenvironmental and paleoclimatic proxy for the Quaternary shifts of the Gulf of Corinth (NE Mediterranean Sea)

Mrs. EUGENIA FATOUROU [1], ***Mrs. Aikaterini Kafetzidou*** [1], ***Dr. Fabienne Marret*** [2], ***Dr. Konstantinos Panagiotopoulos*** [3], ***Dr. Katerina Kouli*** [4]

1. *National and Kapodistrian University of Athens, Natural Sciences, Geology and Geoenvironment, GREECE,* ***2.*** *School of Environmental Sciences, University of Liverpool, UK,* ***3.*** *Institute of Geology and Mineralogy, University of Cologne, GERMANY,* ***4.*** *Department of Geology and Geoenvironment, National and Kapodistrian University of Athens*

M0078 core, recovered during the IODP Exp. 381, is located in the central part of the Gulf of Corinth in central Greece. The Gulf now is connected to the open sea, but in the past, was repeatedly isolated and reconnected to the Mediterranean Sea, during glacial/interglacial cycles, through the 60m shallow Rion sill at its western part (<400ka BP) or through the Saronic Gulf, at its eastern part (>400ka BP). These alternations between marine and (semi-)isolated intervals and their impact on local aquatic ecosystems were investigated through the palynological analysis of the site M0078 deposits, focusing on organic-walled dinoflagellate cysts. Dinocysts are an excellent proxy for palaeoenvironmental reconstructions, as they are sensitive to shifts in the environmental conditions and thrive in a wide range of climatic conditions and habitats, from fresh water to the open ocean.
In the present study, the 610 meters long sequence of site M0078 core was regularly sampled at a mean 2m interval, covering several climatic cycles since the Middle Pleistocene. More than 400 samples originating from marine, isolated, and transitional intervals were analyzed. The microscopic analysis documented the presence of more than 35 different dinocyst species. Two major ecogroups were distinguished, presenting alternations between marine and isolated/brackish conditions. The marine intervals are characterized by high dinocyst diversity, while the brackish intervals are characterized only by the presence of the low salinity indicators, such as *Spiniferites cruciformis, Pyxidinopsis psilata, Caspidinium rugosum, Impagidinium caspienense* and *Lingulodinium machaerophorum* (with processes <10μm). In several samples, *S. cruciformis* is dominant, characterizing the assemblage as monospecific. The alternations between marine and brackish conditions recorded in the Gulf of Corinth reveal changes in surface water salinity and temperature, in response to the Quaternary glacial – interglacial cycles. These seem to be in good agreement with global sea-level changes and trace orbital driven climate shifts as shown in the global Marine Isotope Record.

Acknowledgments: The QECCoRA (Quaternary Environmental Changes in the Corinth Rift Area: the IODP 381 palynological record) project is supported by the Hellenic Foundation of Research and Innovation (H.F.R.I., Project Number: 1026)

Vegetation dynamics through successive glacial-interglacial cycles in a unique Mediterranean setting (Gulf of Corinth, Greece)

***Mrs. Aikaterini Kafetzidou* [1], *Mrs. EUGENIA FATOUROU* [1], *Dr. Konstantinos Panagiotopoulos* [2], *Dr. Fabienne Marret* [3], *Dr. Katerina Kouli* [4]**

***1.** National and Kapodistrian University of Athens, Natural Sciences, Geology and Geoenvironment, GREECE, **2.** Institute of Geology and Mineralogy, University of Cologne, GERMANY, **3.** School of Environmental Sciences, University of Liverpool, UK, **4.** Department of Geology and Geoenvironment, National and Kapodistrian University of Athens*

The sedimentary record of site M0078, located in the Gulf of Corinth, was retrieved during the IODP Exp. 381. The Gulf of Corinth is a semi-enclosed basin, sensitive to Quaternary climatic oscillations and sea-level fluctuations and was repeatedly isolated from and reconnected to the Mediterranean Sea (McNeill *et al.*, 2019a). In the present study, the 610 meters long sequence of site M0078 core has been sampled for palynological analyses at ~2m intervals aiming to obtain a millennial temporal resolution and more than 140 samples have been studied. The dinocyst assemblages encountered in the same samples by a parallel study, record distinct alternations between marine and brackish conditions in the Gulf in response to global sea-level changes and can be correlated with global Marine Isotope Stages. At this Mediterranean setting, the vegetation response during these glacial/interglacial cycles appears to be more complex in comparison with the aquatic ecosystem. The present study traces the unique shifts in vegetation composition and succession of Mediterranean species in the southernmost Balkan tree refugium at a millennial scale since the Middle Pleistocene. Interglacial intervals show high terrestrial pollen concentration suggesting an increase in plant biomass and vegetation cover, while, during glacials, both the pollen concentration and the tree percentages show a decreasing trend, which is encountered in most southern European records. However, the glacial intervals retain surprisingly high abundances of both the deciduous and sclerophyllous vegetation components, which has not been previously reported. Another remarkable feature of the Corinth record is the occurrence of several Neogene relict tree taxa within the catchment until the Late Pleistocene. These findings together with the longer persistence of relict species confirm the uniqueness of the Corinth Gulf terrestrial ecosystems and the refugial character of the area and allow comparison with other regional reference Balkan sites such as the Lake Ohrid record (Sadori *et al.*, 2016; Donders *et al.*, 2021).

Influence of methane release on the composition of organic matter and benthic foraminifera of Brazilian continental margin (SW Atlantic)

Dr. Amanda Gerotto [1], ***Dr. Cesar de Castro Martins*** [1], ***Dr. Renata Hanae Nagai*** [1]

1. *Federal University of Paraná*

The continental margin sediments store large amounts of CH_4 in hydrate deposits. The potential dissociation of gas hydrate layers by environmental changes (ie., changes in sea surface temperature) represents a source of CH_4 that can drastically affect the carbon cycle and Earth's climate. Understanding the biogeochemical parameters that control the dynamics of CH_4 infiltration in these environments is fundamental for the prediction of possible impacts and consequences of the destabilization of these deposits. The CH_4 exudation imprints a differentiated geochemical signature on marine sediments deposited in areas under gas escape. Analyzes of total organic carbon (TOC) concentration, $\delta^{13}C$, TOC, and the isotopic signature of benthic foraminifera have been widely applied in the characterization of environments associated with CH_4 release and in the past reconstructions of exudation activity. However, the ecology of benthic foraminifera in environments associated with CH_4 exudation remains uncertain. The present study aims to explore how CH_4 infiltration in marine sediments affects the chemical composition of sediments and the community of benthic foraminifera from pockmarks and from the Alpha Crucis Carbonate Ridge, CH_4 seepage zones, in the southwestern margin of Brazil (between 24° and 34°S). The TOC, isotopic signatures of $\delta^{13}C$ and $\delta^{15}N$ of organic matter, and living benthic foraminiferal assemblages (Rose Bengal stained, fraction > 63 µm) in surface sediments from ten stations will be evaluated. The foraminifera data will be combined with TOC, $\delta^{13}C$, and $\delta^{15}N$ analyses, providing a proxy calibration (ie., key species associated with CH_4 exudation) that will be applied in the reconstruction of the last 200 years of CH_4 exudation activity in a sedimentary record retrieved in the same area. This study will provide data on the composition of organic matter and benthic foraminifera from the Southwest Atlantic in CH_4 exudation zones and on possible anthropic impacts and environmental changes in the evolution of hydrate deposits.

Resolving the Younger Dryas climate event in Siberia and the Russian Far East.

Siberia and the Russian Far East (SRFE) contain globally important biomes which are established as being responsive to, and a critical driver of local and global climate.

However, due to observational difficulties there remains an incomplete understanding of the complex interactions and feedback between climate, biosphere, atmosphere, oceans, and land in the region.

As such many studies have looked to past examples. The Younger Dryas (YD; G S1: ~12,900 – 11,700 cal. Yr. BP) is conventionally attributed to changes in the Atlantic Meridional Overturning Circulation (AMOC) affecting the North Atlantic sector (NAS) most strongly. In the NAS large-magnitude and rapid climate change at the end of the YD is viewed as an analogue for near-future warming, though the specific chain of earth-system processes that drove it differ from contemporary mechanisms. But, YD responses in proxy temperature and moisture data vary in space and time in SRFE in relation to latitude (insolation), longitude (continentality), topography, suggesting multiple controls.

We present the results of a broad syntheses of terrestrial and marine proxy palaeoclimate and vegetation records from SRFE and adjoining regions spanning the late glacial, including the YD, and early Holocene (ca. 14,000 – 10,500 yrs. BP), with the aim of distinguishing temporal and geographical patterns in climate responses and testing hypotheses on the likely degree to which different components of the global climate system drove such changes (i.e. Asian Monsoon system, Atlantic and Pacific climate-ocean system).

Seventy proxy records were selected for adequate chronologies (at least one before, after and during the YD) and resolution (at least 2-3 samples) through the YD. Calibrated age-depth models for data sets with uncalibrated radiocarbon dates were done using R package ‘Bacon’ with IntCal 20.

47 sites with pollen data were used to examine shifts in vegetation across the region. Other sites reported faster-responding proxies, including atmospherically driven isotopes ($\delta^{18}O$), lake productivity-driven geochemistry ($\delta^{13}C$, TOC, TN), the remains of short-lived organisms (chironomids, diatoms, foraminifera), elemental geochemistry and alkenones.

Initial results show a stronger YD response in the West and North and a muted response in the South and East of the region.

Reconstruction of Holocene hydroclimate and vegetation from geochemical and biogenic proxies, Marais geluk wetland, Free-State, South Africa

***Dr. Jenny Sjöström* [1], *Prof. Antonio Martínez Cortizas* [2], *Mr. Andreas Nylund* [3], *Ms. Alice Hardman* [4], *Dr. Rienk H. Smittenberg* [1], *Dr. Jan Risberg* [5], *Dr. Elin Norström* [6]**

The Holocene climate history of Southern Africa still remains inconclusive despite an increasing amount of proxy records from the region. This might be related to the diversity of proxy records, how the proxies are interpreted, or that some proxies (e.g. vegetation) respond to more than one forcer (e.g. hydroclimate, fire, temperature). Here, a 175 cm peat sequence from Free-State, South Africa, was analysed for isotopic ($\delta^{13}C$), elemental (CS-XRF), mineral (pXRD), molecular (FTIR-ATR), grain size (Malvern 3000) and GSSC phytolith composition. The chronology was retrieved through AMS radiocarbon dating (n=7). The IR signal enabled identification of the main inorganic (clays, biogenic silica, quartz, iron oxides, gibbsite) and organic (fresh OM, carboxylic OM, OM-clay associations, and charcoal) peat components. The result indicate that the early Holocene was dominated by silt sized, minerogenic, sediments, indicative of fluvial transport. The $\delta^{13}C$ values indicate that a mix of trees (C_3), shrubs (C_3) and grasses (mainly C_4) existed in the surrounding landscape during this period. Taken together, the results suggest that mostly moist conditions prevailed in early Holocene. After 8000 cal BP the organic content and biogenic silica started to increase while the grain sizes continually decreased, likely reflecting increased productivity and a successional change from mainly minerogenic sedimentation, towards organic accumulation. After 6000 cal BP the $\delta^{13}C$ values became less depleted, indicative of increasing (C_4) grasses and less trees and bushes (C_3) in the landscape, suggesting that increasingly dry conditions prevailed. Less depleted $\delta^{13}C$ values are sustained between 4070 and 2250 cal BP (~18‰) reflecting a dominance of C_4 vegetation, while the phytolith data indicate that a mix of C_3 and C_4 grasses persisted in this phase. The IR results record increased quartz and charcoal content during this period, suggesting dry, erosive conditions and increased fire activity. The grain size data show highly variable results during this period (mode: 5–25 µm). The last 2000 years are characterized by increased variability, both in productivity, vegetation, and mineral input, suggesting variable hydroclimatic conditions, in line with previous studies of the region.

Sub-decadal scale environmental responses to hydro-climatic changes in the Middle Atlas Mountains, Morocco – learning from historical sources and a high-resolution multi-proxy lake sediment record

The Western Mediterranean region including the North African desert margin faces major environmental challenges in the context of global climate change in terms of rising temperatures, a higher recurrence of drought events and a decrease in annual precipitation. Additionally, human activities have significantly altered the montane landscape over the past century through deforestation and agricultural practices.
As a condition to state further prospects, it is crucial to comprehend past and present hydro-climatic patterns and their geo-ecological impact. The Moroccan Middle Atlas is considered a transition zone between the Atlantic, Mediterranean, and Saharan air masses, and is therefore of unprecedented interest in order to comprehend regional climate variability and to assess emerging hydrological, geomorphological and ecological impacts.
Despite the growing number of limnological studies from the Middle Atlas, there still is a strong need for coupling palaeolimnological results at the sub-recent time scale with historical cartographic information, meteorological data, and underlying climatic forcing. Lake Sidi Ali (33°03' N, 5°00' W, 2080 m a.s.l.) provides a unique archive for understanding environmental changes throughout the 20th century. At least during the past 100 years, the lake has experienced at least three significant lake-level changes in the order of several meters. We were able to reconstruct and semi-quantify these alternations with the help of historical sources, topographic maps, and satellite imagery. In addition, we implemented a multi-proxy analytical approach on a 145-cm long sediment record, including pollen, $\delta^{18}O$ and $\delta^{13}C$ analysis of ostracod shells and CNS elemental analysis. A reliable age model based on 25 ^{210}Pb measurements and one radiocarbon dated cedar needle enables the correlation of sediment geochemical variations to lake-level changes.
We examined meteorological precipitation and temperature data to evaluate their influence on these fluctuations. Furthermore, we have indications for a temporal coupling of Atlantic climate patterns (North Atlantic Oscillation, NAO; Atlantic Multidecadal Oscillation, AMO) with Sidi Ali's lake-level variations and we provide a more detailed insight into the responsiveness of local vegetation to the climatic and anthropogenic changes of recent decades. This study will thus help to better elucidate the interactions of lake hydrology and vegetation response to future environmental change.

Quaternary glauconitization process on the Guadiana shelf (Northern Gulf of Cadiz)

Dr. Adrián López Quirós [1]***, Dr. Francisco José Lobo*** [2]***, Dr. Isabel Mendes*** [3]***, Prof. Fernando Nieto*** [4]

1. *Department of Stratigraphy and Paleontology, University of Granada, 18071, Granada, Spain,* ***2.*** *Instituto Andaluz de Ciencias de la Tierra (IACT), CISC-UGR,* ***3.*** *Centro de Investigação Marinha e Ambiental, University of Algarve, Faro, Portugal,* ***4.*** *Department of Mineralogy and Petrology, University of Granada, Granada, Spain*

Clay minerals are major constituents of materials deposited in marine environments. Green-clay (glaucony) authigenesis, particularly in the marine and diagenetic realms, has played an important role in the understanding of Cenozoic climates. However, the genesis, depositional setting and paleoenvironmental implications of glaucony occurrences in the continental shelves/margin off southern Iberian Peninsula are loosely constrained. In this study, Holocene glaucony grains extracted from a sediment core retrieved from a highstand muddy depocenter off the Guadiana River, northern Gulf of Cadiz, were investigated by digital microscopy, X-ray diffraction (XRD) and electron microscopic methods (SEM-EDX and TEM-HRTEM). This multi-proxy approach allows to assess the physico-chemical conditions that prevailed during the glaucony-forming process in the northern Gulf of Cadiz, and to establish paleoenvironmental conditions that favoured glaucony formation during the recent Holocene highstand.

In the studied sediment core, glauconitization occurred mostly by the replacement of faecal pellets during ~4.2-1.0 cal. ka BP. XRD and TEM-HRTEM analyses indicate that glaucony consists mainly of R1, with minor presence of R0, smectite-rich (nontronite with minor berthierine layer) interstratified glauconite-smectite. It consists of 35-75% glauconitic layers and 65-25% of interstratified smectite layers. The occurrence of shallow radial cracks in the pellet surface along with globular and caterpillar-like biomorphic to low packing density lamellar-flaky nanostructures, mineralogical properties, and K-poor content (~0.4 atoms p.f.u.), indicate a low mature glauconitization process. The mineralogy, chemistry and detailed morpho-textural properties demonstrate that glaucony has formed *in situ* (autochthonous). Conditions for the Holocene glaucony authigenesis occurred in an open-shelf environment at water depths of ~70 m, under suboxic, partially reducing conditions near the sediment-water interface. These environmental conditions were triggered by protracted low sediment supplies and recurrent winnowing action. Furthermore, our dataset provide evidence that (bio)availability of iron was not a limiting factor for glauconitization at our study site. There, iron was supplied by alteration of continent-derived minerals (from natural to anthropogenic weathering) and from ferruginous-rich upwelling waters.

Direct but delayed positive correlation between dolomite and calcite ratios in Lithuania lake sediments and the climatic signal in the Greenland GISP2 record

The Late Pleistocene to the Holocene is a time interval that covers the climate transition from a cold to a warm interglacial regime. Many studies have focused on estimating environmental responses to climatic forcing in the Baltic region using palynological and stratigraphic proxies of glacial and periglacial settings. Ūla River Valley crosses the outwash plain formed in front of the former ice margin South East from the distal slopes of Baltic highlands of the Pomeranian stage of the Last Glaciation. Deposits in the distal part of the outwash plain are drifted, forming high dunes in many places. In the Ūla River Valley, there are several outcrops with sandy deposit sequences, including peat, gyttja and calcareous sediments interbedded between the sand layers. Herein we describe the mixed lacustrine-aeolian succession of the Zervynos-2 section (southeastern Lithuania), located in the northeastern part of the European Sand Belt. The succession and the sedimentation styles were characterized by granulometric parameters, structural features, dolomite/calcite ratio, and the paleobotanical macro-remains. Our analyses revealed that the Zervynos-2 paleolake formed on the sandur (outwash) plain during the final stage of the Pleistocene. The sudden submergence of a sandbody-constrained paleovalley caused the onset of lake sedimentation. Carbonate ratios and macro-remains from the lower gyttja material showed the presence of substantial millennial-scale oscillations, which suggests a delayed response to the isotopically derived paleotemperatures. The transition to the fast sand sedimentation started approximately in the Middle Holocene and is interpreted here as being caused by the warming and drying of the climate in the Baltic region. The upper Holocene portion of the section represents the transition to exclusively aeolian sedimentation with lower accumulation rates likely related to a long-term cooling trend. The results support the conjecture that there is a direct but delayed positive correlation between dolomite and calcite ratios in lake sediments and the climatic signal in the Greenland GISP2 record.

This research was funded by a grant (No. S-LL-18-2) from the Research Council of Lithuania

Initial approaches to histotaphonomic change in submerged wetland landscapes. The case study of the GNLQ1 extinct faunal assemblage

Mr. Sebastian Yrarrazaval [1], ***Dr. Isabel Cartajena*** [2], ***Mr. Diego Carabias*** [1], ***Dr. Carla Morales*** [3]

__1.__ Millennium Nucleus Ocean, Heritage & Culture, __2.__ Millennium Nucleus Ocean, Heritage and Culture, Chile Departamento de antropología, Universidad de Chile ARQMAR, Center for Maritime Archaeology Research of the Southeastern Pacific, Valparaíso, Chile, __3.__ ARQMAR, Center for Maritime Archaeology Research of the Southeastern Pacific, Valparaíso, Chile

The exceptional nature of the site GNL Quintero 1 (GNLQ1) located on the coast of central Chile, as the only submerged Late Pleistocene landscape reported for the south-eastern Pacific coast to date. Makes understanding the nature of its faunal assemblages in regards to their depositional dynamics, paramount to clarify how and why these kind of fossil records were preserved in such particularly fragile and shallow deposits. GNLQ1 deposit presents itself as a challenging sample from a taphonomic perspective due to its association with both lacustrine/wetland and maritime exposure conditions. Due to ongoing discussion in the literature about how to compellingly understand patterns of surface submarine modification together with the complicated dynamics that potentially produce osteological assemblages in these types of lacustrine environment shorelines, we opted for an initial approach centred around histotaphonomic modification to understand the diagenetic alterations that the samples underwent in these particularly exceptional conditions. A selection of the dated sample between 28-21ka consisting of Artiodactyls (*Paleolama* sp., *Lama gracilis*, Cervidae), Perissodactyls (Equidae) and Xenartrans (Folivora) were embedded in clear resin and cut in 30 µm thin sections, which were ranked afterwards according to histoanatomical integrity of structures using the Oxford Histological Index (OHI), stemming from this different varieties of microscopical modifications related to bacterial, mycological and cyanobacterial modification were recorded, to which finally a broad measure of cracking, sediment or crystal inclusions and potential collagen content was assessed. Overall, the histotaphonomical recorded variables in the selected sample coincide with the current interpretation of sedimentation under freshwater/wetland conditions observed particularly in the presence of subaerial modifications, on the other hand the onset of maritime related modifications might have appeared coinciding with the exposure of the Late Pleistocene – Early Holocene bone assemblage in the Mid Holocene marine transgression, exposing the GNLQ1 sample to marine fouling in relatively recent times.

Middle Miocene development of the modern-like Antarctic Circumpolar Current.

The Antarctic Circumpolar Current (ACC) is a key component of Earth's climate system due to its strong influence on the global overturning circulation, ocean heat and CO_2 uptake and storage. The timing and mechanisms of the development of a homogeneous and deep circumpolar flow remain disputed, despite the critical significance of the ACC for Earth's climate. Here we present neodymium isotope and sortable silt records from two pelagic sedimentary archives in the Southwest Pacific and South Indian Ocean (DSDP 278 and ODP 744, respectively) spanning the last 31 million years (Ma). Our data demonstrate that a modern-like deep-reaching circumpolar current did not exist before the Middle Miocene. This contrasts the long-held convictions that the development of a strong, deep ACC was solely controlled by the opening and deepening of Southern Ocean gateways, and resulted in significant glaciation across the Eocene-Oligocene Transition (34 Ma). We suggest that besides tectonic pre-conditioning, the expansion of the Antarctic ice sheet and sea ice during the Middle Miocene Climate Transition played a vital role in driving intensification of Southern Westerly Winds and establishment of a deep-reaching circumpolar flow.

Middle Miocene East Antarctic Ice Sheet and Southern Ocean interactions.

The East Antarctic Ice Sheet (EAIS) underwent a major expansion during the Middle Miocene Climate Transition (~14 Million years ago (Ma)), resulting in ~60 m sea-level drop. The drivers of MMCT cooling and associated ice expansion are not fully understood, in particular the role of Southern Ocean dynamics. Here we present new data from two Middle Miocene (~15-12 Ma) marine sedimentary archives recovered offshore Prydz Bay, East Antarctica. By studying Ocean Drilling Program (ODP) Site 1165 located on the continental rise off Prydz Bay (64◦27.27° S, 67◦13.08° E, 3537.5 water depth) and ODP Site 744 located on the Southern Kerguelen Plateau (61° 34.66´S, 80° 35.43´E, 2307 m water depth), we provide new insights into the interactions between the Antarctic Circumpolar Current (ACC) and EAIS dynamics offshore Prydz Bay. Neodymium and strontium isotopic composition of Middle Miocene (~15-12 Ma) detrital sediments from ODP Sites 1165 and 744 were generated to constrain changes in sediment provenance, recording changes in ice sheet dynamics. Neodymium isotope ratios (ε_{Nd}) from fossil fish teeth from ODP Site 744 were used to trace regional water masses and ocean circulation changes for the same period. Additionally, mean sortable silt and biogenic silica records generated from both ODP sites were used to track changes the position and strength of the ACC. Overall, our results indicate that changes in the Southern Ocean played a key role in the behavior of the EAIS during the Middle Miocene.

Towards a UV-B reconstruction using FTIR spectra of Cedrus atlantica pollen; the Holocene record from Lake Sidi Ali, Morocco.

Dr. Benjamin Bell [1]***, Mr. Tianyuan Wang*** [1]***, Dr. William Fletcher*** [2]***, Dr. Johannes Schmidt*** [3]***, Prof. Christoph Zielhofer*** [4]

1. *Quaternary Environments and Geoarchaeology Research Group, Department of Geography, School of Environment, Education and Development, The University of Manchester,* ***2.*** *School of Environment, Education and Development, The University of Manchester, Manchester, United Kingdom,* ***3.*** *Institute of Geography, Leipzig University,* ***4.*** *Universitat Leipzig*

Ultraviolet-B (UV-B) radiation influences all biological life on Earth and may also influence the Earth's climate systems. Instrumental records of UV-B radiation are relatively short; thus, it is unknown how UV-B has changed over long timescales or what influence this has had. Pollen and spores which are traditionally analysed to identify changing vegetation composition, can also be used as a proxy for UV-B. Compounds within pollen that respond to UV-B radiation (Ultraviolet Absorbing Compounds, or *UACs*) are preserved within sporopollenin in sub-fossil records. These compounds can be measured using Fourier-Transform Infrared Spectroscopy (FTIR), where increased UV-B levels result in greater concentration of UACs, which opens the door towards UV-B reconstruction. We analysed the FTIR spectra of sub-fossil *Cedrus atlantica* pollen grains from a core collected from Lake Sidi Ali, Morocco, with previously published pollen and sedimentary records. Pollen grains were isolated from samples taken at a ~200-year resolution spanning ~11,000 years – no chemical treatments were used for the pollen isolation to preserve the chemical signature of the pollen. We also analysed modern *Cedrus atlantica* pollen collected from across Morocco using the same protocols as the sub-fossil pollen, to use as a modern analogue calibration for the fossil record. Preliminary analysis shows that there have been changes in UAC concentrations over the Holocene, indicating changing UV-B levels through time. However, challenges remain for full quantification of UV-B levels from FTIR spectra, including issues surrounding processing of spectra, identification and quantification of peaks, and comparisons between modern pollen and sub-fossil sporopollenin FTIR spectra. We will compare our results with the Holocene ^{10}Be-based total solar irradiance (TSI) and ^{14}C-based sunspot reconstructions, testing the hypothesis that major changes in solar activity should also be evident in the UV-B record.

Late Pleistocene cryogenic phenomena and their links with cold hydromorphic paleosols in North-Western Siberia as a key to correlate ancient environments

***Dr. Vladimir Sheinkman* [1], *Prof. Sergey Sedov* [2], *Dr. Elizabeth Solleiro-Rebolledo* [3]**

1. Institute of Environmental and Agricultural Biology, Tyumen State University, Tyumen, 2. Instituto de Geología, Universidad Nacional Autónoma de México, Mexico City, 3. National Autonomous University of Mexico

New data obtained by authors allow them to share the concept that ice sheets never occupied North-Western Siberia over the Pleistocene. It implies development of non-glacial surface processes in this region. Contrary to the south of West Siberia where continuous stratified loess mantle was developed, in North-Western Siberia the sedimentation was more heterogeneous. However it forms a complex largely controlled by permafrost factors, when horizons generated by paleocryogenic processes interacted with paleopedogenesis are spread much more uniformly. They are specific for certain chronological intervals and could serve thus as reliable stratigraphic markers for inter-regional correlation. The authors revealed several major Late Pleistocene stratigraphic levels identified and studied, and accompanied by the indicators of paleocryogenic and cryopedogenic processes in the sedimentary sequences of the high river terraces on both sides of the Siberian Uval, a highland at the right-hand Middle Ob' River's bank. The lowest level identified terrace sections yielded U/Th dates 100-120 ka BP and thus is attributed to the MIS-5 thermochron. It represents a pedocomplex in which the lower paleosol unit has micromorphological signs of clay illuviation (indicative of taiga pedogenesis) whereas the upper one consists of the peat and gleyic horizons – the product of cryohydromorphic pedogenesis. The second (intermediate) pedostratigraphic level lies above the MIS-5 level being separated by the alluvial sediments. Its paleosols have ^{14}C-dates from the soil organic materials in the range of 25-35 ka BP and thus correspond to MIS-3 thermochron. These paleosols show macro- and micromorphological features of redoximorphic processes and frost action indicative of soil development under tundra-steppe ecosystems with permafrost. The third level corresponding to the end of MIS-2 (^{14}C-dates – 10-16 ka BP) was identified in the upper parts of the high terrace sections. Pedosediments filling large polygonal ice wedge pseudomorphs present this strongly gleyed paleosol. In some profiles at least two stages of the ice polygonal wedge development were identified. We are to associate this paleosol development with the warming events at the end of MIS-2. The uppermost level represents the Holocene Podzol complex developed after the surface deposits become thawed: it occurred, according received ^{14}C-dates, 6-7 ka BP.

Investigate Late-Quaternary Meltwater Pulses through sedimentological, micropaleontological and geochemical approach: preliminary results

Climate changes and sea level rise during the next century are two of the main environmental challenges to face by the modern society. Sea level change responds to a variety of processes including ocean's thermal expansion and ice sheet melting in the polar areas. The latter have been responsible for past abrupt relative sea level rises known as meltwater pulses (MWPs) that deeply changed the Earth's physiography after Last Glacial Maximum by submerging the paleo coastal areas. MWPs are short-lived global acceleration in sea-level rise resulting from intense glacial melting, surge of large ice streams into oceans and intense iceberg discharge during ice sheet disintegration. The main concerns related to the present fast global climate changing is the possibility that sudden drastic ice loss from Greenland and/or in the West Antarctic Ice Sheet would lead to a new abrupt acceleration of the relative sea level rise with consequent inundation of vast coastal areas and/or to cause an abrupt slowdown of the Atlantic Meridional Overturning Circulation (i.e. Golledge et al., 2019). To better understand the dynamics and risks associated with the onset of past meltwater pulses, their impact on thermohaline ocean circulation and climate it is pivotal the geological study of the well preserved and most recent MWP events occurred during the Late Quaternary, particularly those occurred during the Last Glacial Termination. Here, we present some preliminary results of the sedimentological, micropaleontological and geochemical investigation of 4 sediment cores collected on the Western margin of the Svalbard archipelago, next to the Fram Strait.

Pollen productivity estimates for past land cover reconstruction in Turkey

Mrs. Esra Ergin Erdogmus [1], ***Dr. Laurent Marquer*** [2], ***Mr. Ugo Bisson*** [2], ***Dr. Florence Mazier*** [3], ***Prof. H.Nuzhet Dalfes*** [1]

Quantitative reconstructions of past land cover play an important role to assess the long-term perspectives of climate and anthropogenic land-cover changes. Pollen-based quantitative vegetation reconstructions have been a challenge since the start of palynological studies due to the non-linear relationship between pollen assemblage and the related plant abundance. Pollen-based modelling approaches have been developed to correct this non-linear relationship. In order to use such modelling approaches, one needs to get a reliable set of relative pollen productivity estimates (RPPS). RPP is one of the most critical parameters to apply quantitative pollen-based vegetation models such as REVEALS and the Landscape Reconstruction Algorithm. Most of the RPP has been done in Europe and the northern hemisphere, however, only two studies have been carried out so far in southern France and southeastern Romania for the Mediterranean plant taxa. There is a critical need to increase research about RPPs in the Mediterranean basin to get reliable past land cover and land use reconstructions for this region. Southern Anatolia is an important region for its long history of human settlements and key role in the Mediterranean culture. In order to better understand the relation between plant land cover and land use there, the present study aims at first providing a set of RPPs for Turkey and the Mediterranean region in general that can be used to run the pollen-based vegetation models.In a second step, the resulting set of RPP is used in the REVEALS model runs based on the fossil pollen records collected from Golhisar Lake in Burdur. To calculate the RPP values modern pollen data were collected from mosses and soils from 21 sites within a 50 km radius around Golhisar lake. These data have been combined with the modern regional and local vegetation maps by using the ERV model to assess the pollen and vegetation relationship. We present the first results and their applications to reconstruct past land cover and land use around Golhisar Lake over the last 18.000 years, and we further discuss what this new set of RPPs implies in terms of perspectives for future RPP studies in the Mediterranean region.

The ‘Ona Paleovalley’: A major submarine slope failure system in the southwestern Scotia Sea (Antarctica)

***Dr. Adrián López Quirós* [1], *Dr. Francisco José Lobo* [2], *Dr. Carlota Escutia* [3], *Dr. Fernando Bohoyo* [4]**

1. *Department of Stratigraphy and Paleontology, University of Granada, 18071, Granada, Spain,* ***2.*** *Instituto Andaluz de Ciencias de la Tierra (IACT), CISC-UGR, Granada, Spain,* ***3.*** *Instituto Andaluz de Ciencias de la Tierra (IACT), CSIC-UGR, Granada, Spain,* ***4.*** *CN Instituto Geologico y Minero de España (CSIC), Madrid, Spain*

The southern Scotia Sea hosts several small oceanic basins developed through continental break-up and oceanic spreading during the Cenozoic. Ona Basin is the southwestern most basin of the Scotia Sea. It is bounded by several structural highs: the Shackleton Fracture Zone to the west, Terror Bank to the east, and the South Scotia Ridge to the south. The southern part of the basin is further divided in two sub-basins (the western and eastern Ona basins) separated by the submarine relief called Ona High. The Ona Basin is mainly affected by two major water masses, the deeper branch of the Antarctic Circumpolar Current flowing eastwards and a westward flowing branch of the Weddell Sea Deep Water (WSDW). Interaction between mass movements and contouritic processes are likely to occur as a consequence of the complex geologic, physiographic and oceanographic setting. A combined approach including geomorphological, stratigraphic and seismic analyses allows us to document, for the first time, the record of repeated large-scale submarine landslides in the western Ona Basin. A major morphological feature named as *‘Ona Paleovalley’* is genetically related to large-scale Middle Pleistocene to recent mass movements. Deposition of large-scale mass transport deposits (MTDs) formed a template which guided and fostered major valley incision during the Middle Pleistocene. The valley infill records channelized depositional periods with possible development of turbidites alternating with erosive events when sediments were evacuated basinwards. This morpho-sedimentary pattern is attributed to the interplay between tectonic events leading to gravitational processes and the channelized flow of the WSDW.

Fossil pollen, spores and non-pollen palynomorphs registered in the sediments of the high-Arctic lake Tenndammen, central Svalbard

Dr. Anastasia Poliakova [1]***, Prof. Antony Brown*** [2]***, Prof. Inger Alsos*** [2]

1. *The Arctic University Museum, UiT-The Arctic University of Norway, NO-9037 Tromsø, Norway / Institute for Chemistry, University of Hamburg, Grindelallee 117, 20146 Hamburg,* ***2.*** *The Arctic University Museum of Norway, Tromsø*

High microfossil diversity of 15 spore and 56 pollen types with 60 non-pollen palynomorphs (NPPs) has been recovered from the lacustrine sediments from Tenndammen (Colesdalen, Nordenskiöld Land, Western Spitzbergen, Archipelago of Svalbard). The core Te2019 (N 78°06.118′; E 15°02.024′, altitude 5 m asl; 85 cm long and 60 mm in diameter) was obtained from the depth of ca 2 m and subsequently studied for sedimentary ancient DNA (*seda*DNA), botanical microfossil (pollen, spore, NPPs) and macrofossil (seeds and tissue fragments) as well as lithostratigraphy, XRF, LOI, grain size analysis, and portable optically stimulated luminescence (pOSL). The microfossil diversity of Te2019 core appeared unusually rich for such High Arctic area. We present 22 plates of about 400 microphotographic images in the form of an illustrated pollen and spore atlas. From the full assemblage, 23 pollen types were recognized as exotic (i.e. extra-regional, not produced in Svalbard), whilst 22 other types were sourced from regional and local vegetation of Colesdalen and Svalbard archipelago. These source plants included a high number of relatively thermophilus tundra plants, those are either only known from Colesdalen (i.e. *Betula nana*) or restricted to a few locations in Svalbard including other sites in Colesdalen (i.e. *Arnica angustifolia*, in pollen – *Arnica/Taraxacum* type; *Polemonium* (*boreale*), *Koenigia* (*islandica*), *Campanula* (*rotundifolia*), *Vaccinium* (*uliginosum*). Local pollen types of four Saxifragaceae species with clear exine sculpture are described: *Micranthes nivalis*, *Saxifraga cernua* type, *Saxifraga cespitosa* type, and *Saxifraga oppositifolia* type. For 12 pollen types (e.g. Caperaceae and Poaceae types, Ranunculus/Coptidium, Polygonaceae indet.) the source vegetation is unclear or has a mixed, regional and extra-regional origin. The 15 most common pollen types are found within the count of the first ca 30 grains, and a linear increase in pollen diversity is observed within the count of the first ca 40 grains which reaches 27 types reaching 47 types at 88-100 grains and at the count of 300 grains, only 9 additional rare pollen types were added. This study can contribute further palynological and palaeoecological investigations in Svalbard and assist to our understanding of the regional and extra-regional pollen diversity in the High Arctic.

115 years of sedimentation – a detailed analysis of reservoir sediments in the Urft Reservoir, central Europe

Dr. Georg Stauch [1]***, Mr. Alexander Esch*** [2]***, Mr. Lukas Dörwald*** [1]***, Dr. Eberhard Kümmerle*** [3]***, Dr. Simone Lechthaler*** [1]***, Prof. Frank Lehmkuhl*** [1]***, Dr. Philipp Schulte*** [1]***, Ms. Christina Schwanen*** [1]***, Dr. Janek Walk*** [1]

Reservoir sediments potentially provide detailed and continuous information on land use and land cover changes and climatic events in in the related catchment area. The Urft reservoir is located in the Eifel Mountains in western Germany and was built between 1900 and 1905. At the time of its construction, the Urft reservoir was the largest reservoir (45.51 million m^3) and drove, with 12 MW, the most powerful water storage power plant in Europe. In November 2020, the reservoir was almost completely drained for inspection work, which enabled detailed mapping and sampling of the reservoir floor and its sediments, respectively. A digital surface model (DSM) was constructed on the base of several UAS (Unoccupied Aerial System) surveys. Topographic maps with a scale of 1:1,000 from the year 1897 were used to reconstruct the valley floor prior to the flooding. By combining these two datasets, the spatial distribution of the sediment thickness accumulated over the past 115 years was assessed. Temporal information, e.g. sedimentation rates, were obtained from several sediment cores from the upper part of the reservoir. Dating of the sediments is based on a detailed Cs-137 chronology from one of the cores. An additional UAS survey was conducted following the catastrophic flooding event in the northern Eifel Mountains in summer 2021 to quantify the flood-related sedimentation by a single event.

Compared to other reservoirs in Europe, the rate of sedimentation in the Urft reservoir throughout the past century is quite homogenous and sediment inflow is relatively low. However, deposition during individual events play an important role. During the event in summer 2021 up to 30 cm were deposited in the upper part of the reservoir - an example for the punctuation of a constant sedimentation rate by a single extreme event. In addition, the anthropogenic influence on the sediments in the form of mining-induced sediment-bound contaminants and the microplastic content was analysed. Preliminary data point to at least one additional extreme inflow event in the late 1980s.

Subsurface framework of the Pozuelo Mound complex – mound architecture

Archaeological investigations rely on time and labor-intensive excavation techniques. While providing detailed information on ancient lifeways through recovered artifacts and stratigraphic information, the data recovered is very site specific, and often lacks environmental or geological context. Geophysical investigations of a site can provide insight into the possible location of additional, buried cultural deposits, as well as a site-scale context for the area and link the site to the broader setting. These approaches are not mutually exclusive. When paired, they can offer both local and regional insights.

In May and June 2022, a multidisciplinary team of archaeologists, geologists, geophysicists and geotechnical engineers spent 10 days investigating the environmental context of a low-relief, human-constructed four-mound complex south of Chincha, Peru using Electromagnetic Resonance Tomagraphy (ERT) and stratigraphic analysis. Each mound has a relief of 3-5 meters above the surrounding cultivated plain, and is arranged in a roughly N-S orientation. Previous archaeological excavations at the site date the earliest occupation to 900 BCE, with construction and occupation associated with the Paracas Culture. While the site is located in the Peruvian coastal desert, the earlier work found evidence of wetland sediments and vegetation. The focus of the current investigation was to provide a large-scale stratigraphic understanding of the mound architecture to assist in understanding the archeological context and distribution of cultural artifacts.

The team employed an ABEM Terrameter LS2 with 81 pins and spacing between 0.5 and 5 m to acquire ten lines. The results show correlation with stratigraphy reveled in archaeological unit 31 on the southern-most mound, as well as geological information provided by previous excavations. ERT data also shows evidence for a mound-within-a-mound construction in the northernmost mound, which is not observed at other mounds at the site. Supporting results show that basal units in archaeological unit 31 are regional extensive and underlie the area. This paper will present the results of ongoing data processing of data and interpretation.

Subsurface framework of the Pozuelo Mound complex – the environmental context

Prof. Allen Gontz [1]***, Ms. Caeli Connolly*** [2]***, Prof. Alice Kelly*** [3]***, Prof. Daniel Sandweiss*** [4]***, Ms. Elizabeth Leclerc*** [4]***, Mr. Edwards Alzamora Yupanqui*** [5]***, Mr. Richard Espino Huaman*** [6]***, Ms. Christine Bergmann*** [7]***, Prof. Charles Stanish*** [7]***, Prof. Henry Tantaleán*** [8]

1. *Clarkson University,* ***2.*** *School of Earth and Climate Sciences, University of Maine,* ***3.*** *Climate Change Institute, University of Maine,* ***4.*** *Department of Anthropology & Climate Change Institute, University of Maine,* ***5.*** *INGEOTECON,* ***6.*** *Universidad Nacional San Luis Gonzaga de Ica,* ***7.*** *Department of Anthropology, University of South Florida,* ***8.*** *Universidad Nacional Mayor de San Marcos*

In June 2022, a multidisciplinary team of archaeologists, geologists, geophysicists and geotechnical engineers spent 10 days investigating the environmental context of a low-relief, human-constructed four-mound complex south of Chincha, Peru using Electromagnetic Resonance Tomagraphy (ERT) and stratigraphic analysis. Each mound has a relief of 3-5 meters above the surrounding cultivated plain, and is arranged in a roughly N-S orientation. Previous archaeological excavations at the site date the earliest occupation to 900 BCE, with construction and occupation associated with the Paracas Culture. While the site is located in the Peruvian coastal desert, the earlier work found evidence of wetland sediments and vegetation. The focus of the current investigation was to provide a paleo-environmental context for occupation and mound construction, and to develop an understanding of the spatial relationships between the mound structure and the surrounding and underlying alluvial plain. A total of ten ERT lines, with a total length of approximately 600 m, were collected using an ABEM Terrameter LS2 with four cables. Stratigraphic analyses of archaeological excavation data, including a four-meter deep unit in the adjacent alluvial plain and a nearly 5-meter deep unit in the mound, served as ground truth. Surveys utilized the full capacity of the system's 81 data points. Pin spacing varied between 0.5 and 5 m, depending on the purpose of the survey and length of the survey line. Five lines were located on the southern-most mound (Mound D) to link the excavation and underlying stratigraphic information to the geophysical data. Five additional lines were acquired on the third mound to the north (Mound B) to examine subsurface mound architecture and help establish the regional subsurface stratigraphy.

Stratigraphic analyses suggest basal sediments are fine-grained, water-lain deposits overlain by a thick clay layer, overtopped by aeolian sands, with approximately a meter of mound fill at the top. Deposits underlying the mound showed evidence of liquefaction, likely the result of strong seismic shaking.

This paper will present results from the joint ERT surveys and stratigraphic analyses, and the project's effort to provide a geological and environmental context for the archaeology of the site.

Middle Dniester canyon as a refugium for Gravettian communities – case study: Doroshivtsi III site (Western Ukraine)

Prof. Maria Łanczont [1]***, Prof. Przemysław Mroczek*** [1]***, Dr. Larissa Kulakovska*** [2]***, Dr. Olesia Kononenko*** [2]***, Mr. Dariusz Bobak*** [3]***, Prof. Marta Połtowicz-Bobak*** [4]***, Mr. Karol Standzikowski*** [1]***, Dr. Vitaly Usik*** [2]***, Dr. Laëtitia Demay*** [5]***, Prof. Adam Nadachowski*** [6]***, Dr. Anna Lemanik*** [6]

1. *Maria Curie Skłodowska University, Institute of Earth and Environmental Sciences, Lublin,* ***2.*** *Institute of Archaeology, National Academy of Sciences of Ukraine, Kyiv,* ***3.*** *Foundation for Rzeszów Archaeological Centre, Rzeszów,* ***4.*** *Institute of Archaeology, University of Rzeszów,* ***5.*** *UMR 7194-Département de Préhistoire, Muséum National d'Histoire Naturelle, Paris,* ***6.*** *Institute of Systematics and Evolution of Animals, Polish Academy of Sciences, Cracow*

The Doroshivtsi III site is one of the Late Gravettian sites in the Middle Dniester valley. Our research (2019, 2021) was a continuation of the work in 2006-2010. The site is associated with a Late Pleistocene low terrace on the right bank inside the canyon, overlain by loess-like sediments. The sequence in the upper part, to a depth of ~5 m, comprises stratified, carbonate aeolian-colluvial sediments, consisting of silt, sand and clay in variable proportions and subordinate admixtures of local rock detritus in small solifluction lobes. These sediments (20-22 ka age) are poor in archaeological artefacts. Lower to about 12 m depth there are two sets of palaeosols separated by a package of periglacial stratified silty-sandy sediments. The upper set is formed by a series of thin soil horizons ranging from an incipient pedosediment to a well-developed tundra-gley type, which are overlain or separated by loess layers. Their OSL age is 24-41 ka. Artefacts occur in several levels of this part of the sequence, particularly intense in the 6.2-8.2 m interval. Few remains of small mammals were found in sediments between 5 and 8 m. The lower pedocomplex is formed by two interstadial soils. Below this is a series of slope sandy-silty sediments (~4 m) resting on channel gravels (~3 m).

Seven cultural layers were distinguished during the 2006-2012 survey; ten, much poorer – in 2019 and 2021. The data suggests that the number of layers distinguished during the older survey should be reviewed. All levels with artefacts contain numerous animal bones mainly of mammoth, reindeer and horse; a higher than expected proportion of mammoths with *in situ* deceased individuals was observed. Most of the calibrated radiocarbon dates are associated with the LGM (HS-2). Two underlying layers with artefacts were also identified, a higher possibly Gravettian and a lower indeterminate Upper Palaeolithic level. It is not easy to correlate the geological and cultural layers determined during the previous and current research.

Research carried out as part of the grant of National Science Centre, Poland (2018/31/B/HS3/03125) "Environment and culture of Gravettian and Epigravettian gatherers and hunters in the Middle Dniester valley".

Environmental and climatic changes in the Nihewan Basin, NE China, during ca. 1.7 to 0.9 Ma

Mr. Ahmed H. Moghazi [1]***, Prof. Hailong Zhao*** [2]***, Prof. Chengjun Zhang*** [3]***, Prof. Steffen Mischke*** [1]

1. *University of Iceland, Institute of Earth Sciences,* ***2.*** *College of History Culture Hebei Normal University,* ***3.*** *School of Earth Sciences & Key Laboratory of Mineral Resources in Western China Lanzhou University*

The thick Pleistocene sediment sections of Nihewan Basin in NE China are intensively studied since ca. 100 years because of its rich mammalian fossil record and abundant stone artifact-bearing layers. They provide a detailed terrestrial sediment archive for reconstructing the palaeoenvironmental changes during early times of hominin occupation in East Asia. To better understand the mechanisms underlying past climate and environmental changes in the basin, three sediment sections at the Dachangliang location were lithologically investigated at centimetre scale and sampled for the application of a multi-proxy toolbox of sedimentological, magnetic susceptibility (MS) and micropalaeontological analyses. Observable variations in grain size, colour, sedimentary structures, concentrations of magnetic minerals and the ostracod assemblage were identified. The exposed sediments are lithologically mostly relatively homogeneous, they partly include laminations of various thickness, horizontal and ripple bedding, and bioturbation features. They mainly represent varicoloured silt-sized materials of probably reworked loess deposits, partially interbedded with fine-grained sand layers and minor contributions of clay-sized particles. The partly carbonate-rich, light olive gray/pale-brown silts have MS values, whilst high MS values are recorded in yellowish-brown silts/fine-grained sands. These sediments are interpreted to have accumulated in wetlands alternating with deposition on an alluvial plain, and with a lacustrine setting which probably existed from time to time. These different depositional settings are inferred based on the quantification of three dominant grain-size components and the ostracod-assemblage changes (mostly *Limnocythere flexa*, *Ilyocypris* spp. and *Leucocythere* sp.). We correlate our sections with two proximal Palaeolithic artefact-bearing sections (Majuangou and Xiantai) with published magnetostratigraphic data. The correlation shows that our investigated sedimentary sequence was probably formed between ca. 1.7 and 0.9 Ma. The recorded ostracods of laterally apparently consistent white marl beds (dominantly *Cytherissa lacustris*) were used to stratigraphically correlate these sections. The generated long, continuous synthetic sedimentary sequence represents three main wetter periods with three intervening drier intervals, possibly coupled with interglacial (S_{24}, S_{20}, and $S_{9\text{-}1}$) and glacial (L_{24}, L_{20} and L_9) periods which were previously inferred from the palaeoclimatic records of the Chinese Loess Plateau in the southwest of the Nihewan Basin. The inferred climate cycles were probably driven by Milankovitch astronomical forcing.

Al Qawd, the first stratified profile in Duqm, south-central Oman.

Dr. Roman Garba [1], ***Dr. Matthew Meredith-Williams*** [2], ***Mr. Dominik Chlachula*** [3], ***Dr. Amir Beshkani*** [4]

1. *Archaeological Institute of the CAS Prague,* ***2.*** *La Trobe Univesity,* ***3.*** *Archaeological Institute of the CAS Brno,* ***4.*** *Musée de l'Homme*

The Late Pleistocene landscape evolution of South-eastern Arabia has important implications for modern human settlement patterns; however, these are currently under-studied and represented by a limited number of securely dated stratified archaeological sites. The region of Duqm in south-central Oman, Al-Wusta Governorate, completely lacks any dated archaeological material older than the Early Iron Age, despite an apparent wealth of visible surface lithic scatters. Here we present the region's first OSL-based chronology of a stratified sedimentary profile with in-situ lithic artefacts. The Al Qawd site is located 15km westwards (inland) from the modern port of Duqm and is in an area with high-quality chert nodules (a valuable lithic tool raw material) present throughout the landscape. The area features frequent lithic scatters of heavy bifaces and unidirectional large and heavy blades, suggesting long-term use of a uniform technology, or/and high-intensity episodes of the same lithic tool production over a short period of time. Up until now, the chronology has been based on lithic typology (there were previously no radiometric dates), with a postulated span from the Middle and Early Upper Palaeolithic, to the Holocene, based on the minimal presence of the surface patina on some artefacts. This study brings together a variety of complimentary geoarchaeological techniques on a range of scales: from broadscale remote sensing to identify landforms (and their likely chronological order), down to site level stratigraphic and dating techniques. The OSL dates from this study provide insight into the chronology of the Al Qawd lithic scatters and, therefore, the landscape evolution of this part of the Duqm region, informing on how the lithic sites fit into the broader landscape of the region. The results contribute to our knowledge of population dynamics and settlement patterns across the Arabian Peninsula during the transition from the Late Pleistocene to Holocene. The research was conducted as a joint effort of ARDUQ and LARiO expeditions in Oman.

The Roman burgus at Trebur-Astheim and its relation to the Schwarzbach/Landgraben watercourse (Hessisches Ried, Germany) – geophysical und geoarchaeological investigations

***Mrs. Elena Appel* [1], *Dr. Thomas Becker* [2], *Dr. Dennis Wilken* [3], *Dr. Lea Obrocki* [1], *Dr. Peter Fischer* [1], *Dr. Timo Willershäuser* [4], *Dr. Felix Henselowsky* [1], *Prof. Andreas Vött* [1]**

The Romans carried out early river regulation and water management in the Hessische Ried in the 1st century AD. Roman waterways enabled the transportation of troops and material and were of strategic importance to secure the territory of the Roman Empire. Small fortlets, so called burgi, were constructed along the tributaries of the River Rhein. The fortlet at Trebur-Astheim represents such a Roman military site along the Rhein-Limes. Its construction is dated to AD 364/375 and was part of the building program realized during the reign of the Emperor Valentinianus IThe archaeological site is located at the Schwarzbach/Landgraben watercourse which connects the western fringe of the Odenwald with the city of Mogonatiacum/Mainz.

Multi-method geophysical prospection was carried out at the burgus at Trebur-Astheim. We were able to trace the ground plan of the late Roman fortlet showing a rectangle building at the center with a wing wall to the northern and the southern side running towards the present riverbank. On this base, detailed geomorphological and geoarchaeological studies were carried out to clarify how the burgus was connected to the watercourse of the Landgraben/Schwarzbach, to collect information on the structure and function of the building and to establish a local geochronology.

Our results show that the burgus was constructed at the very edge of the Lower Terrace directly facing the watercourse. In front of the burgus, a semi-enclosed artificial basin was detected. Sediments prove that the burgus must have been open towards the fluvial system and that the burgus was not enclosed by a wall from the western side. Based on stratigraphic data, the protruding nose-type Lower Terrace section in between the wing walls was modelled as ramp into the burgus basin to pull vessels on the artificial river bank. There are two different burgus-related sedimentary facies, namely a lower moderate to high-energy fluvial facies right on top of Lower Terrace sands and a subsequent fluvial facies reflecting a clearly reduced flow velocity. The final phase of use of the burgus was dated to the time period 425-599 cal AD. It was thus in use for maximum ca. 235 years.

Holocene landscape reconstruction in the surroundings of the Temple of Pepi at ancient Bubastis, southeastern Nile Delta (Egypt)

Mr. Philipp Garbe [1], ***Prof. Amr Abd El-Raouf*** [2], ***Dr. Ashraf Es‑Senussi*** [3], ***Prof. Eva Lange-Athinodorou*** [4], ***Prof. Julia Meister*** [1]

1. *Physical Geography, Institute of Geography und Geology, University of Würzburg, Germany,* ***2.*** *Geophysics, Zagazig University,* ***3.*** *Ministry of Tourism and Antiquities of Egypt,* ***4.*** *Institute of Egyptology, University of Würzburg*

For temples in ancient Egypt, sacred water canals or lakes that provided water for many types of religious rites and other activities were very specific and important features. In recent years, two of these sacred water canals have been demonstrated for the Temple of Bastet in ancient Bubastis. It has now been investigated whether sacred water canals also flowed around the Temple of Pepi (2300–2250 BCE), located approximately 100m to the northwest, and whether there is a direct connection to those at the Temple of Bastet. To explore the Holocene landscape genesis of the Temple of Pepi, 15 drillings and 8 ERT measurements were carried out in the surrounding area. The results show loamy to clayey sediments in deeper sections of all drillings with a maximum thickness of 1.70m, indicating a marshy or swampy depositional environment. Based on the ceramic fragments found in these deposits, which can be roughly dated to the Old Kingdom (2850-2180 BCE), the area around the Temple of Pepi was most likely characterized by a marshy, swampy landscape during the early construction of the temple. In the course of time, this areal fell dry or was deliberately drained for its subsequent use for occupation. Regarding to the original research question, there is no evidence for a direct connection to the canals of the Temple of Bastet yet.

Humans and waters in Vix/Mont Lassois (Burgundy, France): geoarchaeological questions and methods to investigate a vital resource between opportunities and risks

Ms. Mégane Mignot [1], *Dr. Amélie Quiquerez* [1], *Prof. Jean-Pierre Garcia* [1]
1. Laboratoire ArTéHis, UMR 6298 CNRS, Université de Bourgogne, Dijon, France

The last years of archaeological research at Vix (Burgundy, France) have confirmed the exceptional character of this princely site dating from the Hallstatt period (800 BC – ca. 450 BC). Large residential buildings and oversized fortifications do not only exist on Mont Lassois, as previously established, but similar structures extend into the alluvial plain of the Seine River at the foot of the hill. These new discoveries raise important geoarchaeological questions related to the interactions between humans and the river, and beyond that between humans and water.

Water is a necessary resource for drinking, agriculture, and livestock. It can also be used for many practices (e.g. fortifications, craft productions, navigation, even religious rituals). However, these opportunities are accompanied by risks due to fluctuations in river regime: low water or drought cause stress on availability of the resource, floods or river displacement can lead to destructions. Faced with these, the adaptation and resilience of populations must be examined through interdisciplinary multi-scale methods.

This approach focuses on the Hallstatt settlement, from individual structures to the entire site and its surroundings, but diachronic occupations are also considered. Various geoarchaeological tools are deployed, including sedimentary coring (stratigraphic interpretation, macro-remains analysis, 14C dating), geophysical and geotechnical survey (electrical resistivity tomography and dynamic penetration testing), Lidar and topographic analyses, follow-up of excavations and inventory of archaeological reports. Results allow us to trace back the movements of the Seine course over time, to provide arguments for interpreting archaeological structures and water uses. By reconstructing past soil surfaces, we can also assess erosion/deposition rates and discuss the potential of preservation at different locations. Moreover, models can be proposed regarding changes in hydrological dynamics, landscape evolutions, response to hazards and consideration of water in land uses.

Buried landscapes of the Avon Valley and the Mesolithic of the Stonehenge Area.

Dr. Ben Pears* [1], Dr. Sam Hudson [1], Dr. Mike Allen [2], Prof. Charles French [3], Prof. Chris Gaffney [4], Prof. Vince Gaffney [4], Prof. David Jacques [5], Dr. Catherine Langdon [1], Dr. Julian Leyland [1], Prof. Mike Parker-Pearson [6], Prof. Rob Scaife [1], Dr. Phillip Toms [7], Dr. Chris Tomsett [1], Dr. Ulrike Werban [8], Dr. Lukas Werther [9], Prof. Christoph Zielhofer [10], Prof. Antony Brown [11]

1. *University of Southampton,* **2.** *Allen Environmental Archaeology,* **3.** *University of Cambridge,* **4.** *University of Bradford,* **5.** *University of Buckingham,* **6.** *University College London,* **7.** *University of Gloucestershire,* **8.** *Helmholtz Centre for Environmental Research, Leipzig,* **9.** *Universitat Tubingen,* **10.** *Universitat Leipzig,* **11.** *Arctic University of Tromso*

Whilst the Stonehenge landscape's iconic middle-later prehistory has recently been revealed in even greater detail and breadth, its pre-monumental environmental and archaeological history remains largely hidden. Was the Stonehenge monumental landscape, including cursuses, henges, settlement and Stonehenge itself developed in an empty landscape? What was the scale of pre-Neolithic activity, and how dynamic was the environment during the mid-later Mesolithic? Recent excavations along the River Avon at Amesbury, Wiltshire have revealed a buried potential to provide the Meso-Neo environmental context for the eastern part of the World Heritage site. This project has utilised ground-breaking methodologies including direct-push penetrometry, UAV-borne Lidar, pOSL/IRSL and sedaDNA to investigate the pre-Neolithic fluvial-terrestrial hinterland environment of the eastern part of the Stonehenge World Heritage Site (SWHS) from Durrington Walls to West Amesbury and extended the context across neighbouring catchments with confirmed Mesolithic activity and environmental potential.

Key research questions which have been addressed during this project include, how open the Mesolithic environment was, and how did the species mix change over 4000 years prior to the 3rd millennium BC? Was pine dominant, or was it decreasing in the Late Mesolithic? Is there evidence of pre-Neolithic human landscape and resource management and did this change over the course of the Early to Late Mesolithic? Was hazel managed or facilitated by human activity or related to climate and hydrology? What role did large herbivores, particularly Aurochs (*Bos primigenius*), play in the Mesolithic environment and what is their archaeological significance? Can a step-change be seen in vegetation and erosion/sedimentation in the Mesolithic-Neolithic-early Bronze Age periods and how does this relate to soil history and archaeological visibility? The answer to these questions will provide us with a much deeper contextualisation of the uniqueness and supra-regional significance of the monumentality of Stonehenge.

Shell middens as important archaeological and palaeoenvironmental archive – a case study from western Poland

Prof. Karina Apolinarska [1], ***Prof. Aldona Kurzawska*** [2]

1. *Institute of Geology, Adam Mickiewicz University, Poznań,* ***2.*** *Institute of Archaeology and Ethnology Polish Academy of Sciences, Poznań, Poland;*

Shell middens are common finds recorded at Polish archaeological sites dating from the Neolithic to Iron Age; however, very little is known about the acquisition and exploitation of mussels by prehistoric communities. An archaeological feature discovered recently at Kiekrz (western Poland) has given us a rare opportunity to conduct complex research on a representative and large sample. Our study aimed to recognize the pit's function, the shell deposit's character, its chronology, the season of shell collection and the environmental conditions that prevailed in the settlement's time. The investigations included multi-faceted analyses of archaeological finds (pottery, animal bones, and mollusc shells), charcoal remains, $\delta^{13}C$ and $\delta^{18}O$ shell composition, and ^{14}C dating. The research results indicate that shells of *Unio* were deliberately collected for food ca. 1500 cal. yr BC. They were probably harvested during late summer from the nearby lake. Then the molluscs were steamed in a kind of earth oven. Pine and oak wood from the immediate vicinity was used as firewood during the molluscs' processing. After the meal, shells were probably stored in the pit for further use.

Roman clay pits in the alluvial plain of NE Italy: from their ancient environmental impact to the geoarchaeology signature

Ms. Federica Vanzani [1], ***Prof. Alessandro Fontana*** [1], ***Dr. Giacomo Vinci*** [2], ***Prof. Anna Maria Mercuri*** [3]

1. *University of Padova - Department of Geosciences,* ***2.*** *University of Siena, Department of History and Cultural Heritage,* ***3.*** *University of Modena and Reggio Emilia, Modena, Italy*

In European alluvial plains the present topography has been strongly modified by humans and the soil is often overprinted by different diachronic activities. Recent and modern land use generally reworked multiphase archaeological traces, hampering the possibility to reconstruct past landscapes and infer ancient environmental impact. In the distal portion of the Venetian-Friulian Plain remnants of semi-natural lowland forests are present and they have not been affected by agriculture after the Roman times (i.e., since around 500 CE).
Analysis of DEMs obtained by high-resolution LiDAR data (30 pts/m^2) reveals a complex palimpsest of subtle landforms underneath the woodlands. Elsewhere, in the areas which have been deforested and turned into croplands in recent times, topography is levelled but can be reconstructed through photointerpretation of satellite images and historic aerial pictures. Our investigations recognized six large Roman sites where clay was extracted for bricks and pottery production, leaving from tens to hundreds of square clay pits. These structures were 5-15 m in length and 1-2 m in depth and they let the groundwater table to crop out, but now are generally filled. The quarried areas exploited LGM alluvial clays, and in some cases, they are located where the occurrence of a Roman furnace was unknown. The largest settlement corresponds to the craft workshop of the kilns of Carlino Chiamana, which consists of more than 300 pits, covering an area of 20 hectares. The total extent of all the excavation sites covers about 50 hectares, underlining their profound impact on the landscape. Even today, in the plains of NE Italy, beside centuriation, ancient towns and roads, clay pits areas are among the most resilient archaeological traces. Some of the clay pits are still preserved as depressions underneath the woods, while others are filled and levelled. Stratigraphic investigation was carried out on some of the pits, revealing an infill of lacustrine sediments. These consist of gyttja and peat accumulation, that are promising paleo-environmental archives for the last 2000 years. Notwithstanding, clay pits areas are prone to rapid deterioration due to modern agriculture, thus their recognition as significant archaeological features urges some actions for their preservation.

Reconstructing landscapes through lithics. Raw material acquisition strategies and prehistoric mobility in Central Italy: new data from Grotta Battifratta (RI)

Dr. Elena Carletti [1], ***Prof. Giacomo Eramo*** [2], ***Dr. Luca Forti*** [3], ***Dr. Alessandro Mancini*** [4], ***Prof. Cecilia Conati Barbaro*** [1]

1. *Department of Ancient World Studies, Sapienza University of Rome,* **2.** *Department of Earth and GeoEnvironmental Sciences, University of Bari,* **3.** *Department of Earth Sciences, University of Milan,* **4.** *Department of Earth Sciences, Sapienza University of Rome*

Throughout Prehistory, humans have adapted to the natural environment shaping their coping strategies with the ecosystem. Tracing ancient movement is a key point to detect human interactions with the environment and adaptive mechanisms. Reconstructing past human routes means, indeed, to comprehend the ancient landscape as it was known and perceived and, consequently, its exploitation.
Here, we will discuss the role of lithic data in investigating territorial behavior. Lithics are potentially informative of various aspects of ancient groups as they played an essential role during Prehistory. Siliceous rocks were diffusely exploited to produce stone artifacts and humans developed different supplying strategies to acquire raw materials. Therefore, human groups were deeply aware of the ecosystem they lived in. As a result, characterization and provenance analyses offer an interpretative tool to archaeologists to investigate connectivity and human-environment relationships, revealing to what extent humans exploited the surrounding ecosystem. These theoretical criteria have been applied through a geoarchaeological approach to the investigation of the Sabina region (northern Latium, central Italy), whose raw material sources are still unknown. Non-destructive petrographic analyses have been run on the lithic assemblage of Grotta Battifratta (RI), a cave site showing a long-term occupation from the upper Pleistocene on. The Neolithic sample suggests the exploitation of different siliceous rocks, whose variability has been analyzed using different methods with the aim of identifying raw material sources. The identification of lithic outcrops and deposits will help defining site-catchment areas, linking the site to a larger territory in order to trace spatial mobility and reconstruct the ancient landscape exploited during the Neolithic peopling of the region.

Pottery and ancient landscape: provenience analysis of Battifratta Cave materials

Dr. Emma Chiarabba [1], ***Prof. Laura Medeghini*** [1], ***Dr. Sara Capriotti*** [1], ***Dr. Nadia Marconi*** [1], ***Dr. Luca Forti*** [2], ***Dr. Alessandro Mancini*** [3], ***Prof. Cecilia Conati Barbaro*** [1]

1. University of Rome Sapienza, 2. Department of Earth Sciences, University of Milan, 3. Department of Earth Sciences, Sapienza University of Rome

The relationship between nature and humans in the past is closely linked and complex. The reconstruction of the ancient landscape is essential to understanding human behaviour as the environment has always played a key role in shaping human choices. Integrated approaches to analysing the material culture can reveal further information to understand past environmental change and human choices. In recent years, archaeology has employed interdisciplinary methodologies following geoarchaeological approaches. These approaches significantly enhance the potential of research focused on reconstructing the landscape and the natural resources exploited. In this framework, characterisation analyses can reveal the origin of raw materials and technology. Studies on pottery and clay are strategic as they connect the ancient landscape to raw material sources, production areas and archaeological sites. A good example is Battifratta Cave, a prehistoric site of the Sabina region (northern Latium, Italy) containing Neolithic and Bronze Age pottery. Petrographic analyses in thin sections and FTIR analyses have been performed on archaeological and geological samples to detect the clay sources exploited during the Neolithic. Our ultimate goal is to understand the provenance of the clay used for ceramic production and to discuss prehistoric mobility in the Sabina region.

The sedimentary record of the oldest Roman artificial basin

Portus, the maritime harbor of ancient Rome, is a complex port composed of basins and channels connecting the harbor to the city of Rome via the Tiber River. The still existing iconic hexagonal basin, built under the emperor Trajan (AD 110-112), hosts a unique sedimentary archive of man-environment interactions. Through multidisciplinary investigations involving dating methods, sedimentology, palynology, micropaleontology (ostracods, foraminifers and dinoflagellates) and paleomagnetism we analyzed the environmental changes of the last 3000 years in the area of Rome. We identified a lagoon pre-existing the port and a series of subsequent events starting with the excavation of the Trajan harbor and its opening both to the Tiber River and to the sea. We also characterized the water depth of the basin, the salinity changes, the landscape modifications and the history of the abandonment of the harbor. Anthropocene records are often a conundrum where natural and human forcings blend and are difficult to disentangle. Ancient harbors are precious archives of human-environment interaction. Dating harbor deposits and correlating their stratigraphy are major challenges because of potentially high sedimentation rates over short periods of time, possible dredging events, and location in marginal marine environments. Only the integration of direct and indirect dating methods with the information from historical documentation and the paleoenvironmental data has allowed to reconstruct the complex fluvio-deltaic sedimentary succession of the Trajan harbor where anthropic disturbance ruled for at least two millennia.

The role of pollen and non-pollen palynomorphs in the interpretation of the Neolithic site „Gorjani-Topole“ (Eastern Croatia)

Prof. Dario Hruševar [1], *Dr. Koraljka Bakrač* [2], *Prof. BOŽENA MITIĆ* [1], *Prof. Rajna Šošić-Klindžić* [3]

1. *University of Zagreb, Faculty of Science, Department of Biology,* **2.** *Croatian Geological Survey, Department of Geology,* **3.** *University of Zagreb, Faculty of Humanities and Social Sciences*

The main goal of our work is to understand the social dynamic in the late Neolithic Slavonia (Eastern Croatia) through computational simulations and the development of cultural and natural relations by using archaeological, biological, geological and sociological data. This multiproxy approach, which we implement through the MOPRENS project (https://croris.hr/projekti/projekt/4518?lang=en), should guarantee notable results in the interpretation of the natural and cultural basis of the „junction area“ between Central Europe and Balkan. Geobiological contribution to the project is primarily based on the palynomorphs analysis. However, pollen and plant spores used in the reconstruction or agricultural activities or the interpretation of vegetation changes are usually poorly preserved in archaeological terrestrial environments. In such circumstances non-pollen palynomorphs (NPPs) like fungal spores, algae cysts, amoeba, eggs of parasitic animals, etc. can be of significant importance. However, the limitations in the ecological interpretation of the NPPs, as well as the possibility of determining numerous different microfossils still represent an insurmountable challenge, but important strides have been made in recent decades. In this sense, the preliminary analysed samples from Slavonia, dominated by *Pseudoschizaea*, and accompanied by a low pollen richness, confirms the poor preservation conditions, as well as erosive processes caused by either drying or fires. Others samples, like those in which amoebae were noticed, complemented by the appearance of probably algae (eg. HdV-225, HdV-984, HdV-989), indicates wetter and more oligotrophic conditions. Simultaneously, better preservation conditions in some samples, marked by moisture indicators, result in a greater occurrence of pollen and plant spores. Such conditions contributed to the preservation of cereal pollen, among others, and *Epicoccum* fungi, which confirm agricultural activities of Neolithic communities. Although the preliminary analysed samples are poor in palynomorphs, and they don’t reach statistical minimum of 300 pollen grains, NPPs shed light on the hydrological regime (fungi vs. algae as indicators of moisture vs. drought), trophic state (eg. *Assulina muscorum*), erosion/desiccation (eg. HdV-200, UAB-7, UAB-48, *Pseudoschizaea*) or human influence (eg. HdV-351 and probably *Epicoccum*). By continuing this research, the pollen/NPPs spectrum will certainly improve our understanding of natural and human-induced changes during the Neolithic in the broader Danube area.

Reconstruction of Roman age land cover in Pannonia (Western Hungary) using pollen, anthracological, carpological and GIS studies

Mr. Máté Róbert Merkl [1], ***Dr. Gábor Csüllög*** [2], ***Dr. Gabriella Darabos*** [2], ***Dr. Robert-Csaba Begy*** [3], ***Dr. Andrea Zsigmond*** [4], ***Mrs. Orsolya Csirke*** [5], ***Mr. Loránd Olivér Kovács*** [6], ***Mr. István Molnár*** [7], ***Dr. Ákos Bede-Fazekas*** [2], ***Prof. Enikő Magyari*** [2]

The Romans conquered Pannonia (Western Hungary, EC Europe) between 13 and 8 BC. By the 2nd century the area around Lake Balaton had been romanized through settlements. We can reconstruct quantitatively how land cover has changed through the Roman age, and how arable grazed land enlarged by pollen analyis of large lake sediments, in this case our target is Lake Balaton, from where three 60-cm sediment cores were obtained from 2-4-6 km distance from tis northern shore. Dated by 210Pb, 127Cs and AMS 14C, two of theses sediment have been studied for pollen, macro and micro elemental changes and sedimentary chlorophyll. For the land cover reconstruction we used the LRA-Reveals (Landscape Reconstruction Algorithm) model, which estimates the true vegetation distribution from the pollen distribution, taking into account basin size, pollen productivity and fall-speed of the pollen types. These reconstructions are supplemented with the carpological and wood charcoal records of farm sites (Balatonlelle, Balatonfőkajár, 2-3rd century), a granary (Szabadbattyán, 4rd century) and the roman town Tác-Gorsium (2-5rd century). Plant remains come from various archaeological objects. Among the carpological findings, we found the largest number of cereals and we also observed traces of cultivation in the area around the settlements. In Balatonfőkajár, more than 90 % of the carpological finds were cereals, of which one percent were Triticum aestivum. At Szabadbattyán and Tác-Gorsium, 28 % of the more than 10,000 remains were Triticum aestivum, Secale cereale 10 %, and Hordeum vulgare 7 %. At the Balatonlelle site, the cereal species identified in the highest proportion was Panicum miliaceum, accounting for 31 % of the carpological finds. Based on our observations so far, oak-wood dominates the anthracological findings, which may show the effect of human selection. With our macro botanical study we determine the nature of the environment and land use of the sites, we also deal with the similarities and differences of the land use in Roman times. We process, evaluate and present the data with the ArcGIS GIS tool and software, generalized to different coverage categories.

Luminescence Chronology of reticulated laterite in humid subtropical mountains of South China

Dr. JIANHUI JIN [1]

1. School of Geographical Sciences, Fujian Normal University

Laterite is a red weathering crust developed with various rocks and Quaternary loose sediments as its parent material in the tropics and subtropics regions of the world, and it is also the most widely distributed Quaternary earthy accumulation in China. Since the 1930s, most researchers have believed that the fluvial reticulated laterite in southern China was influenced by the warm and humid climate of the Middle Pleistocene. In recent years, the remains of Paleolithic human activities are often found in the reticulated laterite of southern China. However, the study of laterite chronology is sporadic or there is no critical chronological analysis, which causes uncertainty in the identification and discussion of the ages of reticulated laterite and Paleolithic sites in South China. In this study, a paleolithic site found in fluvial reticulated laterite in South China was systematically tested by quartz optical luminescence dating and geomorphic process analysis. The results show that, (1) The T_3 terrace, an archive of hominin activity in the study area, primarily formed between 56 and 11 ka. (2) Reticulated laterite cannot be used simply to determine the ages of the Paleolithic sites found in this stratum, and typical reticulated laterite cannot be used as a marker for climatic stratigraphy and chronostratigraphy. The formation time of the reticulated laterite varied significantly between different sedimentary facies. The fluvial reticulated laterite in the southern tropics, under suitable hydrothermal conditions, can form within tens of thousands of years or even within 10 ka. (3) Human activities can affect the burial age of reticulated red soil, and the temporal nature of riverine terraces can also lead to an inversion in the age of reticulated red soil.

Late Pleistocene artists in caves: the figurative portable art of Grotta Romanelli (Southern Italy)

Dr. Dario Sigari [1]***, Prof. Marco Brandano*** [2]***, Dr. Jacopo Conti*** [3]***, Dr. Luca Forti*** [4]***, Mr. Giorgio Lai*** [5]***, Dr. Ilaria Mazzini*** [6]***, Dr. Beniamino Mecozzi*** [7]***, Prof. Pierluigi Pieruccini*** [8]***, Prof. Raffaele Sardella*** [9]

With more than 200 decorated objects made on stone and bone, Romanelli Cave has one of the richest records of Palaeolithic portable art of Italy. However, this incredible heritage is only partially edited and the last systematic research work dates back to more than fifty years.

Thanks to the resumption of the investigation activities in the cave, new attention has been rekindled to the study of the portable art objects found in previous historical excavations and dispersed among several institutions in Italy, and the newly discovered engraved objects, which provide crucial information having a precise stratigraphic position.

The decorated objects reveal a variety of raw materials (stone and bone), and diversities in the represented themes (zoomorphic, geometric, anthropomorphic), and decorating techniques (scratching with different tools and or points, and painting). According to the reports from the old excavations, they were found in the uppermost stratigraphic units filling the cave (ISU5), containing Upper Palaeolithic lithic and bone tools, and numerous faunal remains, and recently dated between 13.6 cal ka BP and 11.4 cal ka BP.

At this stage of the research, we selected the rock fragments decorated with figurative themes (zoomorphic and anthropomorphic subjects), analysing: a) the style of the figures and their technological features to investigate changes over time; b) their stratigraphic setting and related chronology; c) the lithology and petrology of the raw material to understand its origin in terms of source-area and the post- or pre-burial weathering processes. The palaeontological analysis supplies further supporting data to identify the animal figures, giving possible connections between the environment surrounding the site and the graphic production. Finally, comparisons with Late Pleistocene portable and parietal art from other Mediterranean sites provide the essential information to propose potential cultural connections at large scale.

A new 270,000 year pollen and charcoal record reveals more than 40,000 years of human landscape modification in Tasmania, Australia

Prof. Michael Fletcher [1], ***Dr. Agathe Lise-Pronovost*** [2], ***Dr. William Henriquez*** [2], ***Dr. Michela Mariani*** [3], ***Dr. Feli Hopf*** [4]

1. *University of Melbourne,* ***2.*** *School of Geography, Earth and Atmospheric Sciences, The University of Melbourne,* ***3.*** *University of Nottingham,* ***4.*** *Australian National University*

The southwest Tasmanian "Wilderness" World Heritage Area is home to what is often considered an ecological paradox: the dominance by a flammable plant community in a cool and wet landscape that "should" host rainforest. This anomaly is understood as the product of burning by Palawa (Aboriginal Tasmanians), yet debate surround the longevity of landscape modification by Palawa people. Here, we explore a new 270,000 year archive of vegetation and fire changes in this region. The data demonstrates a radical landscape transformation immediately following the arrival of Palawa to Tasmania ca. 40,000 years ago. This talk will unpack this exceptional archive in the context of human influence on the earth system and how knowledge of the origin of contemporary landscapes is essential for sustainable management moving forward.

Rupestrian trail: activation of the economy through paleontology and archeology in the northern region of the Mato Grosso do Sul state (Brazil)

Dr. Edna Facincani [1]***, Dr. Lia Raquel Toledo Brambilla Gasques*** [1]***, Dr. Ivo Leite*** [1]***, Dr. Laura Roseli Pael Duarte*** [1]***, Dr. Thiago Marinho*** [2]***, Dr. Carlos Eduardo da Costa Campos*** [1]***, Dr. Sandra Garcia Gabas*** [1]***, Dr. Deusana Maria da Costa Machado*** [3]***, Dr. André Luís Ramos Soares*** [4]

1. *Universidade Federal de Mato Grosso do Sul,* **2.** *Universidade Federal do Triangulo,* **3.** *Universidade Federal do Estado do Rio de Janeiro,* **4.** *Universidade Federal de Santa Maria*

This work aims creating social innovation and sustainable development through the bioeconomy. We seek to induce the citizens and tourists of Mato Grosso do Sul state in the learning of cultural processes and economic circulation, by using archaeological and paleontological remains. Starting from Heritage Education, teaching and learning can be streamlined and expanded far beyond the school environment. Including the community in this process will allow students and other members of the community to discover places, stories, objects, monuments and traditions that were or are important to their history. The paleontological, prehistoric and historical heritage and the environment in which it is inserted offer opportunities to arouse in students, teachers, civil servants, merchants and tour guides feelings of surprise and curiosity, leading them to learn about what a cultural and heritage asset is and to understand that popularizing this knowledge will generate income. From this route, products and services may be generated, strengthening the bioeconomy of the regions involved. In the study area, the paleontological Devonian sites and the archaeological data with up to 12,000 dates provide a unique experience. It is a return to the past, the reconstruction of our ancestors' daily lives and the historical and cultural knowledge provided by fossils (mainly bivalves and trilobites), artifacts, engravings and cave paintings that make archaeological tourism a different and surprising option for tourists. This type of tourist activity can promote contact with the culture of ancient peoples, which allows the tourist to be closer to the Past and provides means of livelihood through marketable generated products, knowledge and involvement of the local citizen. Other UFMS research will also compose this work to activate the bioeconomy, such as: the ceramic axis, whose ceramics are produced along with local cave paintings; the food axis; the chemical-pharmaceutical and botanical axis, that disseminate recipes with plants and fruits from the biomes of Cerrado and Pantanal, both for consumption and for products manufacture. Thus, joining research from different areas produced by UFMS intends to activate the economy of non-industrialized cities which are rich in paleontological fossils and archaeological sites.

Pre-Maori settlement in New Zealand: evidence from Lake Pupuke sediment record through fecal biomarkers and geochemical approach

Mr. Ronald Lloren [1], *Dr. Elena Argiriadis* [2], *Dr. Paul Augustinus* [3], *Prof. Nathalie Dubois* [4]

1. ETH Zurich, Department of Earth Science and Eawag, Department of Surface Waters - Research & Management, 2. Institute of Polar Sciences CNR-ISP, Venice, Italy, Department of Environmental Sciences, Informatics and Statistics, Ca' Foscari University of Venice, 3. University of Auckland, 4. EAWAG

Archaeological records suggest that Maori arrived in New Zealand around 700 to 800 cal BP. Their settlement brought tremendous environment and landscape modifications in the island in place for their horticulture and pasture practices. However, Maori oral traditions imply otherwise; suggesting Iwis, different Maori tribes, could have arrived 3 to 4 generations earlier than expected.

In this study we present downcore fecal sterol coupled with XRF (Ti) and magnetic susceptibility data, TOC, $\delta^{15}N$ and $\delta^{13}C$, in Lake Pupuke, in the North Island of New Zealand spanning 1871 cal yr BP. Fecal sterols (5β-coprostanol + 5β-epicoprostanol) are found in human wastes and are widely used as tracers for prehistoric human presence. Ti and magnetic susceptibility data are used as proxy for terrigenous input and/or erosion. While TOC, $\delta^{15}N$ and $\delta^{13}C$ could be indicative of changes in carbon source.

Downcore coprostanol and epicoprostanol showed peaks at ~700 cal yr BP, which is known to be the Maori arrival. Interestingly, presence of coprostanol and epicoprostanol showed comparable peaks/concentrations at around ~1300 cal yr BP: 500 to 600 years before the known Maori arrival. TOC/CN indicate an overall decreasing trend from 1300 cal yr BP to present, indicative of increasing lake productivity. Magnetic susceptibility and Ti data were constant from 1800 up 700 cal yr BP. Its trend only started to increase just after the coprostanol and epicoprostanol peaks around 700 cal yr BP.

The fecal markers peaking at around 1300 cal yr BP could imply early human presence in the area in concurrence to Maori oral traditions. Geochemical data observed in the sediment record indicate different signals in comparison to the pre and known Maori fecal sterol peaks, proposing that the Iwis arrived in the area could have different approaches in terms of landscape and environment modifications.

Human-environment interactions in Central Queensland from the Pleistocene to the Holocene

Ms. Seadin Gallagher [1]

1. The University of Queensland

The palaeoenvironments of Australia have changed considerably through the Pleistocene and Holocene. Indigenous Australians not only adapted to these changes, but have in turn modified and managed their environment to maintain ecosystems and enhance their subsistence economies. Detailed palaeoenvironmental records are vital for understanding this relationship, but in many regions of Australia such records are currently lacking. This paper presents a new 50,000 year record from Abercorn Springs in Central Queensland. The 5 m-deep core provides the oldest palaeoenvironmental record for the region and fills a critical gap between eastern Australia's tropical north and temperate south, which have been much more extensively studied. Using a multi-proxy approach including pollen, phytoliths, charcoal, and XRF analyses, this presentation explores the relationships between humans, fire, and the environment. Several charcoal peaks throughout the core appear to demonstrate continued human interactions with the landscape, with fire being used to create a more open environment and maintain grasslands, starting from c. 40,000 BP. An extended dry period appears to match with propositions of an extended Last Glacial Maximum (LGM), dating to c. 30,000 BP. Post-LGM, the site continues an overall drying trend, transitioning from a lake to a wetland. Environmental variability is high throughout, with broad trends including a decrease in Restionaceae and *Casuarina*, an increase in pteridophytes, Poaceae, and Myrtaceae, and a constant presence of Asteraceae. There is a marked difference in the record post European contact, likely due to the cessation of Indigenous fire management, the introduction of grazing animals, and the extraction of water from the spring. Not only does this site provide an environmental framework in which to situate the regional archaeological record, but it also demonstrates human agency on the environment and how this relationship has changed through time including through drastic changes in climate such as the LGM.

Vegetation shifts in the rain forest of Central Africa during the Pleistocene-Holocene transition period: preliminary pollen and isotopic evidences from Lake Nguengue, Central African Republic.

Dr. Olugbenga Alebiosu [1], ***Dr. Vincent Montade*** [2], ***Dr. Laurent Bremond*** [2], ***Dr. Olga Yongo*** [3], ***Dr. Charly Favier*** [2]

1. 1Institut des Sciences de l'Evolution (ISEM), University of Montpellier, Montpellier, France, 2. ISEM, University Montpellier, 3. 3Laboratoire de Biodiversité Végétale et Fongique, Faculté des Sciences, Université de Bangui, BP 908, Central African Republic

Tropical rain forests are generally crucial for conservation of biodiversity and earth's biogeochemical cycles. Forest loss due to anthropogenic activities and/or global warming, is undoubtedly a common source of economic, societal and environmental disasters, hence protection of rainforest and its resources, is very critical to mankind. There is also need to understand dynamics of rainforest responses to environmental changes in order to examine their vulnerability and resilience. However, forest dynamics are often gradual and complex processes, hence they are difficult to understand based on only short-term experiments. There is yet a rarity in the availability of continuous records before the beginning of a notable Holocene anthropic influence in Central African lowlands. To provide data over long timescales, this research study aimed at reconstructing vegetation in response to past climatic change in the last 20,000 years in Central African Republic. In the current study, we collected sub-sediment samples from a core at Lake Nguengue, situated towards the northern edge of the Central Africa Republic forest. Pollen, charcoal and isotopic records provided preliminary data, revealing vegetation shifts during the Pleistocene-Holocene transition. From ca. 20,000 years ago in the Pleistocene, there was a persistent establishment of a dry savanna grassland, although it fluctuated in its extent. This continued until 12,000 years ago when rainforest started appearing gradually and climate became relatively more humid, contemporaneous of the African Humid Period. Forest later reached its peak during the Holocene within a typically wet condition and dominated. Although it still dominated the landscape, even after the African Humid Period (5,000 years ago), some fluctuations in the extent of forest, seems to have occurred from the mid- to late Holocene. Based on charcoal analyses, human impact is visible only from the last millennium and it seems to have begun at a later period when compared to other study sites in the region. These outcomes consequently justify that the low elevation study site, is a reliable locus in understanding the dynamics of rain forest responses to past climate change during the mid- to late Holocene transition.

Intensification of rice farming and its environmental consequences recorded in a Liangzhu reservoir, China

Dr. Xiujia Huan [1]

1. Institute of Geology and Geophysics, Chinese Academy of Sciences, Key Laboratory of Cenozoic Geology and Environment

The origin and subsequent development of rice agriculture enabled humans to transition from hunter-gatherers to farmers, thereby profoundly changing human society. However, less attention is focused on when and how rice cultivation practices began to alter the landscape. In this study, sediment from the reservoir inside the Mifenglong dam, Liangzhu hydraulic system was sampled. Accelerator mass spectrometry (AMS) radiocarbon dating and optically stimulated luminescence (OSL) dating results revealed that the duration of the Mifenglong reservoir ranged from 4,900 cal BP to 1,500 cal BP. The results showed that between 2,500 cal BP and 1,500 cal BP, intensive rice farming practices transformed the surrounding vegetation and landscapes through deforestation and changes in herbaceous plant structure. This study provides an insight into the impact of human activities and how they influenced the environment on a local scale, as well as contributing to a deeper understanding of the relationships between agricultural development and landscape changes.

Impact of modern-day landscape activities on the Palaeolithic record of central Narmada Valley, Madhya Pradesh (India)

Dr. Vivek Singh [1]

1. Indian Institute of Science Education and Research, Mohali

In the past, different hominin populations targeted diverse rock types (e.g., quartzite, basalt, limestone, flint) to produce lithic artefacts throughout the prehistoric period. The choice in procurement was based on a range of attributes, including manufacturing potential, technological requirements, intended activity, strength, durability, availability, etc. In the present day, construction is an unavoidable part of development, which is reflected in the expansion of human settlements, giving rise to enhanced mining and quarrying activities for the recovery of various rocks as basic raw materials. Numerous archaeological discoveries have been made across the globe as a result of various extraction and/or construction ventures. Similar trends can also be noted in different regions in the central Narmada Valley, Madhya Pradesh. The present research shows how mining activities within the Narmada floodplain and foothills of the Vindhyan Range have resulted in the exposure of new Palaeolithic deposits. It demonstrates how modern landscape modifications to both surface and sub-subsurface deposits need our constant attention to make sure that appropriate recording of archaeological remains is conducted. This research also illustrates how mining and construction in the central Narmada Valley impact the Palaeolithic record in both positive and negative ways.

Natural environmental change and its impact on early Late Paleolithic people in the northeast central Korean Peninsula during MIS 3 (40–30 cal ka)

Dr. Sangheon Yi [1]***, Prof. Chang-Gyun Han*** [2]***, Dr. Keun-Chang Oh*** [3]***, Prof. Taesop Cho*** [2]***, Dr. Jaesoo Lim*** [4]

1. *Korea Institute of Geoscience and Mineral Resoiurces,* ***2.*** *Yonsei University Museum,* ***3.*** *Quaternary and Paleoenvironment Research,* ***4.*** *Korea Institute of Geoscience and Mineral Resources*

We comprehensively analyzed sediments obtained from an archaeological excavation. A trench sediment profile of Maedun Cave, South Korea, was analyzed geoarchaeologically. Multi-proxy analyses (palynomorphs, grain size, magnetic susceptibility, animal bones, and artifacts) reflected the vegetation, hydroclimate, and lives of prehistoric people at MIS 3 (ca. 40–30 cal ka) in the early Late Paleolithic. The palynoflora consisted of pollen and non-pollen palynomorphs. Under the air-circulation system in the cave, anemophilous pollen flowed in during the day, whereas water-borne pollen and spores, and freshwater algae, were transported by flooding during the summer monsoon rainy season. Mixed conifer and deciduous broad-leaved forest with an understory of pteridophytes flourished around the northeast central Korean Peninsula during MIS 3. Freshwater algae and grass pollen records may reflect precipitation intensity. It is assumed that they had flowed in during flooding caused by high precipitation during the enhanced East Asian summer monsoon, corresponding to Dansgaard–Oeschger events 5 and 8 of $\delta^{18}O$ GISP2 and Hulu Cave. The prehistoric people hunted herbivorous animals in the area around Maedun Cave and sheltered inside it seasonally. They also used the grains of oats growing near the dwelling as a source of food.

New luminescence dates from Middle Stone Age of Bargny 3 site (Senegal) and its implications for the human occupations in West Africa

Dr. Eslem Ben Arous [1], ***Dr. Khady Niang*** [1], ***Dr. James Blinkhorn*** [1], ***Prof. Eleanor Scerri*** [1], ***Mrs. Miren Del Val*** [2], ***Dr. Alicia Medialdea*** [2]

1. *Max Planck Institute for Geoanthropology,* ***2.*** *Centro Nacional de Investigación sobre la Evolución Humana*

The Middle Stone Age (MSA) is the major chrono-cultural phase associated with *Homo sapiens* emergence and evolution in Africa. In South and North Africa, the MSA sites mostly associated with evidence of exploitation of marine resources and advanced cognitive hallmarks are located in coastal area. These sites are questioning the importance of coastal zone as probable corridors for human expansion throughout the African continent. However, due to the scarcity of chronological data, the question of MSA human occupation in the West Africa coast has not been studied in depth. Over the last decade, some archaeological surveys have uncovered a few coastal MSA sites. The Bargny quarries are known since the 40's and were considered complex surface sites. Archaeological surveys led in 2018 and 2021 allowed to discover *in situ* sequence of Bargny 3 (BG3) located in the coastal village of Bargny (Senegal). The archaeological sequence consists of 5 sedimentary horizons. The lower unit, characterized by orange silty sand, is associated with more than 1800 lithics artefacts made from chert: their preliminary technological study reveals classic MSA technologies, including Levallois, discoidal cores associated with a large number of flakes rarely retouched. The archaeological artefacts and evidence of human occupations are absent from the following two units. Then, the uppermost two units attest to the protohistoric presence in this area.

The six samples collected from the BG3 site were dated using the Optically Stimulated Luminescence following the single aliquot regenerative dose (SAR) protocol at CENIEH. Samples were measured on 2 mm multigrain quartz aliquots. Our preliminary OSL ages from the lowest unit demonstrate for the first time the presence of an MSA in coastal West Africa during the MIS 5 and its contemporaneity with the age of the Ravin Blanc I, the oldest MSA site known until today in West Africa. From a multi-method chronological perspective, Electron Spin Resonance (ESR) dating of optically quartz grains is planned for the MSA unit of BG3.

Soil carbonate U-Th ages from the stone tool-bearing PC5 paleosol of the Lakhuti loess section, Tajikistan

Ms. Ramona Schneider [1]***, Dr. László Palcsu*** [2]***, Dr. Thomas Stevens*** [1]***, Dr. Gábor Újvári*** [3]

1. *Department of Earth Sciences, Uppsala University,* ***2.*** *Isotope Climatology and Environmental Research Centre, Institute for Nuclear Research,* ***3.*** *Centre for Astronomy and Earth Sciences, Institute for Geological and Geochemical Research, Eötvös Loránd Research Network*

Migration routes through Central Asia (CA) were key to the expansion of humans from Africa to Asia. Indeed, stone tools are often found in the thick wind-blown dust (loess) deposits and interbedded paleosols, particularly in Tajikistan. These dust deposits can be tens of meters thick and have accumulated continuously over the last 2-3 million years. Large numbers of stone tools are found in some of the ancient soil layers. These generally represent warmer, wetter interglacial periods that were more favourable for human occupation. To understand the history of human activity recorded in these deposits we need to know exactly when the sediment was deposited, and what the past climate and environment was like. As such, here we present the first results of U-Th dating of a soil carbonate from the stone tool-bearing PC5 paleosol at the Lakhuti archeological site, which has previously been correlated with Marine Isotope Stage (MIS) 13. The dated, uniquely whitish-coloured soil nodule was recovered from the PC5 soil at a depth of 1.05 m (from upper paleosol boundary) in October 2021 during a field campaign of the THOCA project (www.thoca.org). The half-cut soil carbonate showed a compact, micritic internal structure with relatively low detrital contamination. Geochemical analyses revealed high ^{238}U (55.8-60.6 ppm) and relatively low ^{232}Th concentrations (0.42-0.44 ppm) in this secondary carbonate, making it an ideal target for U-Th age determination. The corrected $^{230}Th/^{234}U$ ages of the soil carbonate are 349,611±9549 and 369,684±10493 years, close to the MIS 11/10 boundary. These preliminary data suggest that PC5 soil formation and human activity in the region may be related to the MIS 11 interglacial period, roughly 400 thousands years ago, rather than MIS 13.

Establishing a robust chronology for faunal and human evolution in the middle Atbara Valley, Sudan

Dr. Sumiko Tsukamoto [1]***, Dr. Robert Bussert*** [2]***, Dr. Anne Delagnes*** [3]***, Dr. Brian Kraatz*** [4]***, Dr. Khalafallah Salih*** [5]***, Dr. Ali Eisawi*** [5]***, Dr. Faysal Bibi*** [6]

Fluvial sediments of the middle Atbara River, one of the major tributaries of the Nile, in eastern Sudan contain abundant vertebrate fossils and stone tools. From our field investigations between 2018 and 2022, fossils of over 700 specimens, including hominins attributable to Middle Pleistocene Homo, and Acheulean lithic assemblages have been found in the Butana Bridge Synthem (BBS) and the Khashm El Girba Synthem (KGS) in four areas – Al Sharafa, Al Shahateb, Tomat, and Wad Hedi stretching ~100 km along the Atbara River valley. In order to correlate the fluvial strata at these different locations and to establish a robust chronology of the fossil and lithic assemblages, high density optically stimulated luminescence (OSL) dating of sediments as well as radiocarbon and ^{230}Th/U dating of shells and bones were conducted. Both quartz and feldspar minerals were used for OSL dating. For feldspar OSL, the pulsed IR stimulation at low temperatures was adopted to make use of good bleachability and stability of the signal. Furthermore, stringent quality-check criteria were introduced for screening radiocarbon and ^{230}Th/U ages. After the screening, the ages obtained from different dating methods were consistent, and revealed a quasi-continuous aggradation of the fluvial sediments between ~250 and ~15 ka. The sediments with in-situ Acheulean stone tools were dated to ~220-140 ka, indicating the later persistence of Early Stone Age in the Middle Atbara area, compared to the other parts of Africa.

The last 1 Ma record from the fluvial terraces system of the River Somme Valley (Northern France) and the background of the earliest Acheulean occupation of Northwestern Europe

Following the discovery at the end of the 19th century of the famous Palaeolithic sites of Abbeville "Moulin-Quignon" and Amiens "Saint-Acheul" (type-site of the Acheulean), the River Somme valley has been for a long time recognized as the "cradle of Prehistory" in Europe. It is also the place where the first approach combining geology and prehistory, known as "archaeogeology", was conceptualised by Boucher de Perthes (1850). Modern research or "geoarchaeology", combining geology, geomorphology, sedimentology, pedology, palaeontology and archaeology was later developed in the valley, especially during the pioneering works by Bourdier in the 1970s. During the last 30 years, the study of the Quaternary sequences of the Somme basin, coupled with the development of absolute dating methods (ESR on fluvial quartz, ESR/U-series on large mammal teeth, TIMS U-series on calcareous tufa, OSL on sediment and TL on heated flints), has made the Somme terrace system an international reference for both Pleistocene geology and archaeology. It is presently one of the best locations in Europe for the evidencing of the response of river systems to glacial-interglacial climatic cycles during the last Ma. This system, fully incised in the Cretaceous bedrock, is made up of 10 stepped alluvial formations spread over 55 m of relative altitude. The resulting fluvial staircase is covered by thick slope deposits (loess-palaeosol sequences up to 8 m thick), the complexity of which increases with the age of the underlying fluvial sequence. Researches are completed by investigations undertaken on the present valley infilling in which systematic radiocarbon dating allows an accurate correlation between the various units of the morpho-sedimentary sequence and climatic events during the last Glacial-Interglacial cycle. Recent discoveries such as the Gravettian site of Amiens-Renancourt (2013) or the rediscovery of the emblematic Acheulean site of Abbeville Moulin Quignon now dated ca 670 ka (2016) have reinforced the importance of the Somme valley in current researches. This work is thus a fundamental and still evolving contribution to the study of the relationship between Europe's earliest human settlements and climatic and environmental variations and new investigations are planned for 2023 in the frame of the "Lateurope" ERC project.

Multi-method dating reveals 200 ka of Middle Palaeolithic occupation at Maras rock shelter, Rhone Valley, France

***Dr. Maïlys Richard* [1], Mrs. Miren Del Val [2], Dr. Helen Fewlass [3], Prof. Jean-Jacques Hublin [3], Dr. Marie-Hélène Moncel [4]**

***1.** Université Bordeaux Montaigne, UMR 6034, Archéosciences-Bordeaux, **2.** Centro Nacional de Investigación sobre la Evolución Humana, **3.** Max Planck Institute for Evolutionary Anthropology – Department of Human Evolution, Leipzig, Germany., **4.** Muséum National d'Histoire Naturelle*

The Maras rock shelter ("Abri du Maras"), located on the right bank of Middle Rhone River in France, displays a long stratigraphic sequence attributed to Neanderthals. The site is characterised by an exceptional preservation of archaeological remains, including bones that can be dated using radiocarbon (^{14}C) and teeth using electron spin resonance combined with uranium series (ESR/U-series). The sedimentary matrix contains quartz, whose age can be determined using optically stimulated luminescence (OSL) dating.
By combining these dating methods and comparing our data with previous ESR/U-series on teeth, U-series on bones and soda straws, and infrared stimulated luminescence on feldspar, we were able to clarify the occupation time of the rock shelter during the Middle Palaeolithic, for a period spanning over 200,000 years.
Age results for the base of the sequence (layer 6) show that Neanderthal occupation dates back to marine isotopic stage (MIS) 7, between 247 ± 34 and 233 ± 33 ka, and that the site was repeatedly occupied during MIS 5 (layer 5, 127 ± 17 – 90 ± 9 ka) and 3 (up to 39,280 years cal BP).
Our study provides new insights into the timing of the evolution of Neanderthal behaviour at the Maras rock shelter, which seems to have been used as a long-term residency by Neanderthals, specifically during inter-glacial periods, between around 250 and 40 ka.

Chronostratigraphic framework of the Upper Palaeolithic levels from the archaeological site of La Malia rock shelter (Guadalajara, Spain)

Dr. Virginia Martínez-Pillado [1]***, Prof. Lee Arnold*** [2]***, Dr. Martina Demuro*** [2]***, Dr. Mathieu Duval*** [3]***, Dr. Martin Arriolabengoa*** [4]***, Dr. Nohemi Sala*** [3]***, Dr. Adrián Pablos*** [5]

La Malia rock shelter contains a Pleistocene to Holocene sedimentary infill in which at least 3 Upper Palaeolithic levels have been identified based on their composition, texture, colour, sedimentary structures, and archaeological content. A combination of Electron Spin Resonance (ESR) dating of fossil teeth and Optically Stimulated Luminescence (OSL) dating of quartz grains was employed to chronologically constraint the Upper Palaeolithic occupations. For this purpose, several fossil and sediment samples were collected. Preliminary ages yield a consistent Late Pleistocene chronology and roughly correlate these levels to Marine Isotope Stages (MIS) 2-3. These results demonstrate the presence of *Homo sapiens* in inland Iberia during the early Upper Palaeolithic, which adds a new dimension to what we currently know about the mobility and occupation dynamics of our species during this period.

People – Platforms – Palaeolakes. Preliminary results of a palynological analysis from a Lateglacial-Early Holocene lake-site in northern Denmark

Dr. Sascha Krüger [1], *Mr. Claudio Casati* [2], *Dr. Catherine Jessen* [1], *Dr. Søren A. Sørensen* [2]
1. National Museum of Denmark, 2. Museum Norsjælland

A new Lateglacial – Early Holocene site close to Pårup (Sjælland, Denmark) was investigated by the Museum-Nordsjælland revealing lithic assemblages of both, Palaeolithic and Mesolithic typologies.
The location in a former shore-line of lake Søborg featured excellent preservation conditions for organic material. Among these were two wooden platforms made of *Populus tremula* that formerly reached out into the lake and have been dated to the early Preboreal.
A near-site sediment core has recently been taken by the National Museum of Denmark and the objective of a preliminary palynological investigation was to study changes in the local vegetation across the Pleistocene-Holocene boundary.
The find situation, including the wooden platforms, is strongly reminiscent of the Star Carr site (UK). Therefore, we additionally ask whether human action and patterns in shore-line usage can be traced by looking at charcoal particles as well as alterations in the shoreline vegetation (e.g. *Phragmites*).

U/Th dating of Neanderthal-bearing hyena den bone accumulation at Grotta Guattari (Central Italy)

The Tyrrhenian coast of Italy preserves an important number of open-air, rocky shelter and caves with Middle Palaeolithic archaeological succession (Musterian). Despite the abundance of archaeological and archeozoological remains found in many of these caves, the associated finding of Middle Palaeolithic human remains is extremely rare. An extraordinary exception is the “Grotta Guattari”, the investigation of which started in 1939 after the fortuitous discovery of a masterfully preserved Neanderthal skull later known as Circeo I.
In the October 2019 a new excavation campaign was initiated in the inner part of the cave, which was untouched by previous excavation. The new excavation brought to light a considerable number of new human remains as part of a considerable large mammal bone accumulation by hyena. The finding occur in shallow (c. 30 cm) layer of sandy sediments including several levels of speleothems deposition, which allowed to dating with high precision of the cave occupation by hyenas and their bone accumulation, human ones included. Specifically, several U/Th dating consistently indicate a very short period of deposition during marine isotope stage 4 at ca. 65-66 ka. In agreement with this chronology, the top of the archaeological succession of the inner part of the cave, marked by pop-corn-like concretion covering, is dated at ca. 58 ka, which represents a *terminus ante quem* for the abandonment of the cave and its definitive closure until its discovery in 1939.

A new dating advance in archaeology: cosmogenic burial dating with P-PINI at Korolevo I

Ms. Lotta Ylä-Mella [1]***, Dr. John D. Jansen*** [2]***, Dr. Roman Garba*** [3]***, Dr. Jan Kamenik*** [4]***, Dr. Konstanze Stübner*** [5]***, Dr. Vitaly Usik*** [6]***, Dr. Georg Rugel*** [5]***, Dr. Johannes Lachner*** [5]***, Dr. František Veselovský*** [7]***, Mr. Jesper Nørgaard*** [8]***, Dr. Mads Knudsen*** [8]

Terrestrial cosmogenic nuclides have been applied widely as a chronometer in the geosciences and archaeology. Unlike more conventional dating methods, such as luminescence or radiocarbon dating, burial dating with cosmogenic nuclides can access the past few million years of early hominin dispersal. Here, we constrain the age of the lowermost cultural layer at Korolevo I (western Ukraine) by applying a burial dating method that combines cosmogenic beryllium-10 and aluminium-26 measurements with an inversion model known as P-PINI (Particle Pathway Inversion of Nuclide Inventories). P-PINI merges the cosmogenic nuclide production equations with a Monte Carlo method to simulate millions of samples describing all plausible erosion and burial histories, which are then compared to nuclide abundances measured in field samples to determine the most probable burial age. P-PINI has been applied previously in a geomorphological context; here, it is used in archaeology for the first time alongside the conventional isochron burial dating method and we evaluate the pros and cons of each.

On-site and off-site archives: chronological coupling of the Montmaurin multi-level cave system with landscape evolution of the Lannemezan megafan (SW France)

Ms. Coraline Fuchs [1], ***Dr. Claire Rambeau*** [1], ***Dr. Jean-Luc Ponche*** [1], ***Dr. Gilles Rixhon*** [1], ***Dr. Amélie Vialet*** [2]

1. *Laboratoire Image, Ville, Environnement (LIVE UMR 7362), Université de Strasbourg, 3 rue de l'Argonne, 67000 Strasbourg, France,* ***2.*** *UMR 7194 HNHP "Histoire naturelle de l'Homme préhistorique" MNHN-CNRS-UPVD, Département Homme et Environnement du Muséum National d'Histoire Naturelle, 1 rue R. Panhard 75013 Paris*

The Montmaurin multi-level cave system is located in the French Pyrenean foreland. It has become famous since 1949 when archaeological excavations unearthed a human mandible attributed to *Homo heidelbergensis* (i.e. one of the few European specimens retrieved so far). A new research program starting in 2020 aims to study chronologically constrain sedimentary infills of this multi-level cave system, mostly focusing on the Coupe-Gorge cave and its 7m-thick sequence which bears human remains, such as a well-preserved humerus discovered in Summer 2022. The field campaign and analyses carried out over the last three years included high-resolution topographic measurements (laser), Uranium/Thorium dating of flowstone, clay mineralogy and fauna characterisation. However, understanding the caves' sedimentary infills requires an integration into landscape evolution at a broader spatial scale.

Against this background, this new project aims to establish a link at different spatial scales between human occupation at Montmaurin and the geomorphological evolution of the surrounding valleys incised into the Lannemezan megafan. Integrating both subaerial and underground markers, it accordingly focuses on reconstructing (1) the terrace staircase of fluvial valleys around the Montmaurin caves, i.e. Seygouade and Save Rivers, (2) the evolution of karstic networks over time in response to base-level variations, and (3) the caves' sedimentary history, including origin of material, filling phases, as well as post-depositional lateral and vertical movements. This project is based on a multidisciplinary approach which usefully combines complementary methods. The latter include geomorphological mapping, sedimentological analyses (i.e. granulometry, micromorphology, clay mineralogy, magnetic susceptibility), source tracking (i.e. SMIR,), and relative (i.e. portable luminescence reader, weathering rind analysis) as well as numerical (OSL, cosmogenic nuclides) dating. Expected results will bring new insights into the fluvial landscape evolution, i.e. phases of base-level stability and incision, as well as into sediment movements within the karstic network and between the cave's occupation phases. It will ultimately provide a better timeframe for the presence of *Homo heidelbergensis* at Montmaurin.

The impact of climatic changes on human occupation patterns during the Late Glacial recolonization of NW Belgium: an interdisciplinary assessment of Late Glacial sites in the Scheldt valley

***Dr. Possum Pincé* [1], *Prof. Philippe Crombé* [1], *Dr. Dimitri Vandenberghe* [2], *Ms. Nasrin Karimi Moayed* [2], *Prof. Johan De Grave* [2]**

1. Ghent University, 2. Department of Geology, Ghent University, Belgium

During the Late Glacial recolonization of NW Europe, hunter-gatherers preferably settled in sheltered environments and along river valleys and lake edges. However, few hunter-gatherer sites are known in the Scheldt basin of NW Belgium. It is at present not clear whether this scarcity is related to specific taphonomic factors and/or corresponds to a prehistoric reality. Moreover, the few known sites in the floodplains of the Scheldt and its tributaries all seem to date to the Younger Dryas (final stage of the Late Glacial, GS-1, 12.8–11.7 ka cal BP), which recently led to the hypothesis of a possible population shift from the inland lakes towards the riverbanks at the abrupt climatic transition from the overall warm AllerØd (GI-1a-c, 13.9–12.8 ka cal BP) to the extreme cold Younger Dryas (GS-1, 12.8–11.7 ka cal BP). We investigate this hypothesis through intensive geoarchaeological research of inland dunes in NW Belgium, as they represent dry elevations bordering late glacial floodplains, making them attractive spots for human occupation.

Since the age and triggers of inland dune formation in this area were still poorly understood, a first step in this research was to establish a dune accumulation chronology using quartz-based optically stimulated luminescence (OSL) dating and, if possible, radiocarbon dating. A total of nine dunes spread along the Scheldt basin were extensively dated. The resulting ages show that dune formation already started at the beginning of the late glacial (GI-1) and was not limited to the final cold Younger Dryas. Probably, periods of reduced vegetation related to climate deterioration (short, abrupt cooling events) and/or wildfires have stimulated aeolian activity in the previous stages of the Late Glacial. The late glacial age of the dunes further testifies to their potential as occupation spots for hunter-gatherers in that time. Consequently, systematic archaeological coring surveys have been performed on a selection of these dunes to detect sealed Late Glacial sites. The results indicate a decrease in sites during the Younger Dryas, which helps us to obtain a better understanding of the hunter-gatherer responses to the changing environment and climate in NW Belgium during the Late Glacial.

Volcanic ash (tephra) layers to synchronise archaeological and climate records in NW Africa

Lamont-Doherty Earth Observatory, Columbia University, Palisades, NY, 7. School of Archaeology, University Oxford

Archaeological sites in NW Africa are rich in human fossils and artefacts, emerging at the forefront of evolutionary studies. However, these records do not have a precise chronology, preventing assessments of the drivers of cultural/behavioural transitions. Investigations reveal numerous volcanic ash (tephra) layers are interbedded within the Palaeolithic sequences and are likely to have originated from large volcanic eruptions in the Atlantic (e.g., Azores, Canary Islands, Cape Verde). Critically, the same ash layers will be preserved in offshore marine records situated downwind of these volcanoes, meaning they can be used as time-stratigraphic markers to synchronise the archaeological and paleoenvironmental records in this region for the first time. Here we outline the initial investigations into the eruptive history of the source volcanoes and discuss diagnostic glass compositions essential for correlating the tephra layers. Moreover, we present the detailed tephrostratigraphic record preserved in the nearby marine cores (including ODP 958), which has been established using density separation techniques. The sediments contain numerous non-visible (cryptotephra) layers and the volcanic glasses have been geochemically fingerprinted to correlate them to their eruption source. The marine tephrostratigraphy provides a new record of explosive eruptions dispersed to NW Africa over the last ~300 ka, and highlights ash layers that are likely to be in the archaeological sequences. The tephrostratigraphy from the ODP 958 core will provide both relative and absolute age-constraints (via Argon ages of the eruptions) for plant wax and other biomarker analysis, that will be used to generate regional vegetation, fire, and hydroclimate records of the habitats of early humans. This work provides the first steps in establishing a tephrostratigraphic framework for NW Africa and offers new possibilities for comparing climatic and cultural transitions during the Palaeolithic.

Middle Pleistocene Acheulean industrial complex in the last middle terrace of the Lower Guadalquivir (Southern Spain)

***Prof. Rafael Baena-Escudero* [1], *Dr. José J. Fernández-Caro* [2], *Prof. Inmaculada C. Guerrero-Amador* [3], *Prof. María Dolores Simón* [3], *Prof. Miguel Cortes* [3], *Prof. Pedro Cunha* [4], *Prof. Pablo G. Earth Sciences, **5.** Universidad de Salamanca, **6.** Department of Geoscience, Aarhus University, **7.** Technical University of Denmark*

The fluvial terraces of the Guadalquivir River in the Carmona-Sevilla sector preserve a series of alluvial deposits with Acheulean industry that represent the earliest Acheulean presence in the Guadalquivir basin (southern Spain). In a sequence of ten fluvial terraces identified in the sector (T5 to T14), the earliest solitary Acheulean remains have been found in fluvial deposits of the upper terraces (T7 and T8 from the Lower Pleistocene, ca. 800 ka) but without associated fauna. These remains are especially concentrated in the last middle terrace, referred to as “Las Jarillas” terrace (T12 at +29-35 m above the riverbed). Here, three successive lithostratigraphic units have been identified with overlying gravels and sands (USLC-1, 2 and 3) containing numerous lithic artifacts grouped in three sets with bifacial forms (CAB-1, 2, 3). The most common raw material is quartzite and light debitage (R1). In CAB-1 (>580 pieces), these industries are characterized by the presence of bifaces, handaxes, cleavers and trihedral picks realized in rocks of medium and large size (>10 cm). Of the three sets of lithic industries identified, the two lower ones (CAB-1 and 2) are associated with *Elephas* (*Palaeoloxodon*) *antiquus*, *Hippopotamus sp.*, *Equus ferus* and Bovidae, and have been dated to about ca. >220 and 400 ka (quarts-OSL and K-feldspar post-IRIR). This is an archaeological site that, through the study of the lithic industry, stratigraphically documents the successive phases of a full Acheulean between the MIS 11 climatic optimum and the end of the Middle Pleistocene (MIS 6).

Pleistocene human occupation of eastern Australia: new excavations at Minjerribah (North Stradbroke Island)

Dr. Justine Kemp [1], ***Dr. Shaun Adams*** [2], ***Prof. Chris Clarkson*** [3], ***Dr. Tam Smith*** [3], ***Dr. Tiina Manne*** [3], ***Prof. Patrick Moss*** [3], ***Dr. Richard Robins*** [4], ***Mr. Tim Robins*** [4], ***Dr. Errol Stock*** [5], ***Prof. Andy Fairbairn*** [3], ***Mr. Michael Costelloe*** [6], ***Mr. Darren Burns*** [6], ***Dr. Serena Love*** [4]

1. *Griffith University,* ***2.*** *Quandamooka Yoolooburrabee Aboriginal Corporation; Everick Heritage,* ***3.*** *University of Queensland,* ***4.*** *Everick Foundation,* ***5.*** *Triple-E Consultants,* ***6.*** *Quandamooka Yoolooburrabee Aboriginal Corporation*

Two new excavations in a large sand barrier island of Moreton Bay provide clear evidence for human occupation of eastern Australia during MIS3. Luminescence and radiocarbon dating indicate deposition of 6 m sandy sediments over ~150 ka on the downwind flank of a Pleistocene transgressive and parabolic dunefield. The modelled chronology for human settlement was tuned using the chronological model BayLum, including radiocarbon ages together with single-grain OSL ages on quartz. Together this indicates an age of at least 40-45 ka for initial occupation. At this time, the sand island was connected to the mainland across the broad floodplain of the Brisbane River. Sea level had been falling from -60 to -65 m and was still 10 km from the present coastline. Evidence of occupation comes from lithic artefacts, molluscs and limited vertebrate fauna. Over 1300 artefacts were recovered at one site. Tools were constructed from quartz, silcrete, chert, rhyolite and greenstone from extra- regional and local source materials. The changing lithologies may reflect changing territories, trade, and access to stone as the coastline retreated 25 km from the present shoreline at the LGM, and subsequently rose to +1 m, flooding the connection with the mainland by 8 ka. The faunal record shows that various species of adult molluscs are abundant at the site from 6.8 ka until 0.14 ka. The recalibrated ecological record from the nearby Native Companion Lagoon shows peaks in charcoal between 45 and 40 ka that may reflect the introduction of regular anthropogenic burning. Subsequent peaks in charcoal occur at 35 ka, 24 to 20 ka, 14 ka, 12 ka and from 5 ka to the present. Rainforest declined sharply after 20 ka, which may be owing to a more arid LGM climate and the increased continentality of the site. Its persistent absence during the Holocene may have an anthropogenic explanation. Australia's large sand islands are revealed to contain a rich archaeological record of land use and management during a period of major climate variability set against a background of rapid, extreme fluctuations in sea-level.

Exploring the legacy of past land use and cultural burning in Southeastern Australia.

Dr. Shira Maezumi [1]***, Prof. Michael Fletcher*** [2]***, Dr. Michela Mariani*** [3]***, Dr. Simon Connor*** [4]***, Mr. Anthony Romano*** [5]

1. *Max Planck Institute for Geoanthropology,* ***2.*** *University of Melbourne,* ***3.*** *University of Nottingham,* ***4.*** *School of Culture, History and Language, College of Asia and the Pacific, Fellows Rd., The Australian National University, Acton,* ***5.*** *School of Geography, Earth and Atmospheric Sciences, The University of Melbourne*

During the *Black Summer* of 2019-20, southeastern Australia experienced the worst fire season in recorded history. Unprecedented areas of forest burned resulting in catastrophic losses to life, property, and wildlife. In the aftermath of these fires, Indigenous cultural burning has been proposed as a potential management tool to mitigate these extreme bushfires. Following decades of fire-suppression associated with the British Invasion, an Indigenous-style "frequent cool-burn" fire regime has been proposed to help reduce landscape-scale fuel loads and decrease the incidence of extreme bushfires. While based on enormous reservoirs of traditional fire knowledge in Indigenous communities, this assertion needs empirical testing. To address this issue, we analyzed a 1000-year sedimentary charcoal record from Elusive Lake (EL), Victoria (37°44'50.91"S, 149°27'9.58"E) spanning the period of Indigenous cultural burning to British fire suppression. Charcoal data was analyzed using CHAR Analysis to reconstruct fire frequency and fire severity. Fourier Transformed Infrared Spectroscopy (FTIR) of charcoal chemistry was used to reconstruct low (200-300°C), mid (400-500) and high (600-700) temperature fires, as a proxy for maximum combustion temperatures. Preliminary CHAR and FTIR data indicate frequent low-severity and low-mid temperature fires between 1000 to 650 cal yr BP. Fire activity decreased between 650 to 100 cal yr BP indicated by low charcoal concentrations combined with more low-temperature charcoal. In the last century the largest charcoal influx and peak magnitude values in the last 1000 years accompanied by increased high-temperature charcoals suggesting fire severity increased during this period. When contextualized with the regional archaeological data, these data suggest that the fire regime prior to the British Invasion, was characterized by frequent, cool-burn fires, similar to those that characterize Aboriginal cultural burning practices. Following the British Invasion and implementation of fire suppression practices, fires became less frequent, larger, and more severe as a result of the combined factors of warming temperatures and fuel accumulation. Together these data provide a millennial-scale context of the influence of human-mediated fire regimes that can be used to inform modern fire mitigation and management efforts in southeastern Australia.

The battlefield of El Alamein as case study of environmental changes in Quaternary terrains of the Western Desert from WW2 to present urban explosion.

Prof. Aldino Bondesan [1], *Dr. Maria Petriccione* [1]

1. University of Padova - DISSGEA

In 1942, between July and the beginning of November, a series of battles and war actions took place in the Egyptian Desert (namely, Western Desert), near the location known as El Alamein.

The study is devoted to the geological-historical analysis of the environmental impact generated by the development of military operations, including the presence for 60 years of extensive minefields. At the end of the last century, oil prospecting led to the de-mining of the desert area, while on the coast a rising impact due to quarrying of limestones and sandstones and a huge coastal belt of new touristic resorts and facilities deeply changed the littoral. Now the inner part of the battlefield is the site of a large oilfield being extracted by dozens of pumps, while the Mediterranean side will be interested in the growth of the New El Alamein City, a brand-new three-million inhabitants' metropolis.

Desert quaternary geology and geomorphology have both influenced and been impacted by WW2 military operations and post-war oil extraction, quarry extraction, touristic over-exploitation, agri-business and recent urban development.

Artisanal Silk Heritage of West Bengal, India: A story of Colonialism, Globalization and Revival

Ms. Moumita Dhar [1]

1. National Museum , New Delhi , India

West Bengal is a state in the eastern side of India. It was known as the Bengal Presidency which consisted of both West Bengal and Bangladesh. Bengal was famous for its silk production and silk weaving since ancient times. Silk was one of the main textile industries of India which dates back to 2500 BCE. The silk industry in Bengal flourished due to the premium quality of 'Tussar' silk grown in this region and the high skills of native artisans. During the Mughal rule (1526-1761) silk industry in Bengal flourished, attracting many investors from different regions. Weavers from different zones of India were dependent on the silk yarn from Bengal. Bengal was accessible through land and sea routes. Most of the European nations entered India through Bengal and all were drawn to the local silk industry. Silk products were considered highly valued and luxurious items to export to Europe. After the Industrial revolution, Bengal silk became the raw material for European textile industries and India became the biggest market for European finished products. The policy of de-industrialization in India by the British Government, increased land revenue, highly imposed taxes, mismanagement of land, famine, and drought completely ruined the local silk industry. India earned its Independence in 1947 with the cost of partition. Bengal was divided into West Bengal and East Pakistan (now Bangladesh). Many farmers and weavers moved to Bangladesh. After, independence the main focus of India relied on the production of food grains. However, within a few decades, sericulture improved, and the silk industry gradually developed and became one of the leading cottage industries. However, after globalization, the silk industry faced a new problem of fast fashion. Traditional weavers produce traditional wear and are not equipped to follow international fashion trends. Due to India's own clothing heritage, the silk industry survived. The government is also promoting silk as a part of geo-heritage tourism and branding local silk products. In this paper, we will discuss the history, tradition, and policies related to the silk industry before and after colonial rule and the initiatives taken in contemporary times for its revival.

Understanding raw material variability in early percussive tools: exploring the Acheulean of Melka Wakena through laboratory mechanical experiments

Dr. Eduardo Paixao [1], ***Mr. Walter Gneisinger*** [2], ***Dr. Joao Marreiros*** [2], ***Dr. Tegenu Gossa*** [3], ***Prof. Erella Hovers*** [3]

1. *Laboratory for Traceology and Controlled Experiments (TraCEr),MONREPOS, RGZM |Hebrew University of Jerusalem | ICArEHB - Interdisciplinary Center for Archaeology and Evolution Human Behaviour,* **2.** *Laboratory for Traceology and Controlled Experiments (TraCEr), MONREPOS – Archaeological Research Centre and Museum for Human Behavioural Evolution. RGZM,* **3.** *Department of Prehistory, Institute of Archaeology, Hebrew University of Jerusalem*

The evolution of human behaviour is marked by key human decision-making processes linked to the origins of technological variability in the early archaeological record. Investigating the nature and character of such variability is fundamental to access those past human dynamics.
Characterizing lithic tool raw materials with regard to their physical properties is crucial for exploring transformations in human behaviour through time and space. Raw material properties are known to influence artifact functional suitability and efficiency. Such properties have a major impact on the formation of diagnostic use-wear traces, which are necessary for the archaeological recognition and interpretation of artifact functions.
In this study we explore the use of percussive tools from the Acheulian assemblages of Melka Wakena (MW), a site-complex on the Ethiopian highlands that is dated 1.6 Ma to <0.7 Ma. The relatively high frequencies of well preserved, non-knapped tools at the MW assemblages provide an opportunity to explore the potential selection process and the use of this type of materials.
Our approach combines multi-scale, high-resolution analyses with a dedicated experimental program that seeks to differentiate wear formation processes in the raw materials identified at the site. This program includes mechanized controlled experiments to establish high variable control and record multiple variables. This was designed to automatically produce impact motions on the various raw material sampled in the site's area. Here we present the results of the first stage of the experimental project, with a focus on bone as the worked material. All samples are analysed using multi-scale 3D technology to map and quantitatively analyse surface alterations. The generated data will be a significant asset to support the analyses and interpretation of the archaeological tools.

Settlement Patterns of Early Hominids during the Early- Mid Pleistocene Period: A case study of Kanapoi site, West of Lake Turkana.

Ms. Joyce Waweru **[1]*****, Dr. Fredrick Manthi*** **[2]**

1. *Department of History and Archaeology, University of Nairobi, Kenya and Earth Sciences Department, National Museum of Kenya,* ***2.*** *National Museums of Kenya, Nairobi, Kenya*

How humans differ from other animals is central to many anthropological investigations. Such differences have not only been reported through the ESA– MSA transition but also through the emergence of anatomically modern humans. For decades, Scholars have proven that, unlike animals, our ancestors choose different solutions when faced with many problems in partnered ways. Archaeological assemblages from Kanapoi associated with both ESA and MSA lithic industries might reflect the different ways through which toolkits were made to meet different needs, a question central to this paper.

The African Middle Pleistocene that began from 781-126 ka is a crucial period for human evolution, as it witnessed both the lithic turnover from the Early Stone Age, to the Acheulean Industry and the origin of the evolution of modern human lineage. Kanapoi is one such site. The site is renowned for producing some of the earliest evidence of Australopithecus in the deposits dated to 4.195 - 4.108 years old.

Despite yielding very rich hominids and fauna remains, little is known about the archaeology of Kanapoi. Hominid behavior in the manufacture of stone tools that allowed them to survive in drastically changing environmental conditions, remains poorly reported from the site. The only existing literature that ties Kanapoi to hominid stone tool culture is an article by Mary Leakey that dates back to 1966. Using the newly published book on the (Prehistoric Stone Tools of East Africa), lithics from Kanapoi sites were analyzed. Preliminary results point towards a decrease in the size of artifacts in the assemblage from choppers to prepared cores and points. In addition, it points towards the decreased amount of cortex from ESA pieces to MSA-prepared cores. This pattern is unexpected because there are no artifacts that can be associated with the remains of the *Australopithecus anamensis.*

These findings indicate that early hominins had the ability for complex thought required for the procurement and use of resources on the landscape, making them adaptable to changing environments. This study expands the breadth of knowledge on hominid behavior and settlement patterns, adaptability, and resilience strategies during the early Pleistocene.

KEY Words: Settlement, hominids, lifeways

The Acheulean/Middle Stone Age (*MSA*) transition in Africa is often described as a pivotal period in human evolution, manifested by an increasing technological innovation and a regionalization process associated with the evolution of *Homo sapiens*. This view of the archaeological record is based on a continental-wide perspective which opposes two large scale patterns – one, a, theoretically, homogeneous and technological persistent production of large bifacial tools (hallmark of the Acheulean), and the other, a diversity of forms and production methods of the small shaped tools characteristics of the *MSA*. However, very few sites have yielded both Acheulean and *MSA* materials, thus allowing for a more accurate understanding of these changes at a regional scale (ex. 8-B-11 site, Sai Island, Sudan or Garba III, Melka Kunture, Ethiopia).

Here we report on the technological assemblage retrieved from a new site discovered in 2017 in the South-West of the Turkana Basin. Kanyimangin is located within the Kalabata river (an affluent of the Kerio river) circular anomaly, where approximately 15 meters deep sediments are preserved from erosion by a series of five sandstones. Combined palaeomagnetism and biochronological approaches have yielded an age estimate between 0.90 and 1.19 million years old for the site.

344 lithic artefacts have been recovered from the site; 72 originate from two archaeological test pits, while the remaining artefacts were found through archaeological surveys.

The material discovered in the excavations and on the surface appears to have similar technological characteristics. Cores with simple debitage methods (unipolar and convergent), discoidal cores and different types of handaxes are consistent with a possible early and middle Pleistocene occupation of the area of Kanyimangin. However, the presence of Levallois cores and flakes with platform preparation indicate a Middle Stone Age component, whose depositional process still need to be defined.

Even though that majority of the technological information available today comes from surface material, the good preservation of some artefacts together with the presence of some technological refits document the potential of the area from an archaeological point of view.

Holocene hydroclimate reconstruction from tropical South Pacific lake sediments – Emaotfer Swamp, Vanuatu.

Ms. Charlotte Hipkiss [1]***, Prof. David Sear*** [2]***, Prof. Peter Langdon*** [1]***, Prof. Justin Sheffield*** [2]***, Prof. Melanie Leng*** [3]

1. *University of Southampton,* ***2.*** *School of Geography and Environmental Science, University of Southampton,* ***3.*** *British Geological Survey*

The South Pacific was one of the last regions on Earth to be colonised by humans. Human migration in the Pacific occurred in two waves, the first started 3000 yrs BP and saw the Lapita civilisation colonise remote Oceania eastward to Samoa. The second occurred after a long pause approximately 1000 yr BP and saw the colonisation of the three corners of the Polynesian Triangle. Reasons for these migrations are contested, but climate is increasingly thought to have been a factor. Whilst the tropical Pacific experiences high levels of rainfall – up to 6000 mm a year - island communities can experience droughts that put pressure on populations on islands with area limited carrying capacity. Palaeoclimate evidence suggests the South Pacific has experienced shifts between dry and wet periods throughout the Holocene. To date, very little is known about the climate in the tropical South pacific during the first wave of human migration into the pacific, limiting our understanding of its role in decisions to undertake voyaging and subsequent settlement.

Using lake cores from Emaotfer Swamp which is located on the Western pacific island of Efate in Vanuatu, this study utilises a multi-proxy approach including stable isotopes from inorganic and organic material along with Itrax µXRF data to reconstruct a hydroclimate and environmental record over the Holocene. The objective is to identify how the climate has changed over the Holocene in this region and whether there are any synchronicity between changing climate and the timing of human migration and colonisation. The site is adjacent to Teouma, one of the earliest Lapita occupation sites in Vanuatu, constraining the local presence of humans to c. 3000 yr BP. The key findings from the palaeoenvironmental record from Emaotfer are the presence of two potential dry periods occurring 5880-6730 ± 350 yr BP and 531-2131 ± 157 yr BP, the second of which encompasses the period of the second migration phase into Oceania. Thus this study offers new insights and a new record of climatic and environmental change during the Holocene and at the time of human migrations in the western tropical South Pacific.

Newly-developed reliable post-1950AD atmospheric 14C record for the tropics using absolutely dated tree rings from Equatorial Amazon

Dr. Guaciara M. Santos [1]***, Dr. Daniela Granato-Souza*** [2]***, Dr. Santiago Ancapichun*** [3]***, Mrs. Rose Oelkers*** [4]***, Dr. Heather Haines*** [5]***, Dr. Laia Andreu-Hayles*** [4]***, Dr. Quan Hua*** [6]***, Dr. Ana Carolina Barbosa*** [7]

1. *University of California, Irvine,* ***2.*** *Department of Geosciences, University of Arkansas, Fayetteville, AR,* ***3.*** *Centro de Investigación Gaia-Antártica, Universidad de Magallanes,* ***4.*** *Lamont-Doherty Earth Observatory of Columbia University, Palisades, NY,* ***5.*** *Department of Earth and Environmental Science, The University of New South Wales,* ***6.*** *Australian Nuclear Science and Technology Organisation,* ***7.*** *Department of Forest Sciences, Federal University of Lavras, MG*

To calibrate past and present atmospheric radiocarbon (^{14}C) fluctuations, compilations of atmospheric ^{14}C levels using robust archives are required. The last couple of centuries, and specially from 1950 to present, have seen substantial changes in atmospheric ^{14}C. Changes are mostly attributed to burning of fossil fuels (which contain the carbon isotopes of ^{12}C and ^{13}C, but no measurable ^{14}C) and the artificial injection of bomb-derived ^{14}C during the nuclear era (the middle 1950s to early 1960s). Those man-made contributions to atmospheric ^{14}C and the current response of the Earth's system to them are relevant for better understanding of the carbon-cycle, past records and future climate changes. Several efforts have been made to monitor those changes. Present global post-1950AD atmospheric ^{14}C compilations consists of hemispheric and zonal datasets divided into summer for use in carbon-cycle studies, and monthly for more accurate ^{14}C dating of recent terrestrial samples. However, datasets close to the equatorial line still lack high resolution in both space and time. To develop an extended and continuous atmospheric ^{14}C record from 1940-2016, 77 single tree rings from an absolutely dated *Cedrela odorata* sample from Eastern Equatorial Amazon (1°S, 53°W) were measured by high-precision ^{14}C accelerator mass spectrometry (AMS) in replication. A set of 175 radiocarbon measurements have been produced, including results from precise cuts of single tree rings from the calendar years 1962 and 1963 (confirming the calendar's sub-annual tissue growth), and interlaboratory comparisons. Interlaboratory ^{14}C measurements yielded an outstanding precision of 0.17%. From 1970 onward, the Eastern Equatorial Amazon ^{14}C record confirms enhanced-^{14}C due to land respired CO_2 containing high levels of post-bomb radiocarbon. Because of its position (just above Amazon River downstream and estuary areas), this ^{14}C record has not been affected by the local fossil-CO_2 derived from trade route networks operating in Central Amazon Basin. Thus, our new tree ring ^{14}C record will enable for the extension of atmospheric ^{14}C compilations at lower latitudes to a more recent time period, re-evaluate longitudinal symmetries, and to improve determination of zonal borders.

pSESYNTH Project: early insights into building a multidisciplinary paleo-database of the Global South

Dr. Charuta Kulkarni [1], ***Dr. Xavier Benito*** [2], ***Dr. Ignacio Jara*** [3], ***Dr. Manuel Chevalier*** [4], ***Dr. pSESYNTH participants*** [5]

1. Independent Researcher, 2. Continental and Marine Waters Programme, Institute for Food and Technology Research (IRTA), 3. Centro de Estudios Avanzados en Zonas Áridas (CEAZA), 4. Institute of Geosciences, Sect. Meteorology, Rheinische Friedrich-Wilhelms-Universität Bonn, 5. Multiple

While the theoretical basis for fruitful interdisciplinary studies in paleosciences has already been identified, efforts to find feasible strategies to put it into practice using more inclusive and democratic approaches necessitate continued mobilization and collaboration. The lack of such efforts is seen across the Global South, the regions of Latin America and the Caribbean, Africa, Asia, and Oceania, which have been historically marginalized from scientific collaborations. The study of past socio-environmental systems is underrepresented in these regions – yet their diverse landscapes ranging from tropical forests to high-latitude grasslands under climatic as well as anthropogenic threats urge for unbiased understanding of long-term human-environmental dynamics. Such understanding is key to improving the knowledge of pressing environmental issues in the Global South regions inclusive of the most, if not all, developing countries in the world. This has been the core challenge being tackled by the INQUA-funded project titled "The whole is not the sum of the parts: building a synthesis database of past human-environmental systems in the Global South" (pSESYNTH). During 2022, pSESYNTH has taken its first steps to foster collaborations among paleoscientists across the Global South, with the prime goal to build the first-ever multi-disciplinary database of past socio-environmental systems from the regions. The team of more than 55 paleoscientists from 20 different countries with diverse expertise including paleoecology, paleoclimatology, archeology, and data science, have actuated discussions on how paleo-datasets from the respective regions can be fairly consolidated so that they can act as practical analogs of present and project future trends. Through drawing leadership among the ECR cohort, pSESYNTH has encouraged hands-on opportunities for developing three region-specific subgroups – Americas, Asia-Africa, and Australasia-Oceania – that have been stimulating community-led research questions and synthesis of Holocene datasets at the intersection of climate, humans, and environment. While pSESYNTH will continue through 2025, here we bring a summary of the project's initial efforts for knowledge and data exchange, exploration of ideas that link disciplines and approaches, and R Shiny App-based data visualization, all leading to an open-to-all Global South database in the near future.

Environmental history over the Late Holocene from an extreme peatland ecosystem in Cape Horn archipelago, Isla Hornos (Isla Lököshpi), Southernmost South America (~56°S)

Dr. Claudia Mansilla [1]***, Dr. Brian Buma*** [2]***, Dr. Flavia Morello*** [3]***, Dr. Andrés Holz*** [4]***, Dr. Robert McCulloch*** [5]***, Ms. Pamela Soto-Rogel*** [6]***, Dr. Jean Pierre Francois*** [7]

The geographical location of Cape Horn (~56°S) is unique due to its being the southernmost landmass in the Southern Hemisphere (outside of Antarctica), and it reflects the direct influence of the ocean-atmosphere-land interactions which comprise the southernmost forest on the Earth: an ecotonal ecosystem highly sensitive to climate change and with low anthropogenic impact. In this study, we present a multiproxy analysis of two sediment cores taken from a bog dominated by vascular peat-forming cushion plants at Isla Hornos (56°S; 67°W) to examine past variations in the environment during the Late Holocene. A 150 cm core (IH-F-1) was taken from the periphery of a peatland next to *N. betuloides* forest and analysed for pollen and spores to reconstruct the vegetation changes. Peat accumulation was relatively rapid (~0,1 cm/year, spanning *c*.1.6 ka). The vegetation records supported by loss on ignition and tephrochro reveal insights into the environmental history (LIA, c.0.6-0.5 ka) throughout the last millennia at Isla Hornos. To address weather periods of climate, environmental and ecological conditions correlate with archaeological evidence of human occupation on Isla Hornos (1428-1803 CE, previously dated). A second 60 cm core (IH-F-2) was taken from the middle of the peatland (peat accumulation ~0,02 cm/year, spanning *c*.4.2 ka) was analysed to reconstruct the changes in vegetation, and Micro-X ray fluorescence (μ-XRF) ITRAX scanning was conducted to identify major geochemical changes in the record. Optical and X-ray imaging, and magnetic susceptibility data were also carried out to characterise the sedimentology and stratigraphy and to support the paleoenvironmental analysis. The sediment cores were constrained by AMS ages. The records were compared (via statistical analyses and numeric techniques) with more than 10 palynological peat records across Fuego-Patagonia (~52-55°S) to reconstruct past ecosystems changes and to infer shifts climate drivers across the region. Preliminary results suggest major shifts in the pollen abundance and chemical proxies occurred at *c*.1.6 ka. The records also show centennial-scale climate variation in climate, which in turn has been teleconnected to variability in Antarctic temperatures and the position/intensity of the Southern Annular Mode during the Late Holocene.

This research is funded by grants: PAI77180002, FONDECYT 11220705

Palaeoecological changes based on palynological records during the Late Holocene; connections with changes in maritime cultural traditions, Southern South America (~52-56°S).

Dr. Claudia Mansilla [1]***, Dr. Jimena Torres*** [2]***, Dr. Manuel san román*** [3]***, Dr. Flavia Morello*** [2]***, Dr. Robert McCulloch*** [4]***, Ms. Pamela Soto-Rogel*** [5]

1. *Centro de Investigación GAIA-Antártica, Universidad de Magallanes; Cape Horn International Center (CHIC).,* ***2.*** *Centro de Estudios de Historia y Arqueología (CEHA), Instituto de la Patagonia, Universidad de Magallanes; Cape Horn International Center (CHIC),* ***3.*** *Universidad de Magallanes, Cape Horn International Center (CHIC),* ***4.*** *Centro de Investigación en Ecosistemas de la Patagonia (CIEP),* ***5.*** *Institute of Geography, Friedrich-Alexander-Universität Erlangen-Nürnberg, Wetterkreuz 15, 91058 Erlangen*

The climate-environmental change is a key issue for understanding the pathways and/or the adaptive strategies used by past human populations and the complex connections with the physical environment over the time. However, few studies have improved proxy-based environmental reconstruction to achieve more accurate comparisons between past environmental conditions and human behaviour. The objective of this study is to reconstruct the past vegetation changes based on palynological records during the Late Holocene (*c.*4.2 ka) and to integrate and evaluate the connections with changes in the first highly specialised maritime cultural traditions in a key archaeological area in central Estrecho de Magallanes (~53°S). We present a synthesis of six palynological records taken from peatland, which was constructed using continuous well-dated records, two new and four previously published. Tephrochronology (new ages are presented) was used to link records among sites to produce enhanced and reliable past environmental scenery. Then, ^{14}C ages information for periods of temporal and cultural discontinuity was analysed to represent the human occupation as summed probability distributions of calibrated radiocarbon ages. Our synthesis, based on CONNIS cluster analysis, shows that different vegetation ecosystems (sites) responded relatively synchronously (vegetation assemblages) to climatic changes suggesting the same millennial-scale climate variability forcing. Pollen assemblages were delimited at c.4.2-3.3 ka; 3.3-2.2 ka; 2.2-1.6 ka, and the last c.1.6 ka. However, a major climatic and ecological discrepancy was registered at c.3.3-2.2 ka among the records analysed. Discrepancy in term of change in cover forest, pollen preservation, emergence of Pediastrum algae in some peatlands and different patterns of fire activity among the sites, suggesting that our records are marked by increasing ecological instability driven by increasing centennial-scale climate variability. In this study, we discussed, in detail, the ecological instability of this period, likely the ecosystems being driven across tipping point thresholds, and the connection with a maritime culture change during this period. Similar threats, faced by past societies, continue to be one of the main challenges for improving the quality of life today because we live an unprecedented world scenario of environmental and climatic crises.

The Early Pleistocene fossil assemblage from Incarcal-I (Fluvià Valley, NE Spain): first numerical dating results.

Dr. Mathieu Duval [1], *Dr. Bienvenido Martinez-Navarro* [2], *Dr. Oriol Oms* [3], *Dr. Isaac Rufí* [4], *Dr. Leonardo Sorbelli* [5], *Dr. Maria Prat-Vericat* [5], *Dr. Joan Madurell* [3]

1. CENIEH, 2. IPHES-CERCA, Institut Catala de Paleoecologia Humana i Evolucio Social, 3. Universitat Autònoma de Barcelona, 4. Universitat de Girona, 5. Institut Català de Paleontologia Miquel Crusafont

In this work, we provide the first numerical dating results for the palaeontological locality of Incarcal-I (Fluvià Valley, NE Spain), which is famous for its latest Early Pleistocene large mammal assemblage, especially rich in large carnivorans such as the sabertoothed cat *Homotherium*. The locality belongs to a karst complex formed in the so-called limestone of Crespià, in which a series of sinkholes with associated sedimentary infills has been identified and studied over the last four decades. In particular, systematic excavations carried out in one of these cavities, Incarcal-I, have provided ca. 2,000 remains attributed to at least 15 taxa of large mammals. The chronology of this site was initially inferred from biochronology to between 1.5 to 1.2 Ma, depending on the studies. However, Incarcal-I had never been numerically dated until now.

To fill this gap, two molars of *Hippopotamus antiquus* were selected from the Incarcal-I sample for combined U-series/Electron Spin Resonance (ESR) dating in combination with a sequential magnetostratigraphic sampling. The teeth were processed following the most advanced analytical procedures: various enamel samples were collected from each tooth (n=7-10), while several laser ablation ICP-MS U-series profiles were carried out across dentine, enamel and cement in various domains of the teeth. Interestingly, analytical results show very homogenous spatial distributions of the ESR and U-series data. Environmental dose rate was evaluated through numerous laboratory and *in situ* measurements, also showing relatively little lateral variability. First numerical dating results provide a latest Early Pleistocene age for the faunal assemblage, i.e. consistent with previous biochronological estimates, although somewhat younger. Discussion will be focused on the existing uncertainty associated to these numerical age results and the biochronological implications.

Coelodonta antiquitatis dietary adaptations and geographical patterns: responses to palaeoenvironmental changes during the MIS 3

Dr. Antigone Uzunidis [1], *Prof. Florent Rivals* [2]

1. Institut Català de Paleoecologia Humana i Evolució Social (IPHES-CERCA), Zona Educacional 4, Campus Sescelades URV (Edifici W3) 43007 Tarragona, Spain, 2. ICREA, Barcelona, Spain; Institut Català de Paleoecologia Humana i Evolució Social (IPHES-CERCA), Tarragona, Spain; Departament d'Història i Història de l'Art, Universitat Rovira i Virgili, Tarragona, Spain

Coelodonta is one of the emblematic taxa of the Mammoth steppe or the *Mammuthus-Coelodonta* faunal complex. Its first representative occurred in the Tibetan plateau during the Pliocene and, through time it expands widely through Asia and Europe. In Europe, *Coelodonta* reach its peak of expansion during MIS 3 under the form *Coelodonta antiquitatis* with a territory covering almost all the continent including the Southern peninsulas. With its hypsodont teeth and its low head carriage, *C. antiquitatis* is often seen as a grazer specialist well-adapted to the European steppes. Its range of expansion, however, indicates that it inhabited various type of biota. While MIS 3 is considered as a cold stage, the environmental conditions varied greatly from an open steppe in the North of Europe to the persistence of Mediterranean forest in the South. This raises the question of the flexibility of *Coelodonta* and its aptitude to inhabit new biota. In this presentation, we aim to discuss the dietary adaptations of *Coelodonta antiquitatis* using dental wear analysis. Thirteen sites dated of the MIS 3 and located in the North Sea, Britain, Germany, France and the Iberian Peninsula were selected. Our results suggest that *Coelodonta antiquitatis* was, in fact, a flexible species that was very prosperous in the Northern steppe but also able to change its behaviour in the South. Its diet appears more abrasive in South of Europe than northern Europe according to microwear and the opposite according to mesowear. This work will discuss the differences between the two proxies. *Coelodonta* capacity to adopt various diet may explain both its success and its wide range of expansion. It may also explain the conservation of several population in South western Europe during warmer climatic period.

The Hippopotamus skull from the Tor di Quinto area (Rome, central Italy) and its troubled history

Dr. Beniamino Mecozzi [1]***, Dr. Jacopo Conti*** [2]***, Dr. Alessio Iannucci*** [1]***, Dr. Marco Mancini*** [3]***, Mr. Mattia Yuri Messina*** [1]***, Dr. Alex Sarra*** [4]***, Dr. Daniel Tentori*** [3]***, Prof. Raffaele Sardella*** [5]

1. *Dipartimento di Scienze della Terra (PaleoFactory lab.), Sapienza Università di Roma, P.le Aldo Moro, 5, 00185 Rome, Italy;,* ***2.*** *Polo Museale, Sapienza Università di Roma, p.le Aldo Moro 5, 00185, Roma, Italia.,* ***3.*** *Istituto di Geologia Ambientale e Geoingegneria (IGAG), Consiglio Nazionale delle Ricerche, Via Salaria km 29,300, Monterotondo Stazione, 00015 Rome, Italy,* ***4.*** *Cooperativa Fabrica Conservazione e Restauro, Via Ludovico da Casoria 11, 00138, Roma, Italia,* ***5.*** *Department of Earth Sciences, Sapienza University of Rome*

The earliest dispersal of *Hippopotamus amphibius* in Europe has been widely discussed in paleontological literature. Two different hypotheses have been proposed: i) a diffusion occurred during the early Late Pleistocene, based on the record of Barrington locality (MIS 5; United Kingdom); ii) a Middle Pleistocene dispersal, at approximately 0.5 Ma (MIS 13), according to the finding from the Tor di Quinto area (Rome, Italy).

The skull from the Tor di Quinto area, stored at University Museum of Earth Science (MUST), Department of Earth Sciences, Sapienza University of Rome, has been studied by several authors, and always attributed to *Hippopotamus amphibius*. The debate, instead, was and is still focused on its geographical provenance and age. The original toponym, as reported in the first work, was Cava Montanari, but later considered as Cava Nera Molinario. Recent restoration works on the hippopotamus skull from Tor di Quinto area, revealed the presence of clastic sediments inside the cavities of cranium and mandible, and around the teeth. The petrographic analysis of the sediment sand fraction offers the possibility to obtain direct information about the provenance of the deposits and thus to infer the age and stratigraphic context of the enclosing sedimentary unit.

Herein, we present new morphological and biometric analyses of the skull from Tor di Quinto area, after the restoration works. In addition, we investigate the geographical provenance and age of the specimen through the study of archive documentation and historical geological maps, by combing these data with new sedimentological analyses. The results allow to clarify the earliest dispersal of *Hippopotamus amphibius* in Europe, an important bioevent for terrestrial palaeocommunities.

Carrying capacity, available meat and the fossil record of the Orce sites (Grenada, Spain)

Patrocinio Espigares*** [2]***, Dr. Borja Figueirido*** [2]***, Dr. Sergio Ros-Montoya*** [4]***, Dr. Antonio Guerra-Merchán*** [2]***, Mr. Alejandro Granados*** [2]***, Dr. José Manuel García-Aguilar*** [2]***, Dr. Juan Antonio Pérez-Claros*** [2]

1. *Universidad Complutense de Madrid,* ***2.*** *Universidad de Málaga,* ***3.*** *IPHES-CERCA, Institut Catala de Paleoecologia Humana i Evolucio Social,* ***4.*** *Universidad de Malaga*

The Early Pleistocene sites of Orce (Guadix-Baza Depression, SE Spain) record the first hominin populations in Western Europe and provide a wealth of information on the Late Villafranchian large mammal communities. Dated to around 1.4 Ma, Fuente Nueva-3 (FN3) and Barranco León (BL) preserve abundant Oldowan tools, cut and percussion marks on fossils, and a human deciduous tooth in BL. Research during the last three decades has led to the conclusion that the hominins and giant hyenas (*Pachycrocuta brevirostris*) played an essential role in the FN3 and BL accumulations, accessing secondarily the meat resources exploited by saber-toothed felids. Venta Micena (VM) (≈1.6 Ma) is another outstanding Orce site, which preserves an exceptionally rich large mammal assemblage. The VM record predates hominin presence in this region, which provides a point of interest for understanding the previous conditions to the first humans in Western Europe.

Our aim is to analyze whether the record from these sites can be correlated with the representation that the herbivorous mammals had in the paleocommunity and/or with the meat that carnivores and humans could obtain from them, and to compare VM with FN3-BL assemblages. We estimate the carrying capacity (CC) and meat availability (TAB) of the large herbivore community of VM, FN3 and BL, and compare them with the relative abundances of the species at these sites. Estimates are made using paleoecological models that consider survival and mortality profiles.

Results show similar relative percentages for CC and TAB values, although differences are observed between VM and FN3-BL: TAB is more balanced across different body mass categories in FN3-BL than in VM. Comparison with the frequencies observed in the assemblages from the sites shows that both the Upper Level of FN3 and level D of BL resemble the estimated values for CC and TAB. However, the Lower Level of FN3 has a high representation of *Equus altidens*, a pattern not like any of those estimated for CC or TAB. In the VM quarries there is a higher relative abundance than expected of species with medium-to-large body masses and lower of species with extreme, small and very large masses.

Zooming in on the micromammals using microtomography

Mr. Shubham Pal [1]**, *Dr. Marc Furió*** [1]**, *Dr. Pedro Piñero*** [2]

***1.** Departament de Geologia, Universitat Autònoma de Barcelona, Barcelona, Spain; Institut Català de Paleontologia Miquel Crusafont, Barcelona, Spain,* ***2.** IPHES-CERCA, Institut Catala de Paleoecologia Humana i Evolucio Social, Tarragona, Spain; Àrea de Prehistòria, Universitat Rovira I Virgili, Tarragona, Spain*

The recent increase in the use of virtual palaeontology has marked the exploration of a new frontier, especially in three-dimensional imaging of fossil specimens using computed micro-tomography. Some studies have already demonstrated the potential of extracting data from the interior structures of fossils in 3D, digitally correct for deformation and/or fragmentation of the fossils, and even test the biomechanics. In the case of micro-vertebrate fossils, these new techniques allow tiny specimens to be studied without any physical stress or damage, which is of especial interest for rare or type fossil specimens.
Soricids (i.e., shrews), due to their tiny size, rarely preserve complete diagnostic elements in the fossil record. Because their taxonomy is exclusively based in dentognathic remains, postcranial elements of soricids have been largely ignored by most of the specialized authors. In the present study, we have selected some soricid fossils (including several humeri clearly ascribed to one species) and they have been scanned using a micro-CT to study some of their morphological peculiarities. Shrews (and insectivores in general) have shown to be very useful in palaeoecological analyses. With the 3D models resulting from the micro-CT scans, new qualitative and quantitative data is being recovered from this exceptional fossil material. The peculiarities of these humeri of shrews not only potentially tell us about the preferred way of moving (running, diving, burrowing), but they could also provide interesting information about the ontogeny of the individuals. This could be potentially very useful in reflecting local environmental changes, allowing us to further enhance the resolution of palaeoenvironmental reconstructions. Additionally, as suggested by some researchers, combining this data with other techniques such as histology and molecular phylogenetics can be the key to resolving the mess of taxonomic classification of insectivores. However, the biggest limitation is the resolution of the data, it still is not easy to observe potentially useful micro-structures.

Middle Pleistocene hippopotamuses from the Guadalquivir River (southern Iberia)

Prof. Rafael Baena-Escudero [1], ***Mr. Darío Fidalgo*** [2], ***Prof. Inmaculada C. Guerrero-Amador*** [1], ***Prof. Antonio Rosas*** [2], ***Dr. José J. Fernández-Caro*** [3], ***Mr. Federico Durán-García*** [1]

1. *Universidad de Sevilla,* ***2.*** *Museo Nacional de Ciencias Naturales (CSIC),* ***3.*** *Museo Arqueológico y Paleontológico de La Rinconada*

Middle Pleistocene vertebrate assemblages from fluvial deposits of the Guadalquivir River at La Rinconada (Seville) (ca. 0.4-0.38 Ma) have yielded specimens of *Hippopotamus* sp., together with *Equus ferus*, *Palaeoloxodon antiquus*, Bovidae and Acheulean industries. In this chronological range, it has been hypothesized a turnover in Europe of hippopotamus populations, with the entry of *Hippopotamus amphibius* and the subsequent disappearance of *Hippopotamus antiquus*. In the Iberian Peninsula, *H. antiquus* is estimated to have been present since ca. 1.7 Ma, being especially abundant in the Early Pleistocene lacustrine palaeoenvironments of the Guadix-Baza Basin and in the Early-Middle Pleistocene localities of the north-eastern Iberian Peninsula. Scarce are the findings in fluvial terrace, such as the Júcar and Guadiana rivers; or the deposits in caves, as in Sierra de Atapuerca sites or Pontón de la Oliva. *H. amphibius*, on the other hand, has a less clear record and is represented by dubious attributions. Specimens dated from the Mid-Middle Pleistocene (terraces of the Tajo and Jarama rivers, Mealhada or Cova de Bolomor, among others) to the Upper Pleistocene (Cova del Toll and tentatively Cueva de la Lloseta) are attributed to this taxon. In most cases, the presence of *H. amphibius* is associated with lithic industry, as well as with the faunal associations observed in La Rinconada. The presence of these taxa is usually interpreted as an indicator of temperate climatic conditions with permanent presence of water bodies and grasslands. It is more controversial to use the presence of hippopotamuses as a biostratigraphic indicator, as there is no consensus on the taxonomic assignment at the specific level of isolated teeth or most postcranial elements. In La Rinconada Middle Pleistocene sequence, the presence of large canines together with smaller specimens stands out, which has facilitated the consideration of a biometric range in these populations. The results of this study contribute to the context of the transition between the presence of *H. antiquus* and *H. amphibius* populations in Europe, as well as providing valuable information for the environmental reconstruction of the environment of human populations in the south of the peninsula during the MIS 11 climatic optimum.

Pleistocene woolly rhinoceros skulls: A methodological approach

Fossil rhinoceros remains are fairly well represented in the Quaternary fossil record. This is especially true for the woolly rhinoceros (*Coelodonta antiquitatis*). Studies of these finds have taken morphological, osteometric, taphonomic, genetic, and other approaches. The osteometric studies in particular show noticeable nonuniformity in the cranial measurements they present. If we are to consider morphotypic variation within species, skulls with cognitive potential on the taxonomic level should be measured using the same approach.
Our presentation will focus on a methodological approach to the measurement of woolly rhinoceros skulls from Late Pleistocene contexts by proposing a new protocol for skull measurement. Ontogenic, morphological, and osteometric perspectives on rhino skulls will be discussed.
This study was performed under a grant from the National Science Center, Poland (2021/43/B/ST10/00362) awarded to Kamilla Pawłowska.

The Anagni Basin: an Early to Middle Pleistocene palaeontological and archaeological key area in the mammals biochronology of the Euro – Mediterranean Quaternary

The intramontane basin of Anagni (central Italy) hosts three of the most important palaeontological and archaeological sites in Italy, Coste San Giacomo, Colle Marino and Fontana Ranuccio, spanning from 2,2 to 0,4 Ma (Early to Middle Pleistocene). In the last decades an intense scientific activity has been carried out, promoted and coordinated by the Italian Institute of Human Palaeontology (hereinafter IsIPU) in collaboration with different national and international Institutions. Dedicated bore cores, field surveys excavation campaigns and extensive reviews of the archeological and paleontological material housed at IsIPU have resulted in a number of scientific publications that contributed to analyze the dynamics of the mammal fauna of the Mediterranean Europe during the Pleistocene, also providing new constraints to better interpret the location and spatial distribution of early *Homo* during the Middle Pleistocene occupation of this area.

In this work we present a comprehensive state of art of the palaeontological and archaeological research achieved in the last years on the Anagni basin and new data coming from taxonomic analyses performed on the large mammal remains of the aforementioned sites.

Palaeoclimatic and palaeoenvironmental reconstruction for the Late Pleistocene Melitzia Cave, Mani Peninsula Greece from oxygen and carbon isotopes of ungulate enamel

Mrs. Marianthi Tzortzi [1], *Dr. Thomas Tütken* [2], *Dr. Hubert Vonhof* [3], *Prof. George Iliopoulos* [1], *Dr. Andreas Darlas* [4]

1. Department of Geology, University of Patras, 2. Institut für Geowissenschaften, Arbeitsgruppe für Angewandte und Analytische Paläontologie, Johannes Gutenberg-Universität Mainz, 3. Climate Geochemistry, Max Planck Institute for Chemistry, Mainz, 4. Ephorate of Paleoanthropology and Speleology, Greek Ministry of Culture and Sports

The Balkan Peninsula is one of the regions that have acted as refugia during the Last Glacial Period, and due to the favorable climatic conditions, it hosted faunal communities, including humans. Mani Peninsula, in the southernmost part of continental Greece, is a key area for Palaeolithic studies due to the large number of excavated sites containing deposits with cultural artifacts and skeletal remains from the Middle and Upper Palaeolithic, revealing the abundance of human occupation in the wider area during the Middle-Late Pleistocene. Melitzia Cave is one of several karstic cavities discovered on the western coast of the Mani Peninsula that were used by Late Pleistocene hominids as a shelter. The excavated Upper Palaeolithic cultural layers at Melitzia Cave are well dated covering the timespan between 45,500±947.5 BP and 10,915±235 BP. Fallow deer, red deer, and caprine dominate the faunal assemblage.

Here we reconstruct palaeoenvironmental and palaeoclimatic conditions around the cave across the period of the Last Glacial maximum using a stable isotope approach on teeth of the three most abundant ruminant taxa. Their third and second molars were analyzed for stable carbon and oxygen isotopes ($\delta^{13}C$ and $\delta^{18}O$) using two different sampling strategies: bulk enamel reflects the average diet and the hydrological conditions experienced by the animals during the enamel mineralization period, whereas sequential samples along the tooth growth axis track seasonal dietary and environmental changes. Bulk enamel samples of all three ruminant taxa have a mean $\delta^{13}C$ value of -10.2±1.1‰ (n =26; range: -6.5‰ to -12.2‰), reflecting a predominant consumption of C_3 plants such as trees, shrubs, herbs and/or C_3 grass. No major changes in vegetation cover seem to have occurred as the $\delta^{13}C$ values do not display clear changes with time nor between taxa. The mean $\delta^{18}O$ value is -3.3±1.1‰ (n =24; range -5.4‰ to -0.9‰) with a high variance of 2−3‰ in different time bins but no clear changes with time are observed. Serial sampling will provide a more refined picture of seasonality and changes thorough time. Implications for environmental and climatic conditions in this southeastern European refugium during the Last Glacial Period will be discussed.

Overview of the Caprini record from the Early Pleistocene of South Europe, with description of new material from Aghia Kyriaki (Aetoloakarnania, Greece).

Ms. Elpiniki Maria Parparousi [1], *Prof. Dimitris Kostopoulos* [2], *Prof. George Iliopoulos* [3]

1. Department of Physics and Geology, University of Perugia, 2. School of Geology, Aristotle University of Thessaloniki, 3. Department of Geology, University of Patras

The Early Pleistocene Caprini record of South Europe includes the genera: *Hemitragus* (Late Pliocene—Middle Pleistocene), *Pliotragus* (Late Pliocene—Early Pleistocene), *Euthyceros*, *Procamptoceras*, *Gallogoral*, *Megalovis* (Early Pleistocene), *Soergelia* (Early—Middle Pleistocene), *Praeovibos* (Pleistocene) and *Ovis* (Pleistocene—present).

During this period, *Soergelia* and *Praeovibos* were widespread in Europe, whereas *Gallogoral*, *Procamptoceras*, *Megalovis*, *Pliotragus* and *Hemitragus* were relegated in Southern Europe. *Ovis* is evidenced only in Greece, Bulgaria and France, but, later on, the taxon dispersed all over Europe. *Euthyceros* is endemic of Greece, known only from the locality of Sesklo. *Hemitragus* is represented by two species during the Early Pleistocene: *H. orientalis* (Hungary, Bulgaria, Greece, France) and *H. albus*, possibly endemic to the Iberian Peninsula.

A recent preliminary palaeontological study of the site Aghia Kyriaki (Aetoloakarnania, Greece), allowed the identification of 13 different mammalian taxa, suggesting an estimated age of 2.5—1.8 Ma, corresponding to the Middle to early Late Villafranchian. Among the studied material, we attributed few remains to cf. *Procamptoceras brivatense* and *Hemitragus* sp.

The fossil record of both these genera in Greece is scarce. *Procamptoceras* is recorded in Vassiloudi 1 (Mygdonia Basin) and possibly in Volax (Drama Basin), whereas *Hemitragus* sp. is recorded in Mygdonia Basin in Apollonia I (1.2—1.0 Ma) and Krimni-3 (1.8—1.5 Ma) by scanty remains. The new findings from Aghia Kyriaki represent the southernmost presence of the two genera in Greece so far, as well as the earliest presence of *Hemitragus* in Greece.

Most Caprini are quite common in SE and SW Europe, whereas they seem to be poorly represented in other European areas (i.e., North—Central Europe and Italian peninsula). The reasons for this restricted geographical distribution are still not widely addressed. Although the scarcity of Early Pleistocene localities in North—Central Europe could lead to a bias in the fossil record, environmental factors (i.e., ecological preferences) might have played a major role in this matter. Moreover, the Asian origin of many Caprini could explain their stronger presence in Eastern and Southeastern Europe during this period. Further studies are required in order to clarify the dispersal dynamics that characterize this group of bovids.

Quaternary large mammals bioevents in the Italian Peninsula

***Prof. Raffaele Sardella* [1], *Dr. Alessio Iannucci* [2], *Dr. Beniamino Mecozzi* [2]**

***1.** Department of Earth Sciences, Sapienza University of Rome, **2.** Dipartimento di Scienze della Terra (PaleoFactory lab.), Sapienza Università di Roma, P.le Aldo Moro, 5, 00185 Rome, Italy;*

The Quaternary is a time of fundamental climatic shifts and environmental changes that caused a diverse response of the biota. An updated chronology of major bioevents formalized in Italy is summarized and discussed in relation to changes observed in other geographic regions as revealed by the new data.

The beginning of the Quaternary coincides with the extinction of several taxa of subtropical affinities and the spread of a primitive mammoth (*Mammuthus rumanus*) and a monodactyl equid (*Equus* cf. *livenzovensis*). Nonetheless, the paucity of sites of this age likely sharpens the turnover and, in any case, the dispersal of the mammoth is not synchronous across Europe. The “wolf event” is older than what hypothesized 40 years ago, with *Canis* sp. being first documented at Coste San Giacomo at ~2.2 Ma. The same site also recorded *Hippopotamus* sp., which is the earliest well-dated Middle Villafranchian occurrence of a hippo in Europe.

At ~2.0-1.8, the Late Villafranchian witnessed the arrival of the giant hyena *Pachycrocuta brevirostris* and *Panthera gombaszoegensis*. Early faunas of this period document a peak in carnivoran diversity, with the giant hyena being an especially important component for ~1 Myr.

The replacement between *P. brevirostris* and *C. crocuta* occurs at ~0.8 Ma, between Slivia and Ponte Galeria Faunal Units, at the Epivillafranchian-Galerian transition. This also roughly coincides with the replacement between *Sus* cf.*strozzii* and *Sus scrofa*, although suid remains are seldom abundant. Galerian faunas of the early Middle Pleistocene are characterized by the extinction of old Villafranchian species and the dispersal of several newcomers. The general pattern is quite clear, but the timing of these bioevents is not always well-resolved or synchronous across Europe.

In 1997, Italian researchers proposed the Aurelian Mammal Age to name the renewal coinciding with the establishment of “the core of the modern mammal fauna” started in the late Middle Pleistocene. The most important bioevents chosen to typify the Aurelian, namely the appearances of *Canis lupus* and *Ursus spelaeus*, are now recognized as older than previously believed and major faunal and environmental changes seem closer to ~0.4 Ma.

Saccopastore (Rome, Italy), a reappraisal: Neanderthals, large mammal fauna, history and geo-stratigraphy of the site

Dr. Beniamino Mecozzi [1]***, Dr. Caterina Giovinazzo*** [2]***, Dr. Francesca Alhaique*** [3]***, Dr. Biagio Giaccio*** [4]***,***

Saccopastore is a well-known historical site in the north-east countryside of the city of Rome (Italy), located within a meander of the current stream of the Aniene river (tributary of the Tiber), now largely within and buried below the urban development. The stratigraphical succession of Saccopastore was exposed by open-air quarry activities during the early 20th century. In 1929, a human cranium was stumbled upon by workmen; Sergio Sergi ascribed it to *Homo neanderthalensis*. The quarry was then abandoned, but six years later a second Neanderthal cranium was discovered by Alberto Carlo Blanc and Henri Breuil during a geo-paleontological survey. The discoveries prompted the Italian Institute of Human Paleontology (directed by A.C. Blanc) to start systematic excavations in 1936. During fieldwork, well-stratigraphically constrained mammal fossils and Mousterian lithic tools were recovered, which have been added to those already found previously in different layers of the stratigraphy. The stratigraphical succession of Saccopastore was studied by various authors and framed within the widest geological context. The horizon where the two Neanderthals were found was unanimously attributed to the early Late Pleistocene (Marine Isotopic Stage 5e; Eemian). During the last decade, however, a chronostratigraphic reassessment of the deposits throughout the area of Rome (lower basins of the Aniene and Tiber rivers) has claimed for an older age (Marine Isotopic Stage 7). We therefore started a project of reappraisal of the Saccopastore "cold case", focused on the revision of geological and stratigraphical setting of this important site and its paleontological content. The study of archive documentation (photos, geological sections, excavation journals) and geological maps, combined with new sedimentological and geochemical analyses on the original sediments (collected during the '30s excavations and still preserved in the Sergi's Museum), will allow to better define the chronological framework of the Saccopastore succession. Concurrently, the revision of the mammal fossil assemblage will also provide new data on the faunal composition and the environmental setting at the time when these early Neanderthals lived.

An approach to the predator-prey power law in past ecosystems and the reconstruction of early human populations in Western Europe

In a study of modern ecosystems, Hatton et al. (2015) observed that predator biomass scales to a power close to ¾ of prey biomass. This type of relationship is also held between body mass and other biological parameters (eg., metabolism, production, or consumption).

During the Early Pleistocene in Europe, the relationship of the first hominids with carnivores and the prey community may have conditioned the stable presence of hominid populations since meat was a key resource in their dispersal. The modeling of trophic relationships in the communities of Pleistocene large mammal can thus provide information on the ecological conditions in which these early humans developed their lives.

The rich fossil record of the archaeological sites of Orce (Granada, SE Spain) and Sierra de Atapuerca (Burgos, N Spain) offers an exceptional opportunity to analyze the paleocommunities of early humans in the Iberian Peninsula. At Orce, the Barranco León and Fuente Nueva-3 sites show the oldest evidence of human presence in Western Europe, dating to ~1.4Ma. In addition, the nearby Venta Micena site preserves an excellent record of the paleocommunity prior to human presence in the area, thus opening interesting clues on the human exploitation of niches. In the case of the Sierra de Atapuerca sites, they have provided an important collection of human fossils that make these sites unique worldwide. Moreover, these sites preserve a nearly continuous record of the faunal assemblages that inhabited this region in NW Spain more than a million years ago.

Our aims in this work are to reconstruct the biomass ratio of predators (predators, scavengers, and hominins) to their prey in the Orce and Atapuerca sites, and to analyze if these ratios are like those obtained by Hatton et al. (2015) for the African communities. For doing so, we estimate the biomass of predators and prey based on previous studies of the trophic networks of these paleocommunities.

Our results show that the modeling of the Orce and Sierra de Atapuerca paleoecosystems complies with a relationship like that obtained by Hatton et al. (2015) for the African ecosystems (i.e., a scaling with a power close to ¾).

Comparative analysis of brain endocasts in living and extinct "Big Cats", and their implications in paleoecology

Mr. Alfio Moscarella [1]***, Dr. Dawid Adam Iurino*** [2]***, Prof. Raffaele Sardella*** [2]

1. *university of Rome Sapienza,* ***2.*** *Department of Earth Sciences, Sapienza University of Rome*

Felidae is a family of the order Carnivora, characterized by the extant subfamilies of Pantherinae and Felinae, and the extinct Machairodontinae and Proailurinae. The Pantherinae subfamily is represented only by the genus *Panthera*, and includes the "big cats" of the family (lions, leopards, tigers and jaguars). On the other hand, the Felinae includes felids of different genera (*Acinonyx*, *Puma*, *Lynx* and *Felis*). Despite the difference in subfamilies and genera, the brains of living felids are strikingly similar to each other in their external morphology, with little differences reflecting their ecological adaptations. Conversely, the fossil felids show very different morphologies between genera, probably reflecting derived traits and stronger ecological adaptations.
Here we present a discussion on the main morphological traits in brains of both pantherines (extant and fossil specimens from the Middle Pleistocene to recent) and machairodontines as the Late Pleistocene sabertoothed species *Smilodon fatalis*, in order to investigate different encephalic response to different adaptations in living and extinct "big cats" subfamilies, sharing similar ecological niches.

The Quibas site (Murcia, Spain): New herbivores from the early-middle Pleistocene Transition

The Early Pleistocene site of Quibas, located in Sierra de Quibas (Murcia, Spain) was discovered in 1994 and has since then provided abundant material of typical Epivillafranchian taxa. This biochron belongs to the Early-Middle Pleistocene Transition (1.2 – 0.78 Ma), characterised by a change in orbital cyclicity from a 41 kyr cycle to 100 kyr that intensified the climate and culminated in the most important faunal turnover of the Pleistocene regarding large mammals. The Group of Palaeoanthropology of the National Museum of Natural Sciences (CSIC, Spain) and the Institut Català de Paleoecologia Humana i Evolució Social (IPHES-CERCA, Spain) carried out four field seasons from 2015 to 2018 in the site. These provided fossil material from both structures of Quibas: Quibas-Sima (QS) and Quibas-Cueva (QC). Here we present the assemblage of large herbivorous mammals recovered from the field, including the first citation of two taxa new to the locality: a rhino (Stephanorhinus cf. etruscus) and a bison (Bison cf. voigtstedtensis). We also provide the first description of previously mentioned taxa: the fallow deer Dama cf. vallonnetensis and Sus sp. Together with the remaining herbivores, we revised the geographic affinities of the faunal assemblage, which showed a strong European origin with some regionalism. The large herbivorous mammals fall in the typical Jaramillo taxa, coinciding with previous chronostratigraphic approaches, and compared with other Iberian localities Quibas stands out for the lack of hominin fossils or any evidence supporting their presence in the area. This is a peculiar scenario given the human presence recorded in many of the Early-Middle Pleistocene fossil sites that are contemporary with Quibas.

Early Islamic to early Modern Groundwater Harvesting in Aeolian Sand – A review of Plot-and-Berm Agroecosystems from Western Asia to Iberia

Prof. JOEL ROSKIN [1], ***Mr. Lotem Robins*** [2], ***Prof. Revital Bookman*** [3], ***Dr. Itamar Taxel*** [4]

1. *Bar-Ilan University,* ***2.*** *Department of Geography and Environment, Bar Ilan University, Ramat-Gan, Israel,* ***3.*** *University of Haifa,* ***4.*** *Israel Antiquities Authority*

"Plot-and-Berm" (P&B) agroecosystems are relatively unrecognized but traditional, sophisticated in-situ agricultural utilizations of a shallow water table within loose, coastal and inland aeolian sand bodies, that comprise agricultural hinterlands in arid to Mediterranean climates. The agroecosystem is comprised of a checkerboard array of agricultural plots sunken between 3-10 m high man-made berms coated with sediment, artifacts, or vegetation to limit slope and aeolian erosion. Marine and terrestrial organic materials, archaeological material and sediment, depending on the time and environment of the agroecosystem, enrichen the plot sand into a productive anthrosol.

P&B agroecosystems are sporadically spread between Iran, Turkmenistan, Israel, Gaza Strip, northern Sinai Peninsula, Algeria, southwest Spain and northwestern Portugal. Most of these traditional agroecosystems are active and are undergoing human-inflicted environmental and economical stress. Others are abandoned, deteriorating, changing, or under initial restoration and are potential geoheritage sites.

The Caesarea and Yavneh P&B agroecosystems in coastal sand bodies of Israel, dated by numerical methods along with pottery to the Early Islamic period to early Crusader times (9th-early 12th centuries a.d.) may be the first widespread and successful attempts to cultivate aeolian sand in human history. Based on calculations of the amount of work days required for the earthworks to establish the agroecosystem features, we hypothesize that a regional governance initiated the development of these agroecosystems, possibly in response to religio-administrative calls for a type of *mawāt* (Arabic: "dead") land reclamation. In some places, P&Bs may have locally developed in a bottom-up nature. Though active agroecosystems in Portugal, Gaza Strip and Algeria revenue a wide range of seasonal vegetables and also fruit, initiation of agroecosystem construction was probably combined with an economic incentive and demand for a possibly unique crop.

This study presents categorized data of all of the known P&B agroecosystems by geospatial survey and analysis of using Google-Earth imagery, literature review, geoarchaeological work and absolute and relative dating in Israel, and preliminary surveys in Portugal. It attempts to gain insight on the enigma if this unique agrotechnological knowledge may have been gradually transferred since Islamic times, possibly from the Land of Israel to Iberia and to western Asia.

Holocene deforestation history of NE Belgium: an evaluation of pollen- and population-based approaches for reconstructing land cover

Ms. Renske Hoevers [1]***, Dr. Nils Broothaerts*** [2]***, Prof. Gert Verstraeten*** [1]

1. KU Leuven, Department of Earth and Environmental Sciences, Division of Geography and Tourism, 2. Thomas More University of Applied Science

Several methods to reconstruct past land cover are available which can be roughly divided into approaches based on pollen data and approaches based on (estimates of) historical human population. The two most widely used population-based scenarios – KK10 and HYDE – do not agree on the timing and scale of Holocene anthropogenic land cover change (ALCC). By performing pollen-based reconstructions of past land cover and comparing them with the ALCC scenarios, the accuracy of these models could be further improved. In this study, the REVEALS model and non-metric multidimensional scaling (NMDS) are applied to pollen sequences obtained from multiple alluvial floodplains located in the sandy and loamy regions of northeastern Belgium, thereby obtaining the first regional (semi-)quantitative estimates of Holocene landscape openness for this area. These estimates are subsequently compared to the KK10 and HYDE scenarios.

The two pollen-based reconstructions are overall well in agreement and show that forests in northeastern Belgium reached their maximal cover towards 8500 cal. BP. From the Neolithic period onwards, deforestation is detected in both regions, although the loamy region underwent a more rapid and severe land cover transformation. The agreement between both methods implies that NMDS can still be used for detecting land cover changes in case not all of the necessary parameters are available to run the REVEALS model, although in a semi-quantitative rather than in quantitative way. Moreover, NMDS can provide a better understanding of which taxa are related to a particular type of landscape. Taking into account such insights in the interpretation of the REVEALS model output might help to accurately identify the onset of significant human impact on the landscape. The pollen-based reconstructions indicate quite some variability between the catchments, even the ones located within the same region, which is not reflected by the ALCC scenarios. Since alluvial sites often experienced early anthropogenic impact, including pollen data obtained from such sites could not only improve the spatial coverage and accuracy of current pollen-based land cover reconstructions but also improve our understanding of human transformation of the landscape, which can in turn contribute to an improvement of the ALCC scenarios.

Late Holocene natural and human-induced environmental change reconstructed from peat record using a multi-proxy in an oceanic island (Azores)

Peatlands can provide robust, continuous, and high-resolution archives of environmental changes. The main factors influencing the evolution of a peatland can be divided into autogenic and allogenic. Apart from climate, human disturbance, such as deforestation and water drainage, are crucial allogenic drivers of change in peatland ecosystems. Here we present the preliminary results of a multiproxy study, including the analysis of plant macrofossils, chironomids, and testate amoebae on a peatland core (4.5 m) from Lake Prata (São Miguel, Azores). The results of the study indicate that the lake ecosystem underwent a classic succession from a lake (700 – 1800 AD) territorialized through to a peatland (1800 AD–until present) and responded to climate and human changes. During the lake phase, two distant periods were identified. From 700 to 1300 AD, human activities were not detected, and plant macrofossils indicate that the catchment area was densely forested. Environmental conditions within the lake were also relatively stable, with lake organic matter dominated by allochthonous sources and chironomid and tecamebas communities of mostly oligo/mesotrophic taxa, indicating stable and relatively low aquatic productivity. From 1300 to 1800 AD, large-scale landscape modifications and the introduction of mammals were recorded, represented by the decline in trees macrofossils, the increase of grasses macrofossils, and the presence of coprophilous fungi at that time. The rise in the dominance of mesotrophic chironomids and tecamebas, indicates a rise in the lake trophic state. Also, a decrease in sediment total organic carbon/total nitrogen (TOC/TN) ratios at this time indicates a transition toward more lacustrine-dominated organic matter in association with higher nutrient levels. From 1800 AD to the present day, drastic changes from all proxies were recorded. Changes in chironomid and tecamebas assemblages from more open-water to macrophytes taxa associated, increase of macrophytes macrofossils, and increase TOC/TN, at this time indicates near-complete infilling and development of a peatland with paludification, and more recently, transformed to a *Sphagnum* peatland. The non-natural conditions of the present-day Sphagnum-dominated habitat illustrate a prime example of why the Habitats
Directive of the EU requires a long-term perspective.

Reconstructing Land Cover and land use changes in the Iron Age of central Italy

Mrs. Chen Antler [1], ***Prof. Nicki Whitehouse*** [1]

1. *Department of Archaeology, University of Glasgow, UK*

We examine how human and environment relationships have developed over the course of the Iron Age from a regional perspective, and how this relationship manifested in the transformation of land cover and land use. Focusing on the environmental transformation of Central Italy, this paper presents the preliminary results of our investigation into the interaction between the local population and the environment of the region over the course of the 1st millennium BC. This is part of a broader project exploring the connection between environmental modification and identity. It is aimed at estimating how the process of shaping nature into an anthropogenic landscape creates a sense of shared identity among local communities. In our case, tracing the creation of a local Roman identity in some of the earliest activities to modify the environment into a newly what would become the future city of Rome.

Results from the re-analysis of nine pollen sequences will be presented, from eight lakes within 100 km from the city of Rome, including Lago di Mezzano, Lago di Vico, Lago Matiganano, etc. Using age Modelling and the Landscape Reconstruction Algorithm (LRA), the paper sheds light on land use practices within the region and presents information on how specific tree species responded to interactions and helped to shape the anthropogenic landscape. The issues associated with age modeling and re-use of existing data to study land cover changes and linking these with the archaeological record will also be highlighted, including the challenges and limitations of evaluating landscape transformation and reconstructing chronologies based on the characteristics of lake sediments and basin systems. Finally, we briefly discuss the significance of this work with respect to the development of Roman local identities, as the landscape was transformed.

Landscapes of Production: Exploring the palaeoenvironmental context of stone tool quarrying, manufacture, use and deposition on Neolithic Shetland

Ms. Hazel Mosley [1]***, Dr. Will Megarry*** [1]***, Dr. James Schofield*** [2]***, Dr. Gill Plunkett*** [3]

1. *Queen's University Belfast,* ***2.*** *Geography & Environment, School of Geosciences, University of Aberdeen AB24 3UF,* ***3.*** *Archaeology & Palaeoecology, School of Natural and Built Environment, Queen's University Belfast*

The landscape of the Shetland Islands, off the north coast of Scotland, today is a patchwork of farmland, heath and blanket bog. Palynological studies suggest that during the Neolithic the vegetation was much more diverse. Several sites in Shetland show values high of tree and shrub pollen, but due to the problem of wind transport researchers are circumspect about whether these really represent local woodlands, especially in the absence of plant macrofossils to corroborate pollen data.

New radiocarbon dates and reanalysis of Shetland archaeological sites long suspected to be Neolithic, such as Ness of Gruting and the stone buildings at Scord of Brouster, suggest an early Bronze Age chronology for these sites, challenging previously held beliefs about settlement and landuse during the Neolithic and creating a gap in our understanding of this important period. More recently, radiocarbon dates from felsite stone tool quarries in the uplands of North Roe, north-west Mainland, and a cache of polished axes and knives at Modesty in west Mainland indicate extensive quarrying and distribution networks in the early to middle Neolithic. Although found throughout Shetland, felsite artefacts are concentrated on the Northmavine peninsula and adjacent areas of Mainland, reflecting both the natural presence of the raw material and the choices made by the Neolithic inhabitants regarding felsite working practices and networks of artefact distribution.

North-west Mainland has a wealth of Neolithic archaeology and limited palaeoecological coverage, something this project seeks to redress. The upland landscapes around the quarries are different to any sites previously studied in Shetland. Through analysis of pollen and non-pollen palynomorphs from new peat cores, targeting sites close to the felsite quarries and the hoard at Modesty, we examine the landscape context of this important industry and explore Neolithic land-use and vegetation change. This new data is integrated with existing palaeoecological studies to explore regional variations in vegetation. We use pollen modelling approaches to explore taphonomic issues with pollen transport and deposition, and GIS to visualise data, examine variations in land-cover through time, and explore spatial relationships.

Effects of hydrological changes on prehistoric humans in the drylands of the Asian interior

Dr. Kangkang Li [1] ***, Prof. Xiaoguang Qin*** [2] ***, Prof. Bing Xu*** [2] ***, Dr. Zhiqiang Yin*** [3]

1. Institute of Geology and Geophysics, Chinese Academy of Sciences, 2. Institute of Geology and Geophysics, Chinese Academy of Sciences, Key Laboratory of Cenozoic Geology and Environment, 3. China Institute of Geo-environment Monitoring

The causes of prehistoric human movements in the drylands of the Asian interior have long been debated among multidisciplinary scholars. Here, we present the results of the Bronze Age Xiaohe settlements in the extremely arid Tarim Basin of northwest China, whose demise included a long-distance migration along river catchments during ca. 4,000 – 3,300 cal yr BP. We used stable carbon isotope values ($\delta^{13}C$) of archaeobotanical remains, sedimentary face data from the Tarim River catchment, and a compilation of palaeo-environmental evidence in order to investigate the relationships between regional environmental changes and the response of prehistoric societies in this arid region. The results show that the early Xiaohe population was forced to migrate as a consequence of the deterioration of hydrological conditions around settlements. The decline of the Xiaohe Culture occurred in the context of decreasing water availability in the basin interior due to climate change lasting several hundred years. The results are potentially significant for the management of ecologically fragile dryland habitats, particularly the watershed terminus area, threatened by ongoing climate change, specifically in the context of the need to manage scarce water resources to promote sustainable socioeconomic development.

Subsistence strategies of prehistoric hunter-gatherers on the northeastern Tibetan Plateau: zooarchaeological studies of the 151 site

Dr. Jian Wang [1]***, Prof. Dongju Zhang*** [2]

1. College of Earth and Environmental Sciences, Lanzhou University, 2. Lanzhou University

Successful human adaptation to the high and harsh Tibetan Plateau (TP) marks an important progress in human evolution. Despite the recent rapid renewals of the age of the earliest appearance of hunter-gatherers on the TP, from the Last Deglaciation (~15 ka BP, e.g., Jiangxigou 01 site, the Lower Cultural Layer of the 151 site) to the Late Pleistocene (~40-30 ka BP, Nwya Devu site), and to the Middle Pleistocene (~190 ka BP, Baishiya Karst Cave), we know barely nothing about how these hunter-gatherers survived on plateau before the arrival of millet agropastoral economy in the Late Holocene.

Here we present a detailed zooarchaeological analysis of the faunal remains from the Upper and Lower Cultural Layer (hereafter UCL and LCL, respectively) of the 151 site in the southern Qinghai Lake Basin (>3200 masl) on the northeastern Tibetan. The site was excavated in 2014. The dating results and archaeological remains of the site show that it was occupied by Late Upper Paleolithic and Epipaleolithic hunter-gatherers during 15400-13100 cal yr BP for LCL and 9000-6400 cal yr BP for UCL, respectively. Zooarchaeological analysis of the bone assemblages of the 151 site show that the prehistoric hunter-gatherers in the Qinghai Lake Basin shifted their main hunting strategy from random-hunting of large-sized herbivores (*Bos* and *Equus*) in LCL to specialized-hunting of Przewalski's gazelles (*Procapra Przewalskii*) in UCL. However, “Broad Spectrum Revolution”, indicating the abrupt shift of faunal assemblages to be dominated by small animals, didn't happen in the 151 site. The LCL was composed of a single hearth, indicating that the camp was occupied shortly by a relatively small group of hunter-gatherers, probably only of family size. The rich archaeological remains and thicker cultural deposits in UCL indicate that the site became a regional base camp for relatively long occupations by larger groups of hunter-gatherers in Early and Middle Holocene. From these analyses, our understanding of the spread of prehistoric hunter-gatherers to the TP and human adaptation strategies to the high-altitude environments is greatly enhanced.

New evidence of the earliest microlithic hunter-gatherer occupation on the Tibetan Plateau during the last deglaciation

Mr. Yuanxin Li [1], ***Mr. Xuke Shen*** [1], ***Ms. Juanting Yao*** [1], ***Ms. Ting Cheng*** [1], ***Mr. Dongpeng Lin*** [1], ***Prof. Dongju Zhang*** [2]

1. *Key Laboratory of Western China's Environmental Systems (Ministry of Education), College of Earth and Environmental Sciences, Lanzhou University, Lanzhou, 730000, China,* ***2.*** *College of Earth and Environmental Sciences, Lanzhou University*

Archaeological studies show that microlithic hunter-gatherers started to forage on the Tibetan Plateau (TP) more and more frequently since the Last Deglaciation. Comparing to the current general picture of the spatio-temporal distribution of microlithic sites and the microlithic technology traits on the plateau, we know very little about how these microlithic hunter-gatherers first spread to the Tibetan Plateau. Here, we report a new microlithic site Jiangjunfu 02 (JJF02), with an elevation of 2740 meters above sea level, on the margin of the northeastern TP. ^{14}C and OSL dating analysis suggests that hunter-gatherers arrived at the JJF02 site ~16 ka BP and continued to occupy the site until ~13.3 ka BP. Magnetic susceptibility and grain size analyses show that the weakened East Asian Winter Monsoon during 16-12.7 ka BP provides a suitable natural environment for human survival in the region where JJF02 located. Though only a small number of stone artifacts had been collected during the excavation, it is certain that the assemblage is dominated by microblade technology. The synthesis analysis of the site suggests that JJF02 is a temporary site occupied by high-mobility hunter-gatherers, closely related to the contemporaneous microlithic sites in Qinghai Lake basin. Further comparison studies of microlithic sites in the North China reveal that the spread of microlithic hunter-gatherers across the North China and further to the Tibetan Plateau had several stages and was obviously impacted by climate changes. As the earliest microlithic site on the TP, JJF02 has played a key role in the microlithic hunter-gatherers' spread to the Tibetan Plateau and their successful adaptation to the high-altitude environments indicated by their subsequent wide and intensive occupation of almost the entire plateau.

CT scan as a tool to unravel the dynamic of Mediterranean Coralligenous

Dr. Pietro Bazzicalupo [1], ***Dr. Valentina Bracchi*** [2], ***Dr. Giulia Piazza*** [1], ***Prof. Adriano Guido*** [3], ***Dr. Mara Cipriani*** [3], ***Prof. Antonietta Rosso*** [4], ***Dr. Gemma Donato*** [4], ***Dr. Francesco D'Alpa*** [4], ***Prof. FRANCESCO SCIUTO*** [5], ***Prof. Marco Bertolino*** [6], ***Dr. Gabriele Costa*** [1], ***Prof. Rossana Sanfilippo*** [4], ***Prof. Daniela Basso*** [2]

Coralligenous reefs, made up of crustose coralline algae (CCA), represent an important ecosystem of the Mediterranean shelf. The skeletal framework of these bioconstructions hosts a variety of organisms, many of which compete for the space while contributing to the reef growth, while others weaken the structure through their bio-erosive activities. The relationships between builders, destroyers and inhabitants remain elusive. We collected two discrete Coralligenous build-ups off the Marzamemi Coast (South-East Sicily). The first (CBR2_3_7c, 37 m depth) was collected in an area with high Coralligenous cover, and the second (CBR2_4_21c, 36 m depth) from a submarine channel with sparsely distributed build-ups. A Computed-Tomography scan was used for the first time with Coralligenous to reconstruct the internal structure of the two build-ups. Additionally, radiocarbon dating on the two build-ups has been used to determine their age and growth rate. Results show a complex behavior of the Coralligenous inner structure. The framework can be divided into four main density categories (Low, Medium, High and Ultra High), which are associated with different skeletal carbonates and the sediment infills. The structure cavities, either primary or due to taphonomic processes, have been measured as porosity. In the CBR2_3_7c, we observe that the HD material associated with compactly overgrown algal thalli generally decreases from bottom to top, accompanied by an increase in porosity. The CBR2_4_21c, seems instead to show higher percentages of HD material on its top and a counterintuitively high porosity at the bottom of the structure, possibly reflecting an intense bioerosion activity. In both samples the highly resolved analysis points to a non-linear growth of the build-ups. Microfacies observations confirm the tomographic data, revealing denser skeletal/micrite textures associated with the HD material, while more porous and less cemented structures are reflective of the LD and MD materials. With increased porosity, the micrite infills reduce in abundance leaving the support of the framework to the CCA. The understanding of the differences, in terms of structural density, porosity and growth rate, of the two structures might shed a light on the influence of the extremely local environment on the Coralligenous growth and inception.

Skeletons vs micrite in building the framework of the present-day Coralligenous along the Marzamemi coast (Sicily)

The Mediterranean Sea hosts several coralligenous build-up rising from the sedimentary bottom. They are characterized by heterogenous benthic assemblages. In the frame of the project FISR_04543 “CRESCIBLUREEF”, the coralligenous bioconstructions formed along the Mediterranean shelf in front of the Marzamemi village (Sicily, Italy) have been studied to investigate the nature and role of micritic sediments in the growth and stabilization of the bio-structures. For microfacies analysis, thin sections have been examined using transmitted and UV-light. The microfacies revealed a high vacuolar algal skeletal framework with several other organisms' remains (bryozoans, serpulids, echinoids, foraminifers, ostracods, and sponge spicules) and cavities filled with different types of sediments, notably autochthonous and allochthonous micrite. A preliminary point counting, performed on polished thin sections, showed the predominance of calcareous red algae (up to 50.7%) followed by allochthonous micrite (22.3%), empty cavities (13.2%), other bioclasts (4.2%), autochthonous micrite (4.1%), bryozoans (3.4%), serpulids (1.5%), and endolytic sponges (0.6%).

The autochthonous micrite shows peloidal or aphanitic textures, whereas allochthonous micrite (detrital organic and inorganic micrite) shows a denser texture rich in small skeletal and non-skeletal grains. The autochthonous fraction is made of very fine anhedral to sub-euhedral calcite crystals and it is associated with the presence of sponge spicules. Moreover, this fraction shows a bright fluorescence when excited with UV-light suggesting a high content in organic matter. These findings suggest that a double type of organics might be present in the autochthonous micrite: a type trapped among the crystals and a type strictly related to the organic nucleation of the crystals and preserved inside their lattice. On the contrary, the allochthonous fraction displays a very faint to none epifluorescence, testifying only a few amount of sedimentary organic matter trapped among the fine grains of this fraction.

It could be assumed that the autochthonous micrite is formed *in situ* through organomineralization processes of the sponges' soft-tissues and occurs during the formation of the skeletal framework, whereas the allochthonous fraction derives from physical processes including the entrapment of skeletal remains of species living on and inside the coralligenous build-up, this latter taking place after the development of the primary framework.

Low reef coral diversity in the incipient Red Sea (Burdigalian, Saudi Arabia)

Dr. Chiara Pisapia [1]***, Prof. Guillem Mateu Vicens*** [2]***, Prof. Marco Brandano*** [3]***, Prof. Francesca Benzoni*** [4]***, Prof. Hildegard Westphal*** [1]

1. *King Abdullah University of Science and Technology (KAUST), Saudi Arabia,,* ***2.*** *Universitat de les Illes Balears,* ***3.*** *Department of Earth Sciences, Sapienza University of Rome, Italy,* ***4.*** *Red Sea Research Center, King Abdullah University of Science and Technology, Thuwal, Saudi Arabia*

In the Tertiary, temperatures and pCO_2 dropped from high levels of the late Mesozoic to present-day levels, with a plateau in the Burdigalian to Langhian (Lower to Middle Miocene). During the Miocene, scleractinian coral reefs developed into the euphotic ecosystems known from the present-day tropical and subtropical shallow-waters. Coral diversity peaked in the Burdigalian, and declined afterwards. In contrast to this global trend, scleractinian diversity was low in the Red Sea which had only started to open in the Oligocene, and experienced its first marine incursion in the Burdigalian. Here, we report on the hard coral diversity of Miocene reefs assigned to the Burdigalian Wadi Waqb Member (Jabal Kibrit Formation) from outcrops behind the Red Sea coastline near Umluj, Saudi Arabia. Our study confirms that at that time, coral assemblages in the Red Sea were similar to those in the Mediterranean but different from the Indo-Pacific, with the notable exception of the genus *Porites*, being present in both, the Mediterranean and the Indo-Pacific. The observed faunistic differences in the coral dominated benthic assemblages are consistent with the hypothesis that the Afar mantle plume was blocking the connection between the Red Sea and the Indo-Pacific from the Early Oligocene to the Pliocene, while the Red Sea was connected to the Mediterranean through the Gulf of Suez. This blockage may have thus impaired exchange of scleractinian coral species with the Indo-Pacific. Moreover, in addition to the scleractinian diversity survey, we here present a first taxonomic assessment of other relevant reef-dwelling organisms such as coralline algae and benthic foramnifers and provide a comparison to modern day species spectra of coral reefs in the Red Sea.

Fossil coral reef terraces as paleo sea-level indicators since the Quaternary: Records from the Philippines

Ms. Kathrine Maxwell [1], ***Prof. Hildegard Westphal*** [2], ***Prof. Alessio Rovere*** [3], ***Mr. Kevin Garas*** [4], ***Ms. Mirasol Guinto*** [5]

1. Leibniz Centre for Tropical Marine Research (ZMT), Bremen, Germany, 2. Leibniz Center for Tropical Marine Reserach (ZMT), 3. Ca' Foscari University of Venice, 4. Institute of Renewable Natural Resources, College of Forestry and Natural Resources, University of the Philippines, Los Baños, Laguna, Philippines

Coral reef terraces are planar geomorphological sea-level indicators, normally observed along coastal areas, that are formed through repeated bioconstructional and erosional processes. Following our previous work in which we produced a standardized database of Last Interglacial (LIG) sea-level indicators in Southeast Asia, we revisited a site in the Philippines where inferred fossil coral reef terraces were previously reported. Based on previous studies, Late Pleistocene coral reef terraces (rising to about 100-155 meters above mean sea level (m amsl) and Holocene terraces (rising to about 14 m amsl) in age are observed along the western coast of Pangasinan, west Luzon Island. In this work, we present new geomorphic and stratigraphic data on the fossil coral reef terraces in Pangasinan, west Luzon which adds to the limited LIG sea-level indicators in the region. We conducted Real-Time Kinematic Global Navigation Satellite System (RTK-GNSS) surveys along select areas in western Pangasinan to provide precise elevations and geographic locations of these fossil sea-level indicators. We also analyzed available Interferometric Synthetic Aperture Radar (IfSAR)-derived digital elevation models to map and delineate the elevation patterns of these raised coral reef terraces. Based on our analysis, we identified distinct levels of coral reef terraces which may correspond to several episodes of RSL change from the late Quaternary to the present. Analysis of sea-level indicators is important in constraining both regional and global drivers of sea-level change. However, our work proves to be more challenging due to the difficulties of finding pristine dateable materials for radiometric dating and doing field surveys during a global pandemic. Nonetheless, we hope that data from this research will help us further understand the different drivers of past sea-level changes in SE Asia providing necessary geologic baseline data for projections of sea-level change in the future.

The growth of Sabellaria spinulosa bioconstructions in tank experiments

Dr. Alessia de Luca [1], ***Dr. Stefania Nunzia Lisco*** [1], ***Dr. Tamara Lazic*** [2], ***Dr. Cataldo Pierri*** [2], ***Prof. Massimo Moretti*** [3]

Sabellaria spinulosa (Leukhart, 1849) is a polychaete suspension feeder worm that lives in tubes consisting of agglutinated sediment particles held together by a very resistant sticky substance produced by the worm itself. Each individual lives inside the tube he builds, the tubes juxtaposed one another trap additional sediment and give rise to imposing structures that change the backdrop on which they are established. These worms are gregarious organisms able to build bioconstructions known as worm reefs that can contain several thousand of tubes. The worm reefs are present at all latitudes with various genera. The genus Sabellaria is widespread along the North Atlantic European coast and also along the Mediterranean coasts. In the present work, some fragments sampled from the Torre Mileto reef (Apulia, Italy) have been used to set up experiments of tube growth in tanks under controlled conditions (temperature, salinity, pH, turbulence, amount of nutrients, etc.). Three different kinds of sands were used in tanks, in order to understand how Sabellaria selects sediment granules according to their mineral-petrographic composition, shape, size and density. The effect of grain-size on the reef growth were analyzed varying the granulometric range of sands used in the experiments (125-355 μm). The results obtained are of great interest for the understanding of the natural dynamics of the worm reefs in situ.

Historical models of Iranian culture atlas

Dr. zohreh.baseri@gmail.com Baseri [1]

1. ministry cultural heritage

Iran in the early Paleolithic period From three million two hundred thousand years ago The first human signs discovered until about two hundred thousand years ago It can be considered the beginning of the Paleolithic period. One of the most important findings of prehistoric mankind was the use of fire. Containment and use of fire probably It was realized about a million years ago. In the early Paleolithic period, humans through hunting and gathering plants from the surrounding environment, lived their lives, They lived in natural shelters such as caves And they used very simple stone tools in their daily work. Not many findings have been obtained from the early Paleolithic period. In Iran, the oldest human remains in Khorasan river discovery bed has been discovered. Also, in Ganj Par Rostam Abad, Shiv To Mahabad, Darband Cave, Gilan. south and east of Tabriz, Ladiz, 65 km south of Zahedan, Around Khwaja Sistan mountain, Helilan narrow bridge and some scattered places of human settlements It was discovered in the early Paleolithic period. The tools of this period are called Asholi tools. It should be noted that at that time Central Asia had a milder climate And many rivers and lakes were seen in the region. For example, the Persian Gulf continued until near Mosul And there were many lakes in the center of the Iranian plateau It is possible to see the current small lakes of Iran, such as Lake Urmia, He considered Qom, Ni Riz and Hamon to be remnants of the waters of that era . Fossils of many sea creatures from these seas It is left in Central Alborz.The oldest works of this period in Iran belong to The lower Paleolithic period is New And it is between 200,000 and 100,000 years old. Iran has received attention in the New Paleolithic era in which small groups lived in the corners This period has been divided into three parts: lower, middle and upper. New Paleolithic era in which small groups lived in the corners This period has been divided into three parts: lower, middle and upperMiddle Paleolithic

Palaeoecological Reconstruction of the Flora, Vegetation, Landscape and Palaeoethnobotany at the remarkable Late Palaeolithic / Early Mesolithic Rock Shelter of Flözerbändli (Muota Valley, Canton of Schwyz, Switzerland)

Prof. Jean Nicolas Haas [1]***, Dr. Benjamin Dietre*** [1]***, Dr. Irka Hajdas*** [2]***, Mr. Walter Imhof*** [3]***, Mr. Ferdinand Kleyhons*** [1]***, Mr. Werner Kofler*** [1]***, Prof. Walter Oberhuber*** [1]***, Mr. Werner Schoch*** [4]***, Ms. Hannah Stanger*** [1]***, Mrs. Irene Swidrak*** [5]***, Prof. Timothy Taylor*** [6]***, Dr. Urs Leuzinger*** [7]

1. *Department of Botany, University of Innsbruck,* ***2.*** *Laboratory of Ion Beam Physics, ETH Zürich,* ***3.*** *Muotathal,* ***4.*** *Labor für quartäre Hölzer,* ***5.*** *Kitzbühel,* ***6.*** *Univerzita Komenského v Bratislave,* ***7.*** *Amt für Archäologie Thurgau*

Palaeoecological analyses of Palaeolithic and Mesolithic archaeological sites are relatively rare for Central Europe. Here we present palynological, macro-botanical and charcoal determination results for the anthropogenic rock shelter frequentation between ca. 10300 and 8400 BC in the context of the exploitation and use of plants by prehistorical hunter-gatherer societies. This remarkable abri of Flözerbändli is famous for its unique and decorated antler fragment from the Epi-Palaeolithic (radiocarbon dated to 10,519-10,028 BC), which was decorated with rows of pit marks probably using a flint tool. During the Epi-Palaeolithic and Early Mesolithic, the local arboreal vegetation consisted of pine, birch, juniper, alder, lime and hazelnut. Collected hazelnuts were used as nutritious and staple food as revealed by the regular occurrence of hazel nutshell parts in the archaeological layers of the Flözerbändli rock shelter. In addition, the stratigraphy of the abri contained some charred seeds of herbs, such as from Caryophyllaceae and from St. John's wort (*Hypericum* cf. *perforatum*), which is remarkable, as the latter plant is known as a remedy for medicinal purposes until today. Considering the maturity of most of the palaeoethnobotanical finds, the rock shelter was predominantly used during the summer or autumn months. Interestingly, yew wood (*Taxus baccata*) was used as firewood in the rock shelter as revealed by abundant charcoal finds, eventually taking advantage, that this wood is relatively smoke-free when burnt. Eventually, the charcoal remnants may be the result of extracting yew poison from fresh twigs in order to lubricate the arrows of the prehistoric hunters. The palynological context confirmed the Younger Dryas and Early Holocene vegetation to be expected in a central Alpine valley at 740 m a.s.l. for that time. However, algae remains such as from *Trachelomonas* and *Mougeotia*, which both occur in stagnant water, do point to the transport of water to the rock shelter, which in terms of water was, and is, an extremely dry living spot since the Epi-Palaeolithic.

A palaeo-reconstruction of Devensian ice-flow phasing in the Vale of York.

Ms. Holly Jenkins [1], *Dr. Bethan Davies* [2]

1. Durham University, 2. Newcastle University

Ice provenance and dynamic behaviour between the British-Irish ice sheet has been subject to controversy in recent years. Several studies of clast lithology and glacial morphology have alluded to the inland extension of the North Sea Lobe into north-east England and the Vale of York. However, the extent that the North Sea Lobe extends into the Vale of York, and its dynamic interactions with the Stainmore and Wensleydale ice masses is as yet unknown. This study aims to reconstruct the complex provenance of the Vale of York ice lobe through clast lithological and matrix geochemical analysis. Multivariate statistical methods were applied to the datasets in the form of a PCA and Cluster Analysis, to aid in the correlation of Vale of York tills to BIIS and NSL type sites. Indicator erratics for NSL (Cheviot volcanics and flint), Scottish (greywacke and metasedimentary lithologies), and Lake District (felsic tuff) provenance were found in several tills and were central to tracing till provenance. Major and trace metal, and clast lithological cluster analyses have identified at least two occasion where the NSL and Eden-Stainmore ice converges at Scorton Quarry in the north of the Vale of York. NSL ice has been traced as far south and west as Norton Mills. Deposits to the west (Marfield Quarry and Lightwater Quarry) are dominated by a local Wensleydale ice signature and lack evidence of North Sea ice.

Insights into the longterm behavior of North American ice sheets from newly identified Middle Pleistocene Margins

Mr. Phillip Kerr [1]

1. Iowa Geological Survey

Newly identified Middle Pleistocene glacial boundaries and ice flow indicators have been delineated in the Midwestern United States using a novel drainage network analysis. The glaciated region beyond the last two glacial maxima is tectonically stable, and the topography is dominated by a thick package of glacial sediments deposited throughout the Quaternary. As this landscape was created by continental ice, the last ice advance covering an area would be the primary driver for drainage organization. This morphology would largely persist until burial during subsequent glacial episodes. By inverse, the modern drainage network is a palimpsest record of previous glacial advances.

To create a model identifying indicators of glacial advances within drainage networks, this study mapped moraines, meltwater flow paths, and current drainages within two younger ice lobes: the Des Moines and Illinois lobes. The ~MIS 2 Des Moines Lobe flowed south into central Iowa and disrupted the headwaters of basins. In contrast, the MIS 6 Illinois Lobe advanced westward into southeastern Iowa which blocked and dammed the lower reaches of watersheds. These findings show the newly formed drainage network is not deranged but is in fact highly organized due to glacial landforms; both ice advances imprinted their lobate silhouette across basins, leaving a moraine-derived, trellis-pattern network.

Using these diagnostic patterns on the older landscape, a series of northern- and eastern-sourced lobes were identified, and their cross-cutting relationships were used to establish their relative age. These analyses indicate that at least four lobes advanced from central Canada and two-to-three flowed out of the Great Lakes Region during the Middle Pleistocene. Additionally, all ice avoided southwestern Wisconsin. Older, northern advances appear to have been buried by eastern lobes, suggesting a shift in the Middle Pleistocene that caused ice in eastern Canada to extend further south. These new margins represent the first step in an effort to build a new terrestrial-based framework for the behavior of the Laurentide Ice Sheet throughout the Early and Middle Pleistocene. These findings can inform numerical models dealing with previous iterations of the Laurentide Ice Sheet and will guide future work unraveling the Midwest’s complex glacial sediment package.

Determining the retreat chronology of the Green Bay Lobe, Wisconsin, USA during the last deglaciation using cosmogenic nuclides from exposed bedrock

Mr. Jeremy Brooks [1], ***Dr. Lucas Zoet*** [2], ***Mr. Andrew Jones*** [1], ***Dr. Patrick Colgan*** [3], ***Prof. Paul Bierman*** [4], ***Dr. Shaun Marcott*** [1]

1. *Department of Geoscience, University of Wisconsin-Madison, Madison, Wisconsin, USA,* ***2.*** *Department of Geoscience, University of Wisconsin-Madison, Madison, WI 53706, USA,* ***3.*** *Department of Geology, Grand Valley State University, Allendale, Michigan, USA,* ***4.*** *Rubenstein School of the Environment and Natural Resources, University of Vermont, Burlington, VT, USA*

A precise chronology of ice sheet retreat during the last deglaciation is important for evaluating how paleoclimate, sea level, and ice sheet dynamics co-evolve during past periods of rapid warming. This information is necessary to constrain what climatic triggers lead to rapid deglaciation, which advances understanding of modern ice sheets experiencing similar rapid warming today. Deglacial chronologies of the Laurentide Ice Sheet retreat are based on radiocarbon dating of organic matter and cosmogenic nuclide dating of moraine boulders, but existing data has numerous spatial and temporal gaps that complicate interpretations of ice sheet retreat and its relation to global sea level and climatic triggers. The Green Bay Lobe was a major lobe of the southern Laurentide Ice Sheet, but material suitable for radiocarbon dating is sparse possibly because of permafrost conditions in the region. Here, we test and add to the existing deglacial chronology of a major lobe of the southern Laurentide Ice Sheet (Green Bay Lobe, Wisconsin) using *in situ* cosmogenic radionuclide dating (^{10}Be and ^{14}C in quartz) collected from glacially eroded bedrock promontories and glacial erratic boulders located between major moraine sets. We present new cosmogenic nuclide dates spanning a 175 km north-south transect of the Green Bay Lobe. These data will fill spatial and temporal gaps in the Green Bay Lobe retreat chronology and test whether previous relative or correlative dating assumptions based on moraines and till stratigraphy are accurate. Paired cosmogenic nuclides (^{14}C and ^{10}Be) will also allow inference of rates of subglacial erosion on bedrock outcrops during the last glacial period.

A chronological database from Greenland - GreenDated

Prof. Nicolaj Krog Larsen [1], **Dr. Ole Bennike** [2]

1. Globe Institute, University of Copenhagen, Denmark, 2. GEUS - Geological Survey of Denmark and Greenland, Department of Groundwater and Quaternary Geology Mapping, C. F. Møllers Allé 8, Building 1110, 8000 Århus C, Denmark

GreenDated aims to compile and assess all published radiocarbon, optically stimulated luminescence (OSL) and cosmogenic isotope dates from Greenland. Our goal is to make an open-access database and use the information to make a well-constrained deglaciation chronology of the Greenland Ice Sheet the last c. 20 ka. Previous attempts have compiled some of the exciting data (e.g. Dyke et al., 2002; Sinclair et al., 2016); others have been focusing on a sub-set of the data for example by compiling the oldest dates at the outer coast and close to the present ice margin extent (Bennike & Björck, 2002; Funder et al., 2011). In this compilation, we use a similar protocol as the DATED-1 database from Eurasia (Hughes et al., 2015) and the SvalHolo database from Svalbard (Farnsworth et al., 2020). Until now, we have compiled >5000 ^{14}C from c. 600 papers, and >1000 ^{10}Be dates from c. 100 papers. We have so far not compiled the OSL dates but estimate that there are <200 dates in c. 30 papers. The plan is to compile all published data with a cut-off date ultimo 2022 and make them available ultimo 2023.

1. *Durham University,* ***2.*** *Department of Geography, Durham University, Durham DH1 3LE, UK.,* ***3.*** *British Antarctic Survey,* ***4.*** *School of Biological and Environmental Sciences, Liverpool John Moores University,* ***5.*** *University of Newcastle,* ***6.*** *School of Geosciences, University of Aberdeen, Aberdeen, UK,* ***7.*** *The University of Manchester,* ***8.*** *Monash University*

This project focuses on the Northeast Greenland Ice Stream (NEGIS), a key sector of the Greenland ice sheet (GrIS) because it controls ice flux into the NE Atlantic (an area sensitive to freshwater input) and holds a sea-level equivalent (SLE) of ~1.4m. This sector of the ice sheet is known to have undergone dramatic retreat during the Holocene Thermal Maximum (HTM) and is predicted to be vulnerable to future climatic changes. This work aims to reconstruct the past behaviour of the NEGIS and understand ice/ocean/atmosphere feedbacks over 100 - 1000yr timescales.

Along 79N fjord during the last Glacial Maximum (LGM) the NEGIS was coalescent with local ice caps, with warm-based ice operating up to ~850m asl. The earliest exposure age constraints for the initiation of ice stream thinning are 23 - 20 ka and this is concomitant with grounding line retreat from the outer continental shelf edge at ~19.5 ka. Continued retreat of the ice to the mid-shelf by ~ 15 ka is matched by onshore thinning between 18 – 15ka. The development of a pronounced grounding zone wedge complex in the mid Norske trough can be dated to ~15 - 13 ka and this temporary stability is manifest onshore in a staircase of perched delta and lateral moraines that mark a reduction in the ice stream thinning rate around 12.5ka.

The NEGIS retreated through the inner continental shelf between 12 – 10 ka and was pinned at the eastern end of 79N fjord by 9.2 ka. The ice stream then calved rapidly between 9.2 and 8.0 ka due to marine ice sheet instability into deep water. This led to a period of open marine conditions in 79N fjord during the Holocene Thermal Maximum. However, post ~4.5 ka Neoglacial cooling triggered ice stream/shelf regrowth and the cessation of marine conditions. The rapid retreat of the ice stream and disappearance of the 79N ice shelf at the opening of the Holocene due to increased air and ocean temperatures will be mirrored in future decades as we move into a + 2°C world.

Was there an ice shelf on Baffin Bay during the Last Glacial Maximum?

Dr. Pierre-Olivier Couette [1], ***Dr. Patrick Lajeunesse*** [2], ***Dr. Jean-François Ghienne*** [3], ***Dr. Boris Dorschel*** [4], ***Dr. Catalina Gebhardt*** [5], ***Dr. Dierk Hebbeln*** [6], ***Dr. Etienne Brouard*** [7]

Ice shelves are floating ice platforms extending beyond grounded ice sheets on continental margins. They play a major role in the stability and mass-balance of marine-terminating ice sheets by acting as buttresses that restrain rapid ice flow and loss of ice to the ocean. The glaciological significance of ice shelves is relatively well established for the stability of modern ice sheets of Antarctica. Past ice shelves of the Arctic, however, are poorly documented while their role for the stability of former ice sheets remains mostly unknown. The existence of an ice shelf in Baffin Bay during the last glacial episode has recently been suggested and debated, but this hypothesis has remained inconclusive due to the absence of physical evidence. Here we present swath bathymetry and seismostratigraphic data that reveal a large moraine system extending along the continental slope off Baffin Island independently from glaciers grounded on the outer shelf, demonstrating that a 500-m thick ice shelf covered northern Baffin Bay during the last glacial episode. This ice shelf likely had a profound impact on the stability of a series of major ice streams that drained the interior of the Laurentide, Innuitian and Greenland ice sheets. Climate warming and global sea-level rise in the early stage of deglaciation possibly contributed to a large-scale collapse of the ice shelf, removing the buttressing effect which led to the destabilisation and reorganisation of tributary ice streams from these three ice sheets. These findings support the idea that ice sheets around northern Baffin Bay did not contribute significantly to rising sea level before Meltwater Pulse 1A (MWP-1A – 14,650 years ago).

MIS 3 records of ice sheet history and climate change in northern Sweden

In the central parts of northern Sweden, a relict pre-Late Weichselian landscape has been preserved due to frozen-bed conditions of the last ice sheet covering the area. Characteristic of this landscape is eskers and drumlins showing ice flow from the NW and Veiki moraine, a type of ice-walled lake plains formed due to melting of debris covered stagnant ice. Earlier studies have shown that the preserved landforms are from the Weichselian glacial period, however, which stadial/interstadial phase they belong to has been debated. We have studied sedimentary records from the relict landscape with the aim to date the glacial history and improve earlier studies of Weichselian interstadial climate and vegetation. Methods used are OSL-dating, radiocarbon dating, pollen analysis, macrofossil identification and stable isotope analysis of leaf waxes. Our OSL-dates of the Veiki landscape give ages of 56-39 ka which implies that the moraine was formed during MIS 3. Since the Veiki landscape was formed due to down wasting of stagnant ice at the easternmost margin of an ice sheet in central northern Sweden, the ages are evidence of a phase where we had an intermediate-sized ice sheet in Scandinavia. Through comparisons with other data on glacial history and climate we suggest that the ice sheet advance prior to Veiki moraine formation occurred during Greenland stadials 16.1-15.1 (56.5-54.2 ka) and that final melting of the ice within the landscape took place during GI-14 (54.2-48.3 ka). Pollen, macrofossils and leaf wax stable isotope data give additional information about the interstadial conditions. We analysed d^2H_{wax} from the sites Riipiharju and Rauvospakka and observe that the clear climatic shift from cold to warm conditions reflected in the pollen signal in the Riipiharju sequence is also reflected as a change in the isotope data. For Rauvospakka the isotope data indicate more climatic variability than inferred by the pollen data.

Did the Roone ice shelf suddenly retreat during the Last Glacial-Interglacial Transition?

Dr. Dieter Tetzner [1], ***Dr. Liz Thomas*** [2], ***Dr. Claire Allen*** [1], ***Prof. Eric Wolff*** [3]

1. British Antarctic Survey, 2. British Antarctic Survey (BAS), Natural Environmental Research Council (NERC), High Cross, Madingley Road, Cambridge CB3 0ET, UK., 3. University of Cambridge

Recent modelling studies suggest significant mass loss and rapid collapse of the West Antarctic Ice Sheet (WAIS) has occurred in the past, making recent predictions that anthropogenic warming could lead to a loss of the WAIS in the next few centuries particularly alarming. However, major uncertainties exist regarding the past and future stability of the WAIS and its ice shelves. To better predict the fate of the WAIS under future warming scenarios, we must first determine how stable is the ice sheet and its ice shelves in response to forcings. This can be achieved using accurate paleoclimatic records during past climate transitions.

The Last Glacial-Interglacial Transition (LGIT), 20,000-6,000 years ago, is an ideal period to assess the relationship between climate, ice sheets and sea level. During this period, the temperature in Antarctica increased by over 11° Celsius and the global mean sea level rose 125-130 meters. Marine sediment records suggest the Ronne ice shelf, the second largest ice shelf in Antarctica, presented considerable retreats in response to the changing environmental conditions. Despite the global relevance, to date, the magnitude and timing of these retreats are still uncertain.

Here, we present a centennial resolution diatom record from the Skytrain ice core during the LGIT. The diatom diversity in Antarctic ice cores closely represents the proximity of the nearest open water source. Antarctic coastal domes present diatom assemblages dominated by locally sourced sea ice species. This contrasts with the diatom diversity observed at inland sites, which are dominated by open ocean species indicating long-range transport. We use these characteristic signatures to track past changes in the proximity of the nearest open water source, providing new evidence to explore the potential sudden retreat of the WAIS during the LGIT, causes and timing.

Quaternary stratigraphy and glacial history at Peace River, Alberta: Implications for mapping and modeling of older continental ice sheet limits in western Canada

Dr. Roger Paulen [1], ***Dr. Alwynne Beaudoin*** [2], ***Dr. Martin Ross*** [3]

1. Geological Survey of Canada, 2. Royal Alberta Museum, 3. University of Waterloo

The number and style of the continental Laurentide Ice Sheet (LIS) glacial advances in the western prairies of North America has been the subject of debate, especially in the Peace River district of western Alberta and eastern British Columbia. Given its northern Alberta location, resolving the glacial record of this area has important implications for understanding the evolution of the LIS, especially during its earlier (pre-Late Wisconsin) phases. The Quaternary stratigraphy documented in Alberta's Peace River lowlands has been subject to conflicting interpretations. This is probably due to the absence of a single complete stratigraphic sequence preserved at any one section (reflecting extensive landsliding along the Peace River valley), and a lack of chronologic control for lower parts of the sequence.

The valley-fill sediments located at the confluence of the Heart and Peace rivers, within the town of Peace River, Alberta, provide perhaps the best record in the Interior Plains of western Canada of an almost continuous sequence of Quaternary sedimentation extending from the bedrock surface to present. Here, a 187 m thick composite stratigraphy records the transition from preglacial fluvial sedimentation (Unit 1), to a penultimate proglacial sedimentary sequence (Units 2 and 3) that is conformably overlain by interstadial fluvial sediments (Unit 4) of possible MIS-3 age, or older (based on limiting radiocarbon dates). In turn, these sediments are overlain by a Late Wisconsin ice advance/retreat cycle of sedimentation from the LIS (Units 5-8). The sequence is capped with Holocene loess with paleosols, containing mollusc and plant macrofossils. The only till unit in the stratigraphy (Unit 7) is from the Late Wisconsin glacial advance. Clasts of Canadian Shield lithologies in the lower fluvial sediments (Unit 2) are derived from southwestward draining southern Buffalo Head Hills catchments, where multiple, older glacial sediments have been documented. Consequently, we argue that there is evidence for only a single continental (Laurentide) glaciation in the eastern Peace River district, similar to what is defined to the southwest in Quaternary exposures along the Smoky River.

Late Quaternary glacial history of the Sjuøyane archipelago, northern Svalbard

Prof. Anders Schomacker [1], ***Prof. Helena Alexanderson*** [2], ***Dr. Wesley R. Farnsworth*** [3], ***Dr. Mark Furze*** [4], ***Dr. Sofia E. Kjellman*** [1], ***Dr. Nina Kirchner*** [5], ***Prof. Riko Noormets*** [6], ***Dr. Vincent Jomelli*** [7]

1. *Department of Geosciences, UiT The Arctic University of Norway, N-9037, Tromsø, Norway,* ***2.*** *Department of Geology, Lund University, Sölvegatan 12, SE-223 62 Lund, Sweden,* ***3.*** *Globe Institute, University of Copenhagen, Denmark,* ***4.*** *The University Centre in Svalbard,* ***5.*** *Department of Physical Geography, Stockholm University,* ***6.*** *Department of Arctic Geology, University Centre in Svalbard,* ***7.*** *Aix Marseille Univ, CNRS, IRD, INRAE, Coll France, CEREGE, Aix-en-Provence, France*

Sjuøyane are the northernmost islands of the Svalbard archipelago. Little is known about their glaciation and relative sea-level history, deglaciation, and postglacial environments. Here we present preliminary results from two Quaternary geological field expeditions to Sjuøyane and discuss challenges and potentials. We also present new cosmogenic exposure ages of bedrock and boulders to reconstruct the timing of the last deglaciation. The ultimate goal of this study is to better understand the history and behavior of the northern margin of the Weichselian Svalbard-Barents Sea Ice Sheet. Being the northernmost land area on Svalbard, Sjuøyane are strategically well located for this purpose.

Coastal sedimentary sections along several of the islands provide insight into the Weichselian and Holocene stratigraphy. We identified two coarsening-upwards marine sedimentary sequences. Previous studies have interpreted these sediments as evidence of a pre-Late Weichselian and a Late Weichselian glaciation. Our radiocarbon and luminescence ages indicate a glacier advance before ~40 ka.

The postglacial marine limit sits at 18 m a.h.t. in Isflakbukta, Phippsøya (one of the islands). Above that, we identified an upper pre-Last Glacial Maximum marine limit marked by a clear bedrock erosional notch with wave-eroded bedrock, large water-worn boulders, and rounded cobbles. Ages from raised beaches and deltaic sediments at Parryøya (one of the islands) suggest that the island was ice free at *c.* 11.2±0.3 cal. ka BP.

Stratigraphic reconstruction of the lower/middle Pleistocene transition in the western sector of the Garda end-moraine system

Mr. Dylan Cook [1]***, Dr. Giovanni Monegato*** [2]***, Dr. Catharina Dieleman*** [3]***, Dr. Naki Akçar*** [3]***, Dr. Giancarlo Scardia*** [4]***, Prof. Susan Ivy-Ochs*** [5]

1. *Department of Earth Sciences, ETH Zürich,* ***2.*** *CNR - IGG,* ***3.*** *Institute of Geological Sciences, University of Bern,* ***4.*** *Universidade do Estado de São Paulo,* ***5.*** *ETH Zurich*

The Lake Garda region in Northern Italy hosted repeated glaciations by the Adige-Sarca glacier during the Pleistocene, forming Lake Garda, the Garda end-moraine system, and an extensive suite of glacial and glaciofluvial deposits. Late Alpine tectonic activity uplifted the area west of present Lake Garda over the course of the Pleistocene, shifting subsequent glacier advances eastward. Reconstructing the timeline and extent of earlier glacier advances in the western Garda end-moraine system has been made difficult by the limited availability of exposures and challenges in determining absolute ages for pre-Last Glacial Maximum deposits. This study sets out to constrain the absolute timing of glacial and glaciofluvial deposits at two sites in the western Garda end-moraine system, the Calcinato Moraine and Ciliverghe Hill. A cut-and-cover railway construction project briefly exposed a succession of Pleistocene deposits at both the Calcinato Moraine and Ciliverghe Hill in the spring of 2022, allowing for detailed stratigraphic description and sampling of crystalline clasts from the exposed units for isochron-burial $^{26}Al/^{10}Be$ dating. Prior paleomagnetic investigations indicates the basal units of the exposed successions may be in the range of MIS 22 – MIS 16 in age. The results of isochron-burial dating of these briefly exposed sediments may potentially provide an independent temporal constraint for paleomagnetic data, building upon current research projects examining deposits from the early Pleistocene in the western Garda end-moraine system, with the possibility to contribute significantly to our understanding of past glaciations and interglacial periods in the Southern Alps.

Early Middle Pleistocene glaciations and interglacials in Poland

Prof. Leszek Marks [1]

1. Polish Geological Institute - National Research Institute

The lower boundary of the Mid-Pleistocene is identified, based on magnetostratigraphic examination of deposits at 3 sites, namely Kończyce and Kozi Grzbiet in southern Poland and Kalejty in northeastern Poland. Generally, the early Mid-Pleistocene (MIS 19-12) consists of 2 interglacials and 2 glaciations in Poland. A sequence of these stratigraphical units starts within the complex Podlasian Interglacial (Cromerian I-II), interglacial optima of which correspond presumably to MIS 21, 19 and 17, and they are separated by cool intervals of MIS 20 and 18. A maximum extension of the early Mid-Pleistocene glaciations and the age of the first one are represented by a till and the admixture of the Scandinavian material in fluvial deposits in proglacial valleys, in southern Poland located in front of the advancing ice sheet. Such deposits exotic material are traditionally named the mixed gravels. The Sanian 1 Glaciation (Donian?) was the most extensive in Poland and during its maximum, the ice sheet overpassed a latitudinal river valley located along the northern margin of the Carpathians and then running through the Dniester valley to the Black Sea. This fore-Carpathian river was reactivated after the Sanian 1 Glaciation, being active during the following Ferdynandovian Interglacial (Cromerian III-IV) that has been previously correlated with MIS 15-13 but at present, it is considered to be mostly the equivalent of MIS 15. The ice sheet of the next, Sanian 2 Glaciation (Elsterian), occupied a limited area and its extension was presumably similar to the Odranian Glaciation (Saalian) of the late Mid-Pleistocene. The research was done within the project no. 2017/27/B/ST10/00165, funded by the National Science Centre in Poland.

Pedostratigraphy of the Baluchabad loess-paleosol sequence, Northern Iran

***Mr. Zaniar Amiri* [1], *Prof. Farhad Khormali* [2], *Dr. Martin Kehl* [3], *Dr. Christian Zeeden* [4], *Prof. Manfred Frechen* [5]**

***1.** Dept. of Soil Science, Gorgan University of Agricultural Sciences and Natural Resources, Iran, **2.** Gorgan University of Agricultural Sciences and Natural Resources, Gorgan, Islamic Republic of Iran, **3.** Institute of Geography, University of Cologne, **4.** Leibniz Institute for Applied Geophysics, Hannover, Germany, **5.** Leibniz Institute for Applied Geophysics (LIAG)*

The early to middle Pleistocene climate changes and global cold and warm stages remain widely unknown in northeast Iran. Mainly due to the paucity of regional sedimentary records the early to middle Pleistocene climate changes and global cold and warm stages remain unknown in northeast Iran. Loess deposits are one of the sedimentary archives that well-preserved information about paleoclimatic changes. The loess-paleosol sequence (LPS) of Baluchabad is located at the north face of Alborz Mountain and contains twelve paleosols with varying weathering degrees that are well distinguishable by their clear boundaries from loess layers. The detailed study of the 54 m-long sequences has a high potential to reconstruct the paleoenvironmental conditions in the area. According to the results of the field description, grain size distribution, and magnetic susceptibility the section has been divided into 4 units. Unit 1 is from top to 20.4 m depth under the land surface and starts with a weakly developed soil (U1S1) identified by a slightly darker color and a weak subangular blocky structure. Among other notable points of this unit is the existence of 3 layers with a higher amount of coarse silt and sand at the depths of 10, 14, and 18 m. Unit 2 is from 20.4 to 34 m depth and contains five paleosols separated by compacted loess layers related to MIS-5 with different degrees of weathering from weak to well-developed pedocomplexes, respectively. Unit 3 from 35-47.7 m below the surface and unit 4 contains 3 well-developed paleosols intercalated with loess layer and sharp upper and lower boundaries making it clearly distinguishable from loess layers. The reddish-brown color of these paleosols, the high percentage of clay content, and the underlying Bk horizons indicate an advanced stage of development of these paleosols. Also in unit 4 existence of iron and manganese (hydr-) oxides demonstrate well-developed paleosols formed under reducing conditions. Generally, the Baluchabad section provides a unique framework for regional and superregional stratigraphy correlation and investigating in detail paleoenvironmental changes during the middle to early Pleistocene.

Establishing the timing of the first Fennoscandian ice sheet advances on the North European Plain

Mr. Kaleb Wagner [1], _Ms. Lotta Ylä-Mella_ [1], _Dr. John D. Jansen_ [1], _Dr. Martin Margold_ [2]

1. GFÚ Institute of Geophysics, Czech Academy of Sciences, Prague, 2. Department of Physical Geography and Geoecology, Charles University, Prague

The Fennoscandian ice sheet (FIS) repeatedly advanced from the Scandes Mountains, with its first inception in the late Pliocene. During major glaciations of the Middle-Late Pleistocene, it coalesced fully with the British-Irish and Barents-Kara Sea ice sheets, forming the core of a singular Eurasian Ice Sheet Complex. Maximal configurations, documented by an asynchronous and discontinuous sedimentary record, depict the FIS extending east from the Dutch Rhine-Meuse delta, fringing the Harz Mountains and Thuringian Uplands in central Germany, and abutting the northern slopes of the Sudeten and Carpathian ranges in southern Poland. Multiple advances throughout the Quaternary inundated the North European Plain (NEP), rerouting major south-north drainages. While these patterns have been considered in detail for the Last Glacial Cycle (LGC), empirical reconstructions of the FIS for earlier Pleistocene glacial periods remain poorly constrained, relying on stratigraphic correlations from palaeoenvironmental data over timescales beyond reach of most conventional geochronometers.

The ^{26}Al-^{10}Be cosmogenic nuclide (CN) pair in quartz provides a well-understood framework for dating glacial deposits across timescales of 10^5-10^6 years. In North America, recent CN applications have bolstered insights into the pre-LGC glaciations, uncovering broader spatial extents for the earliest Pleistocene Cordilleran and Laurentide ice sheets. Although a significant volume of glacigenic material distributed over the NEP has also been speculated to support ages of ≥MIS 12 (478-424 ka), additional scrutiny of the chronologies is warranted in many cases.

Here, we attempt to regionally correlate the earliest glacial strata on the NEP, and link these to a consistent chronology by employing a CN burial dating approach capable of resolving depositional ages up to ~5 Ma. This strategy invokes a source-to-sink framework, coupling inverse Monte Carlo simulation of CN abundances with a rejection sampling module, enabling probabilistic burial-age determination for samples characterized by complex exposure and erosion rate histories which are prevalent within glaciated catchments. Our field sites, spanning locations between the Netherlands and Lithuania, allow for a wide range of potential early FIS geometries. It is anticipated that new quantitative ages bracketing pre-Late Pleistocene chronozones in this region will improve the utility of non-absolute, yet widely-applied, bio- and palynostratigraphic correlation schemes.

Important findings from the TephroMed project III: The cryptotephras of the ICDP Dead Sea deep core during the last 130kya

Dr. Markus Schwab [1]***, Dr. Rebecca Kearney*** [1]***, Dr. Ina Neugebauer*** [1]***, Mrs. Oona Appelt*** [2]***, Dr. Christina Günter*** [3]***, Dr. Nadine Pickarski*** [4]***, Mr. Daniel Redant*** [1]***, Dr. Rik Tjallingii*** [1]***, Prof. Achim Brauer*** [1]

The eastern Mediterranean region has experienced large hydroclimatic shifts throughout the last glacial to glacial period (130-30kya). The region is located between the contrasting humid Mediterranean climate and the Saharo-Arabian desert belt. Important sedimentary archives from lakes allows past changes in precipitation regimes to be reconstructed using multiple proxies. The Dead Sea (Israel) ICDP DSDDP record is an important palaeoenvironmental archive that provides detailed insight into the environmental characteristics and timing of these climatic shifts. This record has undergone extensive palaeoenvironmental and climatic reconstructions (e.g. stable isotopes, pollen) and has been dated through absolute and relative methods (radiocarbon, U-Th, wiggle-matching). However, problems with large chronological uncertainties have prevented detailed insight into the regional climatic (a)synchronies with other palaeoclimatic records in the region (e.g. Lake Van, eastern Anatolia).

The application of cryptotephra (non-visible volcanic ash), is a powerful chronological tool to refine age uncertainty and correlate palaeoclimatic records together, particularly over vast distances. Previous investigations on The Dead Sea record have found important cryptotephra layers within the sediment (e.g. the early Holocene S1 tephra), allowing palaeoenvironmental records to be integrated.

Building upon this work, we present here the important cryptotephra findings from the Dead Sea, part of the TephroMed project. Our cryptotephra investigations focused on intervals of the record that possibly contained glass shards from important eruptions originating from volcanic sources in the Mediterranean region. Numerous tephra layers have been identified. Major, minor and trace element volcanic glass chemistry (Electron microprobe analysis and LA-ICP-MS), with the use of statistical methods, have revealed cryptotephra layers derived from numerous volcanic sources in the Mediterranean. These include Central Anatolia and Eastern Anatolia, Hellenic Arc and the Italian volcanoes. The identification of cryptotephra in the Dead Sea has greatly extended the tephrostratigraphic framework of the region of disparate volcanic regions. Correlations using tephra layers have now been made to other important palaeoenvironmental sites (Lake Van) and archaeological records in the region, including into the Levant and Arabia. This has provided insight into the time transgressive nature of climatic shifts throughout this period.

Volcanic reconstruction of the Belbaşhanı Pumice eruption: a late Quaternary fallout deposit emitted in the Central Anatolian Volcanic Province (CAVP), Turkey

Ms. Rengin Özsoy [1], *Dr. Ivan Sunye Puchol* [1], *Prof. Erkan Aydar* [2], *Dr. Dario Pedrazzi* [3], *Dr. Efe Akkaş* [2], *Prof. Silvio Mollo* [1]

1. Department of Earth Sciences, Sapienza University of Rome, 2. Department of Geological Engineering, Hacettepe University, Ankara, 3. Geosciences Barcelona, GEO3BCN-CSIC, Barcelona

The Central Anatolian Volcanic Province (CAVP), which is related to post-collisional volcanism, has hosted many volcanic events in central Turkey since the Miocene to the present day. The most prominent are the Cappadocian ignimbrites, which cover an area of 20000 km^2 and had been formed between ca. 10 and 2.5 Ma. Since the early Quaternary, the eruptive activity has been concentrated both in basaltic monogenetic volcanic fields and large felsic polygenetic complexes, including Acıgöl caldera, Erciyes, and Hasandağ stratovolcanoes (i.e., the most active, explosive, and dangerous composite volcanoes within the CAVP). Hasandağ volcano, which currently has risen seismic and fumarolic activity, has produced large explosive eruptions during the last million years, in conjunction with several caldera collapses. The pyroclastic deposits formed by Hasandağ comprise ignimbrites, block and ash flows, pumice and ash fall deposits. One of these is the Belbaşhanı Pumice deposit, which age has been estimated at 339± 50 ka by U/Pb dating on zircons and is going to be re-evaluated by Ar/Ar. Belbaşhanı Pumice is a thick fallout deposit, which is well-preserved along the Belbaşhanı valley, located between the eastern flank of Hasandağ and Keçiboyduran volcano. In this work, we have investigated in detail the tephrostratigraphy, deposit distribution, granulometry, glass geochemistry, geochronology, and volcanic ash morphological properties of the Belbaşhanı Pumice aiming at reconstructing isopach/isopleth maps and the physical parameters of the related explosive eruption (i.e., erupted magma volume, column height, tephra distribution, volcanic source, etc.). Preliminary results indicate that this deposit may have been originated via sub-Plinian to Plinian eruption, which started with a steady column that moved to a waxing-waning column at the end, with a distribution axis of the tephra towards the northeast, and a potential volume of Pyroclasts up to 0.5 km^3. In this perspective, physical parameterization of volcanic activity can be pivotal to assess the hazard at Hasandağ, as well as the glass chemistry can contribute to understand the tephrostratigraphic framework, by compilation of a database for tephra correlations and synchronization of distal sedimentary records, which is also important to paleoenvironmental reconstructions and/or archeologic studies.

More than just a dating technique: determining the integrity of lake sediment records through tephrochronology

Dr. Gill Plunkett [1], ***Dr. Thierry Fonville*** [2], ***Dr. Maarten van Hardenbroek*** [3], ***Prof. Andrew Henderson*** [4], ***Dr. Helen Mackay*** [5], ***Dr. Ben Pears*** [6], ***Dr. Patrick Gleeson*** [7], ***Prof. Inger Alsos*** [8], ***Prof. Antony Brown*** [9]

The reliability, accuracy and validity of palaeoenvironmental reconstructions hinge upon the establishment of robust chronological control. Lake sedimentary sequences can be problematic to date for reasons including carbon reservoir effects, sediment disturbance and the in-wash of eroded organic material. Such records do, however, capture run-off from the surrounding area, making them ideal for a host of palaeoenvironmental methodologies, including geochemistry, sedaDNA and lipid biomarker analysis. Here we consider opportunities and challenges presented by sedimentary records from small lakes on islands sandwiched between Ireland and Scotland around the Sea of Moyle, and demonstrate important insights into the integrity of the sediment through the application of tephrochronology. The lakes offer possibilities to reconstruct a history of changing landscapes, environment and population history on the islands, providing an important basis for understanding the sustainability and resilience of complex socioecological systems over the Late Holocene. Initial ^{14}C rangefinder dates from the sequences revealed age-reversals and off-sets that posed barriers for establishing the age of the sediment. The application of tephrochronology presents a solution to the chronology, yet one that is at odds with a series of ^{210}Pb age estimates for the top of the core. The tephrostratigraphic record brings to light, however, systemic sediment disturbance through the sequences that highlight issues with establishing robust age control. We consider the implications of the tephra profile for understanding the palaeoenvironmental reconstructions from the lake sediment, and evaluate from the proxy records, including sedaDNA, whether the sediment mixing is clearly evident in the absence of the tephrostratigraphic data.

Characterization of three large holocene pyroclastic deposits from Mt Erciyes Stratovolcano (Central Anatolia, Turkey): Karagüllü, Perikartın and Dikkartın

Ms. Simge Kaya [1], *Dr. Ivan Sunye Puchol* [2], *Ms. Rengin Özsoy* [3], *Prof. Erkan Aydar* [4], *Dr. Manuela Nazzari* [5], *Prof. Silvio Mollo* [6]

Earth Sciences Department, University La Sapienza of Rome

Mount Erciyes, the largest stratovolcano in Central Anatolian Volcanic Province (CAVP) with elevation of 3917 m, has erupted three voluminous pyroclastic deposits during the Holocene (Karagüllü, Perikartın and Dikkartın) by different flank vents associated with rhyolitic lava-domes. Tephra produced by these large explosive eruptions were injected into the troposphere and the related distal/ultra-distal ashes were found in Black Sea cores (Karagüllü ashes) and in Mediterranean Sea (Dikkartın ashes up to 600 km away from the source). In this work we aimed to petrologically characterize these Holocene deposits by chemical microanalyses of glasses and minerals, in order to better understand the plumbing system beneath Erciyes volcano, and the eruption processes governing the emplacement of the three deposits (Karagüllü, Perikartın and Dikkartın). According to minor differences in chemistry and mineralogy, zircon dating and sequence modeling support synchronicity at 8.9 ± 0.4 ka, as the result of one single volcanic event. Dikkartın products include plagioclase + amphibole + pyroxene + Fe-Ti oxides, whereas Karagüllü and Perikartın products include plagioclase + amphibole + pyroxene + biotite + Fe-Ti oxides. The amphibole geobarometry of Dikkartın, Perikartın, Karagüllü pyroclastic samples return shallow crystallization depths of 1.5-3.7 kbar, 1.5-3.2, and 1.7-4.3 kbar, respectively. Plagioclase phenocrysts from Dikkartın are slightly depleted in total alkali concentration (~1.6-7.6 wt%) relative to those from Karagüllü (~1.9-8.8 wt%). Glass geochemistry (major and trace element) shows that Karagüllü has slightly higher SiO_2 concentrations (~76-78 wt%) than Dikkartın (~75-76 wt%) and Perikartın (~75-77 wt%), whereas Dikkartın has a higher Zr content (~90-200 ppm) than Karagüllü and Perikartın (~30-140 ppm). Additionally, Dikkartın's glass exhibit slightly higher CaO (~1.3-2.5 wt%) and FeO (~1.2-2.3 wt%) concentrations than Karagüllü and Perikartın glasses (~0.8-1.5 wt% CaO and ~0.8-1.6 wt% FeO), although data align along the same compositional trend. Compositional mapping of zoned plagioclase phenocrysts shows that the CaO content increases from rim to core, while the opposite occurs for Na_2O. This normal zoning pattern is also associated with reverse zonation testifying to magma mixing phenomena.

Refining high spatial resolution trace element analysis of single-grain vitreous tephra shards by LA-ICP-MS

1. *Centre for Quaternary Research, Department of Geography, Royal Holloway University of London, Egham, UK,* ***2.*** *Department of Earth Sciences, Royal Holloway University of London,* ***3.*** *School of Archaeology, Geography and Environmental Science, University of Reading, UK.*

Tephra layers, deposited in sedimentary archives can provide unique opportunities to synchronise palaeoclimatic and archaeological records over the Quaternary. Tephra correlation is based on the geochemical characteristics of tephra which are controlled by magmatic process of the source volcano. However, small non-visible ash layers (cryptotephra) shards usually have travelled long distances are usually found with particularly small size ranges, resulting in technical problems during geochemical analysis. Recent analytical developments of EPMA allows precise and accurate tephra major element compositions from very small tephra shards (Hayward, 2012)). The most common technique used to analyse trace elements for small tephra shards is downhole drilling with a very small laser spot, using LA-ICP-MS. However, this remains problematic as small shards are also very thin meaning the laser can ablate through the shard very rapidly limiting the duration of analysis, resulting in problems of downhole fractionation and low precision. This often minimises the application of LA-ICP-MS analyses in distal tephra studies, and restricts them to larger shards. Trace element compositions are important for tephra correlation as tephra from either the same source volcano or different sources can have the indistinguishable major element compositions if the magmatic processes are very similar.

Here we propose a rastering sampling strategy for small tephra trace element analysis on LA-ICP-MS. The rastering sampling strategy has been tested on MPI-DING glass standards and natural cryptotephra shards. The study demonstrates that the method of rastering the laser beam with a small spot size along the tephra surface generates a higher precision analysis profile, without the problem of downhole element fractionation when drilling with a smaller size laser beam. This is important as more ultra-distal cryptotephra being detected in multiple studies across the globe and many of these require trace elements to confirm correlations based in large part so far on major elements only.

New insights into Late-Pleistocene Campanian explosive volcanism using tephra deposits preserved in central Mediterranean marine cores

Ms. Molly Flynn [1], ***Dr. Paul Albert*** [2], ***Prof. Victoria Smith*** [3], ***Dr. Christina Manning*** [4], ***Dr. Roberto Isaia*** [5], ***Ms. Sophie Vineberg*** [6], ***Dr. Sebastien Nomade*** [7]

Volcanoes experience physical and chemical changes spanning their entire life-cycle, giving rise to a range of behaviour, including changes in eruptive style, magnitude and frequency. This makes long-term reconstructions of past activity essential for accurate forecasting of future eruptive scenarios. Routinely, tephra deposits preserved close to the volcano are examined to reconstruct past behaviour, which in turn helps informs hazard assessments. Unfortunately, the burial and destruction of older eruption deposits by more recent activities regularly leads to gaps in the near-source eruption record, and while this is particularly problematic for low- to mid-intensity eruptions, it also extends to large magnitude events, all of which has negative implications for the accuracy of hazard assessments.

Fortunately, tephra deposits preserved in long, continuous and undisturbed sedimentary successions offer opportunities to fill the gaps in explosive eruption records. Here we exploit distal tephra deposits preserved in Mediterranean marine sediment cores from both the Tyrrhenian (DED87-08) and Adriatic (MD909-16) seas to help better constrain the timing and scale of past explosive volcanism at the active Campanian volcanoes (Campi Flegrei, Ischia Island and Vesuvius), Southern Italy. In this contribution we present major (EMP) and trace element (LA-ICP-MS) volcanic glass chemistry for newly identified visible and crypto- tephra deposits identified in the two examined marine sediment sequences. These geochemical fingerprints are used to identify the volcanic source of the tephra deposits, and to provide new insights into the frequency, scale, and ash dispersal of past eruptions at Campi Flegrei and Ischia.

A 30,000 yr high-precision eruption history in the north Izu Islands, off Tokyo, Japan

Prof. Takehiko Suzuki [1]***, Dr. Kaori Aoki*** [1]***, Dr. Makoto Kobayashi*** [2]***, Dr. Masanori Murata*** [3]***, Dr. Fumikatsu Nishizawa*** [4]***, Dr. Takayuki Takahashi*** [5]

1. *Tokyo Metropolitan University,* ***2.*** *Mt. Fuji World Heritage Centre, Shizuoka,* ***3.*** *Research Center for Hazard Mitigation in Volcanic Islands and Urban Areas, Tokyo Metropolitan University,* ***4.*** *Kanagawa Prefectural Museum of Natural History,* ***5.*** *International Research Institute of Disaster Science, Tohoku University*

Quaternary volcanoes in north Izu Islands, the north part of Izu-Bonin Arc, are composed of basalt to rhyolite volcanic islands. Comparing to other Quaternary volcanoes in the main Japanese Islands, their long-term explosive eruption histories established by tephrostratigraphy are limited. To constrain the tempo and frequency of explosive eruptions that occurred at both basalt and rhyolitic volcanoes in this area, we aimed to establish detailed tephrostratigraphical framework for terrestrial and marine tephras in north Izu Islands. Niijima and Kozushima Volcanoes located in the back arc side are originated from rhyolitic magma. Both volcanoes have erupted with less frequency than basaltic volcanoes such as Izu-Oshima and Miyake Volcanoes. Interestingly, Niijima and Kozushima Volcanoes erupted within a short interval of ca. 50 years in 9th century as last explosive eruptions. However, eruption histories for these volcanoes differ during last 30 kyrs. At Niijima Volcano, eruptions with the magnitude equivalent to the latest AD886 event (Nj-My) (>0.1 DRE km^3) have occurred every thousand years since the Miyatsukayama event (12.8-8.5 cal ka) (Kobayashi et al. 2020). On the other hand, at Kozushima Volcano preceding the latest eruption of AD 838 event (Kz-Tj; 0.54 DRE km^3), only Kz-CbA (30-22 ka) and Kz-CbB (ca. 30 ka) events have been recognized as explosive eruptions except unclear Kz-CbA' event (14-12.8 ka?) (Murata et al. 2021). Kz-CbB is stratigraphically immediately below representative widespread AT tephra (30 ka) originated from the Aira Caldera in South Kyushu, SW Japan.

By focusing on two stratigraphically short intervals of Nj-My/ Kz-Tj and AT/ Kz-CbB, it is possible to constrain the tempo and frequency of explosive eruptions on other volcanic islands such as Izu-Oshima and Miyake Volcanoes where eruptions have occurred more frequently.

Advances in New Zealand's Quaternary tephrochronostratigraphy using marine drill sites.

Ms. Katharina Pank [1]***, Dr. Steffen Kutterolf*** [2]***, Dr. Jenni L Hopkins*** [3]***, Dr. Kuo-Lung Wang*** [4]***, Mr. Hao-Yang Lee*** [5]***, Prof. Axel K. Schmitt*** [6]

North Island, New Zealand, hosts one of the most frequently active rhyolitic Quaternary systems in the world, the Taupõ Volcanic Zone (TVZ). The volcanic centres of the TVZ are aligned NE-SW within c. 300 km length and c. 60 km width on central North Island, parallel to the subduction front east of New Zealand. Nine calderas are recognised, and at least 34 caldera forming eruptions occurred during the Quaternary. At present, two volcanic centres, or calderas, are considered to be active.

The volcanic evolution of the TVZ <61 ka has been intensely studied based on onshore studies, but the older eruptive history is less known due to post-depositional erosion or burial of deposits by subsequent eruptions.

We present the Quaternary marine tephra record from eleven deep-sea drill sites covering the proximal and distal marine environment offshore of New Zealand, complementing earlier studies on distal marine sediments. Based on major and trace element compositions, the stratigraphic context and visual appearance of the marine tephras we identified 331 as primary deposits. Correlations between holes and sites across the study area reveal 165 individual Quaternary volcanic events, of which 35 were successfully linked to onshore correlatives.

The marine tephra record complements the Quaternary onshore record and allows to reconstruct the eruptive history of New Zealand's Quaternary TVZ.

There she blows! Unravelling the eruptive history of Aso volcano (Japan) using distal ash (tephra) deposits

Aso (southwestern Japan) is one of the largest active volcanoes in the world, with a caldera that was formed and modified by a series of at least four catastrophic VEI 6 – 7 eruptions between ca. 270 to 87 ka. These caldera-forming events produced widespread ash deposits blanketing Japan and the surrounding seas, with the final Aso-4 event generating pyroclastic density currents that can be mapped over 160 km from source. Between these cycles, and to the current day, Aso is known to have remained very active, but the frequency and dispersal of these events are poorly constrained. This is unsurprising since the proximal exposures are limited and the numerous cataclysmic events have destroyed and buried older deposits. Here, we highlight the critical role that distal records play in evaluating the eruptive history and hazard potential of Aso caldera. We review the known distal occurrences of tephra deposits erupted from Aso, integrating new data from lake and marine sedimentary records across the East Asian/Pacific region. This detailed tephrostratigraphic framework highlights inconsistencies in tephra correlations and suggests large magnitude events were more frequent and widely-dispersed than previously anticipated. To further supplement this record, we use high-resolution sedimentary cores to identify non-visible ash (cryptotephra) deposits erupted from Aso, which provide new insight into the timing and dispersal of both pre- and post- caldera-forming events. The precisely dated Lake Suigetsu sediment core (central Japan) provides the most comprehensive distal eruption record for Aso, despite being over 530 km NE from the vent. The Suigetsu record is utilised to date and geochemically fingerprint (using major, minor and trace element glass compositions) thirteen ash fall events from Aso that reached the now densely populated regions of central Honshu. This work serves as a critical reminder that even in volcanic regions that are intensely studied, numerous large Quaternary explosive events remain poorly understood and many are undocumented. Unravelling the past eruptive history, repose intervals and magmatic characteristics is essential for calderas like Aso which pose a significant threat for populated regions.

Estimating method of the overflowing volume deposits at the Little Ice Age applied to the fossil branch of the Rhône, Bras de Fer (France)

Crevasse splay is one of the landforms of stream hydrodynamic activity (Coleman 1969; Arnaud-Fassetta 2013). When preserved following avulsion, these geomorphological structures can serve as a proxy for the evaluation of a paleo-fluvial activity. The rise in the resolution and precision of spatial data makes it possible to detect and characterize these structures quantitatively and qualitatively.

This work illustrates estimating the volume of sedimentary deposits method applies to crevasses splays of the Bras de Fer palaeochannel, borrowed by the Rhône from 1587 to 1711 AD. Its years of operation, coinciding with the Little Ice Age (LIA), are distinguished by an exceptional development of the delta plain, as much as by this distributor's very brief activity of 124 years. The beginning of its active period is contemporary with a more attenuated period of LIA, while the end of its activity is marked by high hydraulicity and sedimentary inflow (Pichard 2014).

The IGN-LiDAR HD (2021) point cloud turns out to be the appropriate tool for high-resolution (50 cm) topographic analysis. T.J. Fleury's (2021) methodology applied to LiDAR data uses the attributes of each point such as intensity, number of returns as well as return number to produce a high-resolution DEM. Unlike similar products existing since 2015 as RGE Alti and Litto 3D (minimum resolution 1m2), the DEM LiDAR HD enables better identification of river palaeoforms preserved on the surface. It provides details on the micro-topography for imaging the slight altimetry variations of very flat environments. The cartographic spatial delineation of sedimentary deposition forms was made by the semi-automatic recognition classification from the DEM LiDAR HD, combined with ancient aerial images, Sentinel-1 radar images, and Infrared Color Orthoimages.

This data is coupled to the thicknesses of the crevasse splay, bank and floodplain deposits, which were identified in trenches and cores and then digitized in 3D as a Digital Outcrop Model. The 3D model of sedimentary structures was interpolated and extrapolated from these datasets.

Late Quaternary morphotectonic evolution of the Matese lake intramontane basin (Southern Apennines, Italy)

Dr. Ettore Valente [1], Prof. Antonio Santo [2], Dr. Gianluigi Di Paola [3], Prof. Alessandra Ascione [4]

Department of Civil, Constructional and Environmental Engineering, University of Naples Federico II, 3. Department of Biosciences and Territory, University of Molise, 4. Università degli Studi di Napoli, Federico II

The Matese lake Basin (hereinafter MLB) is a NW-SE oriented intramontane basin placed in the core of the carbonate Matese massif. The latter is placed in the axial and seismogenic belt of the Southern Apennines and includes the highest peak of the chain. Historical seismicity indicates that most of the strongest earthquakes (e.g., M > 6.5) that struck the Southern Apennines occurred in the surrounding of the Matese massif (i.e., to the north-east, east, and west of it). On the opposite, earthquakes in the core of the massif are rare and include the M 5.1, 29 December 2013 event. The epicentre of this event occurred to the south-east of the MLB, and shade light on the active tectonics in the central portion of the Matese massif. Noteworthy, the MLB exhibits diffuse fault-controlled landforms such as rectilinear scarps and triangular facets that point to a major role played by tectonics in shaping the basin. Fault strands downthrown the carbonate bedrock and led to the accumulation to a tens of metres thick sequence of lacustrine to alluvial deposits, whose precise thickness has not been defined up to now. In addition, such deposits mainly outcrop to the NE of the basin where large alluvial fan occur. The scarcity of outcropping Quaternary deposits makes the reconstruction of the active tectonics in the MLB hard to be solved. To unravel this issue, we combined detail scale geomorphological and stratigraphical data with geophysical measurements. The former datasets allow recognising the presence of tens to hundred metres long fault strands affecting the Quaternary filling of the basin, whereas geophysical investigation allow detailing the subsurface geometry of the downthrown carbonate bedrock. Furthermore, we collected samples of fluvio-lacustrine deposits with evidence of faults displacements, trying to perform absolute dating of such deposits with the aim of providing chronological constraints to fault activity. Overall, collected data allow discerning the recent morphotectonic evolution of the MLB and may provide useful data for the definition of the active tectonics in this poorly known portion of the Apennine chain.

Impact of the Mid-Pleistocene Transition on Meuse River Terraces in the Southern Netherlands

Mr. Ewerton da Silva Guimarães [1], ***Dr. Kees Kasse*** [1], ***Dr. Freek Busschers*** [2], ***Dr. Renaud Bouroullec*** [2], ***Prof. Ronald van Balen*** [1]

***1.** Earth Sciences, Vrije Universiteit Amsterdam,* ***2.** TNO Geological Survey of the Netherlands, Utrecht, Netherlands*

River terrace deposits are excellent archives of paleoenvironmental conditions. They reflect the tectonic and climatic settings of their time of formation. For this reason, especially the Late-Pleistocene and Holocene terraces have been studied, because of their good state of preservation and their age control. Less is known about Early- and Middle-Pleistocene terraces. The Lower Meuse River, a major tributary of the Rhine River, located in the Southern Netherlands, exhibits a well-preserved terrace staircase which, for decades, has been intensely investigated. The spatial configuration of the terraces is well known, and indirect age constraints are available, which are mainly based on correlations made with the marine isotope record. This allows for delineating the boundaries of the Early, Middle and Late Pleistocene terraces.

The existing spatial and temporal constraints of these terraces make the Lower Meuse River terrace staircase a suitable object of study for understanding the effects of the Mid-Pleistocene Transition (MPT) in northwest European river systems. To achieve that, we aim to compare different terrace levels according to their ages, and main lithological and morphological parameters. More specifically, a comparison is drawn between Early-, Middle-, and Late Pleistocene terraces. Differences in sedimentary parameters and trends are expected as a result of the climatic deterioration and shift in the climate cycle caused at the MPT (1.2 – 0.8 Ma), as well as due to regional tectonics (uplift of the Ardennes massif). The comparative assessment helps to clarify how the Meuse River system responded to the MPT.

To achieve the proposed goals, this work presents an updated Meuse terrace map for the Southern Netherlands and adjacent areas in Belgium and Germany. A dense borehole database containing thousands of data points is used for calculating geometrical parameters of the terraces (thickness, top and base, gradient, incisional steps) and lithological composition.

Middle to Late Pleistocene sea-level markers along the coastal belt between Formia and Minturno, central Italy

***Prof. Marcello Schiattarella* [1], *Dr. Maria Luisa Putignano* [2], *Dr. Giuseppe Corrado* [1], *Prof. Paolo Emanuele Orrù* [3], *Dr. Mario Voltaggio* [2]**

***1.** University of Basilicata, **2.** Istituto di Geologia Ambientale e Geoingegneria, CNR, Roma, **3.** University of Cagliari*

The southernmost coastal sector of Latium, central Italy, shows many markers of Quaternary sea-level changes. The about 30 km-long coastal belt includes the Monte di Scauri promontory, the Formia-Vindicio plain, the Monte Orlando promontory, and the northern Gaeta beach system separated by minor headlands. The whole south-facing arched coastal plain of Formia is relatively narrow being immediately bordered at its back by an impressive mountain ridge mainly made of Mesozoic carbonate rocks. Survey and measurements of sea-level markers have been carried out along the Gaeta Bay coastline and at Monte d'Argento in the Minturno plain. In the Vindicio area, a carbonate clastic deposit, never reported before in the maps of this sector, has been found at about 17 m a.s.l.: petrographic analysis of thin sections of these sediments suggests a deposition in an inter-tidal littoral environment as beachrock deposits. Different cementation facies indicate an early cementation in a littoral environment followed by supratidal main cementation. Altough this formation is similar to the marine bioclastic deposit often morphologically hung along the coasts of southern Italy ("panchina carbonatica" Auctt.), the 230Th/234U isotopic analysis has revealed a Late Pleistocene (pre-Tyrrhenian) age for it. Actually, this deposit may be attributed to the MIS 7.5, so testifying a recent and intense tectonic activity. A staircase of faults affected also the weathered horizon of the calcarenite developed at least during or after the warm climate conditions of MIS 5. Therefore, it can be assumed that the area of Vindicio underwent a significant tectonic stage in Quaternary times, with an average uplift rate of 0.2 mm/yr. At Monte di Scauri and Monte d'Argento sites fossil notches, lithodome holes, beach deposits, and other geomorphological markers are well-exposed along the rocky cliffs and locally displaced by faults. Also between Gaeta and the Circeo promontory, at an elevation ranging from 5 to 10 m a.s.l., other sedimentary and morphological markers are largely present. All these data allowed us to complete the framework of the morphotectonic evolution followed to the mid-upper Pleistocene uplift and indicate that the area was subject to a remarkable tectonic activity up to the MIS 5.1.

Climatic vs tectonic control in Late Quaternary evolution of the eastern Maiella foothills (Central Apennines, Italy)

Dr. Edi Chiarini [1], ***Dr. Felicia Papasodaro*** [1], ***Dr. Alessandro Troccoli*** [1], ***Dr. Domenico Fiorenza*** [1], ***Dr. Letizia Vita*** [1]

1. *Italian Geological Survey ISPRA, Rome*

A case study from an area between the eastern slopes of the carbonate ridge of the Maiella Mountain and the valley floor of the Aventino River (eastern Abruzzi) points out to the importance of torrential and gravitational phenomena, i.e. mass movements, in landscape evolution.
The studied area is dominated by the northwest-trending Maiella anticline and its northern plunging end, by the hilly belt made up of thrusted terrigenous and clayey to marly alloctonous successions, and by monoclinal quite undeformed clayey-sandy and conglomerate deposits. These latter testify the persistence in the northern sector of a marine sedimentation throughout the Early Pleistocene - while the Maiella had already emerged - and quantify the magnitude of uplift since early Middle Pleistocene onwards. Its setting is a consequence of the Early Pliocene-Early Pleistocene compressive tectonics and of the Middle Pleistocene generalized and intense regional uplift.
After the final emersion from the sea and a first phase of continental sedimentation, when debris layers and large systems of alluvial fans have formed at the junction belt between the mountain area and the coast, the foothills east of the Maiella ridge experienced intense denudational and related sedimentary events, in a phase of intense and rapid uplift and relative base-level lowering partly coinciding with the cold climatic pulsations of the Late Pleistocene. Geodynamic and climatic factors have acted in synergy or have opposed each other favoring areal erosive phenomena, debris production, gravitational processes(i.e. mass transport), or deepening by linear incision of watercourses, selective erosion and relief inversion.
This work - developed in the context of the Italian National Geological Mapping Project (CARG) with the aim to propose an example to be exported to other similar contexts - attempts to outline the rapid succession of events that characterized the late Quaternary evolution of this sector of the Apennine chain. A multidisciplinary method that includes field surveys, facies analysis, dating, image interpretation, and topography analysis will be used to investigate predisposing and activation factors, climatic and tectonic control and geomorphological processes that have acted in the past and, to some extent, still act today influencing human activities.

Tropical barrier island systems on the Brazilian equatorial margin, NE Brazil

Ms. Dhulya Rocha [1], *Dr. Helenice Vital* [1]

1. Universidade Federal do Rio Grande do Norte

The northern coast of the state of Rio Grande do Norte (RN) is classified as a semi-arid, semidiurnal mesotidal tropical coast and presents a very intense coastal dynamic. It is an erosion hotspot and in this context is outstanding the presence of barrier island-spits system, which isolate protected areas from the impact of the open sea. These bodies are inserted between two main fault systems, the Carnaubais and Afonso Bezerra systems, were oil industry and onshore wind power are installed. In this perspective, this study has as main objective the characterization of the tropical barrier island systems near the city of Macau/RN, under anthropic pressure, with applications to coastal erosion and environment, and petroleum reservoir analogs as well. The research has data on granulometry, gamma ray profile, calcium carbonate and organic matter content from 27 cores collected by the vibration method, which allows for continuous, undisturbed sampling of poorly consolidated materials. The results indicated the presence of different sedimentary deposits on their marine and terrestrial sides. The cores in the region towards the ocean present vertical sequences with a coarsening upward pattern, with fine sediment deposits, between the base and the intermediate portion, while the upper part of these cores present medium to fine sand. The set of cores facing the continent presents an inverse pattern, with fining upward, containing at its base sediment of coarse sand granulometry, grading towards the top to fine sand. A general fining upward pattern, presenting mud and very fine to fine sand, sometimes with medium sand, organic matter and fragments of bioclasts, were observed in the cores of the lagune area. These characteristics present in the studied cores allowed the identification of tidal flat, mangrove, beach/barrier island and tidal channel deposits, representative of high very energy tropical systems.

Submarine record from eruption-fed vertical density currents, Kermadec arc/Rangitāhua

***Ms. Janne Scheffler* [1], *Dr. Steffen Kutterolf* [1], *Dr. Martin Jutzeler* [2], *Dr. Rebecca Carey* [2], *Dr. Colin Devey* [1]**

1. GEOMAR Helmholtz Centre for Ocean Research Kiel, 2. University of Tasmania

Marine tephra layers are assigned to explosive volcanism that distributes volcanic material through submarine density currents, pyroclastic flows that travel over the sea, and/or as fallout but transitions or combinations of these emplacement processes are still under debate.

In April 2022, the RV *Investigator* voyage IN2022-V02 surveyed submarine and island volcanoes and their adjacent basins in the intra-oceanic Kermadec arc/Rangitāhua. A 5.58 m long piston core was sampled at 2460 m below sea level in a topographically isolated basin 100 km northwest from Macauley volcano. At 3.70 m depth below seafloor, an unusual 34-cm-thick, normally graded and shard-rich interval grades from planar bedded medium sand to cross-bedded fine sand to massive silt. The unit has well-developed scour marks in pelagic mud at its base. The cross-bedded facies dominates the deposit in thickness and comprises multiple ripple sets made of beds with low and high angles. Both planar and cross beds are defined by alternating beds of clear and brown glass shards. Tube-shape shards are the dominant component, foraminifera are common, but pyroxene and feldspar crystal fragments are rare. The composition of the glass shards is dominated by a homogeneous rhyolitic composition, yet sub-dominant andesitic compositions are present. The homogeneous normal grading and glass shard composition strongly suggest the unit is eruption-fed and from a single event. The extensive planar to cross-bedded facies in this unit raise questions on transport and sedimentation processes. Reworking by ocean currents is unlikely in a deep-water basin where no obstacle is present. Vent-derived submarine density currents are an unlikely source because hundreds of m high topographic barriers occur between the closest (50-100 km) volcanoes and the cored site. Our current model includes settling from either an aerial volcanic plume or pyroclastic density currents travelling over water. The unit suggests particle transport by vertical density currents through the water column, followed by lateral deflection upon impact with seafloor into seafloor-hugging turbidity currents. Stratigraphic grading from planar to cross beds suggests transition from upper-flow to lower-flow regimes, demonstrating high velocity currents. Ongoing geochemical and sedimentological studies will further inform on provenance and emplacement processes.

A globally-synchronized absolute timescale for Marine Isotope Stage 19

Radioisotopically dated sedimentary records provide unique information to reconstruct and understand past climate change. Such a chronological constraint is virtually lacking beyond the ranges of radiocarbon and U/Th dating (~55 ka and ~650 ka, respectively), leaving the chronology of most palaeoclimatic records reliant on far-afield and uncertain correlations. New, high-resolution ^{10}Be data, anchored to a detailed, sub-millennial-scale paleoclimate record for Marine Isotope Stage (MIS 19) constrained by high-precision ^{40}Ar/^{39}Ar dating from an Italian lacustrine succession, provide an age of 770.9±1.6 ka for the abrupt recovery of the geomagnetic field intensity that followed the Matuyama-Brunhes reversal. The temporal structure of this reversal proves to be complex and spatially heterogeneous, limiting its utility for high-resolution global synchronizations. By using our radioisotopically constrained record of the steadier ^{10}Be signal as global stratigraphic marker, we propose an inter-hemispheric synchronization of key palaeoclimatic time-series (i.e., the Antarctic EDC ice core and the Montalbano Jonico, southern Italy, and Chiba, Japan, marine successions), which allows reconciling the different chronologies of the millennial-scale events that punctuated MIS 19, the closest analogue to the present Holocene interglacial. Unlike astronomically-tuned records, our independent chronology allows us to assess the influence of astronomical forcing on glacial-interglacial and abrupt climate variability, avoiding circular reasoning.
