XXI Congress of the International union for Quaternary Research

"Time for Change"

ABSTRACT BOOK

doi 10.5281/zenodo.12749221

XXI INQUA 2023

ROMA

doi 10.5281/zenodo.12749221

Organised by

Sapienza Università di Roma

AIQUA – Associazione Italiana per lo Studio del Quaternario

Italian National Research Council

INQUA

Scientific patronage

Società Geologica Italiana

Ministero della Transizione Ecologica

INGV

ISPRA – Istituto Superiore per la Protezione e la Ricerca Ambientale

Sistema Nazionale per la Protezione dell'Ambiente

Società Paleontologica Italiana

EuroGeoSurveys – European Geoscience for Society – The Geological Surveys of Europe

Consiglio Nazionale dei Geologi

Comitato Glaciologico Italiano

SISC – Società Italiana per le Scienze del Clima

AIGeo – Associazione Italiana di Geografia Fisica e Geomorfologia

ENEA – Ente per le Nuove Tecnologie, l'Energia e l'Ambiente

Università degli Studi di Torino

Società Botanica Italiana onlus

Universitas Studiorum Insubriae

AIGA – Associazione Italiana di Geologia Applicata e Ambientale

OGS

Table of Contents

Session 2: Recent advances in understanding the causes of changes in regional and global palaeofire regimes: resources, tools and new approaches

Session 6: Recent advances in understanding the Quaternary geomorphological evolution of continental margins

Session 9: The Anthropocene – Its geo-archaeological indicators and early inceptions through the modern

Session 10: Visualizing Science – The art of communicating science

Session 13: Records of LGM climate and ecosystems dynamics

Session 14: Climate and environmental changes during the Holocene and past interglacials based on biological and geochemical proxies

Session 19: Global characterization of the Neogene–Quaternary (Pliocene–Pleistocene) transition

Session 20: Subglacial erosion, transport, and deposition: from landform and sediment evidence to modeling

Session 21: Records of climate change from MIS 3 and MIS 2 in the Southern Hemisphere: The Lynda Petherick Memorial Session

Session 22: Mountain glaciations and their diversity: Perspectives in geomorphology, geochronology, palaeoglaciology, and palaeoclimatology

Session 25: Islands and their relationship with the continent to investigate time and mode of their colonization by terrestrial vertebrates and Homo dispersal

Session 27: Resilience versus collapse: Human responses to climate change in the Quaternary

Session 28: Timing and structure of freshwater ecosystem response to external forcing: evidence from high-resolution multi-proxy lake and peat bog records

Session 30: A multiscale geoarchaeological approach for the interpretation of palaeo-landscapes and human activities

Session 31: Processes and feedbacks during glacial terminations

Session 33: Quaternary Glaciations: Processes, Sediments and Landforms

Session 36: Conservation paleobiology: late Neogene to Quaternary records as a baseline for conservation of modern ecosystems

Session 37: Reconstructing Quaternary ice sheets

Session 38: Reconciling deformation through Geomorphology, Active tectonics and Paleoseismology investigations along the India plate

Session 40: The Anthropocene as a tool for characterizing recent planetary change and predicting future environmental challenges

Session 42: Ecosystem change and hunter-gatherer behavioral decisions in the terminal Pleistocene Pacific Rim

Session 43: Millennial paleo-landscape reconstructions of coastal areas. From field data to modelling approaches

Session 46: Application of biomarkers and CSIA in Pleistocene archaeology

Session 48: Quaternary climate, landscape and surface processes in mountain belts

Session 52: Eurasia, one continent one common past: cross-continental stratigraphical correlations

Session 55: Understanding the human-animal-environment interface in Quaternary South Asia

Session 58: The new challenges for luminescence dating

Session 59: Past, present and future ice-ocean-atmosphere interactions between the Southern Ocean and the Antarctic Ice Sheet

Session 60: Geoarcheology and paleoenvironmental evolution of the coastal areas

Session 62: Paleoclimate, paleoweathering, paleoprovenance and machine learning on sediments during Late Quaternary Period

Session 78: Subduction zone palaeoseismology

Session 79: The Global Tropics from the Pliocene to the Anthropocene

Session 80: Magnetostratigraphy and Environmental Magnetism contribution to understand paleoclimatic and paleoenvironmental changes

Session 82: Data science and paleoecology: current intersections and advances

Session 83: Quaternary glacier-climate dynamics in the mid & high latitudes of the Southern Hemisphere

Session 84: Extending the limits of ice core science beyond new analytical, conceptual and inter- disciplinary frontiers

Session 85: Loess and dust deposits: beyond local studies

Session 87: Prehistoric hunter-gatherers' adaptation during the Last Glacial in Europe

Session 88: Human-environmental Interactions Along the Ancient Silk Roads

Session 89: Cenozoic sea-level indicators and ice sheet constraints to global sea-level change

Session 92: Zooming into the Quaternary Research in South Asia: Understanding the landscape- cultural-climatic evolution

Session 95: Impacts of abrupt climate change on ecosystems, landscapes and societies through INTegration of Ice-core, MArine and TErrestrial records (INTIMATE)

Session 98: Past vegetation dynamics and their role in climate change

Session 99: Lipid biomarkers as molecular archives of human activity from archeological sites

Session 102: West African Quaternary: understanding past climate oscillations and human responses to anticipate future adaptations

Session 103: Terrestrial hydroclimates: towards quantification and climate model comparisons

Session 104: Novel molecular tools (biomarkers and DNA) in climatic and environmental archives – challenges, advances, and prospects

Session 105: Quaternary mapping across the world and the IQUAME European experience

Session 106: Evolution of coastal environments under natural and anthropogenic processes: the role of geoscience

Session 107: More than the sum: fault re-ruptures and cumulative damage during seismic sequences

Session 108: Equitable and ethical knowledge production in Quaternary Science

Session 109: Animals, environments & humans: diverse perspectives from the Quaternary

Session 118: Cave deposits for in deep understanding Quaternary climate and environment

Session 120: Volcanic impacts on climate and society

Session 121: The anthropology of climate change

Session 123: Advances in tectonic geomorphology, paleoseismology, and multidisciplinary active fault studies

Session 125: African Quaternary Anthro-environments: Palaeoecology and cultural responses to environmental variance

Session 126: Sub-annual to decadal records of environmental change

Session 128: African Acheuleans in the Early/early Middle Pleistocene: triggers, techno-subsistences, time-lines

Session 130: Advancing paleoscience in underrepresented regions: promoting records of past socio-environmental systems in the Global South and beyond

Session 133: Unravelling Mediterranean sensitivity to past rapid climate variability

Session 137: Geological and climate forcings on human groups / ancient societies, and their feedbacks

Session 138: Wet Environments and Human Communities: Interaction and Resilience in the Holocene and Antiquity

Session 139: Holocene Global Landuse

Session 140: Quantifying climate change in Australasia: challenges and opportunities

Session 141: How can the Quaternary sciences contribute to scientific assessment of biodiversity, ecosystems, and nature?

Session 142: Palaeoecology and restoration ecology

Session 143: Environmental responses to climatic and human impacts in endangered biodiversity hotspots: past and present for future

Session 145: Climate Records from Coastal Systems

Session 147: Sea-Level, Ice-Sheet, and Earth system evolution: understanding the past to constrain the future

Session 148: Climate-glaciers interactions in mid-latitude mountains

Session 154: Quaternary research in South America: paleoclimate, tectonic, volcanic and surface processes

Session 155: Linking land and sea - multiple approaches to investigating human-environment interactions in the coastal zone

Session 157: Peatlands through time: developmental dynamics and palaeoenvironmental reconstruction

Session 158: The geomorphic signature of marine and continental Quaternary deposits

Session 159: Human-environment interactions in coastal areas: new ways to learn from the past

Session 162: Astronomical forcing and nonlinear climate feedbacks during the Pleistocene Epoch

Session 163: Quaternary palaeoenvironmental dynamics/variability: promoting multiple proxy records from West-Central Africa

Session 164: Understanding MIS 5d-a: sediments, paleoclimate, chronology and long distance correlation

Session 166: Quaternary palaeohydrology: from the reconstruction of spatial impact of extreme events to long-term changes in catchments and landscapes

Session 169: Quaternary Proglacial Lakes: Sediments, Landforms, Impacts

Session 170: Biotic markers and measures of biodiversity of Holocene environmental change

Session 173: Palaeoclimate records from the Southern Hemisphere

Session 174: Tracing the impact of palaeoenvironmental changes in ancient DNA

Session 176: Tectonic and Climate-driven Landscape Evolution a never-ending challenge for modern society (Thoughts from LEMON project, INQUA - AIQUA)

Session 177: Factors influencing the diversity of loess sedimentary environments and the resulting variability of palaeoclimatic and palaeoenvironmental signals

Session 179: From coastal geomorphology to earthquake hazard (F-Coast2EHZ): new perspectives and multidisciplinary approaches

Session 180: Sedimentary record of past catastrophic coastal flooding (tsunami, storms)

Session 181: Transferring scientific knowledge on Quaternary geological processes and geohazards into disaster risk reduction activities

Session 182: From Cores to Code: Data-Model Integration to Improve Reconstructions and Forecasts of Coastal Change

Session 184: Seismic hazard assessment in populated areas of Latin America: incorporating seismogenic faults

Session 185: Active faults evolution: revelations from different timescales

Session 186: The Long Walk to the Anthropocene: Exploration within Quaternary contexts

Session 187: Equity, Diversity and Inclusion Initiatives in the Quaternary Sciences

Session 190: Paleosol memory of environmental change and man-landscape interactions: from soil profile to geosystem

Session 193: Indo-Asian Monsoon on decadal to centennial-millennial scale and their link to the Indo- Pacific past climate variability

Session 196: Quaternary sedimentary-basins evolution: controlling factors and implications for future scenarios or past reconstructions

Session 197: How can archaeology, palaeoecology, traditional knowledge, and more-than-human approaches contribute towards a more sustainable and culturally informed future?

Session 205: The environment background and human adaptations during the transition or shift from archaic humans to modern humans in East Asia

Session 207: Not only z-corals: Quaternary reefs across the latitudinal and depth gradients

Poster - sessions 2, 35, 55, 60, 66, 89, 90, 98, 137, 186

PADI: the Italian platform for optical properties of dust in ice cores 1500

Dr. Claudio Artoni[1], Dr. Luca Teruzzi [2], Dr. Llorenç Cremonesi [1], Dr. Claudia Ravasio [1], Dr. Deborah Fiorini [1], Prof. Barbara Delmonte [1], Prof. Marco Potenza [2], Prof. Valter Maggi [1]

1. University of Milano-Bicocca, 2. University of Milan

Study of eolian dust transport and its activity in the formation of the regional climate of the Caucasus (Georgia) 1501

Prof. Teimurazi Davitashvili[1]

1. Iv. Javakhishvili Tbilisi State University

High resolution dust fluxes and palaeowind reconstructions from Southern Hemisphere and Southern Ocean terrestrial records of the last 20 kyrs: new approaches and potential pitfalls 1502

Dr. François DeVleeschouwer[1], Dr. Stephen Roberts [2], Dr. Gaël Le Roux [3], Dr. Krystyna M. Saunders [4], Dr. Bianca Perren [2], Prof. Sarah Davies [5], Dr. Thomas Bishop [6], Dr. Charlotte Green [7], Dr. Alexander Whittle [8], Prof. Angela Gallego-Sala [9], Dr. Chuxian Li [10], Prof. Martin Grosjean [11], Dr. Elie Verleyen [12], Dr. Wim Vyverman [12], Dr. Louise Sime [13], Dr. Larissa Schneider [14], Dr. Jeroen Sonke [15], Prof. Dominic Hodgson [13]

1. Instituto Franco-Argentino para el Estudio del Clima y sus Impactos (IRL IFAECI/CNRS-CONICET-UBA-IRD), 2. British Antarctic Survey (BAS), Natural Environmental Research Council (NERC), High Cross, Madingley Road, Cambridge CB3 0ET, UK., 3. CNRS, Université de Toulouse, 4. Australian Nuclear Science and Technology Organisation, 5. Geography and Earth Sciences, Llandinam Building, Penglais Campus, Aberystwyth University, SY23 3DB, UK., 6. Department of Geography, Arthur Lewis Building, Oxford Road, Manchester M13 9PL, UK, 7. British Antarctic Survey (BAS), Natural Environmental Research Council (NERC),Department of Earth Sciences, Royal Holloway, University of London, Egham, Surrey, TW20 0EX, 8. Protistology and Aquatic Ecology, Department of Biology, Ghent University, Krijgslaan 281 S8, 9000 Ghent, 13. British Antarctic Survey, 14. School of Culture, History and Language, College of Asia and the Pacific, Fellows Rd., The Australian National University, Acton, 15. Géosciences Environnement Toulouse, CNRS/IRD/Université Paul Sabatier, Toulouse 3

Understanding the atmospheric variability of the last glacial-interglacial transition in the Southern Hemisphere through paleoclimatic studies of high-altitude loess-paleosol sections in Argentina 1503

Dr. Gabriela Torre[1], Dr. Diego Gaiero [2], Dr. Gael Le Roux [3], Dr. François DeVleeschouwer [4], Dr. Nicolas Cosentino [5], Dr. André Sawakuchi [6]

1. CICTERRA-CONICET, 2. CICTERRA (UNC-CONICET), 3. Laboratoire écologie fonctionnelle et environment (EcoLab), 4. CNRS/CONICET/IRD/UBA, 5. Pontificia Universidad Católica de Chile, 6. São Paulo University, Institute of Geoscience

Simulation of Global Dust Cycle and its Climate Effects During the Last Glacial Maximum 1504

Dr. Qifan Lin[1], Prof. Yonggang Liu [1], Dr. Ming Zhang [1]

1. Peking University

4800 years of human induced atmospheric input of heavy metals and mineral matter recorded in an alpine peatland in Tyrol, Austria 1505

Dr. Clemens von Scheffer[1], Dr. François DeVleeschouwer [2], Dr. Gaël Le Roux [3], Prof. Ingmar Unkel [4]

1. School of Geosciences, University of Aberdeen, Aberdeen, UK / Institute for Ecosystem Research, Kiel University, Kiel, Germany, 2. Instituto Franco-Argentino para el Estudio del Clima y sus Impactos (UMI IFAECI/CNRS-IRD-CONICET-UBA) Dpto. de Ciencias de la Atmosfera y los Oceanos, FCEN, Universidad de Buenos Aires, Ciudad Autonoma de Buenos Aires, 3. Laboratoire Écologie Fonctionnelle et Environnement, Université de Toulouse, CNRS, Toulouse INP, Université Toulouse 3 - Paul Sabatier (UPS), Toulouse, 4. Institute of Geography, Heidelberg University, Heidelberg / Institute for Ecosystem Research, Kiel University, Kiel

Poster - sessions 3, 16, 24, 41, 74, 80, 134, 196

Poster - sessions 4, 47, 85, 103, 118, 148, 162, 173, 176, 177

Poster - sessions 5, 48, 63, 68, 105, 155, 179, 181, 185, 204

Poster - sessions 6, 33, 145, 156, 160, 183

Poster - sessions 9, 36, 42, 43, 46, 69, 70, 71, 84, 88, 92, 99, 102, 112, 138, 163, 169

Reconstructing the paleoenvironment of Southern Levant during Early Pleistocene using oxygen and carbon isotopic compositions in vole teeth **1966**

Mr. Zuorui Liu[1], Ms. Rheia Edgar-Nemec [2], Dr. Amy Prendergast [3], Prof. Russell Drysdale [4], Dr. Orr Comay [5], Dr. Yoav Motro [6], Ms. Michal Zaitzove-Raz [5], Dr. Sarah Pederzani [7], Prof. Miriam Belmaker [8]

1. School of Geography, University of Melbourne, Melbourne, 2. School of Geography, Earth and Atmospheric Sciences, The University of Melbourne, 3. School of Geography, Earth and Atmospheric Sciences, University of Melbourne, Victoria, Australia, 4. University of Melbourne, 5. Steinhardt Museum of Natural History, Tel Aviv, Israel, 6. Israel Ministry of Agriculture, Jerusalem, Israel, 7. Archaeological Micromorphology and Biomarkers Laboratory (AMBI Lab), Instituto Universitario de Bio-Orgánica "Antonio González", University of La Laguna, San Cristóbal de La Laguna, Tenerife, Spain, 8. Department of Anthropology and Sociology, The University of Tulsa

Vole mesowear and microwear as a novel proxy of vegetation structure: application in the early Pleistocene site of 'Ubeidiya, Israel **1967**

Ms. Robyn R. Messer [1], Dr. Orr Comay [2], Dr. Yoav Motro [3], Dr. Tom Curtis [4], Ms. Michal Zaitzove-Raz [2], Prof. Miriam Belmaker[5]

1. Department of Anthropology and Sociology, The University of Tulsa, 2. Steinhardt Museum of Natural History, Tel Aviv, Israel, 3. Israel Ministry of Agriculture, Jerusalem, Israel, 4. Oklahoma State University - Center for Health Sciences, 5. University of Tulsa

The palaeoenvironmental context for early Pleistocene Homo dispersals in the Levant from multi proxy analyses of gastropod shells, Ubeidiya, Israel **1968**

Dr. Amy Prendergast[1], Mr. Zuorui Liu [2], Prof. Russell Drysdale [3], Dr. Kelsie Long [4], Prof. Ian Williams [5], Mr. Timothy Pollard [3], Dr. Sarah Pederzani [6], Prof. Miriam Belmaker [7]

1. School of Geography, Earth and Atmospheric Sciences, University of Melbourne, Victoria, Australia, 2. School of Geography, University of Melbourne, Melbourne, 3. University of Melbourne, 4. School of Culture, History and Language, College of Asia and the Pacific, Fellows Rd., The Australian National University, Acton, 5. Research School of Earth Sciences, Australian National University, Canberra, Australia, 6. University of La Laguna, 7. University of Tulsa

Macrofaunal stable isotopes from 'Ubeidiya, Israel, shed light on environmental setting of an early presence of Homo in the Levant **1969**

Dr. Sarah Pederzani[1], Mr. Zuorui Liu [2], Dr. Amy Prendergast [3], Prof. Russell Drysdale [4], Prof. Miriam Belmaker [5]

1. Archaeological Micromorphology and Biomarkers Laboratory (AMBI Lab), Instituto Universitario de Bio-Orgánica "Antonio González", University of La Laguna, San Cristóbal de La Laguna, Tenerife, Spain, 2. School of Geography, University of Melbourne, Melbourne, 3. School of Geography, Earth and Atmospheric Sciences, University of Melbourne, Victoria, Australia, 4. University of Melbourne, 5. University of Tulsa

Geomorphology and lithology of Dakhla yardangs **1970**

Dr. Driss Chahid[1], Prof. Aicha Oujaa [2], Prof. Larbi Boudad [3], Dr. Arnaud Lenoble [4]

1. Department of Geology, Faculty of Sciences, University Mohammed V, 2. National Institute of Sciences of Archeology and Heritage RABAT, 3. Mohammed V University, Faculty of Sciences, Rabat, Morocco, 4. PACEA - UMR 5199, CNRS, University of Bordeaux

Lipid biomarkers at the Late Pleistocene open-air loess site Ollersdorf-Heidenberg (Austria) 1977

Dr. Marjolein Bosch[1], Dr. Margarita Jambrina-Enríquez [2], Dr. Stéphane Pirson [3], Dr. Freddy Damblon [4], Mr. William Murphree [5], Dr. Carolina Mallol [6], Dr. Walpurga Antl-Weiser [7], Prof. Philip Nigst [8]

Session 2: Recent advances in understanding the causes of changes in regional and global palaeofire regimes: resources, tools and new approaches

Global fire modeling and its potential for paleo fire research

Dr. Stijn Hantson [1]

1. Universidad del Rosario

Fires are an integral part of the Earth System, with the first proxies of fire being found soon after the advent of land plants. Fire frequency has varied widely over the course of the Quaternary Period due to changes in climate, vegetation, and, more recently, anthropogenic impacts. To understand how changes in these drivers, and their interactions, influence the occurrence of wildfires, multiple global fire models have been developed over the course of the last decades. These models vary in the number and complexity of processes represented, with a wide variety of model structures currently available. Global fire models have been incorporated into land-surface and dynamic vegetation models, enabling the representation of fire-vegetation feedbacks, and the potential for these models to project past and future changes in fire occurrence. Here I will give an overview of the current status of global fire models, I will discuss the strengths and weaknesses of the current generation of these models and, finally, I will focus on the potential to use them in paleo fire research.

Exploring the sensitivity of global fire regimes to atmospheric CO2 levels at the Last Glacial Maximum

The occurrence of wildfires is influenced by climate, vegetation properties, ignition sources and human activities. Generalised linear models (GLMs) have been developed to predict the spatial patterns in burnt area, fire size and fire intensity under modern conditions. Such models could be used to predict how wildfire regimes will respond to future changes in climate. One issue raised by such an application is that gross primary production (GPP), which is critical for determining fuel loads, is influenced by climate and also sensitive to changes in atmospheric CO_2 levels.
Here we explore the effect of climate and CO_2 levels on fire regimes at the Last Glacial Maximum (LGM; 21 ka BP), when climate was colder and drier and CO_2 levels were around 185 ppm. We used outputs from three Palaeoclimate Modelling Intercomparison Project climate models, AWIESM2, CESM1.2 and MPI-ESM1.2 to provide a range of simulated LGM climates. Vegetation distribution under these three climate-change scenarios was simulated using the BIOME4 biogeography model and GPP using the P model, a light-use efficiency model which accounts for the physiological effect of CO_2 on productivity. The LGM simulations were compared to a modern-day control simulation with the impact of human activity on wildfires excluded. We conducted two sensitivity experiments to separate the impacts of climate changes from those of lower CO_2, firstly using LGM climate with modern CO_2 levels and secondly using modern climate with LGM CO_2 levels.
The LGM simulations show a global decrease burnt area, with all three climate scenarios compared to modern day, consistent with the observed reduction in wildfire. Comparison with charcoal records from the Reading Palaeofire Database shows the models reproduce regional patterns, both in regions where fire was reduced compared to present and in the more limited areas (e.g. southern China, Alaska) where wildfire was increased. The sensitivity experiments show that low CO_2 levels were key to obtaining realistic reductions in burnt area, since the simulation using LGM climate with modern CO_2 produced much higher levels of burning. These results highlight the importance of accounting for the effect of atmospheric CO_2 on vegetation when projecting future changes in wildfires.

Developing Novel Proxies for Reconstructing Past Fire Histories in South-eastern Australia

Fire is endemic in the Australian landscape, shaping biodiversity and ecosystem change for millennia. As climate change continues to modify fire regimes at local to national scales, bushfires are forecast to increase in severity, intensity and area burnt. However, our existing records primarily rely on remote sensing data, which is limited to the satellite era or the analysis of charcoal and dendrochronological records, which can inform on fire occurrence but do not detect fire characteristics such as severity and intensity. Therefore, to more accurately forecast future fire events and determine whether recent large-scale events, such as the 2019-20 Black Summer Bushfires in southeastern Australia, are the new normal standard, there is an urgent need to develop new tools that can distinguish fire characteristics. Boron isotopes and Fourier Transform Infrared (FTIR) spectroscopy lend themselves as potential proxies due to their sensitivity to changes in vegetation cover and chemical bonds, respectively.

The Upper Blue Mountains in New South Wales (NSW) and Namadgi National Park in the Australian Capital Territory (ACT) are notoriously fire-prone and provide an opportunity to calibrate these techniques. Samples have been collected from sediment reservoirs, including large-order creek beds and swamps, and a radiocarbon-based age-depth model has been paired with results from these two proxies to formulate a long-term record of past fire events. Preliminary results demonstrate an increase in the $\delta^{11}B$ value of sedimentary layers burnt at high severity. This increase results from ash deposition enriched in leaf material and ^{11}B. These layers also exhibit an increase in the aromatic/aliphatic ratio as long-chain aromatic compounds are the first to be decomposed when heated, forming more temperature and decomposition-resistant aromatic compounds. These techniques have the potential to be applied to other national and global fire hotspots to better understand how fire regimes have evolved through time and allow for improved mitigation of and recovery from future fire events.

Capturing wildfire and vegetation gradients along the West African margin in marine sediments: a biomarker approach

Biomass burning has significant impacts on the global carbon system both via emissions of CO_2 and aerosols into the atmosphere and through complex feedbacks with climate and terrestrial vegetation. Organic molecular indicators of combustion—-fire biomarkers—-have become an increasingly useful set of tools for reconstructing the history of biomass burning in order to better understand wildfire variability in various environments and back in time. Previous paleofire work has focused primarily on lacustrine archives, while marine sediments have received less attention. Here we demonstrate that two classes of fire biomarkers, pyrosugars and polycyclic aromatic hydrocarbons (PAHs), preserved in core top sediments along the West African Margin (40°N–34°S) record modern latitudinal gradients of biomass burning on the Iberian Peninsula and along the West African margin. Fire biomarkers normalized to *n*-alkane terrestrial plant waxes reveal higher instances of fire in grassier ecosystems consistent with modern satellite observations. The relative abundance of pyrosugars compared to PAHs broadly reflected the relative proportion of small vs large fires in core top source areas, lending support to its use as a fire intensity proxy. Distribution-based metrics of these compounds often used as fuel source estimators seem to fail in Africa perhaps due to sampling biases in the underlying burn experiment datasets. Plant-wax normalized pentacyclic triterpene methyl ethers (PTMEs), a class of biomarkers especially prevalent in grasses, shows good spatial agreement with the presence of C_4 grasses in particular, while differences between PTMEs and plant-wax $d^{13}C$ suggests shorter transport distances for PTMEs. Deviations from the zonal structure of fire and vegetation on the adjacent landscape within the marine core top transect can mostly be attributed to long-range transport estimated using back-trajectory modeling.

Late Holocene land cover and fire dynamic in Bad Waldsee (SW Germany) mirrored in seasonally laminated sediments and historical archives

Lakes close to human settlements offer excellent archives to investigate the mutual relationship between long-term environmental changes and human activities. The Bad Waldsee project uses the rare spatial proximity of a historically well-documented medieval town and its central lake (Stadtsee) to reconstruct the socio-environmental developments of the city and its periphery during the preindustrial phase of 750-150 cal. Yr BP, the late Medieval period to Modern Times, respectively. The fire events for this time span have been studied using micro- and macro-charcoal records from the Stadtsee sediments. Macro charcoal results showed 15 screened charcoal peaks, which grouped into two phases of biomass burning. The detected burning episodes were compared with regional paleofire trends and interpreted using sedimentological, palynological, and historical data. The first phase in the late Medieval period (653-533 cal. Yr BP) showed high proportions of burned grass and monocot leaves. This phase is followed by a distinct interval of no-burning (533-313 cal. Yr BP) that coincides with the flourishing of the textile industry, cultivation, and processing of cannabis in the vicinity of the Medieval Bad Waldsee. The second phase from 313 cal. Yr BP onwards represents Modern Times with wood as the primary fire fuel. Reconstructed periods of low-magnitude local fires during the late medieval times and after 1750 AD (200 cal. Yr BP) coincided with changes in the type and intensity of land use. Major local and regional historical events like the Thirty Years' war and the fire incident near the town (1386 AD - 174 cal. Yr BP) are also documented by the charcoal sedimentary record. Combined with a previously studied sequence, the entire Stadtsee sediment record allows exploring the role of fire in the central European landscape from prehistory (4000 cal. Yr BP) up to Modern Times. The fire signals from the Bronze Age to the Medieval Period are presently being studied and will be interpreted using a multiproxy approach.

High-resolution biomarker imaging reconstructs 2,000 years of southern California wildfire history

Southern California has been prone to wildfires throughout its history. Exploring the natural variability of wildfire in this region and understanding their large-scale drivers requires wildfire reconstruction at high temporal resolution that extends beyond the limited historical record. High-accumulation varved sediment deposits from the center of Santa Barbara Basin (SBB) off California provide an ideal archive for paleofire reconstruction. However, typical reconstructions using charcoal or biochemical tracers require discrete sampling of the sediment record, limiting the temporal resolution of wildfire records to multi-year analyses. With mass spectrometry imaging (MSI) using laser desorption ionization coupled to Fourier transform-ion cyclotron resonance-mass spectrometry, geochemical fire tracers such as the monosaccharide anhydride (MA) levoglucosan and its isomers mannosan and galactosan can be analyzed on intact SBB sediment sections at sub-mm spatial, and thus interannual temporal resolution.
To assess the feasibility of MSI for high-resolution wildfire reconstruction, a SBB core spanning AD 1900 - 2009 (SPR0901-05BC) was analyzed to enable comparison with observational and reanalysis datasets. The resulting MSI-based record of MA intensity bears a strong resemblance to the areal extent of historically recorded wildfires in this region. In addition to the targeted analyses of MA, we applied untargeted data analysis routines on the MSI dataset to identify additional compounds with distinct distributions indicative of wildfire occurrence or that align with wildfire-facilitating parameters such as vapor pressure deficit. We identified organic acid-like compounds related to wood-burning aerosols that strongly correlate to the MA signal, and thus to the burned area in this region. We additionally applied MSI of fire biomarkers to SBB sediment core MV0811-14TC, comprising the last two millennia. The 100-µm-scale MSI analyses provide sub-annual wildfire and environmental proxies, e.g., sea surface temperature, to examine high-frequency changes in past southern California fire regimes during different periods such as the Medieval Climate Anomaly, Little Ice Age, and Settlement Era.

Revisiting Tswaing Crater: an eco-evolutionary interpretation of fires influence on vegetation assembly in an ancient African grassy ecosystem

Previous fossil pollen and charcoal studies from Tswaing Crater's ~ 230 kyr sedimentary basin in South Africa's grassy biome focused on how climate shaped past vegetation dynamics. While these studies shaped our understanding of past vegetation-climate dynamics; however, high climatic variability in the warm tropics is associated with strengthened roles of disturbance processes from fires, large herbivores, and humans. Recent studies highlight positive disturbance-vegetation interactions as vital for maintaining open grass-dominated mosaic landscapes with high heterogeneity and biodiversity by filtering out plants and animals according to tolerance or avoidance traits. Flammability is considered a key plant trait linked with abilities of individuals or communities to persist in frequently burned open ecosystems where fires are mainly driven by grass fuel loads and limited by tree canopy cover. This often leads to alternate trait-driven stable vegetation community states from patch to biome level. Here, we revisit the Tswaing pollen and charcoal records through the lenses of plant functional traits to identify flammability, tree canopy cover, and grass fuel load gradients. Results from primary axes of two contrasting ordination methods suggested vegetation dynamics were largely driven by grass abundance (Poaceae). Along the primary axes, alternate flammable savanna and fire-sensitive forest taxa occurred at opposite ends with non-overlapping convex hulls. Micro-charcoal abundances along primary axes increased in the direction of savanna taxa. Interestingly, from ca. 75.3 kya, sediment $\delta^{13}C$ values were more positive and micro-charcoal increased, indicating frequent fires, wetland drying, and/or incursions by landscape C_4 taxa. Periods of high Zr/Rb from ca. 162-44 kya, an indicator of soil disturbance possibly caused local herbivory or wetland manipulation corresponded with low micro-charcoal abundance. Furthermore, Artemisia-type pollen associated with forbs and herbivory in open landscapes suggested local biotic disturbances. Together, our results show that pollen and other proxies can be interpreted using plant functional traits underpinned by ecological-evolutionary processes. A shift towards trait-based approaches could be beneficial for reinterpreting past landscapes changes and benefit the restoration of open ecosystem processes in the Anthropocene.

Session 3: Orbital and millennial vegetation changes at global and regional scales during the Quaternary: insights from data and models

Diverse response of global terrestrial vegetation to astronomical forcing, CO2 and ice sheets from orbital to millennial timescales

During the Quaternary glacial-interglacial cycles, the spatial distribution of major vegetation types on the globe was strongly affected by the astronomically-induced changes in latitudinal-seasonal distributions of insolation and by the changes in atmospheric CO_2 concentration and ice sheets. However, the relationship between vegetation and different forcing factors remains complex and not necessarily well understood. In this study, we investigate the vegetation variations on orbital and millennial timescales and their relationship with different factors by combining proxy reconstructions and model simulations. Three representative glacial-interglacial (G-IG) periods, i.e. MIS19-18, MIS13-12 and MIS11-10, which are characterized by different variations of precession, obliquity, CO_2 and ice volume, are chosen.

Our results show that the relative effect of precession and obliquity on vegetation strongly depends on regions and also varies between the G-IG periods. For example, in the subarctic and Mediterranean regions and over most of the mid-latitude lands, obliquity is more important than precession during MIS11-10 due to large variations of obliquity and small variations of precession, whereas by contrast, precession is more important than obliquity in these regions during MIS13-12. Over eastern Africa, Indian subcontinent and East Asia, precession is more important during both MIS11-10 and MIS13-12. Our results show that astronomical forcing plays a dominant role on regional vegetation evolution as compared to CO_2. As quite expected, large Laurentide and Eurasian ice sheets suppress forest and favor grass development over many regions, but exceptions exist and the sensitivity of vegetation response to ice sheets strongly depends on regions. Our transient simulations also reveal the subharmonics of precession signal in the vegetation evolution in the tropics and some extra-tropical regions such as the Mediterranean, but the occurrence and strength of these signals depend on regions and vary in time.

In addition to orbital and sub-orbital scale variations, the astronomically-induced slow variation of insolation could induce abrupt changes and multi-centennial variations in the forest and grass compositions especially in the northern mid-high latitudes. When boreal summer insolation decreases to a threshold, it induces abrupt changes in the AMOC, which in turn affects the climate and vegetation at large continental scale.

Reconstruction of atmospheric CO2 concentration over the past 1.5 million years based on leaf wax (long-chain n-fatty acid) carbon isotope record from the Bay of Bengal.

Atmospheric CO_2 and polar ice volume have been strongly coupled over the past 805,000 years. However, the prior extent of coupling, during times of lower-amplitude ice-volume variability before 805,000 years ago, is unknown because continuous high-resolution CO_2 records are lacking. We reconstructed the past 1,460,000 years of atmospheric CO_2 (~1,700-year sample resolution) by taking advantage of the unique relationship between CO_2concentration and leaf wax $\delta^{13}C$ at IODP Site U1446 resulting from changes in the extent of C_3 and C_4 vegetation in East India. The results indicate that reconstructed interglacial CO_2 concentrations were lower before the transition to large volume variability during the mid-Pleistocene transition (MPT; 900,000 years ago). Prior to the MPT, CO_2 had a secular trend similar to that of deep-ocean carbon isotopes. At orbital time scales, phase analysis indicates that the CO_2 lead relative to ice volume changed to a lag during the MPT. Combined, these findings suggest that deep-ocean circulation controlled the long-term CO_2 trend, and that interaction between CO_2, continental ice, and deep-ocean circulation was reorganized during the MPT, involving a decrease in the carbon storage in the deep Pacific.

Holocene history of the vegetation of the Eastern Mediterranean region

Ms. Esmeralda Cruz [1]***, Dr. Sandy P. Harrison*** [1]***, Dr. Colin Prentice*** [2]***, Dr. Elena Marinova*** [3]

1. *School of Archaeology, Geography & Environmental Science, Reading University, Whiteknights, Reading, RG6 6AH, UK,* ***2.*** *Georgina Mace Centre for the Living Planet, Department of Life Sciences, Imperial College London, Silwood Park Campus, Buckhurst Road, Ascot SL5 7PY, UK,* ***3.*** *Laboratory for Archaeobotany, Baden-Württemberg Cultural Heritage State Office, Geienhofen-Hemmenhofen, Germany*

There are unsolved questions about the Holocene vegetation history of the eastern Mediterranean, including 1) whether vegetation assemblages in the transition from the Late Glacial to the early Holocene have modern-day analogues, 2) whether postglacial reforestation was delayed in the eastern part of the region, 3) what was the geographical extent of temperate deciduous forest at the mid-Holocene, and 4) what were the timing and causes of the re-establishment of drought-tolerant vegetation during the late Holocene. Here we address these questions by using a recently developed pollen-based vegetation reconstruction technique that accounts for within-biome variability in the abundances of pollen taxa to assign fossil pollen samples from 137 records to the biome with which they have the greatest affinity allowing us to reconstruct eastern Mediterranean (33°-49°N, 20°-60°E) vegetation since 12 ky. In addition, we use per-biome threshold values to identify samples that do not belong to any modern biome. We analyse these vegetation reconstructions to examine space and time vegetation dynamics using time series analysis, break-point analysis and mapping. Our results shows that sites with non-analogue vegetation were most common between 11.5 ky and 9.5 ky and mostly in the Carpathian region. The early Holocene change from open vegetation to forest occurred at 10.58 ± 0.74 ky; the eastern records do not show a consistent delay in forest development with respect to the western records. Temperate deciduous forest was more extensive at 6 ± 0.2 ky but the maximum expansion was recorded in the 5.5 ± 0.2 ky and 5 ± 0.2 ky time windows. The peak in the number of forest sites occurred between ca. 4 and 2.8 k and was followed by an abrupt decrease, and this pattern is consistent with speleothem oxygen isotope records from the region. This work provides new insights into debated issues about regional vegetation changes, including the prevalence of non-analogue vegetation during the late glacial and early Holocene, and the expansion of moisture-demanding temperature trees in the mid-Holocene. Although there is no strong signal of late Holocene aridification, changes in the amount of forest are more consistent with climatic changes than anthropogenic influences.

Tracking postglacial expansion of European trees

Dr. Christoph Schwörer [1], ***Dr. Cesar Morales del Molino*** [2], ***Prof. Gerhard Lang*** [3], ***Prof. Brigitta Ammann*** [3], ***Ms. Lieveke van Vugt*** [1], ***Prof. Willy Tinner*** [1]

Integrating pollen records over large spatial scales allows tracking range expansions and contractions of plant species in response to environmental changes in time and space. Even though the creation of isopollen or isochrone maps has a long history in paleoecology, the increasing number of sites, higher chronological precision, and the improved data accessibility in regional or global databases permits to study vegetation dynamics in ever greater detail. Due to ease of data processing, most recent maps are based on pollen percentage thresholds to estimate the first local presence of a taxon. However, this approach is not clearly linked to ecological processes of population dynamics. Instead, we argue that using established biostratigraphic patterns in pollen records, such as the absolute, empirical, and rational limit, would be better suited to infer ecological dynamics such as local population establishment or mass expansion.

Here, we present species maps tracking the local establishment of 29 arboreal pollen taxa for the last 20,000 years based on a curated set of 323 representative pollen records throughout Europe. We also calculated isochrones based on geographic interpolation techniques. The maps highlight the location of refugia of subtropical, temperate, and boreal species during the Last Glacial Maximum and document subsequent range expansion in response to rapid warming during the Lateglacial and Holocene. To our knowledge, the postglacial spread of several Mediterranean species is captured for the first time at the European scale. On the basis of the isochrone maps, we also estimated spreading rates and dispersal distances for all taxa. This assessment is particularly relevant to check if tree species are able to respond fast enough to ongoing and future climate change.

Impacts of the slowdown of the Atlantic meridional overturning circulation over Amazonian vegetation

The Atlantic meridional overturning circulation (AMOC) is a core-tipping element of the climate system that may exceed a critical threshold within a societal-relevant future substantially slowing down and changing global atmospheric circulation. In modern climate, the AMOC regulates precipitation over tropical South America, but the impact of an AMOC slowdown over the Amazon rainforest, another core-tipping element of the climate system, remains unclear. During the last deglaciation, a shutdown of the AMOC (i.e., Heinrich Stadial 1) promoted drier and more seasonal rainfall conditions in northern Amazonia, where modern deforestation and wildfires are less pronounced than in southern Amazonia. Here, we investigate the Amazonian vegetation response to this natural experiment based on pollen and microcharcoal analyses of marine sediment core GeoB16224-1 (6°39.38'N, 52°04.99'W) and species distribution models forced by fully coupled climate models. The pollen analysis of the interval 25–12.8 ka reveals that Amazon vegetation undergone striking changes. During the Last Glacial Maximum, the combination of a significantly colder and relatively drier climate, lower atmospheric CO_2 concentrations, and ca. 120 m lower sea-level transformed the Amazonian landscape. Nevertheless, the Amazon basin remained mostly covered by forests that, however, showed a distinctly different vegetation composition characterized by the expansion of cold- and moist- affinity tree elements. During Heinrich Stadial 1, our data suggest a loss of tropical rainforest suitability over northern Amazonian and a decline in cold- and moist- affinity taxa that occupied the lowlands, while the overall fraction of herbs increased and other major vegetation groups remained relatively stable. Despite the forest cover changes in northern Amazonia, the rainforest was resilient to rainfall shifts in the rest of the basin, related to the past AMOC shutdown. Importantly, our findings indicate northern Amazonia is likely the most vulnerable portion of the rainforest for a future AMOC slowdown. Given the extensive anthropogenic land cover changes already promoted in the southern and eastern portions of the basin, we suggest that a negative synergy between deforestation, wildfires, climate change and AMOC slowdown will bring the Amazon rainforest dangerously close to its tipping point in the near future, if anthropogenic forcings remain unabated.

Centennial-scale climate and ecosystem variability in SE Europe since the Early Pleistocene based on the Tenaghi Philippon archive (Greece)

The limnotelmatic sequence of Tenaghi Philippon (NE Greece) has been recognized since the 1960's as a unique archive of terrestrial climate and ecosystem dynamics for the Quaternary in Europe. We have retrieved and evaluated new sediment cores from Tenaghi Philippon that span the past c. 1.4 Ma continuously based on a vegetation-independent chronology derived by the integration of radiocarbon dating, tephrochronology, magnetostratigraphy, and cyclostratigraphy. These efforts have resulted in a new pollen-based record of Mediterranean ecosystem dynamics at (sub-)centennial temporal resolution (mean: c. 250 years) covering the past ten glacial-interglacial cycles, i.e., ranging from Marine Isotope Stage (MIS) 1 through MIS 21. The vegetation data are augmented by decadal-scale resolution (c. 30 years) XRF-based element geochemical data that provide insight into precipitation variability. The exceptionally high temporal resolution of our datasets and the high-quality age control allow reconstruction of the vegetation response to climatic forcing at time scales that are comparable to the rapidity of present-day and near-future anthropogenic climate change. Our analysis documents two stable vegetation regimes across a wide range of moisture levels, with abrupt shifts from forest to steppe biomes occurring when a threshold in precipitation was crossed. Our results demonstrate that the demise of Mediterranean forests across the Middle and Late Pleistocene ("100-kyr world") occurred within decades and hence shed new light on the vulnerability of Mediterranean forests to the recurring droughts as they are projected for the Mediterranean region in the near future. Ongoing analysis of the lower part of the sequence from MIS 22 to MIS 45 ("41-kyr world") will provide information on whether the dependence of forest biomes on moisture availability persisted during the early Pleistocene at Tenaghi Philippon or whether it was intiatiated across the Mid-Pleistocene Transition following reorganizations in global climate dynamics.

Before the Early Middle Pleistocene Transition: insights on the environmental variability and explosive activity in central Italy during the 1.5-2.1 Ma interval from the L'Aquila Basin lacustrine record

The Quaternary climate is featured by a notable change in frequency and amplitude of the glacial-interglacial cycles, known as the Early Middle Pleistocene Transition (EMPT), which since ~1.25 Ma to ~0.70 Ma gradually shifted from the quasi-symmetrical and weak amplitude cycles with a 41 kyr periodicity, to the strongly asymmetric, high amplitude cycles with a 100 kyr periodicity. While many records from different environmental settings are available for the post-EMPT period, still little is known for the longer Quaternary history preceding the EMPT, mostly because of the scarcity of high-resolution and precisely dated archives spanning this interval. The lacustrine successions hosted in post-collision tectonic basins of the central Apennines, central Italy, have proven to be valuable archives of the dynamic and evolution of the regional climate, ecosystems, volcanism and tectonics during Quaternary. Here we present a new record from a 230 m-long core recovered from the lacustrine succession of the L'Aquila Basin, at Castelnuovo (CN) site. A multi-method dating approach, combining tephra $^{40}Ar/^{39}Ar$ dating, paleomagnetic stratigraphy, and the glacial-interglacial cyclical expression of paleoenvironmental proxy data indicate that the whole CN succession spans the period ~1.5 Ma to ~2.1 Ma; i.e., 600 kyr of history shortly preceding the start of the EMPT. The multi-proxy data from CN sediment core, including major and trace element and Sr-Nd isotope composition of the glass from six tephra layers, and $CaCO_3$ content, scanning XRF element geochemistry, $\delta^{18}O_{calcite}$,clumped isotopes, and pollen analyses from the lacustrine sediments, provided us with a new record of the environmental-climate variability in central Italy spanning twelve glacial-interglacial cycles, from marine isotope stage (MIS) 51 to MIS 78, as well as the first distal evidence of the earliest known calc-alkaline volcanic explosive activity in Campanian Plain.

Session 4: Bridging earthquakes over time scales – from the seismic cycle to Quaternary landscape evolution: contributions from the EDITH INQUA-TERPRO-Terrestrial Processes, Deposits and History Project

Spatial migration of temporal earthquake clusters driven by the transfer of differential stress between neighbouring fault/shear-zone structures.

Uncertainty about the processes responsible for slip-rate fluctuations associated with temporal earthquake clustering is one of the most fundamental, unresolved issues in tectonics, because (a) the strain-rates accommodated by fault/shear-zone structures are the key to understanding the viscosity structure of the crust and hence crustal rheology and evolution, and (b) the strain-rates, and their variability in space and time, control the spatial and temporal occurrence of hazardous earthquakes. In this study we constrain the timing and amplitude of slip-rate fluctuations that occurred on three sub-parallel active normal faults in central Italy over a time period of 20-30 kyrs, using *in situ* ^{36}Cl cosmogenic dating of fault scarps. We identify five periods of rapid slip that lasted a few millennia separated by periods of time of up to 10 millennia with slow or no slip. We show a systematic migration of the location of rapid slip pulses across the strike of the three faults that occurred in two waves from SW to NE. We show that this migration of rapid slip can be replicated by a model where differential stress changes on shear-zones underlying the faults produce strain-rate changes, implying that this is the mechanism that produces the slip-rate fluctuations and temporal earthquake clustering. We show that the pattern of differential stress change is related to the fault geometry in terms of distance and azimuth from the slipping structure. This in turn implies that strain-rate and viscosity fluctuations for studies of continental rheology, and slip-rates for seismic hazard purposes are to an extent predictable given knowledge of the fault system geometry and the implied stress transfer function.

Estimating the long-term slip rate of active normal faults: The case of the Paganica Fault (Central Apennines, Italy)

The footwall of the surface rupturing Paganica normal fault, the source of the 2009 L'Aquila earthquake (Mw 6.1) in Central Italy, was investigated using integrated geological and geomorphological approaches. The aim was to constrain the active tectonics by studying the Raiale River that orthogonally crosscuts the fault trace, where it provides a useful geomorphological marker of long-term fluvial incision and footwall uplift. Using morphostratigraphy and paleomagnetic analysis, the Plio–Pleistocene morphotectonic evolution of the area was reconstructed. Starting from the Late Early Pleistocene–Middle Pleistocene, fluvial dissection was mainly due to marked river downcutting triggered by significant activity of the Paganica Fault, which caused progressive base-level lowering. The Raiale River downcutting formed five Middle-Late Pleistocene fluvial terraces that, along with absolute Optically Stimulated Luminescence (OSL) dating, allowed the identification of paleolongitudinal profiles with a diverging downstream configuration. Terrace dating yielded a minimum incision rate of 0.25 ± 0.02 mm/a, which only partially compensates the footwall uplift and can thus be considered as a minimum value for the Paganica Fault throw rate, which could reach up to ~0.45 mm/a. In parallel, using terrestrial cosmogenic nuclides, a denudation rate of 0.02–0.04 mm/a was measured on the summit of the footwall block. This denudation is in keeping with the drainage incision, suggesting a non-steady state for the fault footwall topography and dominance of relief growth. Last, the analysis of the modern Raiale River longitudinal profile denoted an ungraded status, with two main knickzones that we interpret as transient forms due to tectonic perturbations, likely triggered by activity of the Paganica Fault during the end of Early Pleistocene and the Late Pleistocene. Considering the 2009 L'Aquila earthquake coseismic rupture, we observe that the younger transience on the Raiale River longitudinal profile, if it is of tectonic origin, could have only been produced by much larger seismic events (i.e., Mw > 6.5) than those documented in the area by paleoseismological investigations. The collective results confirmed that conditions of dynamic equilibrium are often not met in the Central Apennines and that the persistence of transient perturbations induced by tectonics should be accounted for.

Slip history of the Vallo di Diano, Auletta and San Gregorio Magno faults (Southern Apennines, Italy) constrained using cosmogenic 36Cl concentrations

The 36-chlorine dating approach can recover slip histories from normal faults, providing information on slip-rate fluctuations produced by earthquake clustering over millennial timescales. It has been suggested that fluctuations in slip-rates are linked to fault/shear zone interactions. Specifically, for multiple parallel faults, clusters of surface faulting earthquakes have been shown to switch across strike between faults to maintain the regional strain-rate. However, for some fault systems faults are predominantly arranged along-strike and their behaviour has received less attention from 36-chlorine studies. Thus, it is not presently known whether normal fault systems with faults arranged along strike versus across strike behave in a similar manner over millennial timescales with regard to earthquake recurrence and clustering. We obtained 36-chlorine results for three faults located along strike in the Southern Apennines (Italy), one of the most seismically active areas in Italy (e.g., 1857, Mw 7.1, in the Val d'Agri and 1980, Mw 6.9, Irpinia earthquakes). The fault system is characterised by either a small number of faults across strike or a single fault accommodating all the across strike strain. Results show that the three faults (Vallo di Diano, San Gregorio Magno and Auletta faults) were active in the Holocene, with each fault exhibiting alternating periods of rapid and less rapid slip, thus accommodating the regional tectonic extension at different times. The faults are <30 km in length yet periods of rapid slip lasting a few millennia exhibit slip of up to 4-5 metres, implying the existence of temporal clusters of surface faulting earthquakes. In particular, the Auletta and Vallo di Diano faults show out-of-phase activity, so that when one fault experiences rapid slip, the other is in a state of quiescence. We discuss the results in terms of their implications for tectonic processes and seismic hazard.

Studying slow-to-moderate faults: New paleoseismic data of an unexplored branch of the Alhama de Murcia Fault (SE Spain)

The Alhama de Murcia Fault (AMF) is one of the main seismogenic faults in the Eastern Betic Shear Zone (EBSZ). In the segment between Lorca and Totana, the fault is composed of five main branches that are considered to join at depth and, therefore, have their own contribution in terms of the seismic history and the slip rate of the main fault. A previous study constrained most of the activity of the fault in this sector by carrying out a paleoseismic analysis in four of these branches, leaving pending the analysis in one of them. This work focuses on the unexplored branch (N2a-AMF) to analyse its seismic potential and to refine the previously estimated paleoseismic parameters of the AMF in the area (El Saltador-La Hoya). We conducted a detailed geomorphological study to accurately map the N2a-AMF and to select a suitable location for the excavation of a paleoseismic trench. We also refined the mapping of N2b-AMF, which has been previously analysed, to better understand the relationship between both branches and the push-up they bound. In the new trench, we identified two different deformation planes (interpreted as fault propagation folds), which would have generated a minimum of 87±4 cm of joint vertical offset. A minimum of three morphogenetic events have been interpreted, providing robust evidence of recurrent deformation in Upper Pleistocene sediments, which implies that N2a-AMF has had activity at least during that period (dating is in course). According to correlation with regional dated units, these events would have taken place in the estimated time interval between 82,4 ka and 39,2 ka, presenting a minimum recurrence of 14,4 kyr. Taking into account the measured vertical offset of 87±4 cm, the minimum vertical slip rate for the last 82.4 ka would have been between 0.010 and 0.011 mm/year. In this work, we present the preliminary results of our ongoing research.

Paleoseismic recurrences obtained from intermittent geological records: New and Revisited trenching sites along the central Alhama de Murcia fault (SE Iberia)

Inter-event time between morphogenetic earthquakes is one of the key parameters used in seismic hazard models and is, in most cases directly obtained from geological observations. Here, we analyze the paleo-earthquake sequence recorded at three nearby sites along the central part of the Alhama de Murcia fault (SE Iberia) by reviewing previously published data and by integrating new results. We discuss the definition of the rupturing events, correlating events among 9 different trenches from three sites, identifying new events previously undetected. Incorporation of new age results and a critical review of the existing chronological data is conducted to build up an improved earthquake chronology for the last 80 ka. Stratigraphical statistical age models obtained through OxCal tool leads to refined earthquake chronologies as compared to previous publications, reducing the uncertainties up to 39%. The integration of paleoseismological data from different trenches is shown crucial to build a more robust chronological model, even when the data from individual trenches is poorly dated or represent a discontinuous record. We discus some examples of published earthquakes chronologies inferred from intermittent versus continuous geological records highlighting the limitations and future perspectives of the use of paleochronologies for seismic hazard purposes.

Clustered activity of Intraplate Faults – relation to the seismic cycle? The silent and slow active faults of Germany: results from paleoseismological trenching

Prof. Klaus Reicherter [1], ***Ms. Sara Pena Castellnou*** [1], ***Ms. Vanessa Steinritz*** [1], ***Dr. Jochen Huertgen*** [1], ***Dr. Stephane Baize*** [2]

1. Institute of Neotectonics and Natural Hazards, RWTH Aachen University, 2. Institut de Radioprotection et de Sûreté Nucléaire

Silent and slow faults in Stable Continental Regions (SCR) or active intraplate regions represent one of the most intriguing problems in active tectonic and fault hazard studies, like in Central Europe. The term “silent faults” is used very variable, “silent” refering either to seismic activity, absence of seismogenic faulting (but possibly creep) or to the scarce geomorphic and geologic visibility of faults. Slow active faults are generally characterized by slip-rates ≤ 0.1 mm/yr, with limited potential to produce topographic expressions in humid/moderate climate or even changing climates, i.e. out of the glacial periods in the Late Pleistocene. The slip-rate of a fault is a fundamental parameter that governs earthquake occurrence and seismic hazard in an area. Due to their long recurrence intervals of partly more than 10 kyrs, earthquakes on low slip-rate faults are often absent from the historical catalogues and the standard seismic hazard assessment processes, but are still visible in the landscape. Some faults show marked linear scarps and topographic steps, as revealed by high resolution DEMs and field surveys. The preservation of tiny scarps in agricultural areas is enigmatic: the process(es) of preserving a c. 50 cm high, single event scarp for 10^3-10^4 years is completely unclear.

We present new fault data from several SCR regions in Germany, the Lower and Upper Rhine Grabens, based on seismological, geophysical and trenching investigations. In general, Holocene surface rupturing events are very rare and their recurrence intervals are large, at around 10^3-10^4 years. Associated slip rates are below 0.1 mm/yr. Recurring paleo-earthquakes are recorded in surficial deposits, as shown in our trenches in the Rhine Grabens, along with secondary earthquake effects. In addition, some normal faults in the Lower Rhine Graben show evidence for the “Clustering and Quiescence” earthquake occurrence, which may explain the longevity of the scarps, and contrast the “One Shot” hypothesis stated for SCR faults. Furthermore, classical concepts like “cyclic earthquake behaviour” or “characteristic earthquakes” are not applicable for SCR faults. This suggest a major influence of the GIA (glacial isostatic adjustment) on the regional stress field in intraplate regions and fault activity.

Quaternary activity and seismogenic potential of intraplate strike-slip faults: Insights from the South Eastern Korean Peninsula

Dr. Sambit Prasanajit Naik [1], ***Mr. Su-Ho Jeong*** [1], ***Mr. Ohsang Gwon*** [1], ***Mr. Kiwoong Park*** [1], ***Mr. Hyeon-Cho Shin*** [1], ***Prof. Young-Seog Kim*** [1]

1. *Pukyong National University*

Moderate to large crustal earthquakes (M>6-7) with possible surface deformation have been reported within intraplate tectonic settings, far from the plate boundary, but the historical record for those regions are too short to estimate the characteristics of the earthquake, recurrence interval, slip rate, and their seismogenic potential. Several damaging earthquakes have occurred in areas having null historical seismicity and very low to moderate slip rates such as the 2001 Bhuj Earthquake in India, the 2008 Wenchuan earthquake in China, the 2016 Peterman earthquake in Australia, and the 2020 Sparta earthquake USA. Paleoseismic studies are crucial for these regions, especially areas without historical earthquakes associated with surface rupture towards having a more realistic seismic hazard assessment. The earthquakes within the intraplate region are mostly distributed along several faults. But most of the paleoseismic studies are confined to active faults with well-preserved morphological expressions. However, our knowledge of strong earthquakes appears to be incomplete for active faults sitting within large fault systems in low slip and low to moderate seismicity areas. Given the lack of such studies within the Korean Peninsula, we have considered the one active fault sitting between the Yangsan-Ulsan Fault System (YUFS) for detailed active fault mapping and paleoseismic investigations. The fault was named Chungundong fault as per the locality. The detailed paleoseismic studies demonstrate the fault has experienced several surface rupturing earthquakes since the Late Pleistocene to the Holocene time with the most recent earthquake around ~4 k.y. With the last event occurring ~4 k.y. ago, the fault appears to be ripe for another large earthquake (moment magnitude, M_w 6-6.5 considering the length of the fault). These results emphasize the potential danger of intraplate continental faults, particularly those sitting close to the urban centers.

Paleo-faulting events of the slip-partitioned Idenokuchi fault that ruptured during the 2016 Kumamoto earthquake sequence, Japan

Dr. Daisuke Ishimura [1], ***Dr. Hiroyuki Tsutsumi*** [2], ***Dr. Naoya Takahshi*** [3], ***Dr. Heitaro Kaneda*** [4], ***Dr. Toshihiko Ichihara*** [5]

1. Tokyo Metropolitan University, 2. Doshisha University, 3. Tohoku University, 4. Chuo Univeristy, 5. Sedimentary Environments Research

The mainshock (Mw 7.0) of the 2016 Kumamoto earthquake sequence occurred on 16 April 2016 (UTC+9), and a ~30-km-long surface rupture appeared along the Futagawa fault and the northern Hinagu fault in central Kyushu, Japan. For this earthquake, InSAR confirmed numerous surface ruptures widely distributed far from the main fault (Fujiwara et al., 2016). Recent advances in remote sensing technology have revealed such complex and numerous surface ruptures (e.g., 2019 Ridgecrest earthquake; Milliner and Donnellan, 2020; Xu et al., 2020). Therefore, in our research group, we have conducted paleoseismic trench surveys on the surface ruptures away from the Futagawa fault (This study; Ishimura et al., 2021) and main surface rupture traces (Ishimura et al., 2022) for discussing the simultaneity between the primary Futagawa fault and secondary faults in the past events.

In this presentation, we present the result of a paleoseismic trench survey at the Idenokuchi fault, which showed normal faulting in the 2016 event and was pointed out that the slip partition occurred in the 2016 event (Toda et al., 2016). The study site is Komori Ranch, ~1.5 km south of the Futagawa fault. We excavated the trench (13 m long, 5 m wide, and 3.5 m deep) at the 30–50-cm south-up surface rupture. Based on radiocarbon dating and tephra analysis, paleo-faulting records for about 15,000 years have been continuously preserved in the trench. A maximum of 8 and at least 4 events (including the 2016 event) were interpreted from the trench walls. In particular, the activity after the K-Ah tephra (7.3 ka) is consistent with the paleo-seismic history of the primary Futagawa and secondary Miyaji faults, and it is estimated that similar activity has occurred at least four times recently. From this, it can be said that the appearance of many surface ruptures in the 2016 Kumamoto earthquake sequence was not a coincidence but an inevitable event.

Session 5:
Multidisciplinary hazard and risk study on active coastal and insular volcanoes

From space to seafloor data, from fieldwork to numerical modelling: an integrated approach to understanding the complex phenomena of tsunamigenic volcanic flows

Dr. Irene Manzella [1]***, Mr. Symeon Makris*** [2]***, Dr. Federico Di Traglia*** [3]***, Prof. Daniele Casalbore*** [4]***, Dr. Paul Cole*** [5]***, Dr. Karim Kelfoun*** [6]

Tsunamis generated by landslides and pyroclastic density currents in volcanic environments are a serious but often underestimated threat. They are complex, cascading phenomena which can be extremely disruptive when occurring at high magnitudes . Fortunately, these major events have a relatively low frequency which leads to a scarcity of data and limited understanding.

Because of their complexity and the multiple hazards involved, they require data from different sources. Data from remote sensing and geophysical networks are needed to continuously monitor the volcanic activity and slope stability together with regular field, areal and marine surveys to assess the everchanging morphology which distinguishes active volcanic environment. At the same time, accurate characterisation of past events is needed to be able, through their back analysis, to improve the modelling of tsunamigenic flows from a hazard assessment perspective.

In this framework, we have studied the 3rd of July 2019 events at Stromboli Volcano, Italy. Stromboli is one of the most active volcanoes in the world, many tsunamigenic landslides (sub-aerial and/or submarine) have occured and a tsunami wave was recorded associated with the July 2019 eruption. This eruption was well documented by the existing dense monitoring network and also with amateur videos and the geomorphological changes were well assessed by pre and post field, satellite and bathymetric data. This allowed us to characterise in detail the event and its timeline. Thanks to the back analysis of the events with the two fluids version of VolcFlow, a continuum mechanics model developed by the Laboratoire Magmas et Volcans (France), we were able to assess the causes of the tsunami and the 'best fit' rheology of the phenomena which generated it. We then carried out a parametrical study to identify the main factors of influence in determining the height and reach of the wave.

In conclusion, thanks to the interdisciplinary and integrated approach used in this study and the international team involved, we were able to obtain a comprehensive and accurate picture of different types of tsunamigenic flows, which ultimately leads to a better understanding of their impact and increased awareness of the risk they pose.

Rapid geomorphological changes in active volcanic settings: the Stromboli case history

Active volcanoes are highly dynamic geomorphological systems, responsive to both gravitational processes and magmatic/tectonic activity. The former are responsible for the transfer of material from steeper slopes to areas with lower gradients, whereas endogenous forcing can generate accumulation of erupted products or alternatively it can trigger moderate to large-scale mass-wasting. In order to quantify the geomorphological processes that occur in active insular volcanoes, integrated topographic and bathymetric surveys and remote sensing techniques are fundamental tools. This comprehensive approach has been applied to Stromboli volcano, where multi-platform and multi-temporal data were collected in the last decade on the Sciara del Fuoco, the steep and unstable, NW submarine-subaerial slope of the volcano.

Topographic data include multi-temporal digital elevation models (DEMs) by Light Detection and Ranging (LiDAR) data and by photogrammetry using images collected by PLÉIADES satellites and Unmanned Aerial Vehicle (UAV). Topographic change detection was also supported by data from high-spatial-resolution (HSR) optical imagery (QUICKBIRD and PLÉIADES), and COSMO-SkyMed Synthetic Aperture Radar backscattering images. Offshore data includes repeated multibeam (MBES) bathymetries and Side Scan Sonar (SSS) backscatter of the submarine flank.

The results show that fluctuations in “ordinary” volcanic activity lead to the accumulation (for higher frequency of explosions) of the erupted material from the crater area on the Sciara del Fuoco slope. In periods of lower frequency of explosions, instead, prevalent reworking by subaerial weathering and by marine processes is observed. The “anomalously intense” eruptive phases, which consists of lava flows emission and/or high-intensity explosive activity with generation of pyroclastic density currents (PDCs), lead to significant accumulation and erosion of the Sciara del Fuoco slope in a very short time. This has three main implications: 1) the alternation of brecciated lava and heterogenous volcaniclastic deposits, with reduced lateral continuity, may play a role in the Sciara del Fuoco slope stability; 2) lava flows or PDCs entering the sea have erosive potential also on the seafloor, with implications in modeling both PDCs and tsunamis; 3) the rapid geomorphological dynamics of active volcanoes require multi-temporal surveys repeated over short time intervals, including a multi-platform approach, to capture rapid changes.

How frequent are major geohazard events in the central Azores volcanic islands? Insights into landslide mapping and dated volcaniclastic turbidites

Dr. Yu-Chun Chang [1]***, Dr. Neil Mitchell*** [2]***, Dr. Julie Schindlbeck-Belo*** [3]***, Dr. Armin Freundt*** [3]***, Dr. Thor Hansteen*** [3]***, Dr. Rui Quartau*** [4]***, Dr. Christian Huebscher*** [5]

1. *Japan Agency for Marine-Earth Science and Technology,* ***2.*** *University of Manchester,* ***3.*** *GEOMAR Helmholtz Centre for Ocean Research Kiel,* ***4.*** *Instituto Hidrográfico,* ***5.*** *Institute of Geophysics, University of Hamburg; Center for Earth System Research and Sustainability, University of Hamburg*

Eruptions, submarine landslides and landslide-induced tsunamis can potentially affect communities badly, so information on their frequencies and magnitudes is urgently needed. We outline work on the central Azores islands, where multibeam bathymetric data have revealed abundant submarine landslide valleys in the uppermost submarine slopes of the islands. Those valleys range in size, with the largest potentially capable of generating tsunamis of >1 m height at source and therefore of concern. The islands are surrounded by flat basins, which likely capture the products of submarine landslides and volcanic eruptions, and thus allow them to be dated. Sediment cores from those basins contain abundant volcaniclastic (VC) turbidites. Of those, only one-third are likely generated by submarine landslides (from evidence including shelf carbonates). The contrast in abundance with the landslide valleys is intriguing. To investigate this further, age-depth models built from the hemipelagic intervals and tephra-stratigraphic correlations are used to date individual VC turbidites. Volumes of the VC turbidites are calculated by multiplying basin areas with bed thickness, also accounting for various distal thinning rates and input directions. Those volumes were used to estimate sediment fluxes. Fluxes of hemipelagic and landslide-generated sediments turn out to be much smaller than fluxes of sediment created on the shelves by erosion and biogenic production. Furthermore, the estimated volumes of turbidite in the basins are commonly larger than 10^6
m^3, only comparable with the largest submarine landslide valleys (i.e., 10^6-10^7 m^3) on the adjacent slopes. These results imply that turbidites in the cores originated only from the largest events; sedimentary flows produced by small landslides instead mostly die out and deposit on the slopes without reaching the basin floors or were too small in the basins to be recorded (e.g., because of bioturbation). The recurrence intervals of eruptions and landslides suggested by age-depth modelling (both ~kyr), therefore, only represent the large events. Our finding highlights the need for sampling the slopes of the islands as well as the basins to recover the spectrum of turbidites more completely.

Geological monitoring of the lava flow on the shelf and slope of La Palma Island during de Tajogaite eruption, 2021

The Tajogaite volcanic eruption took place on the southwestern flank of La Palma Island between September 19th and December 13th, 2021. An oceanographic study of the area was carried out to control the effects of the submarine lava flow on the seabed, developed in three-time windows during the eruption. Changes in morphology, extent, and thickness, have been studied by combining pre and successive post-bathymetric datasets, with 1m of spatial resolution, using an MB710 multibeam echosounder. To characterize the lava flow facies and different substrate types it has been used an ROV-Liropus 2000. The first bathymetric survey was carried out in the most probable arrival zone of lava flow to the sea to establish the pre-eruption characteristics of the insular shelf and slope where several gullies and their head-scarps were located.

On September 28th, the lava flow arrived at the ocean forming two lava deltas: the northern and smaller one located to the south of the Tazacorte harbor, and the southern and main one attached to the north side of the lava delta generated during the 1949's eruption. The new volcanic materials have been identified at least to a depth of 360 m and approximately 1.2 km from the initial shoreline, occupying an estimated submarine area of 35 ha. The northern lava delta has been emplaced on the inner shelf but in the southern one, the subaerial part reaches the old shelf edge where they have rested on a rocky platform and the submarine lava flow has been channeled into shelf depressions and submarine gullies that intersect the shelf border and the upper slope, totally transforming the relief. Lava flows advanced along the seabed both as "aa" and block flows in the proximal area, also forming megapillows of different sizes on the upper slope.

The monitoring of this eruption allowed studying, in real-time, the arrival of a lava flow to the sea and the associated modification of the coast and seabed. Results provide additional information on the development of the eruptive episode on La Palma Island providing a more complete picture of the functioning of the volcanic system.

Post-eruptive coastal erosion of volcanic oceanic islands formed by historical eruptions

***1.** South China Sea Institute of Oceanology, Chinese Academy of Sciences, **2.** University of Manchester, **3.** Instituto Hidrográfico, **4.** Cardiff University*

Coastlines of island volcanoes are dynamic due to their exposure to ocean waves and consequently hazardous from cliff collapses. Historically erupted island volcanoes are useful for such studies as they offer the opportunity to observe how their coasts have evolved throughout their lifetimes. Commonly their young coasts are eroded rapidly as their cliffs are not protected by wave attenuation due to a lack of a littoral platform. We have derived coastline positions from satellite images, survey maps and aerial photos for Capelinhos (Azores, erupted 1958), Surtsey (Iceland, 1967), Sholand (southern Red Sea, 2011), Hunga Tonga Hunga Ha'apai (Tonga, 2015) and La Palma (Canaries, 2021). Post-eruptive coastline erosion rates vary between them as they are subject to different wave regimes. However, results show that in all cases coastal erosion rates were rapid in the early stages following the eruptions but then declined gradually with time. Marine geophysical data collected around the Capelinhos coast reveal how erosion has left a littoral platform. Attenuation of waves crossing such a platform could contribute to the slowing of erosion rates, but modelling suggests that attenuation cannot explain the majority of that change. We suggest that the common slowing of erosion rates is probably due to the outer erupted materials of the cones typically being unconsolidated and erodible, while deeper materials are more consolidated and/or lithified. Consequently, although cliff collapses can become larger with time as cones are dissected by wave erosion, the frequency of cliff collapses declines.

Comparison of seismic and acoustic signals coming from the submarine hydrothermal system of Panarea Island (Aeolian Archipelago, Southeastern Tyrrhenian Sea)

Dr. Agostino Semprebello [1], ***Dr. Gianluca Lazzaro*** [1], ***Dr. Manfredi Longo*** [1], ***Dr. Cinzia Caruso*** [1], ***Dr. Sergio Sciré Scappuzzo*** [1], ***Dr. Paolo Manganello*** [1], ***Dr. Domenico Traina*** [1], ***Dr. Francesco Italiano*** [1]

The observation and analysis of seismic and passive acoustic signals represent an effective method for both short- and long-term monitoring of submarine hydrothermal activity in volcanic areas. In this context, the aim of this work is to present preliminary results of the analysis and comparison of seismic and acoustic signals recorded at the beginning of October 2022, during an experiment focused on short-term monitoring of the Panarea submarine hydrothermal system in the eastern sector of the Aeolian Arc (Southeastern Tyrrhenian Sea). This shallow submarine hydrothermal system, the most active among the hydrothermal systems of the Aeolian Archipelago, has given rise to a strong gas emission in 2002-2003. For the first time, hydrothermal activity is investigated by coupling acoustic and seismic data in order to expand the knowledge of the system behavior. Seismic data collection was performed by using a wideband (120 s - 500 Hz) 3-component Ocean Bottom Seismometer (OBS), while the acoustic data were acquired with a passive hydrophone [1-50000] Hz. Both instruments were integrated into a fixed multidisciplinary underwater observatory which provided power supply and internet connection. The application of various time-frequency analysis methods permitted to recognize different energetic frequency peaks, diverging from the background ambient noise, which characterize both seismic and acoustic signatures. These frequency peaks can be correlated to different source mechanisms, related to fluid dynamics along the discharging cracks. Both the instruments recorded energetic peaks sourced by spasmodic tremor, spanning between 2-30 Hz frequency range. Harmonic and narrow band peaks, centered respectively at 50 Hz and 150 Hz, likely sourced by the discharging dynamic of the brine that seeps out just a few meters away from the instruments were detected as well. Finally, we have performed a directionality analysis of the seismic signals computing the Fourier amplitude spectra as a function of azimuth in the horizontal plane, and this has allowed us to identify and confirm the location of sources in the submarine hydrothermal system of Panarea Island. Furthermore, this study improved the current state of our understanding of the processes related to fluid dynamics and to suggest practical methods of monitoring in extreme environments.

Morpho-acoustic characterization of the submerged portion of La Fossa Caldera (Vulcano Island, Tyrrhenian Sea, Italy) through the integration of multi-temporal multibeam bathymetric data and video footages.

Ms. Denise Petronelli [1], ***Ms. Sofia Stagni*** [2], ***Prof. Daniele Casalbore*** [1], ***Prof. Claudia Romagnoli*** [2], ***Dr. Martina Pierdomenico*** [3], ***Dr. Alessandro Bosman*** [4], ***Prof. Francesco Chiocci*** [1]

The flanks of active insular volcanoes are highly dynamic environments characterized by fast morphological evolution, which may create hazards for local coastal communities. Vulcano Island (part of the Aeolian archipelago, southern Tyrrhenian Sea) is the top of an active stratovolcano, whose last eruption occurred in 1888-1890. The island is characterized by two calderas and part of the younger multi-stage La Fossa caldera is below sea level. The submerged part extends down to depths of 300 m and is bounded by two very steep submarine scarps, with slope gradients up to 80°. This submerged area is characterized by a series of primary volcanic features carved by a network of small gullies that often arrive up to the shallow-water setting, mining the stability of the NE flank of La Fossa cone, as testified by the development of a small tsunamigenic subaerial landslide in 1988. In addition, the caldera has historically been site of intense hydrothermal activity, still ongoing as testified by the subaerial and submarine degassing crisis started in December 2021.

In this work, we present an integrated analysis of high-resolution multi-temporal bathymetric data collected between 2005 and 2022, backscatter data and video footages acquired both from Remotely Operated Vehicle (June 2022) and research submersible JAGO (February 2020). The integrated analysis allows a morphological characterization of the main volcanic and erosive-depositional features characterizing the submerged La Fossa Caldera as well as of the main features related to the degassing activity occurring in very shallow-water.

Session 6: Recent advances in understanding the Quaternary geomorphological evolution of continental margins

Dynamic landscapes in active coastal and submarine volcanoes in the south Aegean Volcanic Arc: Santorini and other volcanoes

Dr. Nomikou Paraskevi [1], ***Mrs. Danai Lampridou*** [2], ***Mrs. Konstantina Bejelou*** [2], ***Dr. Kyriaki Drymoni*** [3], ***Mrs. Stavroula Kazana*** [2], ***Dr. Varvara Antoniou*** [2]

1. National and Kapodistrian University of Athens, 2. Department of Geology and Geoenvironment, National and Kapodistrian University of Athens, 3. Department of Earth and Environmental Sciences, University of Milan-Bicocca

Greece is a rare physical laboratory since it is one of the most seismically and volcanically active areas in Europe. This is associated with the Hellenic subducting system and the regional tectonics that produced an island arc in the late Eocene. The latter has migrated from the N to the S and currently lies in between neotectonic and active tectonic grabens in the Aegean microplate. The activity in the Hellenic volcanic arc initiated on its western margin in the Late Pliocene while the rest of it formed Quaternary centres.

Here we present the most well-known and well-studied onshore and offshore features found on the volcanic islets. The arc comprised several volcanic edifices, with the most intriguing geomorphological agents being the Methana, Milos, Santorini and Nisyros volcanic groups. In particular, we unfold the geomorphological evolution of the arc from the W to the E and present its gradual transition from dome landforms to craters and collapsed caldera landscapes.

Our analyses have shown that although all the volcanic centres share a similar geological evolution as part of the Aegean microplate, their geomorphological fingerprint is highly heterogeneous both along the arc and in an island scale. The volcanic activity in all centres is present onshore and offshore hosting effusive and explosive landforms such as cones, domes, craters and shallow submarine hydrothermal vent fields, respectively. The Christiana-Santorini-Kolumbo volcanic group remains a key agent of geomorphological heterogeneity combining rough landscapes in its interior (e.g., calderas and craters) surrounded by smooth surfaces (erosional features, sculptured ignimbrites) on the outskirts. All the reported geomorphological features thus far demonstrate still a balanced but dynamic interaction between the volcanic and terrigenous environment. The latter is related to dynamic interactions between the volcanic activity and the erosional processes that sculpture the terrestrial and submarine topography along the arc.

Tectonically controlled landforms of the Hellenic Trench and the Aegean back-arc

The Hellenic Trench and the Aegean back-arc display a large variety of seafloor landforms that reflect the complexity of Quaternary tectonics and kinematics. We use the 100 m DTM (EMODnet Bathymetry) and swath bathymetry to describe the geomorphological features and highlight their relationship with the active geological processes.

The Hellenic Trench contains three distinct sectors and encompasses a series of deep troughs, steep slopes, canyons, seamounts:

The northwestern sector marks the 3000 m high escarpment of the dextral Kephallinia transform fault-zone. The Kephallinia Valley has developed along the Kephallinia Fault and is the deeper part of a roughly 200 km long valley that starts from Otranto Strait.

The western sector, the Ionian Trench, extends from the Ionian Islands to the south of Gavdos Island, is oriented roughly perpendicular to the convergence direction and is characterized by compressional and lateral escape tectonics. It features small, isolated, deep (>5000 m) basins, separated by shallower ridges and includes the 5200 m Oinousses Deep.

The eastern sector is characterized by sinistral oblique compression and is delineated by three striking features: the Ptolemy Trench south of Crete and the Pliny and the Strabo Trenches that terminate in Rhodes Basin (4000m). Ptolemy (2500-3700 m) and Pliny (3700-4500 m) Trenches have developed within the Aegean crust. Strabo Trench (3000-3500 m) marks the boundary between the Aegean crust and the Mediterranean Ridge.

The Aegean Sea marks the SSW-wards extending back-arc between the retreating Hellenic subduction and the western termination of the North Anatolian Fault. The morphological puzzle includes: (i) a large number of rhomboid, elliptical or spindle shaped, up to 2500 m deep, isolated basins, (ii) up to > 50% steep, faulted slopes striking NE-SW to ENE-WSW and in NW-SE to WNW-ESE, (iii) seamounts, ridges and islands of tectonic and volcanic origin, (iv) canyons and gullies incising the steep slopes or separating structural lows. Normal, oblique and strike-slip faults control subsidence of the Quaternary basins, the formation of the shallow ridges and mounts, the development of steep slopes in between them and the incision of narrow and deep valleys.

Quaternary basin formation and deformation in the Aegean back-arc area

1. *Inst. Oceanography, Hellenic Centre for Marine Research, Anavyssos, Greece,* **2.** *Hellenic Centre for Marine Research, Anavyssos, Greece,* **3.** *Inst. Oceanography, Hellenic Centre for Marine Research, Anavyssos,*

This work is part of a long-term research project on the geodynamic evolution of the Aegean Sea, in Greece. It includes the reinterpretation of old, analog seismic profiles and recent seismic and swath bathymetry data processing.

The deforming Aegean crust flows towards SW between two major boundaries, the dextral North Anatolian Fault and the Pliny and Strabo Fault Zones. The kinematic model with arc-parallel zones of extension since the Early Pliocene can hardly explain the structural and morphological configuration that evolved during the Quaternary. Recent studies have shown that isolated basins and ridges associated mainly with NW-SE and NE-SW oblique to strike-slip faults and roughly W-E normal faults characterize the Aegean morphology. Large arcuate extensional basins are not observed in the present Aegean morphology.

A two-stage structural evolution of the South Aegean is proposed here: the wide, arc-parallel, Pliocene basins evolved since the Early Quaternary into a more complex structure with multiple basins separated by shallow ridges. The orientation of the individual subsiding and uplifting blocks, predominantly in NE-SW to ENE-WSW and secondarily in NW-SE to WNW- ESE directions, coincides with the strike of the major faults that control the Aegean deformation. Major unconformities have been mapped within the Plio-Quaternary sedimentary sequence of the Aegean basins and are related to the geodynamic, structural and morphological re-arrangement. These unconformities mark the deactivation or re-orientation of the older major, basin-bounding faults and the initiation and propagation of new ones.

The reliable dating of this tectonic re-arrangement is not yet possible. Chronological estimates derive from the interpretation of low sea level prograding sequences and the ODP drilling project in the Cretan Basin indicate an Early Quaternary approximate age for this tectonic change. The driving mechanism of this major change in the geodynamic regime of the Aegean back-arc in the Early Quaternary is not confirmed yet. However, the propagation of the North Anatolian Fault in the North Aegean may be a good candidate.

Variations in the Provenance of Yangtze Delta over the Holocene

Dr. Yuan Shang [1], Prof. Weiguo Zhang [1], Ms. Yinglu Chen [1], Dr. Jiarun Tu [2]

1. East China Normal University, 2. Tianjin Institute of Geology and Mineral Resources, China Geological Survey

The Yangtze Delta, located at the east Asia continental margin, is one of the mega deltas on the Earth system. As a typical tidal dominated delta, it has been formed and shaped under the influences of both fluvial and marine dynamics since the middle Holocene (~7-8 ka). Detrital records preserved in the stratigraphy of the Yangtze Delta system provide abundant information of Asia climate change and land-sea evolution over the Holocene. Deltas nowadays worldwide share a fate of erosion, drowning or shrinking due to global climate change and intense human interventions. Potential risk predictions and long-term sustainable management and protection of the coastal delta systems require a detailed understanding of the sedimentation process and forcing mechanism in shaping the deltas over the past thousands of years. Sediment supply for the Yangtze Delta and its dynamic response to climate change have long been active research subjects. In this study, we investigated three sedimentary cores across the Yangtze Delta, for which the chronology frames have been well established. We used an end-member modelling approach on the bulk grain-size distribution datasets to characterise sediment sub-components and their relative contributions within the three cores. We further provided the detrital zircon U-Pb geochronology for different sedimentary facies of the three cores and compared them with the integrated large-N zircon U-Pb age dataset of the Yangtze River's upper and middle basins. We aim to offer a refined detrital provenance model and quantitative analysis on the sediment supply to the Yangtze Delta through the Holocene. Our data indicate a temporal variation in the provenance of the Yangtze Delta during the Holocene and recognise possible sediment supply from the marine source since the last 1ka.

Reconstruction of the Laurentide Ice Sheet based on a geomorphological analysis of glacial landforms on the Labrador Shelf

Mr. Kai-Frederik Lenz [1]***, Dr. Felix Gross*** [1]***, Dr. Arne Lohrberg*** [1]***, Dr. Pierre-Olivier Couette*** [2]***, Dr. Christian Ohlendorf*** [3]***, Dr. Henriette Kolling*** [1]***, Prof. Ralph Schneider*** [1]***, Prof. Sebastian Krastel*** [1]***, Dr. Catalina Gebhardt*** [4]

1. *Institute of Geosciences, Christian-Albrechts-Universität zu Kiel,* ***2.*** *Département de géographie, Université Laval,* ***3.*** *Institute of Geography, University of Bremen,* ***4.*** *Alfred Wegener Institute Helmholtz-Centre for Polar and Marine Research*

The eastern Canadian margin, especially the Labrador Shelf, is one of the key areas to study climate variations from the Cenozoic to the present. During past glaciations, vast areas of Northern North America were covered by thick ice sheets, such as the Laurentide Ice Sheet (LIS). In periods of melting, these ice sheets released significant amounts of freshwater into the North Atlantic and influenced the ocean circulation, particularly the Atlantic Meridional Overturning Circulation (AMOC). Open questions concerning the effect of global warming on the AMOC stimulate discussions and studies on the mechanisms responsible for the strength and heat flux of this ocean circulation. Since changes in the AMOC are mainly caused by natural climate fluctuations between glacials and interglacials, it is critical to examine the dynamic behavior of the LIS in detail. However, data on the dynamics of the LIS are mainly derived from sediment cores located far offshore in the Labrador Sea and information from the Labrador Shelf is limited to Holocene sequences. Therefore, the aim of this study is to analyse the geomorphological evolution of the Labrador Shelf in order to draw conclusions to the dynamics of the LIS. In particular, we update the knowledge of the extent of the LIS at its distal marine limit and provide constrains on the last ice sheet retreat based on state-of-the-art high-resolution geophysical data imaging from the Labrador Shelf. In 2015 and 2019, we carried out expeditions to the Labrador Sea to investigate the transverse troughs and intervening banks of the shelf by a combination of bathymetric mapping, sediment echosounding and sediment coring. We discovered glacial landforms like grounding-zone wedges and iceberg scours likely related to the last glaciation. Further, we carry out a geomorphological analysis of these landforms to reconstruct the Quaternary evolution of the shelf. In conclusion, we combine our results to a model of the dynamic behavior of the LIS, which can be used to infer possible processes that led to freshwater surges in the central Labrador Sea during the Pleistocene and early Holocene.

3D Mapping and Integrated Geospatial Data of the Molloy Hole (Arctic Ocean)

Prof. Roberta Ivaldi [1], ***Ms. Geraldine Palacios Torres*** [2], ***Mr. Roberto Nardini*** [1], ***Dr. Maurizio Demarte*** [1]

1. *Italian Hydrographic Institute,* ***2.*** *University of Genoa*

Based marine geophysical data collected during the IT-Navy HIGH NORTH20 and HIGH NORTH21 campaigns, a 3D integrated mapping of a region between 78.5-81°N and 1-8°E, where the Molloy Hole is located (Fram Strait – Arctic Ocean), has been developed. The Molloy Hole is the deepest undersea feature of the Arctic Ocean and plays a structural key role in the ocean geodynamics in terms of new ocean seafloor and gravitative mass movement, sink or barrier to the dynamics of the water masses with confined sedimentary processes in the presence of melting ice, polar and Atlantic current. The ocean surface (water and ice), the water column and the seabed data, thanks to an integrated-multidisciplinary approach and harmonization techniques named 'imagery box', has been processed using MATLAB R2021b to obtain a high-resolution 3D model. In particular, the research activities collected water column, bathymetry and acoustic backscatter from multi-beam sonar surveys, CTD data, and sedimentary samples from box corers. The need for a visualization to aid in the comprehensive analysis of all elements of this imaginary box is the main reason behind this research. Consequently, it seeks to integrate in situ and remote sensing measurements in order to provide an integrated mapping of the study area as a one single product. In order to achieve this goal, it is essential to optimize the process by standardizing the file formats so that all data can converge into a complete 3D depiction of the elements that compose the ocean: sea surface, water column and seafloor. The unification of distinct geospatial data should be of great help to scientists when analysing their own 'imaginary boxes'. This mapping is an integrated data product starting from the raw data in order to create a unique processing tool, and to produce a complete and comprehensive depiction of the 3D marine environment. This 3D integrated mapping highlights the undersea features as the drivers of the dynamics of the Molloy Hole from the sea surface to the ocean bottom.

Submarine morphology of Pantelleria Island: interplay between volcanic and erosive-depositional processes modulated by sea-level fluctuations

***Prof. Daniele Casalbore* [1]*, Prof. Claudia Romagnoli* [2]*, Dr. Marilena Calarco* [3]*, Dr. Eleonora Martorelli* [4]*, Dr. Alessandro Bosman* [5]*, Prof. Francesco Chiocci* [6]**

***1.** Department of Earth Sciences, Sapienza University of Rome, **2.** University of Bologna, **3.** RINA Consulting S.p.A., **4.** National Research Council- IGAG, **5.** IGAG - CNR, **6.** Department of Earth Sciences, University of Rome Sapienza*

The study of submarine portions of insular and coastal volcanoes exponentially increased in the last decades through recent advances in seafloor imagery and seismic techniques that allow reconstructing the main volcanic, tectonic and erosive-depositional processes affecting the volcanic edifices. In this study, we analyse the detailed submarine morphology of Pantelleria, a large composite Quaternary volcano belonging to the magmatic district of the Sicily Channel (central Mediterranean Sea), located in a continental rift context.
The most recent eruption at Pantelleria was submarine and occurred in 1891, about 5 km NW of the northwestern coast of the island, producing floating basaltic lava balloons observed at the sea surface. The volcanic edifice is ~36 km long and ~15 km wide, encompassing a surface of approximately 300 km^2. Some …% of the volcano lies below sea level. The edifice is markedly elongated along the NW-SE direction and rises above the Pantelleria Basin between 700 (NW flank) and 1300 (SE) m water depth. The submarine volcanic flanks are characterized by different declivities and distribution of primary (volcanic) and erosive-depositional features. The former ones include volcanic cones, elongated ridges, lava flows, and outcrops. Slides scars, channels, gullies, insular shelf and infralittoral prograding wedges are recognized among the latter ones. Based on the integration of morpho-bathymetric analysis and available seismic reflection profiles, the aim of the paper is twofold: (i) to show the interplay between volcanic, tectonic and erosive-depositional processes, the latter ones also modulated by sea-level fluctuations, in shaping the submarine morphology of the Pantelleria volcano, (ii) to reconstruct the morpho-structural evolution of this edifice, providing new insights on vertical deformations occurred in the Late-Quaternary through the use of marine geomorphic markers.

Millennial-scale patterns of Mid-Late Holocene environmental evolution from the southern Adriatic shelf (Apulia, Italy) as revealed by multivariate data

Prof. Veronica Rossi [1], ***Dr. Irene Sammartino*** [2], ***Dr. Claudio Pellegrini*** [2], ***Dr. Giulia Barbieri*** [1], ***Ms. Chiara Teodoro*** [1], ***Dr. Fabio Trincardi*** [3], ***Prof. Alessandro Amorosi*** [4]

1. *Department of Biological, Geological and Environmental Sciences (BiGeA), University of Bologna,* ***2.*** *National Research Council (CNR), Institute of Marine Science (ISMAR),* ***3.*** *Consiglio Nazionale delle Ricerche - DSSTTA CNR,* ***4.*** *Department of Biological, Geological and Environmental Sciences, University of Bologna*

Due to the complex interplay between river plumes, storms and sea currents, a variety of morphologies and depositional environments commonly typifies shelves. With the aim of better understanding the lateral and vertical succession of shallow-marine facies and associated paleo-landscapes, we analysed the Mid-Late Holocene record of three cores (INV12-15; SI08-27 and COS01-16) retrieved from distinct bathymetric sectors of the Apulian shelf (Southern Adriatic Sea, Italy). Boreholes INV12-15 and SI08-27 are located within the Gulf of Manfredonia, south of the Gargano Promontory, at 15 m and 30 m water depth (wd) respectively, while COS01-16 was drilled at 76 m wd on the open shelf.

Framed into a robust chronological and seismic-stratigraphic framework, a multiproxy approach based on paleobiological (ostracods and benthic foraminifers) and geochemical data allowed us to recognize patterns of environmental evolution and changes in sediment transport pathways over millennial timescales. Under substantial highstand sea-level conditions, stratigraphic variations in meiofauna associations mainly reflect changes in organic-matter fluxes, oxygenation and hydrodynamic levels at the sea-bottom. On the other hand, vertical profiles of trace-metal distribution highlight changes in the relative contribution of Po-Apennine rivers (via the Western Adriatic Current) *versus* Apulian rivers, directly feeding the Manfredonia gulf.

Within the gulf, paleoenvironmental changes are in-phase with shifts in sediment source, testifying the close correspondence between facies patterns and the trajectories of fluvial inputs. Up to ~7000 cal. years BP, the gulf area hosted a shallow-marine environment subject to low-moderate organic-matter fluxes from the Apulian rivers. Afterwards, a fully river-influenced setting occurred, recording a positive trend in organic-matter enrichment under the progressive increase in Po-Apennine riverine input that marks the diachronic development of the Adriatic prodelta mud wedge into the gulf (~6000-2500 cal. years BP). On the open shelf (core COS01-16), the sea-bottom was steadily affected by Po-Apennine inputs that led to the vertical stacking of outer shelf muds (up to ~7000 years BP), progressively more enriched in degraded organic matter (~7000-6000 years BP), with distal prodelta muds (since 6000 years BP) on top.

Seafloor morphology and recent dynamics in the Scoglio Affrica (Northern Tyrrhenian Sea)

Ms. Anna Saroni [1], ***Ms. Federica Maurantonio*** [2], ***Prof. Daniele Casalbore*** [3], ***Prof. Francesco Chiocci*** [3], ***Prof. Massimo Coltorti*** [1], ***Dr. Maurizio Demarte*** [4], ***Prof. Roberta Ivaldi*** [4]

1. *Università degli Studi di Ferrara,* ***2.*** *Italian Navy,* ***3.*** *Department of Earth Sciences, Sapienza University of Rome,* ***4.*** *Italian Hydrographic Institute*

Seabed gas emission phenomena in the Northern Tyrrhenian Sea have been detected using a high resolution swath bathymetry, while nature of seabed and water column were investigated with acoustic backscatter and geochemical data. Since 2017, the Scoglio Affrica islet has been surveyed and monitored after a transient event of gas and fluid emission from the seafloor that originated a geyser above the sea level. These transient phenomena occur very localized both in space and in extremely short time. The complexity of these kind of events requires an integrated monitoring system, which allows us to characterise the seafloor morphology and recent dynamics through a multidisciplinary research. The collected data provided the purpose for detecting new target of the seafloor recent dynamics and gas emissions, such as volcanic morphological features, mud volcanism, particular geochemical composition of water and sediment, as well as petrographic observation and grain size of the latter. This study allowed to obtain insight information on the temporal and spatial evolution of seafloor morphology related to gas emissions in the area of the Scoglio Affrica in order to create a map of the features and emission points referring to the recent dynamics in shallow water. At least four mud volcanic structures are located in this area with different seafloor evolutionary records, including sediment consolidation, fracturing and variation in morphology and depth of the sea bottom, likely related to the inflation/deflation of the mud volcanoes as well as to the wave action.

Quaternary geomorphological evolution related to continental slope and seamount instabilities of the Mallorca Channel (western Mediterranean)

***Ms. Olga Sanchez Guillamon* [1], *Dr. Gemma Ercilla* [2], *Dr. David Casas* [2], *Dr. Desirée Palomino* [1], *Ms. Natalia Martínez Carreño* [3], *Ms. Patricia Bárcenas* [1], *Mr. Luis Miguel Fernández-Salas* [4], *Dr. Juan-Tomás Vázquez* [1]**

***1.** Instituto Español de Oceanografía (IEO, CSIC), Centro Oceanográfico de Málaga, **2.** Institut de Ciències del Mar (ICM CSIC), Barcelona, **3.** Instituto Español de Oceanografía, Servicios Centrales, Madrid, **4.** Instituto Español de Oceanografía (IEO, CSIC), Centro Oceanográfico de Cádiz*

The geological study of the Ses Olives, Ausias March and Emile Baudot seamounts and adjacent areas located in the Mallorca Channel (Balearic Promontory, western Mediterranean) using multibeam bathymetry and backscatter data and high-resolution parametric profiles has allowed us to identify several morphological features of different scales associated to gravitational and erosive-related processes. Major morphological features characterized are slides, slide scars, mass-transport deposits (MTDs) as well as different gully-systems affecting seamounts flanks. Slide scars have been recognized at the top and flanks of the seamounts as well as at the adjacent areas in the central basin. They show diverse geometries that can be affected by scarp faults and pockmarks developing multiple steep scars with lengths of up to 15 km. MTDs are identified throughout the entire study area and present mostly elongated morphologies. They extend between 1 and 11 km from the scars, and locally present perpendicular trajectories between the different sedimentary bodies. They generate seafloor reliefs of more than 20 m and up to 50 ms thick in the seismic profiles, identifying stacks of, at least, three different episodes. In some cases, the movement of the displaced mass in the subsurface have produced a high deformation of the materials located above. Gullies are mostly located on the flanks of the Ausias March and Emile Baudot seamounts, as well as in the north central flank of Ses Olives. They have a rectilinear shapes, although with an irregular distribution, with orientations that vary from NW-SE to NE-SW for the Ausias March and Emile Baudot, respectively, and SO-NE in Ses Olives. They develop small slides and bedforms of turbiditic origin. The integrated analyses have allowed us to calculated that the area affected by sedimentary instabilities is around 10% of the study area (500 km^2) mainly related to tectonics and fluid expulsion processes. This study will offer new insights and understanding of the geological hazard scenario in this sector of the Balearic continental margin.

Geomorphology of the northern and southern continental margins of the Iberian Peninsula: Quaternary interplay of tectonics and sedimentation

Geomorphic evolution of tectonically active continental margins is the result of the interplay of deformation and sedimentary structures. Iberian Peninsula, located in the present-day NW-SE convergent Eurasia-Africa plate boundary, is mainly deformed in the northern Cantabrian margin (NE Atlantic) and in the southern, both Alboran and Gulf of Vera margins (SW Mediterranean). These margins develop elongated highs and basins roughly parallel to the margins. Moreover, faults and volcanic structures affect the southern Iberia margin. All these deformation structures are responsible for the regional configuration and physiographic components of the margin, seafloor topography, as well as entry points of sediment and pathways of the alongslope (bottom currents) and downslope (mass-transport and gravity flows) sedimentary processes.

The deformation structures condition the distribution of deep-sea bottom currents and their sedimentary geomorphic impact is regionally variable during the Quaternary. Contourite features are dominant in the Alboran Sea to the extent that their distribution conditions the physiography. This significant action of bottom currents is linked to the semi-enclosed basin configuration that favours the confinement of the Mediterranean waters. Contrasting, in the Cantabrian and Aguilas open margins, bottom currents are topographically steered by the highs and form local contourite features. Deformation structures also influence the downslope sedimentary processes. Mass-transport and sediment gravity flow features are mostly shaping the Cantabrian and Gulf of Vera margins during the Quaternary. Their occurrence is related to the overstepping or tectonic tilting of the margins, shelf-indenting canyons and narrow shelves. Contrasting, those features are less extended in the Alboran Sea, where their formation is related to seismicity, overstepping of highs, fluid dynamics and turbidite systems. These results indicate that the regional tectonic style of deformations driven by the inherited crustal heterogeneities can be considered a main factor that determines the Quaternary geomorphic sedimentary processes. All these results indicate that the regional tectonic style of deformations driven by the inherited crustal heterogeneities can be considered a main factor that determines the Quaternary geomorphic sedimentary processes.

Bedform development along the shelf-incising Carchuna Canyon, northern Alboran Sea (western Mediterranean Sea)

***Mr. Javier Cerrillo-Escoriza* [1]*, Prof. Aaron Micallef* [2]*, Dr. Francisco José Lobo* [3]*, Dr. Ángel Puga-Bernabéu* [4]*, Ms. Patricia Bárcenas* [5]*, Dr. Irena Schulten* [2]*, Dr. María Luján* [6]*, Dr. Maria José Sánchez* [7]*, Dr. Olga Sánchez-Guillamón* [5]*, Mr. Álvaro Carrión-Torrente* [3]**

***1.** Instituto Andaluz de Ciencias de la Tierra (IACT), CSIC-Universidad de Granada, **2.** University of Malta, **3.** Instituto Andaluz de Ciencias de la Tierra (IACT), CISC-UGR, **4.** Departamento de Estratigrafía y Paleontología, Universidad de Granada, **5.** Instituto Español de Oceanografía (IEO, CSIC), Centro Oceanográfico de Málaga, **6.** Departamento de Ciencias de la Tierra, Universidad de Cádiz, **7.** IOCAG, Universidad de Las Palmas de Gran Canaria*

This study focusses on improving our understanding of bedform forming processes in shelf-incising submarine canyons, using the Carchuna Canyon as a case study. To achieve this aim, we used: (1) multibeam bathymetric data, (2) grain-size data, (3) sub-bottom acoustic profiles, and (4) Flow 3D Hydro to simulate flow conditions along the canyon.

The Carchuna Canyon is deeply incised in the shelf, and its head is located just 200 m off the coastline. The axial channel in the upper segment is covered by crescent-shaped bedforms (CSBs), with downcanyon evolution from fine sands into very coarse silts. Sets of CSBs also occur in the lower segment axial channel, where sediments change from very fine sands to distal coarse silts in levees. On the open slope east of the lower segment, two types of sediment bedforms have been identified: sediment waves with decreasing size downslope and two trains of N-S large scours.

Acoustically, three acoustic facies were identified in the sub-bottom profiles were determined in the lateral deposits. The lower facies exhibit undulating and discontinuous low to medium amplitude reflections with laterally variable thickness. The middle facies are characterized by a transparent acoustic response. The upper facies develop an undulating seafloor. Flow simulation suggest the highest average flow velocity along the canyon thalweg. Out of the valley, average velocities are higher on top of the bedforms crests, whereas the higher Froude number values occur in the lee side of bedforms.

The occurrence of CSBs in the axial channel point to down-canyon turbiditic flows along the channel, possibly conditioned by the extensive shelf incision of the canyon and its proximity to the coastline, which favour the capture of littoral sediment transport and the formation of gravity flows. The bedforms outside of the axial channel are linked to turbidity current spill over meander bends, resulting in the formation of net-depositional (sediment waves) or net-erosional cyclic steps (scours) due to repeated hydraulic jumps.

In the recent past, paleo-bathymetric steps possibly favoured the formation of sediment waves out of the valley. These bedforms exhibit an upslope asymmetrical migration pattern, suggesting lower energy flow through time.

Are present-day infralittoral prograding wedges (IPWs) reliable geomorphological indicators of current sea level? A challenge to their use from the Campania Region IPWs Database (CRID).

A census of 83 Infralittoral Prograding Wedges (IPWs) was carried out in the Central-Eastern Tyrrhenian Sea, to learn more about their morpho-bathymetric variability and test their reliability as geomorphological indicators of current sea level. A dataset reporting for each IPW the main morphometric indices (distance from the coast, depth, foreset and tospet slope angle, length, direction), the ground elevation (GEB) in the backshore and more, the effective fetch (EF) and the maximum significant height of the storm waves (Hs) to which they might be exposed, was then implemented (Campania Region IPW dataset, CRID). GEB, EF and Hs are environmental descriptors related to the external forcings acting on each IPW and accounted for by the energy of the relief and the local sea state. The multi-regression analysis among indices highlighted a significant correlation of IPWs depth with EF and Hs and a moderate correlation with GEB. The Principal Component Analysis (PCA) evidenced two clusters of indices, where depth and distance appear as being governed by sea state forcing and foreset and topset slope angles by the energy of relief in the backshore, respectively. The outcomes emerged from the observational law on present-day IPWs were then applied to relict IPWs, sited on the continental shelf and at the shelf margin, with the aim of establishing their original depth of formation, and test their reliability as proxies for past sea levels. The original depth of relict IPWs was roughly established by adopting a simplified equation that relates the depth to the EF. This procedure provides an analytical method for gauging the original depth of relict IPWs in the eastern Tyrrhenian Sea by using an easily computable geographical index.

In conclusion, this study explores the relationship between the depth of present-day IPWs and sea storm wave climate at a regional scale and provides clues for using relict IPWs as geomorphological proxies of past sea level stands. A wider dataset recording a larger number of IPWs indices would consent to extend the observational law on present-day IPWs to a Mediterranean scale and strengthen the applicability of the method to a spatially-broader set of relict IPWs.

Controlling factors on the geomorphology of mixed siliciclastic-carbonate margins: A case study from the Quaternary Belize margin

Ms. Laura H. Bührig [1], Prof. Jeffrey Nittrouer [1], Prof. Daniel R. Parsons [2], Dr. Stephen M. Simmons [3], Mr. Michael Jenkins [4], Prof. André W. Droxler [5]

1. Texas Tech University, 2. Loughborough University, 3. University of Hull, 4. Belize Port Authority, 5. Rice University

Along mixed siliciclastic-carbonate margins, sediment dispersal to adjacent basins is not necessarily primarily controlled by sea-level variations and terrestrial sediment supply, but also by the cohabitation of the reef and siliciclastic systems. Although both systems are well studied individually, the co-evolution of siliciclastic and carbonate systems and their mutual impact on continental-margin geomorphology is still poorly understood, which is reflected in the paucity of numerical and conceptual models of mixed siliciclastic-carbonate margins. The aim of this research is to better understand the mutual influences on the geomorphological evolution of mixed siliciclastic-carbonate margins of (1) the siliciclastic river system progradation onto emerged shelves, including its deltas reworked along coastal beach ridges and slope fans, and (2) the reef establishment, growth, and exposure through the sea-level cycle.

For this purpose, the co-evolution of the late Quaternary mixed siliciclastic-carbonate English Caye Channel (ECC) system was studied along the Central Belize margin. The ECC system comprises (1) a well-developed river drainage system of infilled incised valleys, parallel and landward of the coralgal barrier reef, merging into (2) the ECC itself, a km-wide partially filled incised valley crossing the barrier reef, and (3) at its mouth, on the seaboard of the barrier reef, a well-developed shelf-edge delta and linked slope fan. We investigated: 1) the role of pre-existing reef-created seafloor topography in governing the geomorphology of the ECC system, and (2) the impact of the ECC fluvial system as a substratum for growth of the Holocene reef system.

The integration of a recently acquired high-resolution bathymetric dataset with literature-derived seismics, existing LIDAR, and drone-based photogrammetry datasets, illuminates the complex interplay between siliciclastic and carbonate depositional systems and their impact on sediment routing across continental margins to adjacent basins.

Our results highlight the need, in developing evolutionary models of mixed siliciclastic-carbonate continental margins, to consider multiple controlling factors of both siliciclastic and carbonate systems at both local and regional scales, without neglecting the potential influence of each system on the other. This approach needs to include late Quaternary unusually high amplitude sea-level fluctuations, pre-existing structurally controlled hinterland and seafloor topographies, and regional oceanographic and sedimentological processes.

Deltas at the shelf edge and their relationship with shelf-incising canyons

***Dr. Cornel Olariu* [1], Dr. Ronald J. Steel [2], Dr. Mariana I. Olariu [3]**

***1.** The University of Texas at Austin, **2.** Department of Geological Sciences, The University of Texas at Austin, USA, **3.** Bureau of Economic Geology, University of Texas at Austin*

It is not always clear why active shelf edges sometimes have a nearby canyon sometimes not. The edge of the shelf in a shelf-to-slope basin setting is dominated by delta depocenters and shelf-incising upper slope canyons. Deltas can reach the shelf edge during forced regressions or normal regressions. On the outer shelf and shelf edge, deltas commonly deliver and deposit sediments into the head of the canyon, thus accreting the upper slope, or in the case of the flows being erosional, incising the upper slope.

Using a review of well documented examples of Quaternary and pre-Quaternary shelf-edge deltas, we explain the key depositional differences between inner shelf deltas and shelf-edge deltas, and we analyze the relationship between the delta depocenter and canyon-head at the shelf-edge.

Shelf-edge deltas are overall thicker than their inner-shelf counterpart, because of the shelf gradient. Soft sediment deformation, growth faults, slumps and incisions of the delta front are characteristic of the shelf edge. Sedimentary structures as signals indicating fluvial, wave and tidal processes vary more rapidly along depositional strike and dip directions in shelf-edge deltas, compared to inner-shelf deltas, indicating more variable depositional conditions. Incisions into delta deposits are usually initiated from the prodelta and delta front rather than from delta plain channels. While there might be differences between icehouse and greenhouse shelf-edge deltas, most of the above observations about shelf-delta architecture hold true.

Slope canyons incise into the shelf and shelf-edge during times of sediment delivery directly from the river or via long-shore currents that trigger erosional sediment gravity flows. However, if the delta-front deliver too much sediment to the canyon head, the upper part of the conduit becomes choked and starts infilling. The presence of erosional versus depositional processes at the canyon head and eventually the entire architecture of the basin margin depends on the behavior of the river/delta generated gravity flows. The sediment flux, reflected in the rate of delta progradation, the sediment caliber reflected in the delta front gradient and the proximity of the delta front to the shelf-edge are proposed as key controls on erosional or depositional behavior of the flows.

Session 9: The Anthropocene – Its geo-archaeological indicators and early inceptions through the modern

A paleo-Anthropocene in Ireland? Irish Bronze Age sedimentary and faunal evidence

Ms. Sarah Ferrandin [1], ***Dr. Gill Plunkett*** [1], ***Prof. Kate Britton*** [2], ***Dr. Neil Ogle*** [3]

1. *Archaeology & Palaeoecology, School of Natural and Built Environment, Queen's University Belfast,* ***2.*** *University of Aberdeen,* ***3.*** *Queen's University Belfast*

Isotope zooarchaeological research in Ireland has identified a sustained positive shift in the nitrogen stable isotopic values of faunal remains during the Middle to Late Bronze Age, which has been hypothesised to have been triggered by an intensification of farming (1750-800 BCE; Guiry et al., 2018, *Science Advances*). If true, the shift would represent an indelible human footprint in the geologic record. However, whether these region-wide changes were triggered by anthropogenic factors (such as deforestation or farming activities) or by natural climatic changes, has not yet been tested. Further investigation of the phenomenon is warranted because there is evidence for episodes of land-use and climate changes during the period of interest. Focusing on samples from across Bronze Age Ireland, this paper will present results from a multi-proxy analysis of sedimentary records and herbivore remains that seeks to explore the context (and cause) of nitrogen isotopic changes identified in faunal remains in previous research. Ombrotrophic peat bogs obtain their nutrients from the atmosphere, meaning their stable isotopic values should reflect climatic fluctuations, unlike lake sediments, which should reflect both climate and land-use changes. In addition to carbon and nitrogen stable isotope measurements of sediment cores to pinpoint the timing of the shift in the isotope record, pollen (from lakes and peatlands) and testate amoebae analyses (from peatlands only) are used to reconstruct land-use and water-table fluctuations. Herbivore bone collagen stable isotopes have also been measured to extend the spatial distribution of the bone dataset presented by a previous study and to refine the timing of the change observed in the bone remains. Through this multi-proxy study, we explore the inter-relationships between the nitrogen cycle, climate and human activity and consider whether there is a case for an early Anthropocene in Ireland.

What are the key transitions within the Anthropocene? Reviewing footprints of human activity, land use, and impact in time and space as a basis for systemic sustainability

Prof. Kathleen Nicoll [1]***, Prof. Andrea Zerboni*** [2]

1. University of Utah, Salt Lake City, Utah, 2. Department of Earth Sciences, University of Milan

Controversies in recognising and defining the Anthropocene stem from the inherent politics around our sustainability, and the degree to which humanity has adversely impacted the planet in such a manner that it is adequately preserved and a unique chronological marker within the global stratigraphic record. But the Anthropocene is much more than a geological timeframe; it is also a state of the human condition, and as such, notions of the Anthropocene require further integration with emerging studies of prehistory and human ecology through a social sciences lens. To many geoarchaeologists and geomorphologists, it is abundantly evident that humans have adversely affected most environments across the globe, even altering the natural hydroclimatic and biotic processes at the planetary scale to a point that threatens our sustainability. Yet, people have intensely modifying climates and landscapes and affecting ecosystems since the dawn of agriculture, city states and empires. Our premise is that deep knowledge of our past provides an important context for evaluating and assessing impact thresholds and strategic solutions for systemic sustainability.

We present an integrated socio-ecological review of the Anthropocene that synthesises environmental change in context of cultural history, political transitions, political crisis events like warfare and disease, crop collapse, soil loss, extreme weather (including hurricanes, floods, droughts), and resource availability, mineral and rock extraction, land modification – as well as the evolution of monumentality and ritual over time. We aim to better contextualise the conditions prior to the great acceleration. Looking back into Antiquity to understand prehistoric and indigenous lifeways provides some relevant examples that demonstrate the resilience of people and their societies. *What is past is indeed the prologue* – as well as the paradigm of our modern existence, which is a time in the Anthropocene when the very persistence of humans themselves is threatened by overpopulation, land misuse, pollution, and resource scarcity, all of which are conditions resulting from our cumulative "footprint."

Tracing the archaeological indicators of Anthropocene in Singida Rural District (Central Tanzania).

***Dr. Makarius Peter Itambu* [1], *Prof. Marina Gallinaro* [2], *Dr. Robert Patalano* [3], *Dr. Patrick Roberts* [3], *Mr. Eliah Mwamakimbula* [4], *Mr. Leonard Muhuri* [5]**

Department of Ancient World Studies, Sapienza University of Rome, 3. isoTROPIC Research Group, Max Planck Institute for Geoanthropology, 4. Department of archaeology and heritage studies, 5. Department of Archaeology and Heritage Studies

African landscapes show more than others the ancient signs of the human impact on the Earth. This work aims to explore for the first time the signs of the anthropic impact in the Singida region (central Tanzania). The area, characterized by an articulated landscape with impressive geoheritages such as plateaus, inselbergs, escarpments, and impressing rocky hills and granite outcrops, was inhabited until the 1990s by hunter-gatherers' communities. Today the intensive exploitation of the land by farmers and uncontrolled activities of quarries are dramatically transforming the environment and ecosystems. One of the objectives of the interdisciplinary project carried out in the area is to detect since when human actions started to impact the landscape and the natural resources.

During the last few years, archaeological surveys, selected excavations, and ethnographic inquiries are tracing a deep history of occupation, ranging from MSA, LSA to historical tradition. The analysis of scatters of lithic artifacts, stratigraphic sequences preserved in rock shelters, and the impressive rock art evidence will contribute to reconstruct the ancient signs of the anthropic impact in the region. The paper aims to present the project's preliminary results, with a particular focus on the potential of the rock art investigation. The first use of digital tools in the recording, including iDStretch, clearly demonstrates a more complex palimpsest of styles and represented various stylistic motifs than the previous studies, and the new record constitutes an improved archive of proxy data for paleoenvironmental reconstruction and past biomes.

Keywords: *Holocene, proxy data, rock art, human environment*

Vegetation resilience in Anthropocene — an example based on pollen analysis of Lake Suigetsu, Fukui Prefecture, Japan

It is said that we have entered a human-dominated geological epoch, eg. The Anthropocene. However, some elements of environment still have resilience and recovered due to the change of human lifestyle. This study shows one example of vegetation resilience by pollen analysis using varved sediment from Lake Suigetsu, Fukui prefecture, Japan.

Lake Suigetsu is located in Japan Seacoast. The first human activity near the lake was recorded in about 13700 cal BP and have been observed continuously after that. The vegetation in the area has changed greatly probably by both climate change and human activities based on pollen analysis. The main activities which were assumed to alter the vegetation in the area were rice cultivation, salt making, reforestation. Recently, human lifestyle has changed, and less utilization of mountain forests has also altered the vegetation. This study makes clear the turning points which altered the vegetation and recent changes using the pollen profile from Lake Suigetsu and shows the resilience of vegetation.

The vegetation change seemed to be caused by salt making in the 4th century and agricultural land transformation, ie. rice paddy cultivation in the 12th century. However, salt making did not influence the vegetation severely and the vegetation recovered soon after the impact. Great decrease of arboreal pollen and abrupt increase of Poaceae pollen were observed around the 12th century when rice cultivation became active. The impact was so great that the concentration of arboreal pollen stayed low until pine plantation started in the 15th century. Until the middle of the 20th century, forests were spotted with pine trees based on the concentration of arboreal pollen. Forest composition has changed gradually from the 20th century probably due to less forest utilization caused by petroleum fuel consumption. Pollen of pine trees decreased and evergreen Oak and other forest elements increased. It seems that forests recovered from bare condition. Japanese cedar plantation also affected the pollen profiles. Although the pollen amount was not as much as that before the 12th century, forests have changed to natural vegetation in the area.

Can Poaceae pollen serve as a proxy of human disturbance in subtropical forests? Palynology and geochemistry evidence from a wetland in southeastern China

Dr. Nannan Li [1], ***Dr. Fengling Yu*** [1]

1. *Xiamen University*

An increase in fossil Poaceae pollen percentage in a sediment core is commonly regarded as an indicator of anthropogenic activities, which might be questionable due to the limited classification and identification ability of Poaceae pollen. To assess the reliability and limitation of using Poaceae pollen as an anthropogenic indicator, we present a wetland record from the Daiyun Mountains in southeastern China. With reference to previously published pollen assemblages, we newly measured the grain size, total organic carbon (TOC) content, $\delta^{13}C_{org}$, and metal elements within the peat sediments to reconstruct the paleo-environmental history for the study area. Our findings provided different interpretations for the late-Holocene vegetation change and its driving forces for the subtropical forest in southeastern China. In line with previous palynological studies, our reconstruction confirmed that a significant vegetation transition happened around 1200 cal. yr BP: Poaceae pollen significantly increased and $\delta^{13}C_{org}$ shifted to heavier values. However, this sharp increase in Poaceae pollen is possibly not caused by intensified human impacts since no lead (Pb) or microcharcoal enrichments were observed during the same period. Instead, redox-sensitive elements suggested the increase in Poaceae pollen is mainly caused by changes in pollen source that are associated with wetland hydroclimate and water-table dynamics: During 3900 to 1200 cal. yr BP, pollen in the wetland sediments originated from the (regional) surrounding uplands and (local) wetland itself, when the peatland was a small pond/lake-like environment. However, as reflected by the sedimentary and geochemical evidence, the little pond/peatland gradually dried up after 1200 cal. yr BP and the local grasses contributed the majority of the pollen assemblage. Consequently, there is a sharp increase in Poaceae pollen within the sediment core and the pollen diagram showed an obvious vegetation transition from warm subtropical forest to open/degraded forest. Despite our records being a single core-based investigation, our multiple proxy-based evidence suggests that ancient human activities in the study area did not have significant impacts on the composition of the vegetation until recent decades. The linkage between Poaceae pollen and human activity in future paleo-records should be carefully examined using multi-proxy-based reconstructions.

Anthropocene microplastics stratigraphy in sediment cores from South China

Dr. Yang Chen [1]

1. *MOE Key Laboratory of Surficial Geochemistry, School of Earth Science and Engineering, Nanjing University*

Microplastics (MPs) are increasingly found everywhere in the Earth surface and regarded as a major, and growing, environmental hazard. Due to widespread distribution and relatively high persistence in deposits MPs are considered a potential stratigraphic marker for the Anthropocene. However, timing of MPs accumulation is not perfectly isochronous in stratigraphic successions. In this study, stratigraphic data of MPs from two sediment cores, one from Huguangyan Maar Lake (HML), and the other from Pearl River Estuary (PRE), South China, were used to reconstruct the history of plastic pollution since 1920s. Microplastics were extracted from sediments by sieving and dense-liquid separation, and determined using micro-FTIR. The abundance of MPs in the HML sediment core ranges from 281 to 2619 items/kg·dw, and most of MPs are polypropylene and rayon fibers which may have originated from tourism activities, the scenic spot or hotel operations and atmospheric precipitation. The abundance of MPs in the PRE sediment core ranges from 511 to 3529 items/kg·dw, mainly composed of rayon and polyester fibers, which may be derived from domestic sewage discharged from upstream and coastal areas and fishery waste fishing gear, and partly from industrial wastewater and port shipping. The two MPs records show the initial increase of MPs abundance in 1950s, coinciding with the infancy of the plastic industry and onset of the Anthropocene. Subsequent rapid growth in MPs during the 1980s and dramatic increase since 2000 indicates increasing plastics production with rapid economic development at that time in China. The study confirms that MPs may serve as a strata marker for defining the start of the Anthropocene.

Global atmospheric mercury deposition flux reconstructed from natural archives 1700-2018

Dr. Qinqin Chen [1]***, Prof. Shuxiao Wang*** [1]***, Dr. Qingru Wu*** [1]***, Ms. Yuying Cui*** [1]

1. *Tsinghua University*

Mercury has contaminated ecosystems globally, but pollution management is hindered by uncertainties of mercury emissions and complicated by ongoing climate change. To better understand the impact of historical emissions and guide future mercury management and ecosystem recovery, we compiled a global atmospheric mercury deposition flux database (1700-2018), inferred from ice, peat, lake sediments, and marine sediments, with a total of 50,770 data, spanning 27 countries/regions across all continents. The inferred fluxes unanimously increased over the three centuries yet with varying levels, from four-fold (peat) to ten-fold (marine), due to different deposition mechanisms. The inferred fluxes indicate that widely adopted high mercury emissions from gold and silver mining were only of local impact and likely overestimated. Instead, coal use drives the recent rising deposition fluxes in Central Asia, East Asia, and Africa, which should be the future mercury management focus. However, rising temperatures will partly offset the effectiveness of future measures in controlling mercury emissions. We find that rising temperatures elevated mercury flux levels in temperate and tropical lakes and peatlands (ca. >12□), due to excess mercury inputs from catchments, including mercury inputs from melting ice to tarn lakes, and enhanced humification, respectively. Importantly, terrestrial environmental management is not enough to pivot increasing deposition trends in marine sediments but only decelerated increasing rates. This is evidenced by the universally increasing trends in all the available marine sediments in Europe, East Asia, and Arctica. The increasing rate in Europe, a region with one of the most stringent environmental regulations in the world, only decreased from 2%/year to 1%/year after the 1970s. Our results highlight future ecosystem restoration challenges regarding mercury pollution in the temporal and tropical lakes and peatlands in developing Asia and Africa and the marine environments across the globe under dual stresses from economic development and climate change. Future research and attention should also be paid to the health risks related to the ecosystem services, e.g., aquatic products and drinking water, provided by these deteriorated natural systems, potentially could be assisted by the global atmospheric mercury deposition flux database.

The Case for a Lunar Anthropocene: Understanding Current and Future Anthropogenic Activity on Earth's Moon

Dr. Justin Holcomb [1], *Dr. Rolfe Mandel* [1], *Dr. Karl Wegmann* [2]

1. University of Kansas, 2. North Carolina State University

Over two decades have passed since atmospheric chemist Paul Crutzen and ecologist Eugene Stoermer declared the end of the Holocene on Earth, arguing that humans have entered a new epoch they termed the 'Anthropocene'. However, 20 years after Crutzen and Stoermer's declaration of an 'Anthropocene,' the term has not been formally adopted by the International Union of Geological Sciences (IUGS) or the International Commission on Stratigraphy (ICS). This is largely due to disagreements about exactly *when* human activity should be measured as a clear stratigraphic marker on Earth, which is necessary to warrant its formal definition as a new epoch within the geological timescale. One issue hindering our ability to pinpoint the Anthropocene is the role of dynamic earth surface processes, which serve to erode records of human activity over time. However, these processes are not occurring on Earth's Moon, where the record of human activity has been preserved since the first impact by the Second Soviet Cosmic Rocket, Luna 2, in 1959. Here, we suggest that the recent history of space exploration, including landings, impacts, and crashes, has resulted in a measurable geomorphic signature of human activity on the lunar surface, marking a major shift in dominant geologic processes of the moon today and in the future. Indeed, since the Luna 2 impact, humans have caused 59 instances of surface disturbances on the lunar surface, or around 0.97 a^{-1} – five orders of magnitude higher than natural impact background. We suggest the shift in lunar surface processes has two important implications. First, these anthropogenic surface impacts could serve as a marker for the beginning of the Anthropocene on Earth, as they stratigraphically correlate well with proposed stratotypes for the Atomic Age – that period between 1952-1962 when atmospheric thermonuclear bomb tests were performed. Second, humans have become a dominant geological force on the moon, suggesting that it may be time to consider the presence of a distinct Lunar Anthropocene. We suggest that scientists should begin having serious discussions about our current and future impact on the Moon's surface, as well as our approach to the preservation of space heritage.

Session 10: Visualizing Science – The art of communicating science

Alexander von Humboldt's fusion of the arts and sciences in the Anthropocene

Dr. Stephen Jackson [1]

1. US Geological Survey

Humanity and nature together face three critical, intertwined challenges in the Anthropocene: rapid climate change, loss of biodiversity, and degradation of the ecological processes upon which humans and other species depend. Knowledge and action concerning all three issues rest on scientific foundations established by Alexander von Humboldt in the first half of the 19th Century. These foundations include atmospheric and ocean circulation and their mutual influences, the mediating role of terrestrial vegetation between the atmosphere and land surface, the impacts of human activities on biodiversity and earth-surface processes, the climatic determinants of species distributions and global biodiversity patterns, the impact of climate on human welfare and activities, and the fundamental sciences of the earth and its environment. Humboldt employed a variety of novel visual and graphical methods to portray and study these patterns and processes, including mapping of isotherms, vertical profiles of physical and biological data, and statistical graphs of environmental and economic data. His scientific visualizations were guided by aesthetic considerations; he aimed to convey scientific observations and processes in a visually pleasing fashion. Humboldt viewed his scientific contributions as one part of a broader, humanistic approach to understanding nature, encompassing the entire range of the arts and humanities in addition to the sciences. His humanistic approach to nature is at the heart of current concerns with environmental change in the Anthropocene. Our emotional responses to that natural world, and our sensory experience of it, are linked with our intellectual curiosity and scientific understanding, motivating our concerns with environmental change beyond the utilitarian consequences. Humboldt's fusion of the sciences, arts, and humanities provides inspiration, as well as potential maps and narratives, for developing a better and sustainable future for nature and for people.

Art & Science: promoting science through art with comic stripes and a 3D fiber-art object

Dr. Serban Raul-David [1], ***Dr. Mihaela Serban*** [2], ***Dr. Giacomo Bertoldi*** [1]

1. *Institute for Alpine Environment, Eurac Research, Bolzano,* ***2.*** *Applied Geomorphology and Interdisciplinary Research Centre, Department of Geography, West University of Timișoara,*

The project “Modelling ground surface TEMPerature LINKed to remote sensing land surface temperature in mountain environments” [TEMPLINK] focuses on improving monitoring and modelling soil subsurface temperature. Ground surface temperature (GST), measured at 5 cm into the ground, is a key parameter controlling all the subsurface biophysical processes at the land-atmosphere boundary. GST is important for multiple geosciences and agricultural applications, being essential for understanding the climate change impacts on various environments. The TEMPLINK project aims to develop a model to predict soil subsurface temperatures from thermal satellite images based on numerical modeling. It represents an innovative multidisciplinary and interdisciplinary approach, combining (i) remote sensing, (ii) thermo-hydrological dynamics, and (iii) cutting-edge numerical modelling (GEOtop model and machine learning algorithms). The model will be generated at a local scale in the Mazia Valley, LT(S)ER: Open air laboratory (South Tyrol, Italy), and applied at a regional scale on the Qinghai-Tibet Plateau to test its worldwide applicability.
To facilitate the communication of this project purpose to a broad audience several outreach materials were prepared: a small cartoon booklet, a 3D fiber-art object, and a flyer. The cartoon booklet presents the project and promotes science through an animated story via comic strips for kids and youth. The fiber art object is representing a miniature 3D model of the Mazia Valley with different rope colors and textures for every land cover type. The model is accompanied by a hanging satellite also made from rope and by a flyer that explains this mix of science and art. The purpose of this object is to promote science through art for reaching a broader audience and can be exposed in art galleries, tourist info centers, or during conferences, workshops, and science fairs. Through these communication materials, the scientific project is reaching a wide audience of different ages, backgrounds, and interests.

Communicating and outreaching palaeosciences through visual arts: lessons from different realms.

Dr. Graciela Gil-Romera [1], ***Dr. Cirenia Arias-Baldrich*** [2], ***Ms. Alejandra Vicente de Vera*** [3], ***Dr. Penelope Gonzalez-Samperiz*** [4], ***Prof. Boris Vannière*** [5], ***Dr. Sarah Eggleston*** [6], ***Dr. Marie-France Loutre*** [6]

Art and science are the two sides of the same coin; these are two ways to understand and describe the world around us and are often closely interconnected. In our rapidly changing planet, society demands sound science communication as scientific concepts need to be transmitted to the general public in the most objective, evidence-based way possible. Outreach is indeed becoming a cornerstone of our duties as academics, and it will become even more relevant in the future. A paradigmatic case is that of paleoscience where sometimes even basic principles are difficult to communicate. While paleoscience is essential to our understanding of current global change, transmitting our findings and the scope of its evidence is challenging.

In a different realm of human cognition, frequently taken far from science, we find art. Art has the power to reconcile us with our reality, reawakening the essence of the easily forgotten value of our own lives by making ordinary occasions or items enticing. Art has been used in scientific illustrations since the Middle Ages; furthermore, aside from its aesthetic value, art has an incomparable power to communicate.

In that regard, the presenting team is accruing an increasing expertise in communicating science to different audiences and through different media, and in this talk we will review different experiences we have had in communication where paleoscience and art overlapped. We will assess the efficiency of each approach, considering the objectives initially posed and the results obtained, as well as how we have been tailoring our communication projects to make paleoscience a more widely understood science. In addition, we will also explain our creative workflow in each action and the importance of using a cross-disciplinary approach in all our projects. Last, we aim to create awareness in the paleoscientific community on the central role that visual arts have when communicating science.

Communicating palaeoenvironmental data through visual art

Dr. Benjamin Keenan [1]

1. *McGill University. Department of Surface Waters, Swiss Federal Institute of Aquatic Science and Technology*

The lowland Maya ancient adapted to their changing environment in different ways, and ultimately abandoned some of their cities in response to a devastating drought around 730-900 CE. We have converted geochemical data into a high-fidelity visualisation using 'game engine' technology to represent the changing population, vegetation and climate of the ancient Maya population over 6000 years based on geochemical analyses of lipids extracted from lake sediments located adjacent to the ancient population centre of Itzan in Guatemala. The project moves beyond conventional data visualisation to create an affectual experience that enables new ways for spectators to engage with complex patterns found in scientific data. The work has been exhibited as a projected installation as well as a film.

A geological plastic-relief model to describe the subsoil of Rome

Dr. Marco Mancini [1], ***Dr. Maria Sole Benigni*** [1], ***Dr. Margherita Giuffrè*** [1], ***Mr. Francesco Versino*** [1], ***Dr. Cristina Di Salvo*** [1], ***Dr. Iolanda Gaudiosi*** [1], ***Dr. Massimiliano Moscatelli*** [1], ***Dr. Maurizio Simionato*** [1], ***Dr. Francesco Stigliano*** [1], ***Dr. Daniel Tentori*** [1]

1. *Consiglio Nazionale delle Ricerche, Istituto di Geologia Ambientale e Geoingegneria (IGAG)*

Quaternary geology, through the study of the shallow rock-sediment record, is fundamental to understand the recent dynamics of our planet and its relations with human evolution and the development of civilizations. Quaternary deposits are functional for human settlements, due to their easy digging, and commonly act as foundation soils and as a substrate for anthropogenic soils, which are often of archaeological interest.

The city of Rome, with its original settlement sited in the Central Archaeological Area (CAA) and comprising the Palatine Hill, Roman Forum and Colosseum, represents a noteworthy case to study the relations between the geological substrate and the overlaying anthropogenic soils, historical monuments and modern-age buildings. The interest of this area is well demonstrated by numerous geo-archaeological excavations, geognostic drillings, outcrops, and by a complex history of land-use transformation.

However, disclosing this large amount of information and disseminating the scientific observations deriving from these data to a wider audience is not particularly easy. Thus, we produced a 3D plastic-relief model of CAA made of polystyrene and stucco at 1:1.000 scale, representing a 1 km^2 wide topographic surface with monuments above, and showing the geologic substrate along selected cross sections up to the 100 m depth. The lithostratigraphic subsoil structure is reproduced in detail with well-differentiated: anthropogenic soils, up to 20 m thick; middle Pleistocene-Holocene fluvial formations and pyroclastic units filling paleo-valleys and interfluves; the Pliocene clayey marine bedrock.

The 3D reconstruction is useful to visualize the conditioning that external morphology and buried morpho-stratigraphic structure exert on natural risk factors. In fact, it is interesting to observe how amplification effects of seismic waves, flood phenomena and slope instability have influenced and will influence the settlement choices of CAA, the subsequent transformations, and the potential consequences of both seismic risk and future climate extremes in the city of Rome. In addition, the model also offers reconstructions of historical palaeontological excavations near the Colosseum, aimed at teaching geo-palaeontological heritage.

A collective expression of time

Dr. Anna Broström [1], ***Mrs. Annelie Nilsson*** [2], ***Mrs. Ebba Gyllenhak*** [3], ***Dr. Karl Ljung*** [4]

1. *Forn till framtid,* ***2.*** *https://annelienilsson.net/,* ***3.*** *Högskolan Kristianstad,* ***4.*** *Department of Geology, Lund University*

How can a human experience the long stretches of time under which our landscapes have been shaped? What do such experiences mean for our connection with a place and our relation to the rapid and world-transforming climate and environmental changes we are experiencing today?

In a collaborative audience participatory art project, we have explored the notion of geologic time at a particular place with the environmental history derived from a 14800-year-old sediment core as a starting point. Our project started as a workshop on the environmental history of lake Vombsjön basin in south Sweden and was part of a candidature for a UNESCO Biosphere Area. The project was a collaboration between a palaeoecologist, a geologist, an artist and landscape historian, and an artist, with participating local residents and visitors.

The artistic project explored the notion of geologic time in a collaborative effort. We used clays and gyttjas from a sediment core from lake Vombsjön as pigments mixed with locally sourced honey to produce paints. Thus, the paints had known ages were also carriers of the traces of past environments and human-landscape interactions. We used the paints to produce a collaborative painting where the participants held a large, stretched canvas between them to which all participants applied paints with ages ranging from 500 to 14500 years old. The participants also reflected on the age of the material used for the paint and aspects of where we were positioned both in time and space. The creative act of a communal painting produced a layered painting that carries the imprint of time, nature and humans, not unlike the present-day landscape. In our presentation, we will display a reproduction of the painting and a video of the performance, and discuss the connections between scientists, artists, the audience, and the changing landscape.

Using Virtual Field Trips to Visualize and Communicate Quaternary Volcanism in the Black Rock Desert, Utah

Dr. Tiffany Rivera [1], ***Dr. Brian Jicha*** [2]

1. *Westminster College,* ***2.*** *Department of Geoscience, University of Wisconsin-Madison, Madison, WI 53706, USA*

Students of geology find placed-based learning to be one of the most beneficial aspects of their education. However, during COVID, it became clear to educators that our method of placed-based teaching is not a guaranteed pedagogy. The pandemic led to geoscience educators exploring innovative technologies to immerse students in field studies without having to be present in the field. This led to the development of virtual field trips which include immersive, online, multimodal, interactive activities that leverage technology and the availability of global satellite data. As we have returned to in-person teaching and the ability to return to our field areas, there is still a strong desire by the geoscience community to produce and use virtual field trips as they increase accessibility of field sites for (1) students who may have mobility differences, (2) for trips that may be cost-prohibitive, (3) for students that are primary caregivers or heads of households. Further, virtual field trips can reduce inequities and improve fairness within the learning environment. In Utah (USA), the Black Rock Desert consists of 2.5 Ma to Recent bimodal, monogenetic volcanism. Episodic volcanic activity produced intriguing landforms and features including cinder and tuff cones, lava tubes, a lava lake, rhyolite domes, pyroclastic deposits, and obsidian flows. This virtual field trip takes the viewer through a series of locations that were chosen to best represent the uniqueness of Black Rock Desert, and aims to increase the general public's knowledge and awareness about geologically young volcanism in central Utah. This self-guided field trip was developed using the Google Earth Web platform, which allows the creator to add images, Google Street View 360 images, videos, web links, and text to map locations that are combined into a trip. In addition, we have developed a K-12 and college-level curriculum that can supplement the field trip.

Stories about climate: Communicating climate science to teenagers with hands-on activities and a comic book

***Mrs. Jade Falardeau** [1], **Dr. Marie-Michèle Ouellet-Bernier** [2], **Mrs. Susanna Gartler** [3], **Mrs. Cassandra Paul** [4], **Prof. Anne de Vernal** [1], **Dr. Etienne Boucher** [5], **Dr. Audrey Limoges** [6]*

1. Geotop-Université du Québec à Montréal, Montréal, Canada, 2. Département de géographie, Université Laval, 3. Department of Social and Cultural Anthropology, University of Vienna, 4. Member of the community of Aklavik, NWT, Canada, 5. Department of geography, Université du Québec à Montréal, 6. University of New Brunswick

Climate change is a source of concern, especially for the younger generations. The potential impacts of the global temperature rise based on climate projections are widely discussed through the media. However, climate science is rarely presented from a long-term perspective, using historical and past climate reconstructions despite its relevance to understanding natural climate variability. The objective of this project was to communicate about paleoclimatology by introducing examples of four methods currently used to reconstruct the climate of the past: micropaleontology, dendrochronology, historical climatology, and local knowledge.

The project is a workshop, online or live, that targets teenagers specifically. Two types of educational materials were produced: a booklet of activities and a comic book. In the booklet of activities, each section starts with description of the methods and ends with an interactive activity. The booklet ends with a take-home exercise for which the participant is asked to interview an elder on his/her perspective of climate change. The comic book tells the story of a youth who undertakes fieldwork in the Inuvialuit Settlement Region in northwestern Canada, searches databases, and experiences exchanges with knowledge holders, scientists, and students. In the comic book, the main character finds clues about the climate of the past in the Mackenzie Delta and finally reconstructs the climate of the last hundreds of years, allowing comparisons with the impact of ongoing global warming.

The local knowledge section was developed through interviews with members of the community of Aklavik. The interviews were used and referred in the educational materials. Throughout the production process, we sought feedback and approval for dissemination from the community of Aklavik. This interdisciplinary science communication project is an example of knowledge mobilization between Indigenous and other local knowledge holders, organizations, and scientists. It also served as an example for the scientific community to team up with local artists to prepare activities visually attractive for a non-scientific audience, and thus contributed to knowledge transfer and bridging the science-community gap.

Exploring the capacity of climate art to communicate climate change from a cultural perspective

Ms. Svetlana Radionovskaya [1]

1. University of Cambridge

The word «art» can be interpreted in very different ways. Institutions such as museums, galleries and art schools, and art critics are the pinnacle of contemporary art and set certain «trends», which are easily spotted in contemporary galleries. Conceptual artworks presented in these exhibitions often go on to generate thousands-to-millions of pounds at art auctions therefore creating an elitist art world.

How can contemporary visual arts (and can they) offer different ways of imag(in)ing the problem of climate change, which would create an experience beyond visual (i.e. emotive and behavioral)? Here, I review «historical» climate art and propose that climate art can be split into three categories: representations (emphasizing visualization and communication of climate change); performance and conceptual art (engagement through immersion and experience); and interventions such as public engagement and activism (invoking motivation to take action). What are the challenges associated with these categories?

According to the art world, the *good art*, i.e. the conceptual art, or “art for art’s sake” as originally described by Clement Greenberg in 1940, appeals and creates a desired experience for a limited amount of people with an attained cultural capital, and thus, I argue that it ultimately fails to communicate climate change to the wider public; yet it’s the preferred category of the art institutions. In the meantime, the *bad art*, which is more illustrative and communicates the climate message clearly, disinterests artistic institutions and critics. This slowed the development, and led to a decline of climate art produced, or displayed in galleries in the late 2000s and early 2010s; however an explosion of climate art popularity has since occurred in the last five years, likely because the issue of climate change has been brought to the forefront of political debate and contemporary culture. Therefore, it remains an open question how to best portray, communicate and create an “ultimate” experience of climate change through art and how to assess the success of these pieces (eg. art critics opinions, public opinions/ interpretations, amount of income generated); but it is clear that collaboration between scientists and artists is desperately needed to develop climate art.

Rethinking Palaeclimatology for Society: co-production strategies for policy engagement

Dr. Celia Martin-Puertas **[1]**, ***Dr. Alice Milner*** **[2]**, ***Dr. Ashley Abrook*** **[3]**, ***Prof. Simon Blockley*** **[2]**, ***Ms. Laura Boyal*** **[1]**, ***Prof. Achim Brauer*** **[4]**, ***Dr. Armand Hernandez*** **[5]**, ***Dr. Gordon Inglis*** **[3]**, ***Prof. Peter Langdon*** **[3]**, ***Dr. Paul Lincoln*** **[2]**, ***Prof. Antti Ojala*** **[6]**, ***Dr. Didier Swingedouw*** **[7]**

1. Dept. of Geography, Royal Holloway, University of London, Egham, Surrey, TW20 OEX, UK., 2. Department of Geography, Royal Holloway University of London, London, United Kingdom, 3. University of Southampton, 4. Helmholtz Centre Potsdam, German Research Centre for Geosciences GFZ, 5. Universidade da Coruña, GRICA group, Centro de Investigacións Científicas Avanzadas (CICA), Spain, 6. University of Turku, 7. University of Bordeaux, CNRS

There is a recognised gap between data generated by environmental and climate scientists and evidence needed by policy makers. This is in part because influencing policy through research is complex and requires skills that might not be valued or common in research systems such as fundamental training in science communication. In particular, Quaternary scientists do not often have impact beyond academia because research questions are theoretically driven instead of responding to societal needs. The current situation of our Earth's system, together with the social movements for climate justice, urge a step change in how policy and scientists approach climate change.

Funded by UK Research and Innovation and supported by both Ministerial Departments and stakeholders, we (the Decadal team formed by palaeclimatologists and Quaternary scientists) are developing a co-production model of research where scientists and end users work in a synergy to develop research questions, produce research, and communicate effectively, to contribute to the policymaking system. Evidence-based insights and improvements in how to better communicate uncertainties to both policy and media are key areas to develop. We discuss, from a scientist's perspective, our communication strategies to engage with policy makers and how to establish closer relationships, reputation and trust, with the shared goal of improving how science is used in decision making. This work is a contribution to the Decadal project.

Time Travel Machines and Other Forms of Science Communication

Mr. Ian Cooke-Tapia [1], ***Dr. Aaron O'Dea*** [2]

1. *Cooked Illustrations,* ***2.*** *The Smithsonian Tropical Research Institute*

Tropical countries have attracted natural scientists from western cultures for centuries, but there remains a profound disconnect between the science and the citizens of tropical regions, especially at the young educational level with pervasive and lasting cultural impoverishment. Panamá has been host country to the Smithsonian Tropical Research Institute for nearly 100 years and is replete with unique geological, paleontological and archeological histories, and yet many people on the Isthmus of Panama remain in the dark about this rich history. In this presentation we showcase Martina and The Bridge of Time–A children's book that aims to offer provision to fill an educational gap. Developed between a visual storyteller and scientist, Martina is a young girl full of questions about her homeland and its history. After finding no answers in her own history books, Martina builds a Time Machine and travels back through time to witness Panama's geological, biological and human history for herself. Martina and the Bridge of Time shows how a deep interest in place can be a core technique in communicating complex ideas to diverse audiences. Focusing on the audience's relationship to their local environment and identifying how these relationships can overlap with existing science stories extrapolated from scientific research can have powerful resonance with local audiences regardless of format. The success of Martina and the Bridge of Time shows the power and potential of intellectual properties as not just carriers of scientific research messaging, audience development and engagement, and ways to develop successful outreach programmes, but also as a tool through which new methodologies of engagement and sustainability can be developed. We use this, and other case studies, to help explore how scientific researchers and creatives can collaborate to produce effective projects that meet both audiences' needs and outreach goals.

A cosmopolitan genome from Valencia during the Roman Empire

Dr. Gonzalo Oteo-García [1]

1. University of Parma - Dipartimento di Scienze Chimiche, della Vita e della Sostenibilità Ambientale

An excavation in the vicinity of the ancient Roman forum of Valencia (Spain) brought to light a series of burials as well as Iron Age Iberian ceramics and other material remains from the Roman period were found in what could have been the river harbor of the city. The majority of tombs were medieval in origin and were linked to the now disappeared parish cemetery of San Lorenzo.

In the oldest strata, two Roman tombs surfaced, a much rarer finding in this part of the city. We were successful in recovering ancient DNA from one of the two individuals, whose remains were mixed with the lower jaw of a pig. The sample was exceptionally well-preserved and revealed a level of endogenous DNA of around 30%, six times higher than usual. This allowed to shotgun sequence the genome to a coverage of 2X, to our knowledge the highest covered genome from the Roman period in Spain. We also radiocarbon dated the sample and obtained and estimated age between 250-400 CE. We determined the genetic sex to be female.

The mitochondrial DNA lineage we recovered from this female is called D4e1. D4 lineages are extremely rare in Europe in ancient and modern populations, but D4e1 exists as the sole European branch representative of the D4 clade (found in 3 modern European samples from Austria, Greece and Czechia). All lineages related to D4 originate in Asia and the others that exist today are common and almost exclusive to East and South Asia.

Our analyses did not find recent traces of Asian admixture. However, the analyses revealed certain genetic affinity to various population while being distinct from all of them. We found that the genome of this woman was a mosaic of genomic contributions from three different sources across the Mediterranean: Iberia, an unidentified central/eastern Mediterranean population and a minor North African source. The high levels of heterozygosity indicate that she is the product of a recent admixture, highlighting the cosmopolitan nature of the inhabitants of the city at th time.

Session 11: Proxy-based reconstructions of atmospheric and oceanic patterns

Distinct phases of peatland carbon accumulation in the southern mid-latitudes driven by southern westerly wind shifts

Dr. Zoë Thomas [1]***, Dr. Haidee Cadd*** [2]***, Dr. Chris SM Turney*** [3]***, Dr. Lorena Becerra-Valdivia*** [4]***, Dr. Heather Haines*** [1]***, Dr. Christopher Marjo*** [1]***, Dr. Stefanie Carter*** [5]***, Dr. Paul Brickle*** [6]

1. *Chronos 14Carbon-Cycle Facility, Mark Wainwright Analytical Centre, University of New South Wales, NSW, 2052, Australia,* ***2.*** *ARC Centre of Excellence for Biodiversity and Heritage, School of Earth, Atmospheric and Life Sciences, University of Wollongong,* ***3.*** *Division of the Deputy Vice-Chancellor, Research, University of Technology Sydney, Sydney, NSW 2017, Australia,* ***4.*** *Oxford Radiocarbon Accelerator Unit, School of Archaeology, University of Oxford, UK,* ***5.*** *UK Centre For Ecology & Hydrology,* ***6.*** *South Atlantic Environmental Research Institute (SAERI), Stanley, Falkland Islands*

Peatlands have been increasingly recognised as an important part of the carbon budget, with estimates suggesting they account for up to 30% of terrestrial global carbon storage. While the most extensive peatlands are found in the Northern Hemisphere, there are substantial deposits in the mid- to high- latitudes of the Southern Hemisphere, but these are underrepresented in global syntheses due to sampling bias. To investigate the timing and drivers of widespread peatland initiation in the southern mid-latitudes after the Last Glacial Maximum, we sampled and radiocarbon-dated basal peats from across sub-Antarctic islands of the South Atlantic region, and collated published basal peat radiocarbon ages from peat forming regions >35°S. We use Kernel density estimate models to investigate spatial and temporal phases of peat initiation and compare with climate proxy records to test climatic drivers. Peat initiation in the southern mid-latitudes commences 20,000 cal years BP and peaks at 13,000 years BP, suggesting that climates were favourable for peat growth at this time. We propose that phases of peat formation identified across different latitudinal belts are driven by a combination of warming temperatures and shifts in latitudinal position and strength of the southern westerly winds, which directly drive precipitation (and effective precipitation) changes in the mid-latitudes. In recent decades, warming of the southern mid-latitudes has accelerated, coupled with a southward shift of the SWW since the mid-20th century. While the impact of these shifts on the establishment and rate of peat accumulation is currently not well constrained, implications from this study suggests that a continuation of these trends may result in net carbon losses.

Plio-Pleistocene variability in the strength of the Pacific Walker Circulation

Dr. David Fastovich [1]***, Dr. Tripti Bhattacharya*** [2]***, Dr. Ran Feng*** [3]***, Mr. Theodor Mayer*** [3]

1. *Syracuse University, Department Of Earth Sciences, USA,* ***2.*** *Department of Earth and Environmental Sciences, Syracuse University,* ***3.*** *University of Connecticut*

Observations from general circulation models and theory suggest that the Pacific Walker Circulation will weaken as temperatures increase from anthropogenic CO_2 emissions. Despite strong evidence, detecting changes in the Pacific Walker Circulation is hampered by the short duration of the instrumental record. Atmospheric CO_2 concentrations during the Pliocene were similar to contemporary concentrations and global temperatures were 2 to 3 °C warmer, making the Pliocene a useful analog to constrain future changes in the Pacific Walker Circulation and benchmark climate simulations. Recent observational studies have demonstrated that isotopes of water vapor in the eastern and western Pacific encode changes in the strength of the Pacific Walker Circulation. In light of this, we develop two records of precipitation isotopes (dD_{precip}) from C_{30} *n*-alkanoic acids in the eastern (ODP1239; 0.672 °S, 82.08 °W) and western Pacific Ocean (ODP1143; 9.362 °N, 113.29 °E) to reconstruct the Plio-Pleistocene evolution of the Pacific Walker Circulation. In the western Pacific, dD_{precip} from site 1143 demonstrates a gradual enrichment which reflects changes in convection, water vapor source, and large-scale dynamics. A long-term increase in dD_{precip} in the eastern Pacific at site 1239 reflects a complex history of regional changes in sea surface temperatures, Andean uplift, and atmospheric circulation changes. Collectively, these two records highlight a complex evolution of the Pacific Walker Circulation through the Plio-Pleistocene, which we interpret in the context of isotope enabled models and modern observations.

New insights into surface-ocean dynamics of the NE Atlantic Ocean across the penultimate interglacial complex from planktic foraminiferal assemblage record of the IODP Site U1385

Mr. Harshit Singh [1] ***, Prof. Arun Deo Singh*** [2]

1. *Department of Geology, Banaras Hindu University, Varanasi - 221 005.,* ***2.*** *Department of Geology, Banaras Hindu University, Varanasi-221005*

Marine Isotope Stage (MIS) 7 (246-190 ka) is uniquely characterized by large amplitude fluctuations of orbital parameters with reduced CO_2 concentrations. Consequently the global ice-volume fluctuated rapidly during MIS 7e to 7c. Therefore, investigation of this rapid switching from the glacial to interglacial state may provide new insights into the understanding of mechanism and feedback processes for climatic shifts. However, studies dealing with MIS 7 are constrained by lack of continuous high-resolutions records with well-established age model. The Iberian margin is an ideal region to obtain high-resolution records of past climatic changes on millennial-centennial timescales which can be compared with records of different climatic regions. We present here planktic foraminiferal assemblage and ANN-based SST records integrated with existing log (Ca/Ti), δ^{13}C and δ^{18}O datasets from IODP Site U1385, off SW Iberia to analyze the pattern and amplitude of climatic events interrupting MIS 8-7 termination, MIS 7 and the MIS 6 inception and to assess the role of atmospheric/hydrological factors on productivity variation and the associated surface-ocean dynamics at centennial-millennial scales.
Our records suggest overall increase in productivity and Iberian pole-ward current (IPC) influence during the warmer sub-stages 7e, 7c and 7a, whereas the colder sub-stages 7d and 7b are characterized by reduced productivity and IPC influence. Moreover, the warmer sub-stages show two-fold variations in productivity and IPC influence. Early phase of sub-stages at MIS 7e (~240-235 ka), 7c (~220-216 ka) and 7a (~202-198.5 ka) suggest low to moderate productivity with increased IPC influence. The weaker trade winds coupled with strong westerly influences over the SW Iberian region might have caused the weakening of upwelling due to the southern shift of the Azores High, a condition similar to the present-day negative North Atlantic Oscillation (-NAO)-like mode. Conversely, late phase of sub-stages at MIS 7e (~235-229.5 ka), 7c (~216-211.5 ka) and 7a (~198.5-195 ka) indicate moderate to high productivity with decreased IPC influence, a condition similar to the present-day +NAO-like mode. Furthermore, severe SST drops with significant productivity reductions are recorded around ~250, 243, 230, 219, 204, 195 and 192 ka, due to stratified waters caused by melt-water arrival from ice-rafting.

The OC3 global data base: high-resolution stable isotope data from benthic foraminifera of the last deglaciation

Dr. Juan Muglia [1]***, Dr. Stefan Mulitza*** [2]***, Dr. Janne Repschläger*** [3]***, Dr. Andreas Schmittner*** [4]***, Dr. Lorraine Lisiecki*** [5]***, Dr. Elisabeth Sikes*** [6]***, Dr. Alan Mix*** [4]

In paleoceanography, carbon and oxygen stable isotope ratios from benthic foraminifera are used as tracers of physical and biogeochemical properties of the deep ocean. We present the first version of the Ocean Carbon Cycling working group database, of stable isotope ratios of oxygen and carbon from benthic foraminifera in deep ocean sediment cores from the Last Glacial Maximum (LGM, 23−20 ky before present (BP)) to the Holocene (< 10 ky BP) with a particular focus on the early last deglaciation (20−15 ky BP). It includes 287 globally distributed coring sites, with metadata, isotopic and chronostratigraphic information, and age models. A quality check was performed for all data and age models. Sites with at least millennial resolution were preferred, because the main goal is to resolve ocean changes associated with the last deglaciation on at least millennial timescales. Software tools were produced to access and analyze the data, and are included with this publication. Deep water mass structure as well as differences between the early deglaciation and LGM are captured by the data in the compilation, even though its coverage is still sparse in many ocean regions. We find high correlations among time series calculated with different age models at sites that allow such analysis. The database provides a useful dynamical approach to map physical and biogeochemical changes of the ocean throughout the last deglaciation.

Last Glacial Maximum Lake sediments capture High Arctic surface warming during Heinrich Event 2

Dr. Willem van-der-Bilt [1], ***Dr. William J. D'Andrea*** [2]

1. University of Bergen, 2. Lamont-Doherty Earth Observatory of Columbia University

Throughout the Last Glacial period, widespread deposition of Ice Rafted Debris (IRD) marks phases of North Atlantic ice sheet instability during cold Stadial conditions. The causes for these so-called Heinrich Events (HEs) remain contested: while initially attributed to internal ice sheet dynamics, there is mounting evidence for external ocean-climate forcing. In the latter scenario, ice rafting was driven by basal melt from a build-up of sub-surface heat in response to weakening ocean circulation. However, coeval shifts from perennial to seasonal sea ice conditions suggest that some heat may have escaped to the surface. We strengthen this notion, by presenting biomarker-based evidence for atmospheric warming from a unique Last Glacial Maximum (30-20 ka BP) lake sediment sequence from High Arctic Svalbard. Alkenone-derived changes in temperature (UK37) and hydroclimate (δD) indicate a rapid shift towards warmer surface conditions and more locally sourced precipitation at the onset of HE 2. These findings are supported by XRF evidence for lake water stratification and a shift towards *n*-alkane distributions indicative of less arid conditions. In conclusion, our data suggests that climate-forced Arctic ice sheet instability during HEs was triggered from below as well as above.

Foraminiferal assemblage response to Mediterranean and Atlantic changes during last deglaciation: A report from the Mediterranean overflow

Mr. Javier P. Tarruella [1], Prof. FRANCISCO SIERRO [1], Dr. Alessandra Asioli [2]

1. Universidad de Salamanca, 2. CNR-ISMAR Bologna

The last 30 ka period is marked by abrupt global changes, in which ocean thermohaline circulation, ice sheets and atmosphere interacted during deglaciation. In the Mediterranean basin, in addition to these changes there were others related to its own thermohaline circulation. Here we use foraminiferal assemblage data to infer paleoenvironmental changes from last 30 ka BP at ~600m depth, on the main branch of Mediterranean Overflow Water (MOW) in gulf of Cadiz. High sensitivity of foraminifera to environmental changes, with species-specific responses, and key location of the studied site allow to reconstruct NE Atlantic surface properties from planktic species and Intermediate Mediterranean water properties from benthic species.

Results showed that MOW strength is imprinted in this site by relative peaks in abundance of elevated epi-fauna, species associated with strong bottom currents and arrivals of shallow shelf reworked taxa. Sequences of benthic assemblages are well-correlated to Eastern Mediterranean dynamics even during periods of depleted ventilation and outflow as sapropel-1, which is the time interval with relatively most severe conditions. During this sapropel-1 period it is reflected the two different sapropel phases, separated by the 8.2 ka event. Heinrich stadial 1 (HS-1) is characterized by a relative peak of infrequent Mediterranean taxa and dominance of species tolerant to organic matter accumulation during its early phase, as observed in Atlantic Intermediate water sites during this period. This is consistent with sinking of MOW and a higher Atlantic influence during HSs. Matching between the studied site and Levantine basin irrespective of MOW strength makes this site valuable to study past changes in Mediterranean basin, excepting moments of MOW core sinking, in which Atlantic influence is notable.

No substantial northward shift of the North Atlantic Polar and Arctic fronts during the mid-to-late Younger Dryas

Dr. Alice Carter-Champion [1], ***Prof. David Thornalley*** [2], ***Dr. Ian Matthews*** [3], ***Dr. Adrian Palmer*** [4]

1. Department of Geoscience, Aarhus University, 2. University College London, 3. Royal Holloway, University of London, 4. Department of Geography, Royal Holloway University of London, London, United Kingdom

The Younger Dryas (YD) stadial is a key period for analysing abrupt climate change. Numerous proxy records of oceanographic changes exist for the YD interval, but reconstructions focus on a few records, extrapolated to represent basin-scale patterns. While model simulations can achieve broadly similar conditions to the marine proxy reconstructions for the period, unrealistic amounts of freshwater are required to obtain these conditions. Weakening of the Atlantic Meridional Overturning Circulation (AMOC) via freshwater input has been cited as the cause of the Younger Dryas but this does not capture the variable conditions seen within the stadial across the North Atlantic region. For example, several terrestrial reconstructions of climate have suggested that migration of the marine Polar Front northwards began mid-way through the YD and that climate over northwest Europe ameliorated from this point in time too, broadly contemporaneous with the deposition of the Vedde Ash (~12 ka Cal BP), a widespread isochron for the North Atlantic region. This work aims to examine the basin-scale changes in surface water conditions within the North Atlantic, using existing and new foraminiferal surface records of change.

A compilation of 82 palaeoceanographic records focused on the YD period is presented for the North Atlantic (~53 - 79°N, -60 - 22°E), using reconstructions of sea surface conditions via proportions of the polar-front indicating *N. pachyderma*. Due to sampling resolution and chronological challenges for many cores, and to effectively test this proposed amelioration in conditions at ~12.1 ka Cal BP, a time-slice approach was adopted, with conditions in the early-YD and the late-YD spatially interpolated. No significant changes were reconstructed from early to late YD based on *N. pachyderma* records, and indeed northward heat transport likely persisted throughout the YD. Minimal changes occur in foraminiferal $\delta^{18}O$ records, although some reduced values within the NW Atlantic in the late-YD may relate to freshwater release via the Hudson Strait or Greenland Ice Sheet. Although often invoked as a mechanism for ocean-atmospheric climate changes, the Polar Front did not appear to shift during the YD, and so alternative mechanisms are required to explain the terrestrial variability evident within YD.

Forcing of Holocene hydro-climatic variability at the North African desert margin inferred from multi-proxy frequency analyses (Lake Sidi Ali, Morocco)

The North African desert margin is considered one of the most sensitive areas to future climate changes. Improved knowledge about Holocene climatic variability and environmental responses on millennial to centennial scale will help to refine scenarios related to future climate changes. During the last two decades, the advances in the study of Holocene and last glacial records from the subtropical North Atlantic and the Mediterranean areas have improved our knowledge about the millennial-scale variability of the Western Mediterranean palaeoclimate and the Saharan dust cycle. The detection of periodicities can help to identify or refute particular forcing mechanisms. To detect periodicities in Holocene climatic variability and geomorphological processes, we use a Holocene sediment record from Lake Sidi Ali in the sub-humid Middle Atlas with a ^{210}Pb and pollen-based ^{14}C chronology. In order to distinguish between lake-internal (e.g. chemical precipitation) and lake-external (e.g. detrital input) processes, which might be driven by varying hydro-climates. We use a high resolution XRF-core scanning record calibrated with conventional ED-XRF analyses. Redfit and Wavelet timeseries analyses reveal distinct periodicities from millennial to centennial scales. The XRF element records reveal three Redfit Proxy Groups (RPG) with distinct periodicities potentially reflecting different forcings which were derived by a correlation analysis of extracted, highly significant frequency analysis spectra. Further, we integrated environmental and climatic proxies from the same core (*Cedrus atlantica* pollen abundance, magnetic susceptibility, δ^{18}O and δ^{13}C values of ostracod shells, grain-size endmembers and total organic carbon) and use their wavelet domains. We identify two main periodicity regimes that affect both, the hydrological regime and the lake productivity and catchment erosion dynamics. The hydrological regime seems to be mainly controlled by Precipitation-Evaporation balances (incl. winter rain variations) driven by North Atlantic and solar forcing (2 kyr and 1 kyr periodicities) as suggested by evaporation related proxies (Ca, Sr, Ca/Ti, Sr/Ti). In contrast, the lake productivity seems to be driven by summer temperature variations. Non-winter related processes (detrital input: Fe, Ti, K, etc. and lake productivity: Si/Ti) have independent periodicities (3.5 kyr and 1.5 kyr) and might be forced by solar and North Atlantic controls.

Evaluation of the predictable component of natural climate variability during the Holocene

The oscillatory behaviour of the climate system on decadal timescales beyond the instrumental record is hard to quantify. Yet knowledge of it is vital to support climate predictions and to put current changes in context of past experiences. We investigate the recurrent component of weather and climate variability in the North Atlantic sector during the Holocene in proxy data. We apply time-frequency analysis to both an annually-laminated climate record from a lake in England, and the Atlantic Meridional Overturning Circulation in a long transient simulation to demonstrate that decadal variability was consistent over the last 6,700 years and prior to 8,500 years before present, which was predominantly linked to solar and ocean forcing. Between these dates, climate variability was dampened on decadal timescales. Our results suggest that meltwater discharge into the North Atlantic and the subsequent hydrographic changes, from the opening of the Hudson Bay until the final collapse of the Laurentide Ice sheet, disrupted the regular climate patterns: suspending the decadal cyclic signals, and lowering the predictable signal of the climate system. Our results have relevance for near-term climate predictions given the current acceleration of the Greenland Ice Sheet melting in response to global warming.

Wind regime changes in the North Atlantic-European region driven by Late-Holocene Grand Solar Minima

***Dr. Poppy Harding* [1], Dr. Celia Martin-Puertas [2], Dr. Jesper Sjolte [3], Ms. Amy Walsh [2], Dr. Rik Tjallingii [4], Dr. Catherine Langdon [5], Prof. Simon Blockley [6], Prof. Achim Brauer [7], Prof. Peter Langdon [5], Dr. Alice Milner [6], Prof. Raimund Muscheler [8], Dr. Marta Perez-Fernandez [6]**

Understanding atmospheric responses to radiative forcing, including the intensity and distribution of wind patterns, is a critical issue, as this might have important implications in the coming decades. Long-term episodes of reduced solar activity (i.e. Grand Solar Minima, GSM) have triggered rapid climate change in the past, recorded in proxy-based records, including varved sediments from Meerfelder Maar, Germany, where the impact of the Homeric GSM (~2800 years ago) was studied. Here we present a reconstruction of increased windy conditions during the same GSM from another varved record, Diss Mere, in England, to support the solar-wind linkage in the North Atlantic-European region. We use diatoms as proxies for windiness and support the palaeolimnological and palaeoclimate interpretation with a multi-proxy approach, including sedimentological, geochemical, and biological (chironomids and pollen) evidence. The diatom assemblage documents a shift from *Pantocsekiella ocellata* dominance to *Stephanodiscus parvus and Lindavia comta*, indicating a shift to more turbulent waters from ~2767 ± 28, linked to increased windiness. This shift is synchronous with changes in ^{14}C production, linked to solar activity changes during the GSM. Both proxy records reflect a rapid and synchronous atmospheric response (i.e. stronger winds) at the onset and during the GSM in the North Atlantic and continental Europe. In order to test whether this solar-wind linkage is consistent during other GSMs and to understand the underlying climate dynamics, we analyse the wind response to solar forcing at the two study sites during the Little Ice Age, a period that includes several GSMs. For this, we have used a reconstruction based on a 1200-year-long simulation with an isotope-enabled climate model. Our study suggests that wind anomalies in the North Atlantic-European sector may relate to an anomalous atmospheric circulation in response to long-term solar forcing leading to north-easterlies modulated by the East Atlantic pattern.

Phase 4 of PAGES 2k: Hydroclimate of the Common Era

Dr. Alyssa Atwood [1]***, Dr. Sarah Eggleston*** [2]***, Dr. Georgina Falster*** [3]***, Dr. Benjamin Henley*** [4]***, Prof. Matthew Jones*** [5]***, Dr. Lukas Jonkers*** [6]***, Dr. Nikita Kaushal*** [7]***, Prof. Helen McGregor*** [8]***, Prof. Anaïs Orsi*** [9]***, Dr. Hussein Sayani*** [10]

The climate of the past two millennia (2k) is vital for developing our understanding of the climate system, as it extends the historical climate record and provides context for recent and future changes. Building on previous phases of the PAGES 2k network, Phase 4 paves the way for a new level of understanding of the global water cycle and enhanced science-policy integration.

Previous PAGES 2k network phases, emphasising temperature reconstructions, fundamentally improved our understanding of global climate changes over the Common Era. These reconstructions received widespread recognition and were featured in the Summary for Policymakers of the IPCC's Sixth Assessment Report. Integration of this data with state-of-the-art Earth systems models, proxy system models and data assimilation yielded a more comprehensive understanding of the associated physical drivers and climate dynamics.

Phase 4 challenges our community to turn its focus towards hydroclimate. Our overarching aim is to reconstruct hydroclimate variability over the Common Era from local to global spatial scales, at sub-annual to multi-centennial time scales, developing a process-level understanding of past hydroclimate events and variability. Our multi-faceted approach includes (1) developing new hydroclimate syntheses that are well-suited for data-model comparisons, (2) improving the interoperability and scope of our data and model products, and (3) facilitating the translation of our science into evidence-based policy outcomes. In this presentation, we report on our activities and progress to date, particularly highlighting the early stages of our data synthesis efforts.

Clam shells reveal the subpolar North Atlantic tipped into the Little Ice Age

Mx. Beatriz Arellano-Nava [1], ***Dr. Paul Halloran*** [1], ***Dr. Chris A. Boulton*** [2], ***Prof. James Scourse*** [3], ***Dr. Paul Butler*** [3], ***Dr. David Reynolds*** [3], ***Dr. Timothy M. Lenton*** [2]

The cooling transition into the Little Ice Age was the last notable shift in the climate system prior to anthropogenic global warming. It is hypothesised that sea-ice to ocean feedbacks sustained an initial cooling into the Little Ice Age by weakening the subpolar gyre circulation; a system that has been proposed to exhibit bistability. Empirical evidence for bistability within this transition has however been lacking. Using statistical indicators of resilience in three annually-resolved bivalve proxy records from the North Icelandic shelf, we show that the subpolar North Atlantic climate system destabilised during two episodes prior to the Little Ice Age. This loss of resilience indicates reduced attraction to one stable state, and a system vulnerable to an abrupt transition. The two episodes preceded wider subpolar North Atlantic change, consistent with the destabilisation of the subpolar gyre and the approach of a tipping point, potentially heralding the transition to Little Ice Age conditions.

Global warming has caused synchronous drying trend over most parts of the Europe since 1860s

***Dr. Wenling An** [1], **Prof. Chenxi Xu** [1], **Prof. Slobodan Marković** [2], **Prof. Shanlei Sun** [3], **Dr. Milivoj Gavrilov** [2], **Prof. Qingzhen Hao** [1], **Prof. Zhengtang Guo** [1]*

Nanjing University of Information Science and Technology

Widespread and frequent droughts are affecting most parts of the Europe in recent years, but it remains unclear when such synchronous drying trend started and how anthropogenic forcing influences. Here we present a new annually resolved tree ring stable oxygen record to reconstruct southern European hydroclimate over the past 300 years. Our reconstruction suggests that the onset of southern European drying trend occurred around 1860s, which marks the onset of extensive drying over most European area except the wetting northern Europe. We demonstrated that global warming has favored decreasing rainfall and increasing evaporation. With enhanced land-atmosphere coupling, the current drought intensification over most parts of the Europe is potentially irreversible.

Interactions between contemporary regional atmospheric dynamics and stable water isotopes in the Southern Ellsworth Mountains, West Antarctica

Firn core water isotope (δ^2H, $\delta^{18}O$) records spanning the late 20th and early 21st century from the Ellsworth Mountains suggest that climate in the 'coastal interior' of the West Antarctic has remained stable over the last few decades. This stability sits in contrast to several ice core records proximal to the Amundsen-Bellingshausen seas, which preserve a signal of late 20th century warming driven by regional climate dynamics, such as the strengthening of the Southern Annular Mode (SAM). Direct temperature measurements from the southern edge of the Ellsworths at Patriot Hills record intermittent, extreme high temperature events during the same time period. These events are driven by high-pressure blocking systems over the Antarctic peninsula that disrupt westerly airflow around the continent, facilitating the delivery of warm air from the Amundsen-Bellingshausen to the West Antarctic interior. To investigate the interaction between the atmospheric circulation and climate signals preserved in local precipitation, we utilise a combination of novel water isotope measurements, major ion chemistry data, and contiguous HYPSLIT airmass back-trajectory modelling. We report on a new 40-year record of contemporary water isotope data from Patriot Hills, extending the current Ellsworth Mountains firn core network a further 60 km south. Using ERA-5 reanalysis data, we conduct contiguous, 5-day atmospheric back-trajectories with the NOAA HYSPLIT model to Patriot Hills over the time period covered by the firn core. We analyse our trajectory data with a synoptically representative clustering scheme, allowing us to generate time-series of bulk and precipitating airmass delivery from different regional sectors such as the Weddell, Amundsen-Bellingshausen, and Ross seas. We evaluate the role of SAM and other climate modes in influencing both local climate and its translation into the preserved water isotope record. Patterns in precipitation-associated airmass delivery are explored as indicating a possible bias in precipitation towards airmasses arriving from the Weddell Sea, potentially masking the influence of warming associated with the Amundsen-Bellingshausen.

Bayesian Methods for Proxy Uncertainty Quantification, with an application using Machine Learning.

The study of past environments have strongly rely on proxy analysis to offer indications from past events that could have change the climate and/or environment. These proxies are found in different types of sediments, and the development of age-depth models has been critical in putting these variations in proxies into a temporal framework. Age-depth models have evolved into complex structures that give not only a point estimator but also a density estimator in the form of hundreds or millions of data from a probability distribution. Unfortunately, there is presently no tool that can include the posterior distribution from the age-depth model into the proxy analysis. As a result, users of age-depth models would only utilise the age-depth model's mean in their analysis. In this session, we will present PUlQue, a recently created tool that permits the use of age-depth posterior distributions in proxy research. This tool provides a proper statistical analysis for proxy analysis without ignoring age uncertainty. Using the results from this tool and instrumental data for Atmospheric Rivers, we trained a machine-learning method to predict Atmospheric Rivers in the sediment record from a lake in California (USA).

Session 13: Records of LGM climate and ecosystems dynamics

The LGM record in unglaciated NW Canada, far-eastern Beringia, recorded by pore ice water isotopes, eDNA and macrofossil evidence from relict permafrost

Relict permafrost in the Klondike region of northwestern Canada records LGM conditions in unglaciated far-eastern Beringia through multiple proxies including pore ice water isotopes, plant and insect fossils, eDNA and vertebrate records. These proxies provide a detailed picture of the transition from open boreal conditions near treeline during MIS 3 to increasingly arid and cold conditions going into the LGM. Bison were prominent during MIS 3, while horses increased in abundance with cold and dry conditions and the initial development of steppe-tundra after ~ 35,000 cal yrs BP. Near the LGM, pore ice water isotopes reach a minima at ca. 16,000 to 19,000 cal yr BP associated with the coldest conditions of the Late Quaternary. Nitrogen isotopes from soil organic matter indicate an enrichment associated with increased aridity, while d-excess from the pore ice is consistent with decreased summer contributions to soil moisture. Full glacial environments (ca. 16,000 to 19,000 cal yr BP) supported steppe-tundra vegetation and an insect fauna dominated by Connatichela artemisia - an endemic weevil associated with prairie sage (Artemisiae frigida). Evidence for the collapse of the mammoth steppe ecosystem begins with slowing of loess accumulation and development of paleosol ca. 13,500 cal yr BP. At this time, Connatichela artemisiae becomes infrequent and Artemisia pollen declines and is replaced by Cyperaceae, before mesic shrubs become dominant. The establishment of shrub tundra is associated with rapid changes in pore-ice isotopes, suggesting that ecological turnover coincided with a shift in atmospheric circulation and moisture availability. Finally, boreal vegetation communities became established ca. 10,500 cal yr BP. Collectively, these data show the close-coupling between late Quaternary large mammal populations, vegetation, insects and pore ice water isotopes providing a detailed archive going into, during and following the LGM in far-eastern Beringia.

Synchronizing ice-core and U/Th time scales in the Last Glacial Maximum using Hulu Cave 14C and new 10Be measurements from Greenland and Antarctica

1. *Physics of Ice, Climate and Earth, Niels Bohr Institute, University of Copenhagen,* **2.** *Helmholtz Centre Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany,* **3.** *Geological Institute, ETH Zürich,* **4.** *University of California, Berkeley,* **5.** *Department of Earth, Atmospheric, and Planetary Sciences, Purdue University,* **6.** *Lund University*

Between 15 and 27 ka b2k (thousands of years before 2000 CE) during the last glacial, Greenland experienced a prolonged cold stadial phase, interrupted by two short-lived warm interstadials. Greenland ice-core calcium data show two periods, preceding the interstadials, of anomalously high atmospheric dust loading, the origin of which is not well understood. At approximately the same time as the Greenland dust peaks, the Chinese Hulu Cave speleothems exhibit a climatic signal suggested to be a response to Heinrich Event 2, a period of enhanced ice-rafted debris deposition in the North Atlantic. In the climatic signal of Antarctic ice cores, moreover, a relative warming occurs between 23 and 24.5 ka b2k that is generally interpreted as a counterpart to a cool climate phase in the Northern Hemisphere. Proposed centennial-scale offsets between the polar ice-core time scales and the speleothem time scale hamper the precise reconstruction of the global sequence of these climatic events.

Here, we examine two new ^{10}Be datasets from Greenland (NorthGRIP) and Antarctic (WDC) ice cores to test the agreement between different time scales, by taking advantage of the globally synchronous cosmogenic radionuclide production rates.

Evidence of an event similar to the Maunder Solar Minimum is found in the new ^{10}Be datasets, supported by lower-resolution radionuclide data from Greenland and ^{14}C in the Hulu Cave speleothem, representing a good synchronization candidate at around 22 ka b2k. By matching the respective ^{10}Be data, we determine the offset between the Greenland ice-core time scale, GICC05, and the WDC Antarctic time scale, WD2014, to be 125±40 years. Via radionuclide wiggle-matching, we determine the offset between the Hulu speleothem and ice core timescales to be 375 years for GICC05 (75–625 years at 68 % confidence), and 225 years for WD2014 (-25–425 years at 68 % confidence). The undercounting of annual layers in GICC05 inferred from the offset is hypothesized to have been caused by a combination of underdetected annual layers, especially during periods with low winter precipitation, and misinterpreted unusual patterns in the annual signal, during the extremely cold period often referred to as Heinrich Stadial 1.

A 35 ka chironomid record and summer temperature reconstruction covering the Last Glacial Maximum from Bergsee (Black Forest, Germany)

Mr. Pierre Lapellegerie **[1], *Dr. Laurent Millet*** **[2], *Dr. Damien Rius*** **[2], *Dr. Oliver Heiri*** **[1]**

***1.** University of Basel, **2.** University of Bourgogne Franche-Comté*

The intermediate location of Bergsee (382m a.s.l.) between the Black Forest and the Alpine glaciers makes it a unique palaeoenvironmental archive that probably recorded the entire Last Glacial Period. Here we present a chironomid record from this lake covering ca. 35 ka including the Last Glacial Maximum. The record is divided into 6 statistically significant biostratigraphical zones. Between ca. 45–32 ka taxa typical for the littoral of relatively warm lakes (*Parakiefferiella bathophila*-type, *Paratanytarsus* and *Tanytarsus pallidicornis*-type) are dominating. Then (ca. 32–24 ka) *Sergentia coracina*-type, a profundal and cold indicative taxon, becomes dominant alongside *P. bathophila*-type. Low diversity and high abundances of *S. coracina*-type suggest the most severe environmental conditions of the record. The third zone (ca. 24–21 ka) is largely dominated by *P. bathophila*-type and warmer indicative taxa replace *S. coracina*-type. In the fourth zone (ca. 21–17 ka) *Paratanytarsus* and *Tanytarsus pallidicornis*-type dominate and the presence of *Chironomus anthracinus*-type suggests slightly warmer conditions and more nutrients in the lake. In the next zone (ca. 17–11 ka), *Corynocera ambigua*, a taxon with uncertain distribution in respect to temperature, becomes the dominant chironomid. The relative abundances of *C. ambigua* match the climate variability of the Lateglacial, with peaks corresponding to the cold phases of the Oldest and Younger Dryas interrupted by the warmer Bølling/Allerød. The last zone (ca. 11–9 ka, onset of the Holocene), shows the highest diversity and presence of warm indicative taxa like *Microtendipes pedellus*-type and *Pseudochironomus*. A first attempt of temperature reconstruction using a calibration dataset from Switzerland and Norway suggest temperatures of ca. 13°C in the lowest part of the record, with coldest values (10°C) inferred for the second zone, a time consistent with estimates of maximum extent of northern Alpine glaciers. However, high abundances of *C. ambigua* make the temperature reconstruction challenging for the Lateglacial by giving exceptionally cold values, which does not agree with warmer reconstructions from other palaeoenvironmental archives. Future work will focus on revising the chironomid record and applying calibration datasets with a more realistic (i.e. warmer) distribution of *C. ambigua* to the latest part of the record.

The ecoclimatic gradient from Central Asian larch timberline reproduces pollen-stratigraphical changes in a continuous LGM lake record at the southern Alpine fringe

***Dr. Cesare Ravazzi* [1], Prof. Flavio Anselmetti [2], Dr. Federica Badino [3], Dr. Paolo Bertuletti [1], Prof. Barbara Delmonte [4], Dr. Giulia Furlanetto [5], Dr. Nicoletta Fusi [6], Dr. Sandy P. During the Last Glacial Maximum (LGM), the southern provenance of moist air masses led to asymmetric ecoclimatic effects on both sides of the Alpine chain. On the northern side, a treeless semiarid foreland was connected to the European Ice Sheet by a continuous loess belt; on the southern side, a mixed coniferous forest steppe persisted throughout the coldest spells. Further south, towards the Adriatic cryptodepression, a continental timberline (sensu Holtmeier, 2009) developed, with the larch forest steppe tapering towards steppe and semidesert megabiomes.

In this work we present quantitative pollen-stratigraphic evidence from the continuous Lake Fimon sequence (northern Italy), together with co-registered sedimentary proxies and modern pollen analogues from the Altai-Sayan Mountains of southern Siberia. We show that their modern ecoclimatic timberline gradient reproduces the pollen-stratigraphic changes observed in our lake record during the Last Glacial Maximum.

The climatic envelope of LGM pollen descriptors shows that the sensitivity of past forest biodiversity to climate changes is driven by the abundance and pollen productivity of W-Eurasian larches (*Larix decidua, L. polonica, L. sukaczewii, L. sibirica*) compared to pines. Furthermore, we avoided harmonization of pine pollen types among fossil spectra and the modern calibration sets, as this depletes the climate sensitivity of pollen analogues. We recall the substantial differences in the ecological envelopes of the pine groups – i.e. the arolla-siberian pine group (*Pinus cembra* and P. *sibirica*), the *P. sylvestris/mugo* group, and of the Mediterranean pines. Pollen spectra dominated by semidesert and steppe treeless vegetation descriptors proved to be less sensitive to changes in thermal continentality. These similarities proved to be statistically robust to the modern analogue technique.

By dating larch charcoal and other terrestrial plant remains we produced a superior-quality radiocarbon chronology, overcoming dating issues typical of mid-latitude treeless biomes.

We recalibrated marine chronologies from the North Atlantic and the Mediterranean using Intcal20 improvements and we compared high resolution marine records with the Lake Fimon pollen record to explore linkages between millennial-scale climate evolution in the North Atlantic and in the Alps during the Last Glacial Maximum and the Alpine Lateglacial (30 to 12 ka).

Last Glacial Maximum to Late Glacial vegetation and landscape history of Central Kamchatka Peninsula (Southwestern Beringia)

Dr. Florin Pendea [1]***, Ms. Ekaterina Mukhametshina*** [2]***, Dr. Vera Ponomareva*** [3]***, Dr. Hans Harmsen*** [4]***, Dr. Maxim Portnyagin*** [5]

__1.__ Lakehead University, __2.__ Institute of Geography, Russian Academy of Sciences, __3.__ Institute of Volcanology and Seismology, Russian Academy of Sciences, __4.__ State University of New York at Buffalo, __5.__ GEOMAR Helmholtz Centre for Ocean Research Kiel, Kiel, Germany

We use a new high-resolution pollen, spore and charcoal record from a former proglacial lake to reconstruct the Last Glacial Maximum (LGM) to Late Glacial (LG) vegetation and landscape history of central Kamchatka Peninsula in the Russian Far East. The paleoenvironmental record, based on a well-resolved radiocarbon chronology, shows a series of millennial-scale changes in the regional landscape that reflect the complex interplay between the planetary radiative forcing and local geomorphological processes. The earliest part of our record (28.4 to 26.3 ka BP) was dominated by a shrubby tundra mosaic interspersed with *Larix* groves and poorly vegetated patches in areas with active fluvio-glacial activity. Between 26.3 and 23 ka BP, open herbaceous habitats expand to the detriment of shrubs. A cryocratic landscape is fully established between 23 and 18.5 ka BP and is characterized by a patchy cold tundra with pioneer/disturbed habitat forbs, graminoids and other herbaceous species. In more sheltered, upland areas small shrubs and isolated *Larix* groves may have been present, while on mesic sites *Populus* was locally abundant. Between 18.5 and 14 ka BP, soil conditions improve, probably under the influence of an increasingly positive planetary radiative balance and lead to the expansion of grasses and, to a lesser extent, tall shrubs. Fire-prone dry grasslands characterize the period between 14 and 12.6 ka BP. From 12.6 to 11.1 ka BP, a period which includes most of the Younger Dryas chronozone (12.8-11.7 ka BP) and the beginning of the Holocene, *Alnus* shrubs expand widely and tree alder (possibly *Alnus hirsuta*) appears in the local vegetation, suggesting an increase in available soil moisture and warmer conditions. A brief re-expansion of grasses (11.1-10.4 ka BP), before the establishment of more typical Early Holocene *Alnus* shrub-fern ecosystems point to unstable climate and landscape conditions during this time. Low but quasi-continuous *Picea* pollen may be evidence of a previously postulated glacial refugium for Kamchatka's enigmatic "conifer island". The aquatic pollen record suggests that the proglacial lake may have had variable water levels before its complete drainage around 12.8 ka BP.

Proxies, models, and people – using transient iTRACE climate models to disentangle proxy and archaeological records during the LGM and deglacial in Australia

The Last Glacial Maximum (LGM; 21±3ka) has been a focus of Australian palaeoclimate and archaeological research for over half a century. Previous models propose it to be a period of extreme cold and aridity, and that past Aboriginal populations collapsed and retreated into small ecological refuges to survive. This view has become increasingly untenable, with evidence of a longer multi-phase climatic downturn and genomic and archaeological data which does not support societal collapse or widespread abandonment of different regions. Here, we compare transient iTRACE climate models with palaeoclimate proxy records to re-examine Australian LGM and post-glacial climates and compare these with compilations of archaeological dates from the new SahulArch database. Multi-site comparison of continuous proxy records suggest an extended period of extreme conditions existed between 28.3-17.3 ka, which resulted in widespread changing vegetation structures. iTRACE climate model outputs suggest overall cooler conditions (-4–9 °C), but no evidence of substantial precipitation decrease over large parts of the continent. Kernel Density Estimates (KDE) of fluvial and lacustrine OSL and TL ages from the two major drainage basins in central and eastern Australia, the Lake Eyre and Murray Darling basins, indicate continued fluvial activity throughout the LGM period. An active monsoon, lower temperatures and reduced transpiration rates would have resulted in the continued functioning of hydrological systems within the two basins. KDEs of ages (^{14}C, OSL and TL) from archaeological sites show relatively unchanged occupation of landscapes and persistent site use across most regions at the peak LGM and post-glacial period, suggesting widespread abandonment or population collapse did not occur in all arid regions.

Climate sensitivity and ecoclimate sensitivity: inherent tradeoffs and past implications for 21st-century biospheric responses

Dr. Jack Williams [1]***, Mx. Adrian George*** [1]***, Dr. Brian Huntley*** [2]***, Dr. Alistair Seddon*** [3]

1. *University of Wisconsin-Madison,* ***2.*** *Durham University,* ***3.*** *University of Bergen*

Two usages of 'climate sensitivity' co-exist: one climatological, one ecological. The earlier climatological usage quantifies the sensitivity of global mean surface temperatures to atmospheric CO_2, with variants differing by timescale and processes. The ecological usage, renamed as ecoclimate sensitivity, is defined as a change in an ecological response variable per unit climate change. Paleoclimatic data, particularly those for the Last Glacial Maximum (LGM) are widely used to constrain equilibrium climate sensitivity, with estimates narrowing to 2.4 to 4.5°C. By contrast, there have been few explicit efforts to use paleoecological data to constrain ecoclimate sensitivity, but high sensitivity is indicated by widespread post-glacial biome-scale ecosystem transformations, continental-scale species range shifts, and high rates of community turnover. When climate and ecoclimate sensitivity are considered jointly, several points emerge. First, because radiative forcing scales logarithmically to $[CO_2]_{atm}$, ecological impacts per ppm $[CO_2]_{atm}$ often also scale logarithmically, although non-linear ecoclimate sensitivities alter this expectation. Second, there is an inherent tradeoff between past estimates of climate and ecoclimate sensitivity, because, for any given past observed ecological event, a smaller climate sensitivity estimates directly imply higher ecoclimate sensitivities. For example, a low-end estimate of climate sensitivity for the LGM (e.g. 2.4°C) would imply a much ecoclimate sensitivity of species and ecosystems. Given past biospheric transformations, we can expect high sensitivity of the terrestrial biosphere to current rises in $[CO_2]_{atm}$, a conclusion that is insensitive to climate sensitivity. Third, biological proxies remain a backbone of climate sensitivity estimates, so to avoid circularity, proxy networks used to constrain climate and ecoclimate sensitivity must be carefully separated. Given the equal importance of climate and ecoclimate sensitivity, equal effort must be devoted to constraining them. Hence, as estimates of climate sensitivity narrow, a critical priority going forward is to assemble networks of paleoclimatic and paleoecological proxies and models to better quantify the processes governing the form and variations of ecoclimate sensitivity across systems and scales.

Session 14: Climate and environmental changes during the Holocene and past interglacials based on biological and geochemical proxies

A Holocene branched glycerol dialkyl glycerol tetraether (brGDGT) record from the high altitude lake Garba Guracha, Ethiopia

The spatially complex climate variability in eastern Africa and the associated driving mechanisms during the last 15,000 years are not yet fully understood. In particular, a lack of paleoclimatic studies from the Horn of Africa prevents a broader spatial understanding of climatic changes in eastern Africa. Therefore, we seek to calibrate and apply new organic geochemical biomarker proxies for temperature in this region, specifically branched glycerol dialkyl glycerol tetraethers (brGDGTs).

In the surface sediments of Bale Mountain lakes in Ethiopia, Horn of Africa, we found a unique abundance of 6-methyl brGDGT isomers, compared to similar eastern African lakes (Loomis et al., 2012; Russell et al., 2018), possibly influenced by the water chemistry of the lake or by changes in the bacterial community. Therefore, we developed a new local brGDGT temperature calibration that also accounts for 6-methyl isomers. We reconstructed Holocene mean annual temperatures based on brGDGTs and analyzed δ^2H of *n*-alkanes extracted from a 1550 cm (~ 16 ka) lake sediment core from high-altitude cirque lake Garba Guracha in the Bale Mountains.

Reconstructed annual mean temperatures (n=35, 4-10°C) indicate that colder conditions prevailed in the high elevation Bale Mountain ecosystem during the Younger Dryas. In addition, we reconstructed a delayed response to the northern hemisphere summer insolation maximum during the Late Glacial and a thermal optimum in the mid-Holocene that coincides with the September insolation maximum at 6°N. Reconstructed δ^2H values, often interpreted as a proxy for precipitation amount or source, show a strong similarities between low-latitude archives in eastern Africa and suggest meridional driven climatic changes during the Holocene rather than an east-west influence.

The sediments of Holzmaar (West-Eifel Volcanic Field, Germany) provide one of the best studied Holocene and Late-Glacial varve records worldwide. However, past publications about this sedimentary record focused mostly on certain time windows and presented data with centennial or sub-decadal temporal resolution. We recovered new sediment cores from Holzmaar in 2019 and applied scanning techniques with high µm-scale spatial resolution to study depositional changes with annual to sub-annual temporal resolution. The existing varve chronology was transferred and updated to the new composite sediment record by applying Bayesian modelling. This chronology enables us to scan the sediment sequence with X-ray fluorescence and hyper spectral imaging and interpret the obtained datasets for the entire Holocene record with up to seasonal resolution. By applying statistical and machine learning techniques (e.g. principal component analysis, CONISS clustering, recurrence plots), we obtain a thorough picture of trends as well as periodic and abrupt changes in sedimentation. How these are linked to external and internal forcing factors, which in turn are related to catchment and lacustrine processes, will be unraveled. By considering all available information, we delineate our findings in a conceptual model for selected periods of the lake's Holocene history.

Unravelling Surface UV-B Variations across the Maunder Minimum and Satellite Era using Sporomorph Chemistry

Mr. Timothy Anane [1], ***Dr. Katherine Holt*** [1], ***Prof. Barry Lomax*** [2], ***Dr. Phillip Jardine*** [3], ***Prof. Mark Waterland*** [1], ***Mr. Bert Verleijsdonk*** [1]

1. *Massey University,* ***2.*** *School of Bioscience, University of Nottingham, Sutton Bonington Campus, Loughborough, United Kingdom,* ***3.*** *Westfälische Wilhelms-Universität Münster, Institut für Geologie und Paläontologie, Münster, Germany*

Solar UV-B radiation is harmful to the biosphere. Prolonged, unprotected exposure to UV-B damages the DNA in skin cells which can be detrimental for humans and animals alike. Plant growth and reproduction can also be negatively impacted by exposure to UV-B radiation. Understanding patterns in the past, present and future flux of UV-B radiation is therefore of crucial interest.

Anthropogenic release of ozone-depleting gases can cause surface UV-B fluctuations, however, natural processes including solar activity, stratospheric volcanic eruptions, geomagnetic field variations, and orbitally influenced variations in insolation also result in ozone perturbation and hence surface UV-B variations. Therefore, to fully assess human influence on ozone, we need to better understand how surface UV-B has varied prior to the industrial and pre-instrumental era. At present, UV-B and ozone measurements are made through satellite observations and ground-based sensing. As these measurements only cover the instrumental era, proxies are needed to reconstruct pre-instrumental variations.

Chemical analysis of sporomorphs is an emerging proxy for surface UV-B levels over geological timescales. Plants increase levels of UV-B absorbing compounds (UACs) (e.g. ferulic acid and *para*-coumaric acids) in their sporomorphs in response to increases in UV-B radiation. Sporopollenin, the exine of sporomorphs is chemically inert, preserving UAC levels over millennia after deposition under anaerobic conditions. This allows preinstrumental UV-B variations to be inferred from measurements of UACs in sporomorphs.

In this work, we utilise Micro Fourier Transform Infrared Spectroscopy (Micro-FTIR) to measure UAC content of pollen grains from lake sediments of Nar Gölü (Turkiye), expanding on similar previous work at that site. We produce a high-resolution UAC record for the Maunder Minimum (1645 – 1710 CE) and satellite era (1977–2010 CE). Comparisons against modelled UV-B and satellite UV-B data, respectively, will be used as a measure of confidence in the UAC records for determining higher resolution patterns of UV-B variation than have hitherto been produced. We also hope to address key questions around relationships between solar activity and surface UV-B receipts. For example, is the apparent cessation in the 11-year solar cycle during the Maunder Minimum as evidenced by sunspots also reflected in surface UV-B receipts?

Linking pollen types to plant taxa – modelling Holocene regional ecological and climate shifts for the Central Sahara.

Mrs. Michèle Dinies [1], ***Dr. Frank Darius*** [1], ***Dr. Birgit Plessen*** [2], ***Dr. Ahmed Saadallah*** [3], ***Dr. Estelle Razanatsoa*** [4], ***Dr. Stefan Kröpelin*** [5], ***Prof. Martin Melles*** [6], ***Dr. Volker Wennrich*** [6], ***Dr. Philipp Hoelzmann*** [1]

Pollen analyses from sediments of the (Central) Sahara document distinct palaeoecological fluctuations during the Holocene. However, the reconstruction of ecological successions remains challenging, because linking of plant species to pollen-types often is restricted on few, selective plant species or genera and may lead to distorted results. We thus established an advanced pollen type – plant taxa assignment based on available publications and databases on pollen morphology of the respective plant species, tribes, genera etc., in order to get a more objective, reproducible interpretation of the pollen spectra.

This assignment of plant taxa to pollen-types builds the basis for a quantified reconstruction of the ecological and climatic shifts during the Holocene in the Central Sahara, based on pollen spectra out of a 16 m long lake sediment core, deposited continuously during the last 10500 years in the Lake Yoa, Ounianga basin, Chad. The pollen-based proxies are compared to delta 18O-measurements on sedimentary carbonate.

In a following procedure the pollen-types plant species assignments are applied to published pollen spectra available for the (Central) Sahara, allowing reproducible standardized, synthetic reconstruction of Holocene ecological shifts. The regional variability of past ecological responses also inform about ecological response ranges in regard of ongoing and future climate changes.

Development of the Nile Littoral Cell during the past 8.2 kyr

Geological Survey of Israel

The history of the Nile Littoral Cell (NLC) in the past ~8 kyr BP was constructed from radiocarbon-dated cores retrieved down-flow the Nile Delta. Grain-size distribution, chemical composition, and Nd-Sr isotopic ratios together with marine derived variables as carbonate content, total organic carbon and its isotopic carbon composition record the variations in transport processes and sediment provenance. From 8.2 to 5.5 kyr BP the record is dominated by quartz sands from the Nile Delta that were recycled due to shelf transgression at the final post glacial sea level rise. Oligotrophic conditions prevailed in the shelf, and the relatively high carbonate content reflects the decrease in Nilotic fines due to increased vegetation and decrease in surface erosion related to the African Humid Period (AHP) wetter conditions. The geochemical signature of the fines represent mostly remobilization of aeolian sediments from the surrounding deserts by the increased runoff. Sea level stabilization, termination of the AHP and the drying of the Ethiopian Highlands resulted in the increase of sediments with a basaltic signature. After ~5.5 kyr BP, fine sediments were supplied seasonally by the Nile, increasing water column productivity and creating a distinct mud belt at water depth exceeding ~35m. Occasional sediment coarsening in the distal NLC likely reflects periodical decrease in Nile floods discharge or contribution from shallower water depth due to increased storminess. With the continuation of the regional aridification and decreasing of the Nile River flow in the last 3 kyr, contribution of dust particles from the nearby lands was recorded in the distal NLC, while the proximal cell continued to be affected mostly by the Nile. A distinct increase in grain size and carbonate content, decrease in TOC content at the topmost part of the record represent the Nile damming in the modern period, which resulted in halting of the seasonal floods suspension.

Responses of sedimentary proxy to hydrological and climatic changes in a maar lake situated at the southern margins of Arabian desert

Mr. Shah Parth [1]***, Ms. Bulbul Mehta*** [2]***, Prof. James Russell*** [3]***, Dr. Ilaria Mazzini*** [4]***, Prof. Nicolas Waldmann*** [5]

1. *University of Haifa, 199 Aba Khoushy Ave., Haifa, 3498838, Israel,* ***2.*** *Indian Institute of Science Education and Research - Mohali, Punjab,* ***3.*** *Department of Earth, Environmental, and Planetary Sciences, Brown University,* ***4.*** *Consiglio Nazionale delle Ricerche, Istituto di Geologia Ambientale e Geoingegneria (IGAG),* ***5.*** *University of Haifa*

Lake sedimentary records from the southern Arabian Desert are scarce. Thus, documentation of the distinct climatic and environmental shifts based on these archives for the mid-late Holocene is of utmost importance. This project aims to identify the onset and periodicities of climatic events based on a reliable interpretation of a set of proxies applied to a lake record from Yemen.

A composite ~1 m long core (JAS) was recovered from the maar lake Karif Shawran, southern Yemen. Geochemical, mineralogical and biological proxies were applied on the JAS core for reconstructing past global changes and providing information on the surrounding terrestrial environment and climate history. The chronology presented here is based on four radiocarbon ages derived from ostracod shells that reach ~3800 yr BP. The lithology of the JAS core consists of lamina-scale alternations of halite and organic detritus layers with an average thickness of 1-3 mm. Moreover, our study reveals turbidite and ash layers within the laminated sequence. Furthermore, XRF data revealed increased physical weathering, marked by higher K/Ti values and lower Ca and Fe normalized count, pointing to high lake-level stands. In contrast, intervals of low lake-level were marked by decreased physical weathering and increased authigenic precipitation of halite crystals coupled with higher levels of Ca and Fe normalized counts. This inference is also supported by a correspondence between lower magnetic susceptibility due to wet/humid conditions with higher levels of total organic carbon and vice-versa. The *n*-alkanes proxies like P_{aq} were generally low, indicating increased aquatic macrophytes in response to lake-level drop due to arid conditions. The ostracod assemblage data suggests the presence of a single euryhaline species *Cyprideis torosa*. Ecophenotypic variation of *C. torosa* valves provided some useful paleolimnological information, such as the variability of salinity ranges in the lake water. These, in turn serve as a linkage to paleoclimatic and paleoenvironmental changes. Overall, this study provides information on the major driving factor behind the hydroclimatic shifts in the region and helps to understand the role of the ITCZ vis-à-vis monsoonal dynamics. Moreover, it develops the initial understanding of long-term strategies in the seasonal prediction for Southern Arabia.

Coral geochemical records as tracers of ecosystem change in the Tropical Eastern Pacific over the late-Holocene

Dr. Jonathan Cybulski [1], ***Dr. Nicolas Duprey*** [2], ***Dr. Sean Connolly*** [1], ***Dr. Alan Foreman*** [3], ***Dr. Erin Dillon*** [1], ***Ms. Brigida De Gracia*** [1], ***Dr. Hubert Vonhof*** [4], ***Dr. Alfredo Martínez-García*** [3], ***Dr. Aaron O'Dea*** [1]

Along the coast of the Tropical Eastern Pacific (TEP), regions of strong seasonal upwelling bring cold, nutrient-rich deep waters into coastal zones, controlling ecological conditions and sustaining millions of people through the production of large-scale fisheries biomass. The TEP is also important for the regulation of global climate and is affected by large-scale processes such as ENSO. How the nutrient dynamics of this region will respond to future climate change and what the implications will be for coastal ecology and human livelihood are critical to know for environmental research, but remains to be studied. Environmental records are needed that capture intra and inter-decadal variation and extend back into millennial time scales where these biotic and abiotic processes play out. To address this, we developed a new sampling approach and constructed two records produced from coral skeletons (n = >600) collected in reef matrix cores and extending over six millennia from the upwelling Gulf of Panamá and the non-upwelling Gulf of Chiriquí. We ask what effects millennial-scale climate patterns have on seasonal upwelling in the region, and how the magnitude of upwelled nutrients influences ecological productivity and even implications for human habitation. To investigate this question, we combined multiple proxies using climatic (carbonate $\delta^{18}O$), nutrient (skeletal-organic matrix $\delta^{15}N$), diagenetic (taphonomic scoring), ecological (benthic community composition), and temporal (U-Th dates) data. Using a Generalised Additive Model-based approach for assessing data variability, we find strong divergences in the nutrient ($\delta^{15}N$; range >5 ‰) records between Gulfs, while $\delta^{18}O$ (range ~2‰) appears more stable. The greatest variation in $\delta^{15}N$ values occurs during times of high reef accretion whereas $\delta^{18}O$ remains constant, suggesting that nutrients, not temperature, are driving reef productivity. Taphonomic, taxonomic, and age models reveal periodic shifts and/or collapses of coral communities that differ between Gulfs. We end by drawing connections between these ecological shifts to the episodic human habitation documented in the region during the late-Holocene, and hypothesize what this may mean under future climate conditions.

Holocene Indian summer monsoon variability in the Northeastern Indian Ocean

Dr. Sijinkumar AV [1], ***Mrs. Gayathri N M*** [2], ***Ms. Ammoose Jayan*** [3], ***Dr. Nath B N*** [4]

1. Assistant professor, Central University of Kerala, 2. Department of Geology, central university of kerala, 3. Research Scholar, Central University of Kerala, 4. CSIR-National Institute of Oceanography, Goa, India

The Indian Summer Monsoon (ISM) is a significant water source for India. Recent studies showed an increasing trend of spatial and temporal variability of rainfall extremes in India owing to the consequences of climate change. The Holocene period has witnessed several climatic perturbations and coincided with the disruption of major civilizations illustrating the human significance of the Holocene climate variability. Recently occurred monsoon-related catastrophic events have urged the importance of understanding the centennial-millennial-scale ISM variabilities in the immediate past, thereby developing reliable predictions for future variations. A better understanding of ISM's timing, magnitude, nature, and forcing mechanisms during the Holocene is vital to portray future manifestations in the present climate change scenario. The Holocene ISM reconstruction varies substantially across different regions and shows large-magnitude fluctuations over the millennial timescale. The intensification of ISM during the Holocene commenced at the beginning of the early Holocene (11.4 ka) with a stepwise increase at 10.6, 9.3, and 8.0 ka. A short period of weak ISM is identified at 8.5 ka, marked changes in the salinity-sensitive foraminiferal proxies, which broadly corresponds to the 8.2 ka cooling event observed in the Greenland ice cores. Weakened ISM during this period is also reflected by increased productivity driven by wind-induced mixing when the upper water column was less stratified. ISM was also stronger during the early mid-Holocene (8.2 to 7.2 and 7.0 to 5.5 ka) and late Holocene (3.5 to 2.2 ka and 2.1 to 1.1 ka). A progressive decline in the abundances of productivity and salinity proxies from 4.2 to 2.0 cal ka suggests a gradual weakening of the ISM during the late Holocene. During the recent cold period, the Little Ice Age, ISM shows alternate strong and weak phases. ISM also shows large spatial variability, with northern part records showing maximum ISM precipitation occurred during the mid-Holocene. In contrast, southern Andaman Sea records show the strongest Holocene monsoon signal during the early Holocene. A systematic assessment of precipitation records based on proxies that track freshwater input and runoff was presented to better understand the spatiotemporal nature of its maximum precipitation during Holocene.

Interglacials of Middle-Late Pleistocene and Holocene in the northwest North Atlantic

At high latitudes of the Northern Hemisphere, Quaternary interglacials were characterized by relatively warm conditions but sea-ice, at least seasonal, and some land-ice, notably over Greenland, remained resilient features. This is documented by paleoclimatic and paleoceanographic records from the northwest North Atlantic area that illustrate the interplay of climate, ice, and ocean in response to the large amplitude climatic shifts of glacial/interglacial oscillations. These records also illustrate large-scale instabilities of the Greenland ice sheet. We illustrate these features based on isotopic, sedimentological, and palynological data from marine sediment cores of ODP site 646, IODP site U1302/03, and U1305, from the Labrador Sea.

Pollen and dinocyst records illustrate the uniqueness of each interglacial, and the high amplitude variations of sub-millennial pacing, during most of them, pointing to regional climate instabilities. The overall results also show that ice-rafting deposition occurred throughout most of the middle-late Pleistocene and Holocene, including interglacials, except the marine isotope stage (MIS) 11. A particularity of the regional records is the low sea-surface salinity during almost all interglacials, again with the exception of MIS 11. In the context of the Labrador Sea, low salinity can be associated with meltwater discharges and/or the export of Arctic waters. The last deglaciation and subsequent Holocene sequence in several marine cores of the area indicate that thermal maximum conditions matched particularly low salinity conditions, linked to the final melting stages of the Laurentide ice sheet, whereas the Greenland ice sheet receded to its latest minimal extent. Hence, the combination of low surface salinity and ice-rafting that characterized most interglacials in the Labrador Sea suggests that ice has remained an important component of the regional climate, which might also explain the high-frequency instabilities recorded in sea-surface conditions. From this point of view, MIS 11 stands out as the only “true interglacial” at the regional scale, without sea ice nor meltwater discharge evidence. Although a much-reduced Greenland ice volume likely characterized the MIS 11, there is no evidence of warmer-than-present conditions in the Labrador Sea during this interval. MIS 11 experienced a climate state distinct from that of any other middle-late Pleistocene interglacial.

Investigating the cause and structure of abrupt climate change events during MIS 11c

Mr. Daniel Parkes [1]***, Prof. Ian Candy*** [1]***, Prof. David Thornalley*** [2]***, Prof. Erin McClymont*** [3]

1. *Royal Holloway, University of London,* ***2.*** *University College London,* ***3.*** *Durham University*

Marine Oxygen Isotope Stage (MIS) 11c (~ 424 – 394 ka) stands out as; 1) an orbitally similar period to the Holocene 2) a time of significant Greenland Ice Sheet (GIS) loss. As the GIS is poised to retreat, understanding the impact this could have on North Atlantic dynamics is of paramount importance.

The tephra layer identified by Candy *et al.*, (2021) linking Marks Tey (MT) (Essex) and ODP 980 (Rockall Trough) makes it possible to investigate relationships between marine and terrestrial changes during MIS 11c. The tephra layer in the varved sediments at MT occurs just prior to an isotopic event, culminating in a ~ 500 yr ecological response. Simultaneously, there is a reduction in Sea Surface Temperatures (SSTs) at ODP 980, indicated by an increase in *N.pachyderma* ~ 415 ka. The aim of this study is to make use of the MT sequence in conjunction with a series of ocean cores to investigate this pre-Holocene Abrupt Climate Event (ACE).

We make use grain size analysis, Ice Rafted Debris (IRD) and foram-census data at 6 North Atlantic sites: IODP U1302 and U1305 (Labrador Sea / Denmark Strait Overflow Water (DSOW)); ODP 983, 984, and IODP U1304 (Iceland Scotland Overflow Water (ISOW)), and ODP 980. MT sediments have been sampled for biomarkers and isotopes to examine the on-shore environmental signal of this event. At MT, results confirm a long-term cooling trend spanning ~ 1500 varve years, punctuated by repeated isotopic incursions prior to/culminating in the ecological response. Ocean data indicates SST cooling event at all sites concurrent with a reduction in current flow strength at all sites except U1304. Each of these sites share common features: (1) being during the first phase of MIS 11c (424 – 410 ka) (2) after the final cessation of IRD (~ 419 ka onwards) (3) ~ 1500 years in duration. Despite chronological issues, it is likely these are concurrent, indicating a pan-North Atlantic cooling event with an ecological response. This is the first study to be able to produce such a high-resolution record of a pre-Holocene ACE.

Multiproxy investigations reveal the environmental succession of the oldest interglacial (MIS 11) detected for the crater infill of Rodderberg, Germany

Interglacials are of increasing interest for Quaternary science because they provide information about natural interactions between climate and ecosystems for conditions comparable to the Holocene as well as for climate projections of the warmer future – but without any human influences. Thus, they are past analogues to constrain impacts and dynamics of the ongoing global warming. To tackle these scientific challenges, we are studying the sedimentary infill of Rodderberg, a silted-up volcanic crater in the immediate vicinity of the city of Bonn in western Germany. The depositional succession encounters lacustrine sediments at the base, loess (partly reworked) in the central part and a Holocene luvisol at the top. Altogether, this sediment sequence covers several glacial-interglacial cycles in superposition, which characterize the depositional record of Rodderberg as a rare and promising environmental archive. The first and most challenging task for our investigations is to establish a robust chronology. For this purpose, we combine radiocarbon and luminescence dating with volcanic ash layers and pollen biostratigraphy to establish the timescale. Based on reconstructed vegetation assemblages and successions for the most pronounced and oldest interglacial of the sediment sequence, the oldest Rodderberg interglacial tentatively dates to 380-430 ka, which chronologically relates to Marine Isotope Stage 11 (MIS 11). This timing is supported by a dated tephra layer deposited during the early temperate phase of this interglacial. Thus, the eruption of the Rodderberg volcanic complex itself dates to glacial conditions before this volcanic eruption, i.e. prior to ca. 430 ka (MIS 12).

Preliminary diatom data provide information about the development of the local lacustrine system, while pollen and stable isotopes of carbonates and bulk organic matter reflect environmental changes of the catchment area. This data is supported by bulk geochemistry as well as by sub-centimetre scale elemental data obtained by XRF scanning. Together, this will provide a holistic view of environmental reactions and their biogeochemical responses triggered by climatic changes as archived by the depositional system of the Rodderberg crater lake during Middle Pleistocene interglacial conditions.

Common characteristics and differences of past and present interglacials in NW Europe: combining malacology and geochemistry

Dr. Nicole Limondin-Lozouet [1] ***, Dr. Julie Dabkowski*** [2]

1. *UMR 8591 CNRS-Université Paris I & UPEC. Laboratoire de Géographie Physique, Environnements quaternaires et actuels,* ***2.*** *CNRS-Laboratoire de géographie physique: environnements quaternaires et actuels (UMR 8591 Université Paris 1 Panthéon-Sorbonne, UPEC)*

NW European valleys are characterised by stepped systems, within which terrace incision and sediment deposition are strongly controlled by climatic cycles. Temperate periods are represented by fine-grained fluvial sediments but malacological studies have demonstrated that full interglacial conditions are registered only in tufa formations at the top of the sedimentary series. Calcareous tufas contain diversified fossils and are particularly favourable for the preservation of rich molluscan communities allowing detailed palaeoenvironmental reconstructions. Besides, geochemical analyses on tufa calcite provide high quality palaeoclimatic information. Multiproxy studies of NW European tufa deposits dated from MIS 11c, MIS 5e and the Holocene have been developed in the last decade allowing the reconstruction of both climate and environment dynamics during those interglacials. The recolonization of forest land snails is shown to follow a pattern common to all the studied interglacials and correlates with increasing temperature and moisture. The order of appearance of species, depending on their ecological tolerance, is linked to temperature increase. The maximal diversity and richness of forest land snails correlates with the thermal optimum and high moisture values in the isotopic data. The latter part of interglacial tufas is characterized by the decline of forest land snails and a marked decrease in temperature.

Beyond this general scheme, differences between interglacials are observed with respect to the presence of extinct taxa and/or species out of their modern range identified as “malacological signatures”. Pleistocene series hold richer communities with numerous central and eastern European current species, whereas Holocene assemblages are characterized by species with mostly western and northern European modern ranges. Comparison of associated isotopic data shows that Pleistocene interglacials, and especially their optima, appear stronger than the Holocene: MIS 11c was wetter and warmer and MIS 5e, experienced wetter conditions than the Holocene. Additionally, investigations on Holocene tufas across temperate Europe show a pronounced decreasing gradient in richness of forest species from east to west while moisture conditions reconstructed from isotopic analyses are higher in the western locations compared with eastern sequences. This demonstrate that beyond climatic conditions, colonisation dynamic of living organisms can also be strongly dependent on distance from refugia.

Palynological analysis of the MIS 11 interglacial from a sediment succession from Fucino Basin, Italy.

There are large gaps in our understanding of how the global water cycle and ecosystems will respond to future global warming. The study of sedimentary records can give us insight into climatic patterns in the past, how ecosystems adapted to warmer temperature conditions, and could serve as analogues for future global warming. The Marine Isotope Stage (MIS) 11c (ca. 426-396 ka) arises as one of the anomalously long and warm interglacials of the past 800 ka, with a global temperature ca. 0.5-0.7 ºC higher and a relative sea level of ca. 6-13 m higher than the pre-industrial Holocene, respectively. The Fucino Basin (Central Italy) contains a continuous lacustrine succession for the last 430 ka including MIS 11, dated by tephrochronology. Paleopalynology can be very useful as an environmental and paleoclimatic tool, through observing the changes in vegetation caused by temperature and precipitation changes. In this study, we present the preliminary results of the pollen analyses of the Fucino sedimentary succession between MIS 11c and the glacial termination V (glacial-interglacial transition between MIS 12 and MIS 11) to reconstruct the environmental change during this period. Our results show that an increase in humidity at the start of the MIS 11c interglacial the Fucino Basin, which is indicated by the exponential growth of the *Abies* population. Also, the generally warm interglacial was characterized by millennial-scale climate variability with several periods when the temperature decreased and the aridity increased, as testified by the *Abies* population decreasing and the *Poaceae*, *Artemisia*, *Amaranthaceae*, *Hippophae*, *Ephedra* and *Pinus* association increasing. The Fucino Basin lacustrine pollen record can provide us with a very accurate vision of the response of the vegetation during a period warmer than pre-industrial Holocene, thus arising as a potential reference fossil scenario that allows us evaluating the potential ecosystem impact of the current anthropogenic global warming.

Detailed record of interglacial palaeoclimates and palaeoenvironments in Northern France calcareous tufas: new data from the sequence of Resson (Eemian) and comparison with the MIS 11c and the Holocene

Detailed continental records of past interglacials where both palaeoenvironnemental and paleoclimatic reconstructions can be achieved are scarce in NW Europe. In this context, calcareous tufas are generally the only sedimentary records of Pleistocene interglacial optima. They are thus key-archives to investigate climate-environment interactions during interglacials for they contain abundant flora and fauna remains (especially molluscs) and their calcite composition allows direct dating as well as geochemical reconstructions of palaeoclimatic parameters. During the last two decades, multiproxy investigations of tufa deposits from northern France, including Caours (Somme basin, MIS 5e) et La Celle (Seine valley, MIS 11c), have provided detailed records of climatic and environmental changes during past interglacials and allowed comparisons with the Holocene.

In the Seine basin, the large tufa deposit of Resson has recently provided the opportunity to expand the record of Eemian environments and climates in the area. The site delivered in the 19th century a rich content in macroflora and large mammal fossils but was little investigated since. New fieldworks involving a multidisciplinary research team have allowed to describe and sample an extended section (>20 m long) of the Resson tufa. The entire 10m-thick sequence was sampled continuously and in parallel for malacology and isotopic geochemistry. Preliminary mollusc data indicate a high richness, especially in the number of both land snails and forest species and document the progressive development of interglacial conditions. Calcite stable isotopes provide a consistent record, showing a regular increase in humidity ($\delta^{13}C$) and warm conditions ($\delta^{18}O$), reaching an optimum in the upper part of the sequence. Compared to Caours palaeoenvironmental and palaeoclimatic reconstructions, where the optimum is strongly marked at the very bottom of the tufa sequence, Resson provides a more dilated record of the progressive establishment of wet and temperate conditions during the early phase of the Last Interglacial. Comparisons with data from tufas assigned to other interglacials from the same area confirm that the Eemian optimum, just as the MIS 11c, was significantly wetter than the Atlantic period while no strong differences are observed between Eemian and Holocene temperatures.

Palynology, palaeoclimate and chronology from the Saalian Glacial and the Saint-Germain II interglacial from two long cores in the Sea of Marmara

The Marmara region (NW Turkey) has a transitional vegetation and climate between Mediterranean and Euxinian. For the last Interglacial period and the following two Saint-Germain Interstadials, no information is available yet. Here we provide the results of the pollen analysis of two sediment cores taken from the Sea of Marmara. We focus on the period below the red-H1 seismic horizon, which corresponds to the last interglacial and a large part of the previous glacial period. A pollen-inferred palaeoclimatic reconstruction is proposed based on the MAT method.

Based on geochemistry that allows inter-core comparison and on a succession of warm and cold phases derived by pollen analysis, a nearly complete sequence from the Saalian Glacial period to the Saint-Germain II Interstadial was obtained, despite the occurrence of hiatuses corresponding often to lowstands.

The *Pterocarya* extinction has been traced from MIS 11 in Italy to Saint-Germain I Interstadial (c. MIS 5c) in the eastern Sea of Marmara, showing a progressive retreat from west to east until the Black Sea region where it is still present nowadays.

Climatic quantification, by the MAT method, indicates warmer temperature and a slightly drier climate than at present, at its peak of the Eemian. This is reflecting a shift of the Mediterranean climate to the NE and a reduction of the Euxinian vegetation.

A history of fire in eastern Australia over two interglacials: one without and one with people

Ethnographic observations suggest that Indigenous people employed a distinct regime of frequent, low-intensity fires in the Australian landscape. However, the timing of this and the ecological impact remains contested. Here, we present detailed analysis of charcoal, including for the first time, a measure of fire severity using Fourier Transform Infrared (FTIR) spectroscopy, at a site in eastern Australia that spans the last two interglacials and their late glacial transitions (between 135-104 and 18-0 cal years BP, broadly equivalent to Marine Isotope Stage (MIS) 6-5 and 2-1, respectively).

The accumulation of charcoal and vegetation composition (from palynology) was broadly similar across both periods, and trends and patterns correlate loosely with Antarctic ice core records (dD). This suggests that climate was a significant driver of fire at the site through both periods. We also found that fire was a distinct feature during these glacial terminations.

Fire severity was mostly lower over the last 17,000 years compared to the penultimate transition and interglacial (MIS 6-5) and this may reflect anthropogenic management of the landscape. We highlight that this signal is not easily discernible in the other proxies examined, including widely used charcoal methods, and propose that any anthropogenic signal is likely to be subtle in the palaeoenvironmental record – reflective of a regular, low severity fire regime. This record does however represent one of the few unequivocal records of the impact of Indigenous people on the fire regimes of Australia.

Insights into the Nature of Climate Variability During the Last Interglacial: A High-Resolution Multi-Proxy Record from the Fucino Basin, Central Italy

Environmental reconstructions of the Last Interglacial (LIG, 129-116 ka) can enhance knowledge of natural climate variability under conditions of excess warmth. The LIG was characterised by a global mean temperature ~0.8˚C warmer than the pre-industrial era, pronounced Arctic warming, and elevated sea level (~6-9 m above present). Exploring the local expression of LIG climatic changes through vegetation dynamics using combined pollen and stable isotope analyses can strengthen understanding of regional responses to a warmer background state. However, a lack of high-resolution palaeoclimatic archives employing a precise, independent, and robust chronological framework remains a primary limitation in investigating LIG climate variability and relating it to changes in other records.

Here, we present detailed palynological, charcoal, geochemical and isotope analyses of a thick lacustrine sedimentary sequence retrieved from the Fucino Basin, central Italy, covering the period from 139 to 107 ka. A crucial aspect of the record is its independent chronology based on direct $^{40}Ar/^{39}Ar$ dating and geochemical fingerprinting of several tephra layers. Pollen and charcoal analyses were conducted at 4 cm intervals representing a sampling resolution of ~80-100 years. Stable isotopic analyses ($\delta^{18}O$ and $\delta^{13}C$) were undertaken on lake carbonates every ~8 cm (~180 years). Annual and seasonal temperature and precipitation was reconstructed from fossil pollen assemblages as a consensus of three different models (WA.m, TWAPLS and BUMPER).

Multi-proxy analyses capture environmental responses to long-term and short-term climatic variability during the LIG at Fucino Basin. The detailed pollen sequence reveals a succession of arboreal phases, interrupted by a series of centennial- to millennial-scale contractions in temperate vegetation. Pollen-based climate reconstructions infer an overall warm and wet climate with peak annual temperatures ca. 2˚C warmer than present day. Comparisons between $\delta^{18}O$ records from the Fucino Basin and an Italian stalagmite (Corchia Cave) suggests a strong hydrological seasonal contrast during the early LIG corroborated by increased Mediterranean taxa abundance and elevated fire activity. The early LIG in Italy emerges as a time of high seasonality with arid summers and enhanced winter precipitation driven by strong Northern Hemisphere summer insolation.

High-resolution environmental and climate variability during the penultimate glacial and the Last Interglacial in the Padul wetland, western Mediterranean region.

The study of past climate periods, similar to the present, is very important to understand how the environments will respond to the rising global temperatures. The Last Interglacial (LIG) warm period, also called Eemian and corresponding to Marine Isotope Stage 5e (~130-115 kyr), is commonly used as a reference for a projected future climate. There are not many long and continuous sedimentary records in sensitive areas as the Mediterranean region where this period is registered. In fact, seasonal characteristics of interglacial climate dynamics are still unknown in this area. The Padul sedimentary sequence provides exceptional paleoenvironmental and paleoclimate information of the last ~200 kyr from the southern Iberian Peninsula. Here we present a detailed palynological study to contribute new insights into vegetation changes in order to infer precipitation and temperature shifts in the western Mediterranean area before, during and subsequently after the Last Interglacial. The preliminary results indicate that the termination of the penultimate glacial was the coldest and driest climatic phase, shown by the maxima in xerophytes (*Artemisia,* Amaranthaceae *and Ephedra*) and minima in Mediterranean forest (*Quercus* total, Oleaceae and *Pistacia*). The beginning of the LIG is characterized by an abrupt decline in xerophytes and an increase in arboreal taxa, especially in Mediterranean forest and conifers, indicating an important change towards an increase in temperature and precipitation. However, it seems that this environmental change was gradual in the Padul wetland as suggested by the general increasing trend in the Mediterranean forest. Millennial-scale variability, observed through periodic increases in xerophytes, also characterized the glacial-interglacial transition and the LIG.

The Last Interglacial and the Eemian in the N-Adriatic region: new insights from an expanded microbotanical record of the Coastal Istria (Croatia)

Here we present the detailed microbotanical study of a 120m-long marine-to-alluvial core MIR1 from the N-Adriatic, which includes a complete Last Interglacial (LIG; ca. 129 to 116 ka) and Eemian (ca. 126-110 ka), providing evidence for centennial-scale events.

The drilling site is located onshore at the mouth of the Mirna River's karst valley, dissecting the outer Istrian limestone plateau, that turned into *rias* during the last two marine high-stands. The most complete transgression sequence, documented between ca. 45 to 75 m of depth, contains an expanded, shallow marine record of the LIG, holding an exceptional potential of co-registered continental and marine biological proxies. We analysed sedimentary and micro-botanical proxies, besides charcoal fragments concentrations as a proxy for fire history.

Vegetation history is marked by a transition from semi-desert and forest-steppe to mixed deciduous-conifer forests during Termination II. A first sharp expansion of deciduous oaks (*Quercus robur* & *Q. cerris* types) is tied to the onset of the penultimate late glacial interstadial, currently dated at ca 132 ka as documented in the $\delta^{18}O$ Corchia Cave record. LIG onset is marked by a second, major step of oaks expansion at ca 129 ka with the development of a typical southern European forest succession, punctuated by events of fire and of moderate forest withdrawal. We propose to tie the first of these events to the sub-millennial C27 cold event at 127 ka. The second part of the temperate phase is considered a post-interglacial Eemian, showing a major turnover in forest composition. Deciduous oaks are gradually replaced by other broad-leaved trees (e.g., *Carpinus betulus*, *Ulmus*), also hosting moisture-demanding species (*Fagus*), and by evergreen Mediterranean sclerophylls (*Phillyrea*, *Olea* and evergreen oaks). Interestingly, the second phase of the Eemian temperate forest is characterized by lower charcoal abundances, compared to full Interglacial conditions and to the Termination II.

The warm-temperate trees are replaced by *Pinus* and *Artemisia*, pointing to the development of forest steppe and semideserts of cold/dry conditions.

Furthermore, we correlated MIR1 with other series from Mediterranean area to compare the ecological record and to distinguish the effect of climatic events at local to global scales.

A not so warm Last Interglacial Period in the SW Pacific, evidence from new dinocyst records

Dr. Fabienne Marret [1], ***Dr. Joe Prebble*** [2], ***Dr. Erica Crouch*** [2], ***Dr. Guiseppe Cortese*** [2], ***Dr. Helen Bostock*** [3]

__1.__ School of Environmental Sciences, University of Liverpool, UK, __2.__ GNS Science, __3.__ The University of Queensland

The Last Interglacial period (LIG) (~130-115 ka) has been the focus of international research interest over the last few decades as its study (either proxy-based or modelling) underlines temperatures globally warmer by 2 to 3 degrees C and a sea level 6 to 9 m higher than present-day. Because these conditions may represent the likely increase in oceanic temperature (~0.6 to 2°C) in the next 85 years as forecast by the latest IPCC scenarios in 2013, it is therefore crucial that LIG climatic variability and its regional expression are understood. Whereas the Atlantic Ocean has been well studied, the SW Pacific Ocean yields sparse records of past LIG conditions. Annual sea-surface temperatures have been estimated in this region for the LIG time-slices using foraminiferal assemblages, and there are a handful of core sites in the region where SST has been estimated using other proxies. To support and test this previous work, the aim is to produce maps of LIG time-slices of annual and seasonal sea-surface temperature (SST), salinity (SSS) and marine productivity, from 55° south to 25° south, over a 40° east-west gradient. To this end, dinoflagellate cyst assemblages from a number of cores, collected east and west of New-Zealand (NZ), are being studied and the Holocene and the LIG records compared. Results show contrasting results with overall annual SST anomalies of the interval 115-130 ka (compared to today conditions) being negative in the north and west, and positive in the east of NZ. Annual SST at 125 ka are overall cooler than present-day, with a maximum of cooling up to about 3°C north of NZ. These new results are comparable to the trends observed by planktonic foraminiferal assemblages, although dinocyst-based SSTs are systematically cooler.

Proxy-based quantitative reconstructions of Eemian climate, Garwolin Plain (Central Poland)

Three pollen sequences from fossil lakes in Central Poland were used to reconstruct the total annual precipitation and mean annual temperature, as well as the mean temperatures of the warmest and coldest months during the Eemian (Marine Isotope Stage 5e) interglacial.

High resolution pollen data from the Struga (profiles St-19 and G-120) and Parysow (profile Pa-19) sites recorded all seven regional pollen assemblage zones (RPAZs) typical for the interglacial in the European Plain. The modern analogue technique based (PPPbase software) reconstructions were linked with the presence of climate sensitive pollen and plant macrofossil indicator taxa in order to obtain a deeper insight into past climate changes.

The temperature dynamics during the climate optimum (E3-E5 RPAZs) of the Eemian Interglacial were of special interest. The highest mean July temperature (+21°C) was estimated based on the presence of Tilia tomentosa in the E4-E5 RPAZs. The highest precipitation totals were confirmed for the hazel phase (E4), which was not only the warmest period, but the most humid as well. A drop in precipitation and temperature occurred during the decline of the following hornbeam phase (E5), which was one of the possible reasons for the marked lowering of the water level in the Parysow lake and its transformation into a peatbog. The terminocratic parts of the Eemian Interglacial (fir-spruce and pine phases, E6 and E7 RPAZs respectively) are characterized by decreasing temperatures, particularly during the coldest month, and rising water levels due to a combination of decreased evaporation and higher air humidity during the transition to glacial conditions.

Deglacial increase of seasonality and associated ecological responses in the tropical North Atlantic revealed in varved sediments of the Cariaco Basin

Dr. Lars Wörmer [1]***, Ms. Jenny Wendt*** [1]***, Prof. Gerald Haug*** [2]***, Prof. Kai-Uwe Hinrichs*** [1]

1. MARUM-Center for Marine Environmental Sciences, University of Bremen, 2. Max Planck Institute for Chemistry

The varved sediments from the Cariaco Basin, off Venezuela, are among the most valuable marine high resolution climate archives. One of their unique characteristics is that varves persist well into the Younger Dryas cold period (12.9-11.7 kyr b2k), allowing to reconstruct high frequency climate and environmental variability across the most recent transition from a cold to warm period: the Pleistocene-Holocene boundary.

Here, we present our approach to decode the information stored in this archive via mass spectrometry imaging of molecular proxies. This technique enables µm-scale mapping of molecular proxies, which results in climate and environmental reconstructions with sub-annual resolution. Paired with elemental mapping and high-resolution sediment images, molecular proxy data can further be deconvoluted into season of deposition, thus allowing an assessment of past seasonality.

We analysed a section spanning ~700 years of varved sediments across the Younger Dryas-Holocene transition for a suite of molecular proxies and biomarkers with this approach, and demonstrate that this most recent event of abrupt global warming led to strongly increased sea surface temperature seasonality. We further evaluate how this change affected marine ecology and how it relates to seasonality on land.

With this contribution, we aim at presenting the approach of mass spectrometry imaging to the broader community studying varved deposits and at demonstrating the sensitivity of high frequency tropical climate and environmental variability across critical climate transitions.

A comparison of δ18O records derived from planktonic foraminifera and pteropoda from off Oman margin over the last glacial-interglacial cycle

***Ms. Mugdha Ambokar* [1], *Dr. Rajani Panchang* [2], *Mr. Omkar Janrao* [1], *Dr. Naveen Gandhi* [3], *Dr. Pankaj Baghel* [4], *Dr. Phaninder Reddy* [3], *Ms. Khushi Gorakh* [1]**

1. *Marine Bio-geo Research lab for Climate & Environment (MBReCE), Department of Environmental Science, Savitribai Phule Pune University,* **2.** *savitribai phule pune university,* **3.** *Indian Institute of Tropical Meteorology,* **4.** *Inter University Accelerator Centre, New Delhi*

The present study presents paleoclimatic results generated on a sediment core retrieved from the upper shelf of the Oman margin. It represents the glacial-interglacial period from 29,000 to 3,000 years BP. Stable oxygen and carbon isotopes have been generated using planktonic foraminifera (*Globigerinoides. ruber*) and Pteropoda (*Limacina inflata*). It is the first study from the Arabian Sea based on the comparison between responses of calcitic foraminifera and aragonitic pteropoda to the changing fresh water influx and temperature variations in the water column. The $\delta^{18}O_{L.\ inflata}$ shows more prominent climatic boundaries, and more events than the $\delta^{18}O_{G.\ ruber}$. The $\delta^{18}O_{L.\ inflata}$ also, throughout the core responds prior to $\delta^{18}O_{G.\ ruber.}$ The records suggest that the aragonitic pteropods are more temperature sensitive than the calcitic foraminifera, making them more efficient proxies for the paleoclimatic reconstruction.

Biomarker and chironomid inferred temperatures from varved records across Europe during the Holocene: trends, precision and seasonal indications

Dr. Ashley Abrook [1], ***Prof. Peter Langdon*** [1], ***Dr. Gordon Inglis*** [1], ***Prof. Achim Brauer*** [2], ***Dr. Celia Martin-Puertas*** [3]

Annually laminated (varved) lacustrine sediments are invaluable to palaeoclimatologists as they not only provide a tool to establish highly-resolved chronologies, but they also facilitate palaeoclimate reconstruction in unprecedented detail. In turn, this enables an assessment of the relationships between different proxies and the disentanglement of proxy-climate variability (e.g. seasonal vs annual components). Whilst annually laminated sequences are somewhat restricted spatially; long and continuous varved records do exist across continental Europe and analysing a network of these sites allows for the deciphering of climate heterogeneity. Our work aims to develop palaeotemperature reconstructions from varved lake records to assess not only heterogeneity in palaeoclimate, but also to highlight and provide comparisons between different proxy-based palaeoclimate reconstructions. Here we present preliminary results from chironomid-inferred mean July temperature reconstructions and lipid biomarker-based palaeotemperature reconstructions from a select number of varved records across continental Europe. We focus our analysis on two separate time-periods a) over the last 200-years and b) between 5.0 and 6.4 ka BP, covering peak Holocene summer warmth in north-west Europe. This approach enables a calibration with modern instrumental records but also enables a test of proxy-climate variability under different climate background scenarios, including those warmer than the present day. The data from the sites has a temporal resolution of between 4 to 17-years per sample and we will compare the chironomid- and biomarker-inferred temperature reconstructions in terms of trends across the two proxies, precision of the reconstructed data series and variability between seasonal responses, including spatial variance. Ultimately, this work will produce decadal to sub-decadal climate reconstructions and will be used to reconstruct the different modes of climate variability that operated during the Holocene. This work is a contribution to the Decadal project.

Paleoenvironmental evolution of Laguna Seca lake (Sierra Nevada, southern Iberia) since the Late Glacial

Northern Arizona University

Laguna Seca lake at 2259 masl has provided the longest alpine sedimentary record in southern Iberia, registering the last ~18 kyr in a ~14-meter-long sediment core. The oldest part of the sedimentary record represents a phase of subaerial debris flows and a small glacier/nivation hollow. The sediment characteristics abruptly changed at ~15.7 cal kyr BP, when a lake environment was established. A multi-proxy approach (magnetic susceptibility, organic geochemical analyses in bulk sediment, XRF core scanner data, and algae identification) has allowed the characterization of three different environmental phases in this lake. Deep lake conditions are identified from ~15.7 to ~10.6 cal kyr BP, agreeing with overall increasing precipitation in southern Iberia coinciding with augmenting summer insolation. This part of the record is characterized by grey lutites with high total organic carbon (TOC) content, high algae productivity, high vascular plant inputs (high C/N ratio) from the catchment and low Fe/S ratio, suggesting low oxygen conditions in the water-sediment interphase. Between ~10.6 and 8.2-8.0 cal kyr BP higher TOC and low Fe/S ratio are also recorded as well as higher algae content and low C/N ratio suggesting high aquatic production and more algae contribution to the local organic matter pool. This period registered the highest lake levels agreeing with summer insolation maximum and highest precipitation in southern Iberia. An abrupt lowering of the lake level is recorded after 8.0 cal kyr BP in the area. This is deduced by the decrease in TOC and algae in the sediments and more siliciclastic contribution from the catchment basin, evidenced by a high increase in siliciclastic elements (Si, Al, K, Ti, among others), with increased oxic conditions in the water-sediment interphase pointed out by the high increase in Fe/S ratio. Additionally, a potential increase in north African aeolian inputs (rich in Fe cations and Fe compounds) can be interpreted for the Middle and Late Holocene, evidenced by high Fe/Al values. This environmental change agrees with an aridification trend previously observed in the southern Iberian Peninsula.

European tree migrations during the Holocene

***Ms. Minxue Tang* [1], Ms. Mengmeng Liu [2], Dr. Sandy P. Harrison [3], Dr. Colin Prentice [4]**

***1.** Department of Life Sciences, Imperial College London, Silwood Park Campus, Ascot SL5 7PY, UK; School of Archaeology, Geography & Environmental Science, University of Reading, Whiteknights, Reading, RG6 6AH, UK, **2.** Department of Life Sciences, Imperial College London, Silwood Park Campus, Ascot SL5 7PY, UK, **3.** School of Archaeology, Geography & Environmental Science, University of Reading, Whiteknights, Reading, RG6 6AH, UK, **4.** Georgina Mace Centre for the Living Planet, Department of Life Sciences, Imperial College London, Silwood Park Campus, Buckhurst Road, Ascot SL5 7PY, UK*

Recent climate change has caused changes in phenological responses and some shifts in species ranges, but it is unclear whether trees will be able to migrate fast enough to keep up with projected future changes in climate. Observed changes in the distribution of trees during the Holocene (11.7 ka – present) provide a way of documenting tree migration rates in response to climate change. However, there is an ongoing debate about whether tree migration patterns during the Holocene reflect climate change directly or were a lagged response to these climate changes. We use fossil pollen samples from 1305 sites across Europe to reconstruct past changes in summer temperatures (MTWA), winter temperatures (MTCO), growing degree days above a baseline of 0° C (GDD_0) and an index of plant-available moisture (RTMI) during the Holocene. We then used these reconstructions with a generalised additive model (GAM) of the climate space of *Picea abies* and *Fagus sylvatica* to predict the changing distribution of these two trees in response to climate changes through the Holocene and compare this with observations of their actual distribution. We show that climate adequately explains the northward and westward expansion of *Picea abies* during the past 12,000 years. However, the climate-based predictions show a faster and larger northward expansion of *Fagus sylvatica* than was actually observed, providing evidence that other factors, including migration lag from glacial refugia, were an important control on the spread of this species. The application of this modelling approach to the migration of other European trees during the Holocene will provide insights into their adaptive capacity in the face of climate change.

Sensitivity of the French Mediterranean mountains to climate change and human activities since the end of the last deglaciation

Dr. Rosine Cartier [1], ***Dr. Florence Sylvestre*** [1], ***Dr. David Au Yang*** [1], ***Dr. Corinne Sonzogni*** [1], ***Dr. Christine Paillès*** [1], ***Dr. Kazuyo Tachikawa*** [1], ***Dr. Elodie Brisset*** [2], ***Dr. Frédéric Guiter*** [2], ***Dr. Laurence Vidal*** [1]

1. Aix Marseille University, CNRS, IRD, INRAE, College de France, CEREGE, Aix-en-Provence, France, 2. Aix-Marseille Université, CNRS, IRD, Avignon Université, IMBE, Europôle de l'Arbois, 13545 Aix-en-Provence, France

Managing water resources and environmental risks in high mountain environments is of major importance for societies around the Mediterranean. Current climate changes show faster warming at high altitudes and in the Mediterranean region than the global average (+2°C compared to pre-industrial levels). The Hydro-ALPS project aims at providing new continuous paleoclimate records in order to improve regional climate models by integrating processes occurring at millennial time scale. The close interactions between human activities, climate change and the occurrence of extreme events, will also be explored using a multiproxy approach (sedimentology, geochemistry, palynology). Emphasis will be placed on the use of diatoms, microscopic siliceous organisms abundant in alpine lakes.

This contribution presents the first results from the coring of Lake Petit in September 2022 (Valdeblore, France) located at 2200 m a.s.l. Previous studies covering the last 4800 years, have revealed the high diatom content of the sediments and high sensitivity of the lake ecosystem to past climate variability. This new coring has allowed us to retrieve a 7 meters-long sedimentary sequence that extents environmental reconstructions up to the early stages of the lake infilling. The majority of the record is composed of olive to brown diffuse laminae of diatomaceous sediments and the bottom 30 cm of an alternation of millimeter-thick light blue clay and black laminae. In comparisons to previous studies in this region (e.g. Lake Allos, Lake Vens, Lake Long Inférieur), this sedimentological succession suggests that the sequence dates back to the end of last glaciation (likely from the Younger Dryas).

The chronological framework of the different lithological units will be determined by ^{14}C analyses on macroremains of terrestrial origin. First inferences on the lake and watershed evolution will be based on CHNS analysis and biogenic silica content of bulk sediments, X-Ray Fluorescence core scanning and diatom assemblages. Additionally, oxygen isotopic composition ($^{18}O/^{16}O$ or $\delta^{18}O$) in modern waters will be analyzed to better understand the current hydrological functioning of Lake Petit. The new $\delta^{18}O_{diatom}$ record will be used to evaluate lake water temperature, lake water balance (P/E) and precipitation sources.

Holocene seasonal temperature evolution and spatial variability over the Northern Hemisphere landmass

The origin of the temperature divergence between Holocene proxy reconstructions and model simulations remains controversial, but it possibly results from potential biases in the seasonality of reconstructions or in the climate sensitivity of models. Here we present an extensive dataset of Holocene seasonal temperatures reconstructed using 1,310 pollen records covering the Northern Hemisphere landmass. Our results indicate that both summer and winter temperatures warmed from the early to mid-Holocene (~11–7 ka BP) and then cooled thereafter, but with significant spatial variability. Strong early Holocene warming trend occurred mainly in Europe, eastern North America and northern Asia, which can be generally captured by model simulations and is likely associated with the retreat of continental ice sheets. The subsequent cooling trend is pervasively recorded except for northern Asia and southeastern North America regions, which may reflect the cross-seasonal impact of the decreasing summer insolation through climatic feedbacks, but the cooling in winter season is not well reproduced by climate models. Our results challenge the proposal that seasonal biases in proxies are the main origin of model–data discrepancies and highlight the critical impact of insolation and associated feedbacks on temperature changes, which warrant closer attention in future climate modelling.

Pattern of precipitation changes in eastern China during the Holocene

***Dr. Qiao-Yu Cui* [1], *Prof. Yan Zhao* [2], *Dr. Chen Liang* [3], *Prof. Zhuo Zheng* [4], *Prof. Chunmei Ma* [5], *Prof. Xiayun Xiao* [6], *Dr. Quan Li* [1], *Dr. Feng Qin* [2]**

A certain number of case studies and model simulations reveale that over the Holocene there represent several dry-wet spatial patterns in eastern China. However, the accurate spatiotemporal changes of the Holocene precipitation over eastern China remains unclear, which hinders our understanding of the mechanism of East Asia monsoon evolution and the prediction of precipitation changes in the future. Here, we present a synthesis of pollen-based precipitation reconstructions over the past 12,000 years based on thirty high-resolution pollen records selected from the eastern monsoon region of China. In general, the overall trend of the precipitation changes in the eastern China increases at first then decreases afterwards, but with different precipitation phase. Therefore, four regions, i.e., South China, the middle-lower Yangtze River, North China and Northeast China, are divided for regional comparisons. The synthesized precipitation series shows that i) during the early Holocene (12-9 ka), the precipitation in eastern China increases consistently, but with higher values in South China and more significant fluctuations in the middle-lower Yangtze River; ii) during early-middle Holocene (9-6.5 ka): the spatial pattern of precipitation presents as “north wetting and south drying”, in which the south region refers to the South China indicated by the low precipitation values; iii) during the middle Holocene (6.5-3 ka): a reversed pattern of “north drying and south wetting” is formed in eastern China, inferred from rapid decrease of precipitation in Northeast China and gradual decrease in North China and the middle-lower Yangtze River, but increase in South China; iv) during the late Holocene (after 3 ka) , the precipitation in eastern China increases generally decreases. This spatiotemporal precipitation variability is better visualized by northward and southward shift of the 400 mm precipitation contour reconstructed by this study. Comparison of the rain belt changing with potentially climatic drivers suggests that solar radiation and ITCZ south-north migration will drive the change of monsoon intensity and the migration of rain belt in eastern China. This study provides quantitative evidence of precipitation variation in the monsoon region of eastern China.

Fire history since the LGM period in the Qinling Mountains, east-central China

Ms. Yao Zhang [1]***, Dr. Qiao-Yu Cui*** [2]***, Prof. Aifeng Zhou*** [3]***, Prof. Simon Blockley*** [4]

1. *College of Earth and Environmental Sciences, Lanzhou University,* ***2.*** *Key Laboratory of Land Surface Pattern and Simulation, Institute of Geographical Sciences and Natural Resources Research, Chinese Academy of Sciences,* ***3.*** *Lanzhou University,* ***4.*** *Department of Geography, Royal Holloway University of London, London, United Kingdom*

Fire frequency and intensity are increasing with the global warming in recent years. Fire activity can change forest cover from a “carbon sink” to a “carbon source”, which has an important impact on the global carbon cycle and climate changes. Therefore, the study of fire history and regimes at long time scales can provide a theoretical basis for future fire management and biodiversity conservation in forest areas. In this study, the alpine lake sediments (Daye Lake) in the Qinling Mountain Range were used to explore the interaction between fire, vegetation and climate changes, as well as human activities since the LGM period in east-central China based on charcoal and black carbon. The results show that the increase of fire activity during the last glacial period was controlled by arid conditions under the weak East Asia summer monsoon in Qinling region. Human activities played an important role on fires activities since the middle Holocene and human-induced fires became more common than the natural fires in the late Holocene because clearance of wasteland for agriculture and warfare increased fire frequency. Fire peaks were determined by biomass and vegetation composition affected fire intensity. The biofuel was dominated by woody plants in the last glacial period inducing high intensity fires and herbs have more contributions over the mid-late Holocene due to high fire frequency. With future increasing temperature, the increased vegetation cover and extreme climate events may increase the fire risk in the Qinling Mountain Range. Therefore, it is important to strengthen scientific management and monitoring of the forest ecosystem for regional ecosystem conservation.

Late Pleistocene to Holocene Black Sea transition from a lake to a marine basin: geochemical and biotical approaches

Dr. Mihaela Melinte-Dobrinescu [1], ***Dr. Gabriel Ion*** [2], ***Mr. Dan Vasiliu*** [1], ***Mr. Andrei Briceag*** [1], ***Mr. Tiberiu Sava*** [3], ***Mrs. Naliana Lupascu*** [1], ***Dr. Eliza Anton*** [1], ***Mr. Adrian Gherghe*** [1]

1. *National Institute for Research and Development on Marine Geology and Geo-ecology – GeoEcoMar,* ***2.*** *National Institute of Marine Geology and Geo-ecology - GeoEcoMar,* ***3.*** *Horia Hulubei National Institute for Physics and Nuclear Engineering*

During the Last Glacial Maximum (LGM), the Black Sea evolved as a giant fresh to brackish-water lake. In the Early Holocene, an outstanding event took place in the Black Sea: the end of the lacustrine stage of this basin caused by the reconnection with the Mediterranean as a consequence of the last deglaciation, which led to the onset of a marine anoxic regime in the basin, similar to the present day one. This paper presents the investigations carried out on 13 gravity cores, located in the W Black Sea, at water depths between 140 and 1,315 m. All three Upper Pleistocene-Holocene units of the Black Sea, namely the Lacustrine Lutite (Unit 3) – the oldest, the Sapropel Mud (Unit 2) and the Coccolith Mud (Unit 1) – the youngest, have been intercepted. Unit 3 contains a distinct red-brownish depositional interval, which occurs only in the W Black Sea. The recorded absolute ages indicates that the oldest core interval in Unit 3 is about 21,000 years BP, being situated in the cooler interval of LGM. Towards the lower part of Unit 2 an absolute age of 7,420 years BP was observed, while towards its top an age of 4,232 is recorded. The lacustrine sediments of Unit 3 enclose mainly Ponto-Caspian ostracods, except for the top part of the same unit, within the red-brownish interval, where the Mediterranean taxa occurs. Calcareous nannoplankton taxa are missing in the Black Sea pre-connection stage, but few specimens of *Emiliania huxleyi* are present at the top of Unit 3, just below the deposition of Unit 2 (Sapropel Mud). This finding indicates that the salinity was at least 10-11 ‰ (lowest limit of surviving for *Emiliania huxleyi*) prior the Sapropel Mud deposition. The above-mentioned biotic modifications are accompanied by significant geochemical changes, i.e., isotope values, including the shift of $d^{18}O$ from the Late Pleistocene to Holocene times and important fluctuation of $CaCO_3$, TOC (Total Organic Carbon) and OM (Organic Matter).

The Holocene of Sweden - what do we know and what is left to answer?

Prof. Stefan Wastegård [1]

1. Dept. of Physical Geography and Bolin Centre for Climate Research, Stockholm University, Stockholm, Sweden

Research on Holocene climate variability has a long history in Sweden going back to the Late 1800s and many ideas and concepts about changes in temperature and precipitation during the Holocene originated in Fennoscandia. The Holocene climate evolution in Sweden follows a pattern in common for many northern latitude records, following the summer insolation trend of the NH. A rapid warming at the Pleistocene-Holocene boundary at c. 11,650 cal a BP was followed by the Holocene thermal maximum between c. 8000-5000 cal a BP. A transition to colder and wetter conditions starts c. 4000 cal a BP, or in some records already around 6000 cal a BP, and lasts until the late 1800s CE. There is evidence from proxy records for climatic anomalies such as the 8.2 and 4.2 ka BP events and the Little Ice Age (LIA) but only scarce evidence for some other events, such as the 10.3 ka BP event. Despite the multitude of investigations, several research questions remain unanswered and remain to be addressed. Some of these questions will be addressed in this presentation.

Stable isotope, biogenic calcite crystal structure and biotic proxy based low stands of Lake Balaton at 8.2 and 5.3 kyr BP, the largest shallow lake of Central Europe

1. *ELTE Eötvös Loránd University, Institute of Geography and Earth Sciences, Department Environmental and Landscape Geography, Budapest H-1117, Hungary,* ***2.*** *MTA-PE Air Chemistry Research Group, Veszprém, Hungary; Air Chemistry Research Group, University of Pannonia, Veszprém, Hungary,* ***3.*** *Centre for Astronomy and Earth Sciences, Institute for Geological and Geochemical Research, Eötvös Loránd Research Network,* ***4.*** *Geographical Institute, Research Centre for Astronomy and Earth Sciences, Budapest, Hungary; Institute of Geography and Earth Sciences, Eötvös Loránd University, Budapest, Hungary,* ***5.*** *Romanian Academy, Institute of Speleology, Cluj-Napoca, Romania and Universität Bayreuth, BayCEER, Bayreuth, Germany,* ***6.*** *Laboratoire EDYTEM UMR CNRS 5204 Université Savoie Mont Blanc,* ***7.*** *MBFSZ, 1143 Budapest*

Increasingly frequent periods of drought fundamentally change the sediment-water balance in continental waters (rivers, lakes), and consequently the water quality. This is especially true for shallow, large lakes, like Lake Balaton. In this lake, biogenic calcite precipitation contributes over 80% of the total sediment accumulation. To understand how past lake level changes correlated with trophic level, lakeshore occupation and land use changes 1 full Holocene and 1 short (last 500 years) sediment core from the central part of the lake was studied for TOC, TN, micro-XRF, TEM, XRD, ICP and chlorophyll together with chironomid, diatoms and pollen analyses. For dating, $^{210}Pb/^{137}Cs$ and AMS ^{14}C measurements were used on pollen extracts and plant macrofossil samples. Regional plant cover estimates were made by the REVEALS model.

Biogenic carbonate precipitation in Lake Balaton produces calcite and Mg-calcite. Their relative proportions strongly depend on the Mg saturation of the water. Modern observations prove that increased Mg-content in the biogenic calcite correlates with increased evaporation of the water. Using this relationship for the past and corroborating it with $d^{18}O$ and $d^{13}O$ measurements and TEM derived crystal structure, we found two periods of Mg-calcite increase in the Holocene, at 8200-7900 and 5300-4600 yrs cal BP that likely indicate drier climatic conditions connectable to well-known rapid climate change events. Pollen data showed that the watershed was characterised by increased forest fires during these intervals. Our data furthermore show that the lake was characterized by mesotrophic deeper water with strong biogenic carbonate precipitation from 4200 cal BP until AD 1700, which was followed by a sudden increase in organic productivity between AD 1700-1750, simultaneously with a decrease in water-depth. Sediment accumulation (0.15-0.43 mm yr^{-1}) and sedimentary P (0.32-0.5 mg g^{-1}) content was fairly even in the Holocene, and did only accelerate in the second dry period in the central Szemes Sub-basin suggesting that high stand have not been connected with increased P-recycling. The second low lake stand phase coincides with the Baden occupation of the lakeshore, where we see changes in the d18O records overall pointing to a cold period at 5300 cal BP. Supported by NKFIH129167, RRF-2.3.1-21.

Abrupt early-Holocene climate and vegetation dynamics in a high-resolution lake core sequence from northern Finland

1. *Department of Geosciences and Geography, University of Helsinki, Helsinki, Finland,* ***2.*** *The Arctic University Museum of Norway, Tromsø,* ***3.*** *Centre for Palaeogenetics, Stockholm, Sweden.,* ***4.*** *Institute for Biodiversity and Ecosystem Dynamics, University of Amsterdam, Amsterdam, The Netherlands,* ***5.*** *Environmental Change Research Unit (ECRU), Ecosystems, Environment Research Programme, University of Helsinki, Finland,* ***6.*** *Swedish Musem of Natural History, Stockholm, Sweden*

Holocene proxy data indicate repeated abrupt, sub-millennial disruptions in northern hemisphere climate in the early part of the current interglacial (12–8 ka), commonly linked to the climatic and oceanic impacts of freshwater routing and outburst floods related to the residual ice sheets in North America and Europe. However, the precise climate signals of these abrupt events remain poorly resolved, including the amplitude and seasonality of associated temperature and moisture changes, as well as spatial expression and possible inter-regional correlations. This is due to the paucity of high-resolution proxy datasets, as well as seasonal biases in the available proxies, hampering a consistent hemispheric detection and characterization of the events.

In this study, we describe a core sequence from Kuutsjärvi, northern Finland (67.75°N 29.61°E), analysed for climate and vegetation proxies including pollen, plant macrofossils, sedimentary ancient DNA (*sed*aDNA), as well as conifer stomata and non-pollen palynomorphs (NPP's) analysed from pollen slides. A quantitative mean July air temperature reconstruction is prepared from the pollen data using a calibration model ensemble including both classical and machine-learning approaches. With robust chronology (23 radiocarbon dates) and high resolution (mean pollen sample interval 47 years and mean *sed*aDNA interval of 157 years over 10.7–4 ka), the Kuutsjärvi proxy data reveal a sequence of abrupt climate and vegetation shifts over the early Holocene.

Our data show a transient presence of both *Picea* (spruce; pollen, stomata, and potential *sed*aDNA evidence) and *Larix* (larch; pollen evidence) around Kuutsjärvi over ca. 9–7 ka. This is the first confirmed find of *Larix* in Finland during the Holocene. Two deforestation spikes occur at 10.4 and 10.1 ka, possibly correlative with a two-pronged signal of the 10.3k climate event in Greenland ice-core δ^{18}O data and in speleothem proxies for the East Asian summer monsoon. A strong tree minimum at 8.4–8.0 ka is correlated with the 8.2k climate event based on timing and a temporal progress (gradual build-up, sharp recovery) matching Greenland δ^{18}O records. Shallow-water indicators in the NPP record suggest a fall in moisture balance in northern Fennoscandia during the 8.2k event.

Holocene Climate and Environmental Change in Southeast Iceland

***Ms. Sarah Walton* [1], *Dr. Naomi Holmes* [1], *Dr. Robert Storrar* [2], *Dr. Jonathan Bridge* [1], *Dr. Gordon Bromley* [3], *Dr. Timothy Lane* [4], *Ms. Amy Lally* [5], *Ms. Gwyneth Rivers* [6], *Dr. Christopher Darvill* [7]**

Understanding natural climate variability is an important topic of discussion, with particular focus on the Holocene. Iceland's location provides an excellent opportunity for understanding Holocene North Atlantic climate variability and ocean circulation. Changes in the boundaries of major atmospheric and oceanic currents in the North Atlantic play an important role in both regional and global climate change and are known to impact changes in terrestrial climate in Iceland.

Palaeolimnological studies in Iceland have demonstrated their potential for reconstructing Holocene terrestrial climate and producing both quantitative and qualitative palaeoclimatic reconstructions using chironomid (non-biting midges) based temperature reconstructions. However, these studies are focused in the north and northwest, with little known of southeast Icelandic climate prior to the Little Ice Age (ca. 1250-1900 AD). Southeast Iceland also comprises Europe's Largest ice cap, the Vatnajökull ice cap, which has several outlet glaciers that are sensitive to changes in climate and provides an excellent opportunity to examine glacier chronology and extent in response to changing climate and marine conditions.

This study combines geomorphological and palaeolimnological evidence to reconstruct Holocene climate and palaeoenvironmental change in southeast Iceland. Lake sediment cores have been collected from high altitude lake Káravatn, to provide the first chironomid-based palaeoclimatic reconstruction in southeast Iceland. Quantitative analysis will include ITRAX x-ray fluorescence and x-radiography, particle size analysis, magnetic susceptibility, and organic matter content, alongside radiocarbon dating and potential tephrochronology. These complementary proxies will give insight into the presence of tephra, lake productivity, soil erosion, organic matter content and catchment disturbance. Glacial geomorphological mapping has been carried out at nearby Skálafellsjökull, a southeast outlet glacier of the Vatnajökull ice cap, using a high resolution aerial orthophoto and digital elevation model, collected using an uncrewed aerial vehicle. Samples for cosmogenic He-3 nuclide dating have been collected from glacial erratic boulders from nearby mountain Skálafellshnúta, to constrain ice thickness and extent since the Younger Dryas.

This evidence from southeast Iceland will help to refine Holocene climate history, as well as further understand the relationship between North Atlantic Ocean circulation, terrestrial climate change and glacier response in this key region.

Deducing the timing of oceanic and ecosystem regime shifts south of Iceland across abrupt late Pleistocene climatic transitions: a multi-record, multi-method approach to geochronology

Independent chronological constraints on paleoceanographic reconstructions from marine sediments are vital when comparing local regime shifts with global atmospheric and oceanic circulation patterns through time and space. To investigate oceanic and marine ecosystem responses to abrupt climate change, we retrieved sediment cores from the Iceland and Irminger Basins (S-SW Iceland), situated along the inflowing Irminger Current and within the known region of polar frontal positions. We apply a multi-method chronological approach to a selection of these cores. At varying resolutions, we estimate that these records date from Marine Isotope Stage (MIS) 3, with one record likely extending back to at least 80 ka BP. We apply a range of geochronological techniques to constrain the timing of sea (sub-) surface temperature regime shifts derived qualitatively (planktonic foraminifera assemblages) and quantitatively (stable isotopes and Mg/Ca palaeothermometry). Dating methods include radiocarbon and paleomagnetic (relative paleointensity, paleosecular variation) dating, as well as tephrochronology, given the proximity to and extent of Iceland´s explosive volcanism. Dating methods independent of climatic variation (such as tephrochronology and relative paleointensity dating used here) are rather powerful as they allow us to establish appropriate local reservoir corrections to marine radiocarbon dates back through time. Secondly, by avoiding tuning our proxy records to e.g., ice core stratigraphy, we can better constrain lead/lag events of local oceanic and ecosystem regime shifts south of Iceland to millennial-scale global changes. Ultimately, this multi-method approach will allow us to establish a much needed reference event stratigraphy for future paleo-studies in this dynamic region.

Late Pleistocene to Holocene depositional environments in the Southern East Siberian Sea

Dr. Daria Ryabchuk [1], ***Mrs. Ekaterina Nosevich*** [1], ***Dr. Vladimir Zhamoida*** [1], ***Dr. Alexander Sergeev*** [1], ***Dr. Ekaterina Taldenkova*** [1], ***Dr. Leonid Budanov*** [1], ***Mrs. Zinaida Pushina*** [1], ***Mr. Igor Neevin*** [1], ***Dr. Leila Bashirova*** [1], ***Mrs. Ekaterina Ponomarenko*** [1], ***Ms. Diana Prishchepenko*** [1]

1. *Independent Researcher*

New data on the geological sequence, composition, and genesis of Quaternary deposits in the most poorly studied area of Russian Arctic – southern East Siberian Sea and southwestern Chukchi Sea - were collected during marine geological expeditions of A.P.Karpinsky Russian Geological Research Institute (VSEGEI) carried out in 2018 and 2020. During these cruises, 3400 km of seismic survey (UHR) and sub-bottom profiling (SBP), 3200 km of side-scan sonar survey and multibeam echo sounder, 191 surface sampling sites (box corer) and 31 long cores (gravity corer) were obtained. Five acoustic units of Quaternary deposits were identified. The upper two (Late Pleistocene and Holocene) were studied in the sampled sediment cores. Processing and interpretation of geophysical data, and the multiproxy study of sediment cores, including layer-by-layer grain-size, geochemical, diatom, palynological, and microfossil analyses as well as radiocarbon dating, were used for reconstructing geological development of the region in accord with palaeoclimatic and palaeogeographic aspects of its environmental evolution in the Late Pleistocene and Holocene. During the Sartan cold epoch (MIS 2) the studied offshore area was exposed. No glacial landforms were found of the seafloor. During the first warming stage and the onset of transgression (18-11 ka BP) the studied area remained exposed. According to lithology, geochemistry, diatom and microfossil analyses, sediments of this age mainly accumulated within shallow freshwater thermokarst lakes and river valleys. Pre-Holocene bottom topography predetermined the east-west direction of the shallow shelf flooding. By 11 ka BP, a large semi-enclosed lagoon was formed to the east of Wrangel Island, in the Chukchi Sea. About 10 ka BP, the area around Wrangel Island was separated from the mainland by straits, and elongated estuaries were formed within palaeovalleys of the Kolyma and the Indigirka rivers. By 8.5 ka BP, the palaeocoastline in the eastern East Siberian Sea was close to the modern one, while New Siberian Islands remained connected with the mainland. Sea level rise in the Holocene was irregular as evidenced by characteristic submerged landforms (longshore bars, underwater terraces, foredeltas, etc.) and stabilized around 5 ka BP. This research was supported by the Russian Science Foundation, project 22-27-00412.

The Climate Complexity of Atmosphere, Water Masses & Ice-Drift Patterns in the Nordic Seas: New Insights from the Holocene

Dr. Henning A. Bauch [1]

1. *Helmholtz Centre Alfred Wegener Institute for Polar and Marine Research c/o GEOMAR, Kiel*

Temperature-sensitive climate proxies from the north polar latitudes – ice cores, terrestrial and marine archives alike – show a tight connection to northern insolation with highest temperatures noted in the early Holocene. For further in-depth understanding of the post-glacial environmental development within and around the Arctic the Nordic seas are of special interest because it comprises a through road for the oceanic heat from the N. Atlantic via the Norwegian Atlantic Current (NAC) northward on the one hand and the southward flow of polar waters from the Arctic Ocean on the other. The situation leaves the formation of three oceanographic water mass components separated by the Arctic Front (AF) and the Polar Front (PF).

Using O-isotopes, planktic foraminiferal assemblages and ice-rafted detritus (IRD). It is shown that highest surface temperatures occurred between 11 and 9 ka. An intermittent cold phase around 8 ka is associated with IRD and increases of polar species *N. pachyderma.* Afterwards, higher surface temperatures were regained but started to decrease at the AF after 6 ka, concomitant with a persistent occurrence of IRD and a cooling trend which continued until today. Within the warm NAC water mass, by contrast, relatively stable and warm conditions persisted until 2.5 and 1 ka, in both planktic and benthic O-isotopes. Although variability among certain foraminiferal species would indicate some surface changes, the abundance of *N. pachyderma* increased to 70 % during the last 1ka (i.e., during the Little Ice Age). That drastic increase was associated with highly variable O-isotope values throughout the entire water column.

While records until the mid-Holocene (5-6 ka) occurred under circumstances still related to the overall post-glacial environmental reorganization (i.e., deglaciation, global sea-level rise and associated Arctic Ocean sea-ice expansion onto the vast shelf areas), the situation observed since then is interpreted to be mainly driven by atmospheric circulation changes. The atmosphere forced more Atlantic surface water towards the Arctic during the last few millennia, a situation which invigored water mass dynamics and frontal system changes in the Nordic seas.

A Holocene multiproxy record to assess ice-ocean interactions and ecosystem changes in Melville Bay, northwest Greenland

Amplified warming of the Arctic region is leading to enhanced discharge from the Greenland Ice Sheet and accelerating loss of sea ice. These rapid changes in the Arctic cryosphere affect the ocean circulation, earth's albedo, ocean-atmosphere heat and gas exchange and polar ecosystems. At the base of the marine food web, primary producers such as sea ice microalgae and phytoplankton (including diatoms and dinoflagellates) are important in sustaining higher trophic levels. Marine sediment records are valuable archives holding past environmental information to assess how a changing cryosphere impact the marine ecosystem functioning and structure. We will present results from a recently retrieved Holocene core from Melville Bay, Northwest Greenland (gravity core LK21-IC-St26-GC1; 75°19'10.67"N, 61°54'24.44"W; water depth 912 m). Melville Bay is a climate-sensitive region receiving substantial volumes of meltwater discharge from the Greenlandic Ice Sheet that is subject to strong seasonal sea ice variability. Furthermore, this region benefits from a protection status as a marine wildlife sanctuary. We designed a multi-proxy approach to reconstruct past seasonal sea ice, ocean circulation and marine productivity changes based on biomarkers (Highly-branched isoprenoids or HBIs, including IP_{25} (Ice Proxy with 25 carbon atoms), phytosterols and microfossils (dinoflagellate cysts and foraminifera) as well as bulk descriptors of organic matter composition (e.g., total organic carbon (TOC), nitrogen (TN), sulphur (TS), calcium carbonate (CaCO3) and stable isotopes (13C and 15N)). We explore past responses to climate variability recorded in this Melville Bay sedimentary archive and implications on the ecosystems under a sustained warming trend in the Arctic region.

A promising archive of High Arctic Holocene temperature variability: lake sediments from Peary Land, North Greenland

Dr. Tobias Schneider [1], ***Dr. François Lapointe*** [2], ***Dr. Bianca Perren*** [3], ***Prof. Nicholas Balascio*** [4], ***Prof. Raymond Bradley*** [2], ***Prof. William D'Andrea*** [1]

Arctic amplification of global warming is resulting in alarming rates of temperature rise in the High Arctic, and rapid changes to landscapes and ecosystems. To constrain the sensitivity of High Arctic sites and make meaningful predictions about future change, we must examine the sensitivity of these regions to past changes using natural archives. We will report on the potential of the varved lake sediments of "Lake SW" in Peary Land (82.1°N, 35.7°W), located 3km northeast of the Storm Iskappe glacier, as a high-resolution temperature archive to expand the regional temperature history beyond the instrumental measurement period. The sediments were collected in August 2021 and a robust chronology was established using a combination of varve counting and radionuclides (^{210}Pb, ^{137}Cs, ^{241}Am and ^{14}C). A suite of scanning techniques was then employed (computed tomography, µX-ray fluorescence scans, hyperspectral imaging) together with alkenone-thermometry (U_K^{37}), C/N- and diatom analyses to reconstruct the lake's productivity (green pigment concentrations and fluxes, *GP*), anoxia (bacterio pheophytin concentrations and fluxes, *BPhe*), and temperature histories over the last millennium.

We observe the highest *BPhe* values between ~1490-1900CE suggesting a phase characterized by prolonged anoxia. Simultaneously, the diatom assemblage along with low alkenone-derived temperatures indicate cold and dark icy conditions characteristic for heavy ice cover. This phase coincides with the LIA, and thus might be caused by regular perennial ice-cover extents that increase thermal stratification of the water column (oxygen depletion). Between ~1900-1990CE an increase in *GP*, and a diversification in the benthic diatoms may be associated with larger moating around the lake, more nutrient input and slightly higher water temperatures. The period after ~1990CE is characterized by the arrival of planktonic diatoms, the warmest observed alkenone-derived temperatures, and a significant decrease in *BPhe* suggesting extended periods of open water. Further statistical comparison of the *GP* and temperature will reveal whether the productivity is limited by temperature, which would allow proxy-to-proxy-calibration to increase temporal resolution of the temperature record.

We present evidence that sediments from "Lake SW" are a promising high-resolution archive of local temperature variability for the late Holocene in an area that is lacking high-resolution terrestrial paleoclimate records.

Holocene Hydroclimate, Catchment Development and Ontogeny as Drivers of Arctic Lake Carbon Cycling

Lakes are an abundant feature in the Arctic, and act as long-term storage and atmospheric source of carbon (C). The fast warming in the Arctic is coupled with an intensified water cycle due to the sea ice decline enhancing atmosphere-ocean interactions. Climate change can potentially alter lake C cycling through higher temperatures enhancing aquatic productivity, but also through increasing precipitation as rain that may amplify terrestrial C load. Thus, the rate of C accumulation and the sources of organic C to lakes will potentially be altered. However, the link between hydroclimate change and C cycling in Arctic lakes is not fully understood. Lake sediments allow the study of C cycling responses to past climate fluctuations.

Here, we present records from Lake Kuutsjärvi, northeastern Finland, to examine Holocene changes in the quality and quantity of organic C in the sediments (total organic C and nitrogen -N, and $\delta^{13}C$, $\delta^{15}N$) and their possible coupling with regional hydroclimate change ($\delta^{18}O$ from fossil chironomid head capsules). We use modern-day materials to calibrate both geochemical approaches. Modern lake OC sources differentiate discernible geochemical groups for terrestrial vegetation, aquatic vegetation (~benthic mosses), as well as phytoplankton. Lake water and precipitation water isotopes collected over full annual cycle show that the lake represents isotopic composition of local precipitation, even in summertime. The results show that climate is the main driver of the C accumulation rates and the proportional contributions of aquatic and terrestrial sources through time, data also demonstrates the important role of changes in lake ontogeny and catchment land cover. Organic C accumulation rate (OCAR) was low in the early Holocene, then rising with higher terrestrial contribution during the Holocene Thermal Maximum (HTM) and subsequently decreased significantly with increasing contribution from aquatic production. The warm HTM climate likely changed the hydrologic mode towards partially closed, and together with the denser vegetation increased the terrestrial C load. In the late Holocene, apparent OCAR slowdown was caused by sediment infilling, while aquatic sources predominated probably because of the upsurged moisture that opened the system and allow terrestrial material to flow out of the lake.

Nuanced responses of seasonal sea ice to a warmer Arctic climate during the Holocene Thermal Maximum

While climate model simulations provide valuable insight into potential future Arctic sea-ice scenarios, marine geological archives offer key information on how sea ice responded to substantial climatic warming in the past, particularly during periods characterized by warmer-than-present conditions. The HTM (Holocene Thermal Maximum), ~10.0-6.0 cal ka BP, was the last major period of warm climate expressed in warmer air and ocean temperatures across the globe. Although a result of orbitally-forced summer insolation, the HTM constitutes a valuable parallel to the greenhouse-gas-driven setting of a current (and near-future) warmer world. At higher latitudes in the Northern hemisphere, the HTM has been proposed as an interval of reduced sea ice and increased Atlantic water inflow, similar to a projected future warmer Arctic Ocean. Two sediment archives elucidate the early Holocene HTM evolution of high Arctic seasonal sea ice in the northern Barents Sea (>80°N), a key area for Atlantic-Arctic Ocean water interaction in a hotspot of current climate warming. HBI (highly-branched) biomarkers (IP_{25}, $IPSO_{25}$, HBI III, HBI IV) unequivocally demonstrate the persistence of spring seasonal sea-ice as high as 55% between 11.7 and 9.1 cal ka BP. Concomitant high $\delta^{18}O$ in benthic foraminifera and elevated phytoplankton biomarker (HBI III, HBI IV) concentrations indicate the influence of warm Atlantic-derived bottom water and peak bioproductivity, respectively. Our results highlight the nuanced and complex cryospheric response to climate warming, showing High Arctic sea ice persisting in a setting of warmer-than-present spring and summer conditions under a concomitant increased inflow of subsurface Atlantic Water. This raises important questions about the fate of Arctic sea ice, oceanography, and ecosystems (including commercially important fisheries) in an increasingly warmer climate driven by anthropogenic factors.

Methane cycling in lakes in Alaska in response to warmer and wetter conditions during the Holocene

Global temperatures are increasing at an unprecedented rate, with northern high-latitude regions warming almost twice as fast as the global average. High-latitude landscapes hold a large proportion of the world's freshwater lakes and ponds, which are highly vulnerable to climate change and a natural source of methane, a fundamental greenhouse gas. As temperatures rise, methane emissions from these lakes are also expected to increase; however, the magnitude and timing of this increase remains uncertain.

Proxy-based estimates of lake-methane production during warmer periods, such as the early Holocene (8,000 - 11,000 cal BP) can help validate model simulations of how much methane can be produced and released in lake systems under warmer climates. These proxies include the stable-carbon isotope values ($\delta^{13}C$) of aquatic invertebrate remains and bacterial hopanoids. The $\delta^{13}C$ values measured on sedimentary remains of these proxies are lower when methane-derived carbon is an important part of the lake carbon cycle. We provide proxy-based estimates of methane production from lakes in Alaska that suggest that during the Holocene Thermal Maximum, methane availability could have been 2-5 times higher than at present.

Tracking circulation change in the western North Atlantic during the Little Ice Age using a multi-proxy approach

Ms. Wai Ching Rachel Chu [1]***, Dr. Christelle Not*** [2]***, Prof. Anne de Vernal*** [3]***, Dr. Benoit Thibodeau*** [1]

1. *The Chinese University of Hong Kong,* ***2.*** *The University of Hong Kong,* ***3.*** *Geotop-Université du Québec à Montréal, Montréal, Canada*

The Little Ice Age (LIA), a period from approximately 1350 A.C. to 1850 A.C., is characterised by an abnormal cooling in the Northern Hemisphere. The role of ocean circulation for the onset of the LIA is still equivocal. Notably, potential changes in the western North Atlantic circulation were highlighted during this period and the changes were found to be linked to a relatively weak Labrador current. Since these studies were based solely on oxygen isotopes, it is difficult to ascertain the cause of the observed change in oxygen isotopic signals to either a change in circulation and water masses influencing the coring location for this study, or to a change in water temperature, or even a combination of both. Therefore, to better understand the ocean circulation dynamic over the LIA in the western North Atlantic, the previously established oxygen isotope result will be constrained from the Mg/Ca ratio data in this study.

Two cores collected in the Laurentian Channel were selected for this study: 1) CR02-23 (48º42.008'N, 68º38.894'W), will be used to establish a Mg/Ca calibration curve against instrumental temperature over the last 60 years; 2) The section covering LIA will be analysed in high-resolution in MD99-2220 (48º38.32'N, 68º37.93'W). The two cores are selected because of the high sedimentation rate in the Laurentian Channel and the already-available oxygen isotopic data. The benthic foraminifera species, *Globobulimina auriculata*., was selected for the Mg/Ca ratio paleo-temperature reconstruction because it has been well-calibrated in other regions and has a high temperature sensitivity.

Using these data, new knowledge about the potential role of ocean circulation and its linkages with cooler condition during the LIA will be produced.

Calibration of subfossil chironomids as paleoclimatic indicators in eastern Canada and application for forest ecosystem dynamic studies

The concept of reference state is increasingly used to guide environmental policies and management. This is notably the case for Quebec forests, where the pre-industrial natural state serves as a reference for the ecosystem-based management of the modern forest. Palaeoecological records can help define a reference state by providing ranges of natural variability in relation with climatic fluctuations. This kind of approach requires appropriate and independent reconstructions of vegetation, perturbation regime and climate at local and regional scales. However, in temperate and boreal regions, paleoclimatic and vegetation data are often derived from pollen assemblages, leading to circular reasoning. Consequently, other paleoclimatic proxies independent of vegetation should be used. Our long-term goal is to develop the use of subfossil chironomids from lake sediment as summer temperature indicators in eastern Canada, with the final purpose of carrying out multiproxy studies on the dynamics of forest ecosystems. We assessed the environmental control of the modern distribution of chironomid taxa with assemblage data from surface sediment samples distributed along a climatic gradient ranging from the Canadian Arctic to the temperate zone of New England. Canonical analysis identified summer air temperature as the main factor influencing taxonomic composition of assemblages. Thus, as already indicated by previous work in Europe and North America, we confirmed the potential of chironomids as paleoclimatic indicators and a well performing temperature inference model has been developed. This new transfer function was then applied to a 9000-year chironomid record from Lake Charrier, located at the temperate-boreal transition zone of Quebec. This allowed the reconstruction of the major postglacial climatic changes, like the initial warming after the retreat of the Laurentian ice sheet, the Holocene thermal maximum and the Neoglacial cooling. The joint analysis of the summer temperature reconstruction with charcoal and pollen records also provides new insights into the climatic control of forest ecosystem dynamics in the region during the Holocene.

Chironomid-based palaeotemperature and precipitation oxygen isotope estimates for the North Atlantic region (Azores archipelago)

The location of the Azores Archipelago in the North Atlantic makes this group of islands an excellent setting to investigate past long-term temperature and precipitation changes in the middle of the North Atlantic region. Here, we present a chironomid-based temperature reconstruction and oxygen isotope composition from chironomid head capsules for the last 1500 years, using Prata Lake sediment record (São Miguel, Azores). The reconstructed mean July air temperatures range between 15.0 and 9.1ºC. The highest temperature values (13.5±1.5ºC) were recorded during the Medieval Climate Anomaly (MCA), transitioning to the lowest temperature values (ranging from 10.5 to 12.7°C) during the Little Ice Age (LIA). Also, changes in lake water oxygen isotope composition from chironomid head capsules were recorded with more positive ∂^{18}O values (18.2±0.2‰), during the MCA and more negative values (vary between 14.8‰ and 17.6‰) during the LIA, indicating a positive shift in the precipitation-evaporation balance and/or heavier precipitation in the winter relative to summer. The chironomid inferred changes in temperature and precipitation track north Atlantic temperature and isotope records indicating that the previously reconstructed high latitude MCA warming and LIA cooling extent to the mid-latitudes of the central Atlantic region. In comparison with past climate model simulations of the region, an overall humid with warmer-than-usual conditions dominated the end of the MCA, and colder temperatures between 1400 and 1500 CE. Changes in the North Atlantic Oscillation (NAO) and Eastern Atlantic (EA) pattern during the last millennium suggest they would be controlling regional winter precipitation and summer temperatures, respectively.

Sedimentary biomarkers and leaf wax hydrogen isotopes reveal complex Holocene climatic and environmental dynamics in the Sumava Mountains, Central Europe

Lipid biomarkers preserved in lake sediments are increasingly being employed to reveal various facets of past climate and environmental dynamics. For example, hydrogen isotopic ratios (δ^2H) from plant cuticular waxes were used to infer past atmospheric circulation changes or variability in climate modes, while GDGT compounds from bacterial membrane as proxies for palaeotemperature. However, not all processes controlling lipid biomarker and their isotopic variability, that operate at the local scale, are well understood. This, added to the scarcity of Holocene palaeoclimatic records in Central Europe, limits our understanding of continental hydrology and its links to finer-scale palaeoclimatic variability and past vegetation and disturbance dynamics. Here we determine δ^2H from sedimentary leaf waxes to reconstruct Holocene moisture patterns and branched (brGDGT)/ isoprenoid GDGTs (isoGDGT) from sediment organic matter to derive temperature variability, based on a lacustrine archive located in the high coniferous forest belt of Šumava Mountains, Czech Republic. We then employ pollen, charcoal, sediment geochemistry and locally-downscaled climate models to explore local factors (e.g., vegetation structure and type, canopy density, soil characteristics, natural and anthropogenic disturbances) potentially affecting the biomarker signal and reconstructed values.

Results show strongly depleted δ^2H values around 11.5, 9.5, 7.5-7 and 3-2 ka BP and strongly enriched values around 8.2 ka BP. A decoupling between δ^2H of the long-chain n-alkanes originating from higher terrestrial plants, as opposed to medium-chain n-alkanes related to aquatic plants occurred around 6 ka BP and likely reflects the isotopic composition changes due to increasing canopy density of primary forests, soil paludification and absence of disturbances (fire, erosion). The major hydrological patterns over the late Holocene follow the NAO index variability. Reconstructed temperatures based on brGDGT and isoGDGT show a similarly ascending trend until 6 ka BP and diverge thereafter. We interpret the diverging brGDGT values as locally influenced by soil pH, due to the progression of podsolization and paludification processes affecting the catchment soils. Conversely, isoGDGT largely follow winter insolation trends and appear to reflect winter water temperature.

Our data highlight the utility of assessing sedimentary biomarkers within a palaeoecological multiproxy dataframe to disentangle the complex biomarker signals in lacustrine archives.

What do dinoflagellate cyst sedimentary records in the Santa Barbara Basin tell us about the changing ocean?

Dr. Vera Pospelova [1]***, Dr. Manuel Bringué*** [2]***, Dr. Kenneth N. Mertens*** [3]

1. Department of Earth and Environmental Sciences, University of Minnesota, 2. Natural Resources Canada, Geological Survey of Canada, Calgary, 3. Ifremer, LITTORAL, Concarneau, France

Understanding abrupt environmental changes, including those caused by the rapidly warming oceans is a challenging task and requires a compilation of long-term environmental or paleoenvironmental data. Such data are hard to obtain and often even harder to interpret because of unevenness in sampling coverage or potential issues with assembling and interpreting data at different timescales. Dinoflagellate cysts are sensitive and reliable paleoenvironmental indicators, and their use has increased over the last decades, especially for high-resolution applications in the Pacific Ocean. Dinoflagellates are one of the most diverse and abundant groups of microalgae in coastal environments and are major primary producers. During their life cycle, many dinoflagellates produce highly resistant organic-walled resting cysts that accumulate in sediments, and their records contain information about upper water masses at the time of deposition.

In this presentation, we summarize what we have learned from high-resolution dinoflagellate cyst sedimentary records that span from seasonal to annual, annual to decadal, decadal to centennial, and centennial to millennial scales in the Santa Barbara Basin (SBB), southern California. The SBB is a deep semi-enclosed basin located on the NE Pacific margin and is characterized by high primary productivity and restricted deep-water circulation resulting in exceptionally preserved sedimentary records under anoxic conditions. The basin has been extensively studied over decades and can now be considered one of the best-researched sites on dinoflagellate cysts in the world. Cyst census data from the contemporary sedimentary trap record, last century sediments, as well as from the Holocene and the Last Interglacial cores allow us to observe changes in the ecosystem responding to the warming ocean. We attempt to reconcile these inferences and provide a unifying interpretation of our observations.

Response of palynological and chemical proxies to climate variability in the southern Gulf of California from ~4,487 to ~260 years BP.

Dr. Javier Helenes [1]***, Dr. Juan-Gabriel Flores- Trujilo*** [2]***, Ms. Lita Castañeda-Betancur*** [1]***, Dr. Miguel-Ángel Huerta-Díaz*** [3]***, Dr. Karla-G. Mejía-Piña*** [4]

Synchronous response from geochemical and palynological data from laminated sediments in La Paz Basin, allow recognition of centennial variations on rainfall and marine productivity from ~4487 to ~260 years BP. Concentrations of the paleoclimate proxies Ti and Fe (terrigenous input) and Mo (anoxia) were obtained by X-ray fluorescence analyses and total organic carbon concentrations (TOC, primary productivity) with a CO2 coulometer. Concentrations of marine (dinoflagellates and copepods) and continental palynomorphs (pollen and spores) indicate changes in marine primary productivity (MPP) and rainfall (RF). Our chemical results have significant statistical correlations and graphic similarity with palynological data obtained from some of the same samples. Concentrations of TOC show an increasing trend through time, and correlate with heterotrophic dinoflagellates and copepods, indicating the predominance of MPP. Values of these proxies separate four intervals: from 4375 to 3050 BP the values are low, reaching medium values from 3050 to 1500 BP, while from 1500 to 900 BP the MPP is low, and from 900-290 BP, reach their highest values. Concentrations of Ti and Fe are statistically and graphically correlated with spores and autotrophic dinoflagellates, indicating their reliability, as proxies for RF. Values of these parameters are relatively stable, and define four intervals. From 4375 to 3700 BP, they represent low RF; then, from 3700 to 3000 BP, RF increased to medium values, and from 3000 to 600 BP, RF increased to high values, with a short dry period from 1250-1200 BP, after which RF reached its highest values (1050 to 600 BP). Finally, from 600 to 290 BP, RF reached mainly medium values. The proxies used in this work allow identification of regional conditions as an extreme drought period (1280-1070 BP) reported in southwestern North America, or global events like the Medieval Warm Period (1078-706 BP) and the Little Ice Age (706-260 BP).

Do past forest fires influence Daphnia abundances in small headwater lakes of British Columbia, Canada?

Dr. Colin Courtney-Mustaphi [1], ***Dr. Oliver Heiri*** [1], ***Prof. Michael Pisaric*** [2]

1. University of Basel, 2. Department of Geography and Tourism Studies, Brock University

Small subalpine lakes in thin soil, crystalline rock catchments are sensitive to catchment scale nutrient releases after high severity forest fires. High-resolution sediment-charcoal records provide evidence of past fires and concentrations of *Daphnia* resting stage egg cases (eggless ephippia) preserve a proxy signal of past abundances, which represent part of the secondary trophic level within the lake. The Holocene sediment record of a small (<100 m diameter, 0.35 ha area), shallow (2.4 m maximum depth), fishless, headwater lake (2074 m asl) in south-east British Columbia, Canada, provided a continuous record (median 14 years per sample) of both charcoal and sclerotized ephippia, analysed to explore temporal relationships and test links between fires and *Daphnia* production. Subsamples of 1 cm^3 were wet sieved (150 micron mesh) to retain charcoal and larger *Daphnia* ephippia. The accumulation rates of charcoal and *Daphnia* ephippia were positively correlated (r=0.42, n=663 samples). Peak-to-peak analyses showed significant synchrony (99% CI) of ephippia abundance peaks at time windows of 20-70 years after charcoal peaks that supported an interpretation of multidecadal-scale interactions between fire, forest recovery and the aquatic ecosystem. Additionally, the high concentrations of *Daphnia* ephippia offered an opportunity to quantify variations in ephippium dorsal length and to index ephippia opacity, both variables can be considered as proxy indicators of adult female *Daphnia* body size and degree of melanin pigmentation of ephippia. These physiological variables relate to visual predation pressure from trade-offs between camouflage and UV protection of eggs and were measured at a lower resolution downcore (n=35). There was little variation in ephippia dorsal length throughout the Holocene (mean=0.812 ± 0.072 mm, n=1246 individuals measured) and ephippia opacity decreased slightly over the Holocene with a higher proportion of more abundant darker ephippia during the early Holocene. The relationship between fires, forest succession and nutrient release into lakes occurs at scales from decades to a century post fire. These time scales coincide with the forest succession that follows severe fires and suggest long-term links between forest development and the aquatic trophic cascade.

Reconstructing past environmental change over the Holocene through marine and terrestrial proxies at Lyttelton Harbour, Banks Peninsula, New Zealand

Ms. Johanna Hanson [1]***, Dr. Catherine Reid*** [1]***, Prof. James Shulmeister*** [1]***, Dr. Matiu Prebble*** [1]***, Ms. Atun Zawadzki*** [2]***, Dr. Quan Hua*** [2]***, Dr. Christopher Moy*** [3]

1. *University of Canterbury,* ***2.*** *ANSTO,* ***3.*** *University of Otago*

Low elevation terrestrial and marginal marine settings will be sensitive to future changes in global sea level, temperature, natural hazards and environmental variability. It is of key importance to understand past environmental changes in order to provide baseline information on the pre-anthropogenically modified state of environmental systems and understand natural variability in these systems. Here we present a reconstruction of past environmental conditions over the Holocene at the marine-terrestrial interface at Lyttelton Harbour, Banks Peninsula, New Zealand. Banks Peninsula is a culturally, geologically and historically significant location in New Zealand representing among other things the southernmost limit for indigenous (Maori) agriculture, specifically kumara (sweet potato) cultivation in New Zealand. The peninsula also contains many micro-environments and significant terrestrial and marine resources for human populations. It is both a poorly understood and highly modified landscape. Here we present results from three sediment cores collected along a transect of the marine-terrestrial interface at Head of the Bay, Lyttelton Harbour to describe past environments, and rates and types of changes, in these environments through time. The environmental history is built up from micro-fossil analyses (foraminifera and palynomorphs), geochemistry (micro X-ray Fluorescence), geochronology (lead-210 and radiocarbon dating) and sedimentology (granulometry and sediment classification) to decipher natural and anthropogenic changes in land use, shallow water marine environments, vegetation cover, and erosion processes in the middle to late Holocene.

Coccolith productivity variations during the Holocene: influence of the NAO in the Mediterranean Sea.

Dr. Pietro Bazzicalupo [1]***, Prof. Patrizia Maiorano*** [2]***, Prof. Angela Girone*** [2]***, Prof. Maria Marino*** [2]***, Dr. Marie-Alexandrine Sicre*** [3]

In this work, we generated two high-resolution multi-proxy reconstructions from the Western and Central Mediterranean (Alboran Sea and South Adriatic Sea, respectively) over the Holocene period, using calcareous plankton assemblages and biomarkers. The two deep-sea marine cores analyzed (ODP-976, 1108 m wd, in the Alboran Sea and ND14Q-AR2, 1013 m wd, in the South Adriatic) are located in well-known climate-sensitive locations: the Alboran Sea, influenced by water exchange between Surface Atlantic Water and Deep Mediterranean Water, and the Adriatic Sea where river runoff and discharge of the Po River have a strong impact. These paleoclimatic proxies register, in high details, local/regional environmental changes that are driven by variations of atmospheric and oceanic circulations. Coccolithophore assemblages at both sites clearly show orbital-scale variations and short-term centennial scale variability known as Holocene Rapid Climate Changes (HRCC), that superimpose over the main trend. The comparison with several marine and terrestrial proxies allows us to interpret these hydrological variations as the result of atmospheric circulation forcing. In particular, in the Alboran Sea, short periods of increased productivity occur when Atlantic water inflow is stronger, accompanied by more arid conditions on land. In the Adriatic Sea, on the other hand, coccolithophore assemblages and terrestrial biomarker abundances are linked to increased humidity and flood activity in the Alpine region. In both cases the observed variability seems to be related to the North Atlantic Oscillation (NAO). Overall, our results underline the ability of calcareous plankton and biomarkers to capture high frequency environmental fluctuations in the Mediterranean Sea.

Ostracod faunal assemblage response to palaeohydrology, lake-level changed and carbon cycling in a Jamaican marl lake

Prof. Jonathan Holmes [1], *Ms. Hannah Greeenway* [1], *Dr. Michael Burn* [2]

1. University College London, 2. Liverpool John Moores University

Ostracods are small, generally benthic or epibenthic, aquatic crustaceans, which produce low-Mg shells that are often well preserved in Quaternary lake sediments. Fossil lacustrine ostracod species assemblages have variously been used to reconstruct temperature, hydrochemistry, water depth and hydrological habitat and ostracod-shell calcite is use for geochemical analyses in palaeoenvironmental reconstruction. In lakes, the full potential of ostracods as palaeoenvironmental proxies may not be realised owing to incomplete information about the ecological tolerances of species in assemblage and limited knowledge of the workings of the modern lake. Here, we show using a study of Wallywash Great Pond, Jamaica, how the use of ostracod assemblages as proxies for lake-level and hydrology can be improved by using complementary palaeohydrological information and by an understanding of modern limnology of the lake modern ostracods from Jamaica. Wallywash Great Pond is a small (area=76 ha, maximum depth=5 m) karstic lake in SW Jamaica. Previous work on late Pleistocene sediments from the lake suggested that changes in facies and ostracod assemblages reflected variations in lake level in response to precipitation-evaporation balance. More detailed, higher resolution investigations of sediments from the common era show that although previous interpretations are generally true, there is greater subtlety in the reading of the record when evaluated with oxygen and carbon isotope data and modern limnological investigations. Ostracod assemblages and sediment type (organic mud to marl) suggest deepening of the lake midway through the sequence, around 800 CE. However, this seems at variance with stable-isotope data, which may suggest a switch to lower precipitation-evaporation (P-E) balance. Taxonomic uncertainties associated with the dominant deepwater species can be ruled out as an explanation of the discrepancy based on modern collections In Jamaica. Instead, supposed shallow-water taxa are associated with more organic-rich sediment and lower oxygen-isotope values. Distribution of ostracods and sediments in the modern lake suggest that the organic-rich sediments represent greater inflow of groundwater that is undersaturated with respect to calcite under wetter conditions rather than lower P-E. Our findings illustrate the importance of modern limnological and multiproxy investigations in the interpretation of ostracod faunal records from shallow lakes.

Late Holocene transition from natural to anthropogenic forcing of vegetation composition and fire regimes in the western Nanling Mountains, subtropical China

Ms. Mingying Quan [1], ***Prof. Wei Zhong*** [1], ***Mr. Xiaojun Wang*** [1], ***Ms. Bingxiang Wang*** [1], ***Mr. Tianhang Li*** [1]

1. School of Geography, South China Normal University Guangzhou

Understanding the response of forest vegetation to climate, fire regimes and human disturbance is crucial to provide valuable insights to protect current and future ecosystems. However, such studies were poorly carried out for the montane areas of subtropical East Asia with large forests. In this study, we examined pollen and charcoal records of a 95 cm–long peat core from the Daping swamp in the western Nanling Mountains in subtropical China, in order to assess the regional vegetation and fire history and discuss the possible interactions among vegetation, fire, climatic change, and human activities in late Holocene. Our results indicate that the vegetation dynamics and fire regimes were mainly controlled by climate change with minor human disturbance during 3140–2230 cal yr BP. After ~2000 cal yr BP, the residents expanded to deep montane areas and engaged in hunting and logging as their survival strategy, while no strong evidence of farming was detected. The sharp increase in charcoal concentration after 630 cal yr BP suggests a large scale of human activities from the lowland to the higher montane areas, probably due to the official plan to develop terrace land for agricultural use and the rapid population growth since the Yuan Dynasty, which agrees well with the observed vegetation shift from dense forests to more open landscape. Our results strongly show 630 cal yr BP marked the important transition timing from natural to anthropogenic forcing of vegetation composition and fire regimes in the western Nanling Mountains, subtropical China. Regional comparison of charcoal records reveals that human disturbance in the montane areas was significantly intensified later than that of the coastal areas in southeast China. This spatial asynchronized timing and extent of human activity intensity in subtropical south China was likely related to the development of agriculture, as well as to the increase of population and migrations in Chinese history.

Phosphate oxygen isotopes: a palaeoenvironmental proxy from lake sediments

Dr. Andrew Smith [1], ***Dr. Alistair Seddon*** [2], ***Prof. Katherine Willis*** [3], ***Dr. Ana Prohaska*** [4]

Understanding controls on regional nutrient dynamics is not just fundamental for combatting modern pollution but also to untangle drivers and consequences of past environmental change. Like nitrogen (N), phosphorus (P) is a limiting nutrient in many systems, including tropical soils, which support highly productive and diverse ecosystems. How P has cycled within the environment over time may therefore exert a critical influence on regional biological diversity and productivity. Where detailed study into the life cycle of carbon (C) and N has been facilitated through stable isotope tracing, P research has been restricted as it only has one naturally occurring stable isotope. Here we explore the potential for utilising the oxygen (O) isotope composition of phosphate (PO_4) within lake sediments to trace temporal variations in P sources and cycling over time. We use sediments from Bulusan Lake (Philippines) as a show case of this approach. Previous work showed variable trace element concentrations (including P) and vegetation productivity markers over the last 1,400 years, linked strongly to regional volcanism. Initial evidence from stable phosphate oxygen isotope analysis of the lake sediments indicates that whilst volcanism could be thought to have an immediate soil fertilisation effect through the addition of P rich ash, this effect is at first limited by an associated reduction in soil pH. Reductions in soil pH cause P to become bound to Fe and Al, reducing P solubility and initially limiting bioavailability of this new source of P. However, in the years following ashfalls it is clear from the stable isotope data that mineral P from volcanic ash is released and cycled. Vegetation productivity indicators are strongly linked to P over longer time scales within the Bulusan record; indicating that this volcanic P addition may act as a fertiliser for surrounding nutrient poor soils and the rich rainforest ecosystem they support.

Session 15: Understanding regional and global monsoons changes across timescales

Upper ocean thermal state and monsoon rainfall

Dr. Mahyar Mohtadi [1], ***Prof. Zhimin Jian*** [2], ***Dr. Yue Wang*** [2], ***Dr. Haowen Dang*** [2], ***Prof. Yair Rosenthal*** [3], ***Dr. Martina Hollstein*** [1], ***Dr. Matthias Prange*** [1]

1. *MARUM-Center for Marine Environmental Sciences, University of Bremen,* **2.** *State Key Laboratory of Marine Geology, Tongji University, Shanghai,* **3.** *Department of Marine and Coastal Science, Rutgers University, New Brunswick*

Monsoon reconstructions suggest that same forcing mechanisms result in a nonuniform spatiotemporal rainfall response. Modelling efforts are critical to understand the competing impacts of different forcings on rainfall and support a substantial regional character. However, simulating past rainfall changes remains a difficult task particularly in the tropics, where models show a large spread in regional rainfall amount and differ from reconstructions. Upper ocean temperature (UOT) is one of the main sources of uncertainty when simulating past and future monsoon rainfall. To decipher the coupling between UOT and monsoon rainfall, particularly under warm climatic conditions, we combine a network of proxy-based reconstructions of UOT and rainfall from the Australasian monsoon realms with numerical model simulations. We show that the thermal state in the upper 200 m of tropical oceans is more sensitive to insolation gradient, rather than ice volume changes, and is critical for changes in monsoon precipitation on interannual to orbital timescales. Equilibrium simulations suggest that the upper tropical ocean acts not only as a moisture source but also as an amplifier of relatively small changes in the forcing, thereby regulating the global hydrological cycle.

Subdecadally resolved molecular proxy-based sea surface temperature reconstructions from the northeast Arabian Sea and implications for the Indian monsoon strength between 11,000 and 2,000 years BP

Dr. Igor Obreht [1], Dr. Andreas Lückge [2], Dr. Lars Wörmer [1], Dr. Mahyar Mohtadi [1], Prof. Kai-Uwe Hinrichs [1]

1. MARUM, University of Bremen, Bremen, Germany, 2. Federal Institute for Geosciences and Natural Resources, Hannover, Germany

Coupled land-ocean-atmosphere interactions play a crucial role in climate variability on all time scales. Among these interactions, monsoons are one of the most important phenomena in low latitudes. The Indian monsoon rainfall has a direct effect on the livelihoods of two billion people in the Indian subcontinent. However, monsoon dynamics on short time scales and their forcing mechanisms are still not fully elucidated.

Sea surface temperature (SST) variability from the northeast Arabian Sea is determined by the intensity of winter monsoon strength on centennial to millennial time scales, where stronger monsoon causes lower SST, and vice versa. In order to constrain high-resolution changes in monsoon intensity and its forcing mechanisms on decadal time scales, we reconstructed SST from the northeast Arabian Sea using alkenone- and GDGT-based SST proxies with a spatial resolution of 200 μm. Such resolution was obtained by applying mas spectroscopy imaging on sediment from finely laminated sediment core SO130-289KL (23°07.34′N, 66°29.84′E, 571 m water depth).

The 200 μm spatial resolution translates into a temporal resolution from 1 to 5 years, resulting in the first continuous subdecadally resolved SST record from the low latitudes between 11,000 and 2,000 years BP. In this presentation, we will examine the dominant periodicity from the SST time series in the multidecadal and centennial time bands. Moreover, we will constrain the decadal to centennial amplitude of proxy-based SST variability, and asses its implication for the Indian monsoon intensity. Ultimately, we will examine the decadal to the centennial phase relationship between alkenone- and GDGT-based SST proxies. This will allow testing the previously proposed hypothesis that when alkenone- and GDGT-based SST proxies are in anti-phase, the northeast Arabian Sea expresses stronger Indian monsoon, and vice versa.

Long-term and short-term vegetation responses of the central Cerrado to climate and anthropogenic activities during the Holocene

Ms. Katerine Escobar Torrez [1]***, Dr. Marie-Pierre Ledru*** [1]***, Dr. Raquel FRANCO CASSINO*** [2]***, Ms. Paula Ribeiro Bianchini*** [3]***, Dr. Elder Yokoyama*** [3]

1. *ISEM, Univ Montpellier, CNRS, EPHE, IRD, 34095,* ***2.*** *Departamento de Geologia-Universidade Federal de Ouro Preto,* ***3.*** *Instituto de Geociências, Universidade de Brasília*

The principal objectives of this study were to evaluate the different responses of the association between vegetation, fire and climate of the central Cerrado under both natural and anthropic disturbances during the Holocene. Our study area is located in Central Brazil, Lake Feia close to the capital Brasília. To reach our goals, vegetation, climate changes, and fire activity were reconstructed using pollen and macrocharcoal deposited in a sediment core from a lake and the chronology was based on accelerator mass spectrometry radiocarbon analyses. Additional XRF analysis was used to determine changes in sediment. Our results showed full development of the Cerrado vegetation in central Brazil started 6000 years ago and followed a two-step process. A long-term influence driven by the increase in summer insolation showed first an open cerrado replaced after 5000 cal yr BP by a woody cerrado. A short-term millennial-scale variability since 4830 cal yr BP that includes 7 intervals of retreat and expansion of the gallery forest due to local changes in hydrological conditions under a continuous fire activity with two extreme peaks at 3340 and 1290 cal yr BP. We conclude that vegetation changes at lake Feia provide evidence about the sensitivity of the Central Cerrado to climate conditions and human inferences. During the Late Holocene, the frequent shifts in northern and southern SASM boundaries drove the expansion and regression of the different floristic assemblages of the Cerrado. A continuous biomass burning under a low fire regime was abruptly interrupted by two intervals of higher fire activity during moist climatic conditions and likely related to human settlements in the region of Lake Feia reinforcing the regional archeological studies.

Multi-decadal to centennial scales variability in the East Asian Summer Monsoon around the 5.5 kyr B.P. climate event

Ms. Fang Wang [1], Prof. binggui Cai [1], Prof. Chuan-Chou Shen [2], Prof. Hai Cheng [3], Mrs. Miaofa Li [1], Ms. Tingting Li [1], Prof. Ming Tan [4], Prof. R. Lawrence Edwards [5]

Key Laboratory of Cenozoic Geology and Environment, Institute of Geology and Geophysics, Chinese Academy of Sciences, 5. Department of Earth Sciences, University of Minnesota

Understanding the variability in mid-Holocene climate on multi-decadal to centennial scale, including the well-known "5.5 kyr" cold event, is important to better evaluate the East Asia Summer Monsoon (EASM) change under increasing global warming scenarios. In the last few decades, stalagmite oxygen isotope records have been widely used as a proxy of EASM, however, most of high-resolution stalagmite records are from southern China. In this study, a four-yr resolved $\delta^{18}O$ record of a stalagmite TW704 from north-eastern China was used to reconstruct regional precipitation and EASM from 5.82 – 4.77 kyr BP (before 1950 AD). The inferred EASM variation generally agrees with previous published stalagmite records from southwestern and central China, suggesting synchronous variations of the EASM on decadal to centennial scale in monsoonal China. Our new record also features relatively large decadal-centennial EASM oscillations in the northern China with two centennial-scale weak EASM events, centred at 5.6 and 5.0 kyr. The former one corresponds to the well-known "5.5 kyr" cold event occurred in the high-latitude North Atlantic Ocean. The depressed EASM events were probably caused by prolonged periods of El Niño, resulting in decreased precipitation over north-eastern China. Our study supplies robust evidence to support the hypothesis that ENSO plays an important role in the EASM during the mid-Holocene.

Asynchronous Holocene Optimum in East Asia monsoon region recorded by stalagmites and its underlying climate dynamics

Mr. Ming-Qiang Liang [1], ***Dr. Qiuzhen Yin*** [2], ***Prof. Hong-Chun Li*** [3], ***Dr. Yong Sun*** [4], ***Dr. Peter Hopcroft*** [5], ***Prof. Ting-Yong Li*** [6], ***Mr. Zhipeng Wu*** [7]

1. *Earth and Life Institute, Georges Lemaître Centre for Earth and Climate Research, Université catholique de Louvain, Louvain-la-Neuve, Belgium,* ***2.*** *Earth and Life Institute, Georges Lemaître Centre for Earth and Climate Research, Université catholique de Louvain, Belgium,* ***3.*** *National Taiwan University,* ***4.*** *State Key Laboratory of Tibetan Plateau Earth System, Resources and Environment (TPESRE), Institute of Tibetan Plateau Research, Chinese Academy of Sciences,* ***5.*** *University of Birmingham,* ***6.*** *Yunnan Key Laboratory of Plateau Geographical Processes & Environmental Changes, Faculty of Geography, Yunnan Normal University,* ***7.*** *Georges Lemaître Center for Earth and Climate Research, Earth and Life Institute, Université catholique de Louvain, Louvain-la-Neuve, Belgium*

Reconstructions of Holocene Optimum (HO) in East Asian summer monsoon (EASM) regime from speleothem versus other proxy records have yielded divergent phase relationships with the EASM and local precipitation. This apparent discrepancy has been partly attributed to the uncertainties in the climatic representation of Chinese speleothem oxygen isotope (δ^{18}O) records. Here we conducted a data-model comparison along with a water moisture budget analysis to assess the role of thermodynamic and dynamic components in controlling mid-summer and spring rainfall during early and mid-Holocene, and to compare with the precipitation changes referred by the stalagmite δ^{18}O records. Our results show that 1) a marked southward shift of the HO period from 10000~6500 yr BP in North China (NC) to 9000~5500 yr BP in Yangtze river valley (YRV). During the Holocene, the variation of the summer total precipitation is dominated by precession in NC, ice sheet in YRV. 2) An incoherent orbital-scale speleothem δ^{18}O variability in EASM regime indicate that speleothem δ^{18}O is largely controlled by the large-scale circulation and concomitant latitude shifts of monsoon rain belt.3) The intensified hydroclimate in YRV in mid-Holocene was contributed to excessive rainfall in summer, especially for increasing the convection/total precipitation ratio, which leads to the lightest speleothem δ^{18}O during the mid-Holocene. The excessive rainfall in summer mainly from the enhancement of convective activities that is caused by the southward shift of monsoon rain belt.

Simulated Air-Ocean interaction in the western North Pacific since the Last Glacial Maximum

1. The Kuroshio Current affects the modern sea level and brings warm and salty water to the marginal seas of the midlatitude East Asia. Since the Last Glacial Maximum (LGM), while the proxy data suggest the subarctic control in the Kuroshio Extension (KE) region during cold intervals, it is not yet clear what specific role played by air-ocean interaction in the vicinity of the western boundary current most efficiently caused such distinction from the present condition.
2. Here, we examine the simulated air-ocean coupled variability in the Kuroshio and the Extension region during the LGM and the mid-Holocene using Paleo Model Inter-comparison Project 4 data archives.
3. Especially, the variability in the meridional location and axis orientation of the north hemispheric Westerly jet associated with the paleo-Arctic Oscillation under such contrasting mean states across the multi model simulations. In addition, for selected models with high enough temporal resolution outputs, storm track activity is analyzed for the two different climate periods in comparison with the present.
4. Finally, the mean and the variability of the simulated Kuroshio with different models are assessed for the contrast under both the LGM and the mid-Holocene climates.

Spatially heterogeneous responses of climate in East Asia to insolation, CO2 and ice sheets during MIS-5

Dr. Anqi Lyu [1], ***Dr. Qiuzhen Yin*** [1]

1. *Georges Lemaître Centre for Earth and Climate Research, Earth and Life Institute, Université catholique de Louvain, Louvain-la-Neuve, Belgium*

Marine Isotope Stage (MIS) 5, lasting from ~130 to ~70 thousand years before present (ka BP) , is characterized by climate oscillations consisting of three interstadials and two stadials. Many climate simulations have been performed for the warmest MIS-5e period, but few has been made to cover the entire MIS-5 to investigate the climate variability during this long period. To study the relative impacts of insolation, CO_2 and Northern Hemisphere ice sheets on the internal variations within MIS-5 and spatial variations of the East Asian climate, two sets of snapshot simulations with different combinations of forcings by a step of 2 ka covering the whole MIS-5 period are performed with HadCM3. Moisture budget analysis is carried out to investigate the processes related to changes in summer precipitation. Our results show that EASM climate in different subregions have different sensitivity to astronomical forcing, CO_2, and ice sheets. The variability of temperature and precipitation within MIS-5 is mainly controlled by precession with strongly pronounced sub-stages of MIS-5 which correspond to precession minima and maxima, but their magnitudes are modulated by CO_2 and ice sheets. Within the range of its variations during MIS-5, the CO_2 concentration can cause similar degree of warming as insolation. However, the influence of CO_2 on precipitation is much weaker than the influence of insolation, and the relationship between summer precipitation and CO_2 is not statistically significant in most subregions in East Asia. Insolation and CO2 affect the summer precipitation by the dynamic and thermodynamic processes, respectively. Although ice sheets induce large cooling in the mid-high latitudes of both hemispheres, their impact on the precipitation and temperature in East Asia is quite small as compared to the impact of insolation, varying between regions and sensitive to the area and height of the ice sheets and the background insolation. Ice sheets influence the EASM precipitation mainly through the vertical dynamic processes which is strongly associated with the ice sheet-induced wave train at the hemisphere scale.

Primary productivity variability in the Northwestern Arabian Sea since the Last Glacial Maximum : A significant role of mineral dust inputs

Ms. Alice Karsenti [1]***, Dr. Charlotte Skonieczny*** [2]***, Dr. Stephanie Duchamp-Alphonse*** [1]***, Dr. Xinquan Zhou*** [3]***, Mr. Serge Miska*** [1]***, Ms. Kara Labidi*** [1]***, Mr. Julius Nouet*** [4]***, Mr. Olivier Dufaure*** [1]***, Dr. Catherine Kissel*** [5]***, Dr. Franck Bassinot*** [5]

1. *Paris Saclay University - GEOPS Laboratory,* ***2.*** *Université Paris-Saclay, CNRS, GEOPS, 91405, Orsay,* ***3.*** *Tongji University,* ***4.*** *GEOPS Université Paris-Saclay, CNRS,* ***5.*** *LSCE*

The Arabian Sea (AS), located in the Northwestern part of the Indian Ocean, is surrounding by desertic regions (e.g. Arabian Peninsula, Pakistan) and thus, receives important amounts of mineral dust through regional winds. This oceanic area is also under the influence of Indian monsoon surface winds that create a coastal upwelling off Somalia and Oman during summer and a convective mixing north of 15°N during winter. Mineral dust, coastal upwelling and convective mixing bring important amount of nutrients to the euphotic zone and make the AS, one of the most productive oceanic regions in the world. Numerous studies of the imprint of primary productivity (PP) in the AS in the past show the significant influence of nutrient inputs from the coastal upwelling. However, a recent study based on the analysis of coccoliths from sediment core MD00-2354 (61.48°E, 21.04°N; 2740 mbsl), and the use of Earth System models, demonstrates that convective mixing and probably mineral dust inputs might have a major influence on PP in the northwestern AS since the Last Glacial Maximum (LGM). As this time interval encompasses a glacial-interglacial transition with rapid fluctuations of ice sheet volume and atmospheric CO_2 concentration, it is therefore a perfect case study to explore the impact of key Earth's climate forcing mechanisms on the PP of the AS for both, past and future climate conditions. Yet, mineral dust component is still poorly documented by data in the AS, which limit interpretations of their influence on PP. Based on a multi-proxy characterization of the marine core MD00-2354 that combines detrital fraction grain-size distribution, clay mineralogy composition as well as bulk geochemical composition, we provide for the first time, a high-resolution (~200 yrs) eolian signal in the Northwestern part of the AS since the LGM. Preliminary results indicate millennial changes in atmospheric conditions as well as dust emission/deposition capacity in the area in coherence with previous low-resolution eolian records. The comparison of the newly obtained eolian signal with the high-resolution PP signal obtained on the same site indicates a significant role of mineral dust inputs on PP since the LGM.

Changing positive to negative temperature-moisture relationship at the start of the Holocene predicts future drying of East Africa

Characterized by national economies which rely heavily on crop agriculture and highly variable annual rainfall from year-to-year, East Africa is endemically vulnerable to water scarcity. Whereas future climate projections for the region predict increased rainfall during the 21st century as global temperatures continue to rise, meteorological observations record a trend towards drier conditions in the recent decades. Paleoclimate reconstructions have a clear role to play in understanding the stability of the relationship between temperature and moisture balance across a large range of climate states and in elucidating how this may develop over the next decades to centuries. However, there is generally a shortage of climate proxy records from continental low-latitude settings which are both long and detailed. We analysed glycerol dialkyl glycerol tetraethers (GDGTs) in the continuous and depositionally uniform sediment record of Lake Chala (Kenya/Tanzania) to provide the first paired temperature and hydroclimate reconstruction from equatorial East Africa spanning Marine Isotope Stages (MIS) 4 through 1. Our record shows that the Heinrich-1 megadrought period (~18,000-15,000 years ago) was both the driest and coolest episode in the last 75,000 years. Contrary to most low-latitude regions worldwide, the Last Glacial Maximum was fairly wet by comparison, continuing the wet conditions which prevailed through most of MIS4 and MIS3. Temperature and moisture balance in easternmost Africa both responded strongly to orbital precession but also show a significant obliquity signature. Moisture balance also shows the so-called half-precessional cycle (~10,500 year), typical of regions in the heart of the tropics, where the sun passes overhead during both the vernal and autumn equinoxes. The long-term positive relationship between continental moisture balance and temperature during the last glacial period switched to negative at the start of the Holocene 11,700 years ago, indicating that when atmospheric CO_2 exceeded 250 ppmv a tipping point was crossed linked to the opposing influences of elevated temperature on monsoonal precipitation and continental evaporation. Our results imply continued climatic drying in eastern equatorial Africa and diminishing future water resources, notwithstanding climate-model projections of increasing rainfall.

Reconstructing the role of temperature changes in determining the glacial-interglacial aridity variability in tropical regions

Dr. Manuel Chevalier [1]***, Dr. Brian M. Chase*** [2]***, Dr. Lynne Quick*** [3]***, Prof. William Gosling*** [4]***, Dr. Carlos Cordova*** [5]

1. Institute of Geosciences, Rheinische Friedrich-Wilhelms-Universität Bonn, 2. Centre National de la Recherche Scientifique, 3. Oklahoma State University

Considerations of past climate change in tropical regions focus primarily on precipitation, as variability in rainfall seasonality and amount is much stronger than that of temperature. While hydrological changes at most timescales are unquestionably large, and likely important drivers of tropical environmental changes, recent reanalysis of several pollen records from southern Africa and South America using the probabilistic pollen-based climate reconstruction method CREST (Climate Reconstruction SofTware) has highlighted the strong imprint of temperature variability on vegetation, with, for example, the influence of lower temperatures and evapotranspiration on water availability compensating for reduced precipitation during the Last Glacial Maximum. This highlights that at some timescales – such as glacial-interglacial cycles and transitions, when temperature changes are large – temperature changes have the potential to modulate and even balance the impact of precipitation changes. Similar results have also been observed from some of the PMIP3 climate simulations, which further highlighted that the intensity of this 'temperature effect' on aridity (precipitation minus potential evapotranspiration) varied spatially and depended on the background level of local precipitation. Since many palaeoclimate records representing aridity are commonly interpreted primarily in terms of changes in rainfall amount, the potential exists for a misinterpretation of these records. In this talk, we demonstrate that (co-)quantifying past temperature, precipitation, and aridity changes across the tropics and subtropics can be critical for understanding where and when the 'temperature effect' is most prevalent and, subsequently, for achieving a more comprehensive understanding of past monsoon dynamics.

Drivers of Australian-Maritime Continent monsoon changes in PMIP simulations of mid-Holocene and Last Glacial Maximum climate

Dr. Josephine Brown [1], ***Ms. Yanxuan DU*** [1], ***Ms. Tea Jones*** [1]

1. School of Geography, Earth and Atmospheric Sciences, University of Melbourne, Victoria, Australia

The Australian-Maritime Continent monsoon (also known as the Indo-Australian monsoon) is a complex regional monsoon which is influenced by both local and remote drivers on a range of time scales. Future projections under global warming indicate strong agreement between climate models on an increase in monsoon precipitation over the Maritime Continent but low agreement on the direction of change over northern Australia. We examine the Australian-Maritime Continent monsoon in simulations of mid-Holocene (6 ka) and Last Glacial Maximum (21 ka) climate from the latest set of Paleoclimate Modelling Intercomparison Project (PMIP) global climate models. Model simulations are compared with available proxy records from the region. The mid-Holocene simulations demonstrate strong model agreement on the response of the monsoon to reduced Southern Hemisphere summer insolation and increased insolation in the pre-monsoon season. The Last Glacial Maximum simulations produce a more complex response, with less model agreement. Changes in seasonal heating and moisture transport due to the expanded continental shelf interact with dynamic and thermodynamic responses to global cooling and regional changes in temperature gradients.

Timescale dependent fingerprint of the East Asian Summer Monsoon during the last Glacial and its interaction with vegetation

The East Asian Summer Monsoon (EASM) is fundamental for the water supply of more than a billion people in East Asia. It has undergone major changes during the Pleistocene. It varied nearly synchronously with orbital-scale insolation and millennial-scale warming and cooling events in the North Atlantic which are associated with abrupt changes in the Atlantic Meridional Overturning Circulation (AMOC). Yet, the spatial fingerprint of these variations and their interaction with local vegetation remain uncertain. Here, we present vegetation and climate reconstructions from a pollen record in Northeastern China covering the last 70kyr with unprecedented sub-centennial resolution. Today, the site is located at the northernmost edge of the EASM. During the last glacial, its position at the ecotone between cool mixed forest and steppe led to a pronounced imprint of past climate changes in the local vegetation. We show that vegetation changes are likely driven by hydroclimate changes and occurred synchronously with water isotope variations in Chinese speleothems. However, the ratio of orbital- over millennial-scale vegetation variations is three times higher than in the isotope record. While carbon dioxide changes likely amplified orbital-scale vegetation variations, this suggests that orbital- and millennial-scale variations of the EASM possess different spatial fingerprints: insolation and greenhouse gas forcing leads to strongest changes in the northern monsoon domain while AMOC changes manifest mostly in the southern monsoon areas. Accurate simulations of these fingerprints are important for future water EASM projections under increasing greenhouse gas concentrations and potential AMOC weakening.

Reconstructing temperature variability of monsoonal East Asia using branched tetraether membrane lipids and clumped isotopes of land snail shells in the Chinese Loess Plateau over the past 75,000 years

Ms. Jingjing Guo [1], ***Ms. Louise Fuchs*** [1], ***Dr. Martin Ziegler*** [1], ***Prof. jibao Dong*** [2], ***Prof. Youbin Sun*** [2], ***Dr. Francien Peterse*** [1]

Our understanding of (past) East Asian Monsoon (EAM) climate variability and its drivers is still under development. For example, past variations in EAM strength recorded by speleothem $\delta^{18}O$ shows a strong link with precession, whereas those reflected by magnetic susceptibility records from the Chinese Loess Plateau (CLP) additionally contain a strong glacial-interglacial fluctuation. Although both records are generally assumed to reflect variations in East Asian Summer Monsoon (EASM) precipitation, the discrepancy in orbital forcing suggests that speleothems and magnetic susceptibility actually record different aspects of EAM climate.

Here, we aim to identify a possible temperature component in loess-paleosol sequence by reconstructing a continuous, high-resolution, absolute temperature record for the past 75,000 years, for which we use temperature-sensitive soil bacterial membrane lipids, so-called brGDGTs, and clumped isotopes (expressed as Δ_{47}) of land snail shells stored in Yuanbao section on the western edge of the CLP.

Our two independent temperature records show the same variability over the past 75,000 years, albeit with an offset in their long-term trend. However, the temperature records do not reflect the same clear millennial scale and glacial-interglacial variability that is recorded by magnetic susceptibility in the same sequence. The distinct trends of these records can be explained if our temperature proxies primarily record summer temperatures, which might be linked to low latitude climate processes through the EASM, and magnetic susceptibility represents a more annually integrated climate signal that also involves high latitude processes. This scenario would imply that high latitude processes are a more important control on EASM precipitation variability than temperature on the CLP.

Millennial- and orbital-scale drivers of Australia's hydroclimate during the Last Glacial Period: insights from subaqueous speleothems

While initiated in the NH, recent evidence suggests that the abrupt climate events of the Last Glacial Period were propagated across the globe in a matter of decades. The influence of these events on monsoonal systems is well-established across China and other parts of East Asia where abrupt North Atlantic cooling was accompanied by weakening of the monsoon. Conversely, these events appear to have coincided with a stronger South American monsoon. Though few and far between, some studies suggest that the Indo-Australian Summer Monsoon and Southern Hemisphere Westerly Winds also experienced substantial displacement during the LGP in response to cooling in the North Atlantic.

Lying on the boundary between tropical and mid-latitudinal climate systems, Mairs Cave (South Australia) is perfectly positioned to provide insight into migrations of the IASM and SHWWs. The cave contains pendulites: stalactites with an external overgrowth of subaqueously precipitated calcite. The stalactites in Mairs Cave were initially submerged by ~ 89 ka by rising groundwaters, which partially flooded the cave. From that point forward, the pendulites grew subaqueously during periods of regional groundwater recharge and lay dormant during comparatively dry periods when the water table receded.

Preliminary growth rate and trace element results from two pendulites from Mairs Cave appear to support the theory that the IASM and SHWWs experienced southerly displacement in response to millennial-scale cooling in the North Atlantic. Meanwhile, hiatuses in pendulite growth coincide with minima in SH summer insolation, suggesting that Australian rainfall patterns are also governed by the position of the IASM on orbital time scales. The significance of these results are two-fold: not only do they provide insight into global climate dynamics during the Last Glacial Period, but they also provide a climatic contextualisation for the expansion of humans across the continent, which heralded the beginning of the world's oldest continuing culture.

East Asian Monsoon evolution during glacial terminations I and II at Lake Suigetsu, Japan

Ms. Charlie Rex [1]***, Dr. Richard Staff*** [2]***, Prof. Melanie Leng*** [3]***, Prof. Jaime Toney*** [1]***, Dr. Emma Pearson*** [4]***, Dr. Jonathan Tyler*** [5]***, Prof. Takeshi Nakagawa*** [6]

The East Asian Monsoon – constituting summer (EASM) and winter (EAWM) modes – is a critical component of the global climate system, driven by semi-annually reversing temperature gradients between Continental Asia and the Pacific Ocean. Understanding East Asian Monsoon behaviour during periods of warming is now critical, in light of recent anthropogenically-driven climate change. A network of high-quality records of palaeomonsoon evolution are key to our understanding of the underlying dynamics of this system. The two most recent glacial terminations (TI, 22–10 ka and TII, 136–124 ka) are amongst the best-preserved examples of warming periods in the Pleistocene, however, there are limited records available for these intervals and in most cases seasonal contributions remain unresolved.

Japan is ideally situated to detect changes in East Asian Monsoon behaviour because it is located beneath the seasonally migrating monsoon front and between two water bodies, which results in heavy precipitation during both EASM and EAWM seasons. Here we present records of EAWM behaviour across TI and EASM behaviour across TI and TII derived from analysis of the Lake Suigetsu sediment cores (Fukui Prefecture, Japan). These cores contain information from the present day to >160,000 yr BP, and hence offer a rare opportunity to study both TI and TII at high precision in the same high-quality terrestrial archive. Oxygen isotope analysis of diatoms and hydrogen isotope analysis of biomarkers were used as proxies for monsoon precipitation at a centennial (TI) to bicentennial (TII) resolution.

This bi-proxy approach establishes the similarities and differences between winter and summer monsoon evolution across glacial terminations. Additionally, the excellent chronology for the Suigetsu sediment cores facilitates comparison of our records to global benchmark records (e.g., ice cores, speleothems) outside the monsoon region. This permits investigation into cross-continental teleconnection relationships and provides vital contextualisation of East Asian Monsoon intensity in the global picture of climatic rearrangement. We observe time-dependent influences of both Northern Hemisphere and Southern Hemisphere climatic patterns on our records, related to the changing position of the monsoon front.

Exploring Late Quaternary African Humid Periods from Saharan dust deposits off West Africa

1. *Université Paris-Saclay, CNRS, GEOPS, 91405 Orsay, France,* ***2.*** *LSCE-IPSL, Laboratoire des Sciences du Climat et de l'Environnement (CEA-CNRS-UVSQ), Paris-Saclay,* ***3.*** *Université Lille, CNRS, Université Littoral Côte d'Opale, UMR 8187 – LOG – Laboratoire d'Océanologie et de Géosciences, F-59000 Lille, France,* ***4.*** *Université de Bordeaux, CNRS, UMR 5805 – EPOC – Environnements et Paléoenvironnements Océaniques et Continentaux, 33615 Pessac, France*

Through the Quaternary, variations of insolation received over Africa have governed the monsoon dynamics in this region, generating a recurrence of intense rainfall periods. These African Humid Periods (AHP) are characterized by a major transformation of the Saharan hydrological cycle, favouring the development of vast fluvial systems and tropical humid ecosystems in the currently hyper-arid Sahara Desert. In the present-day context of global warming, understand the environmental mechanisms and responses associated with these dramatic swings between two extreme hydroclimatic states appears crucial in order to improve climatic projections of these vulnerable areas. In this study, we propose to originally reconstruct AHP by studying the Saharan dust deposited in sediments of the Northeastern Atlantic Tropical Ocean. In fact, past modifications of Saharan dust deposited off West Africa, in addition to retrace atmospheric circulation changes (wind intensity and direction), indirectly reflect Saharan hydrological cycle variabilities (dust sources availability, aridity). Here, we present a high-resolution (1 sample/200yrs) multi-proxy characterization of the Saharan dust deposited continuously through the last 240ka - a period punctuated by eight AHP - in the marine core MD03-2705 (18°05N; 21°09W; 3085 mbsl). We combine dust flux, grain-size distribution, clay mineralogy and geochemical compositions in order to explore changes in the Saharan hydroclimate and atmospheric circulation over North Africa on orbital timescales, with a particular focus on the mechanisms associated with the recurrence of the AHP.

Seasonal bias introduces distinct signatures in monsoon records from inorganic and isotopic proxies in loess

Ms. Louise Fuchs [1], ***Ms. Jingjing Guo*** [1], ***Prof. Enno Schefuß*** [2], ***Prof. Youbin Sun*** [3], ***Prof. jibao Dong*** [3], ***Dr. Martin Ziegler*** [1], ***Dr. Francien Peterse*** [1]

Based on paleoreconstructions of the East Asian Monsoon (EAM) climate, the intensity of summer precipitation associated with the EAM is presumed to strengthen in response to ongoing warming. Most reconstructions are based on oxygen isotopes ($\delta^{18}O$) of cave speleothems and on grain size (GS) and magnetic susceptibility (MagSus) in Chinese loess sequences. Strikingly, the speleothem $\delta^{18}O$ records is dominated by precession signal, and lacks glacial-interglacial change, which argues for a strong control through changes in summer insolation. The MagSus and GS in the loess show a glacial-interglacial pattern that strongly resembles the amplitude and structure of deep sea oxygen isotope records, which in turn suggests a strong relationship with ice volume and global climate change.

To further investigate the distinct cyclicities in the speleothem and loess proxy records, we here generate a 140,000 year long record of plant wax hydrogen isotopes (δ^2H_{wax}) for the Yuanbao section on the western Chinese Loess Plateau. δ^2H_{wax} and speleothem $\delta^{18}O$ both reflect the isotopic composition of rain water. δ^2H_{wax} is analyzed for the same loess section as the GS and MagSus proxies thus allowing to directly compare all records. Like the speleothem $\delta^{18}O$ record, δ^2H_{wax} does not exhibit a strong glacial-interglacial variability, but is instead dominated by changes at precession and millennial scale variability. We suggest that the isotopic signal in the precipitation is linked to the summer season, as the plant wax signal is generated during the growing season. Similarly, the $\delta^{18}O$ of the speleothem record represents a summer signal as suggested in previous studies. The large glacial-interglacial amplitude in the MagSus record and its strong link to global ice volume could in turn be related to the length of the summer season, and thus a yearly integrated climate signal in these records. The amplification of winter cooling during globally cool periods with large ice volume is consistent with sea ice and snow cover feedbacks.

Middle to Late Quaternary TOC data from a Japan Sea sediment core MD01-2407, a long archive of the Arctic climate beyond the Greenland ice cores

Prof. Fujio KUMON [1]***, Dr. Yuko TAKIZAWA*** [2]***, Prof. Akira HAYASHIDA*** [3]

1. *Center for Advanced Marine Core Research, Kochi University,* ***2.*** *Institute of Low Temperature Science, Hokkaido University,* ***3.*** *Department of Environmental System Science, Doshisha University*

The Japan Sea is a semi-closed marginal basin located between the east Eurasia Continent and the Japanese islands, connected to the open seas through the four straights shallower than 140 m in sill depth. This topographic feature implies that the eustatic sea level change has a significant affect on the input of open sea water and the circulation of deep water in the basin in the geologic time. For the past 650 ka, we measured total organic carbon (TOC) and total nitrogen (TN) contents of a sediment core MD01-2407 recovered from the Oki ridge in the southern Japan Sea to reveal a high-resolution history of the biological productivity in relation to the global climate change, at 1 cm interval (~130-year interval on average).

Except for the interglacial ages *in sensu stricto*, the TOC profile illustrates a unique quasi-periodic fluctuation with high TOC contents in the warmer periods and low TOC contents in the cold/cool periods in the majority of cases (~90% of the total periods). The TOC fluctuation patterns consistent with a sea level curve LR04 on a longer time scale, and those in the glacial ages of 10-110 ka BP are very similar to the delta^{18}O profiles of the Greenland ice cores such as NGRIP on time scales of Dansgaard-Oeschger events. This result suggests that the TOC profile of the Japan Sea provides an older Arctic climate record in the glacial ages beyond the time interval covered by the Greenland ice cores, potentially serving a regional stratigraphic standard for the middle to late Quaternary in East Asia. The TOC content in the offshore sediments is controlled by a delicate balance between biological productivity in the euphotic zone and organic matter decomposition in the water column. Moreover, the position of the Arctic polar front migrates in connection with the global climate change, influencing nutrient availability by deep water upwelling and decomposition potential by oxygen supply in the water column. A scenario which explains how the Arctic climate controls TOC content in the Japan Sea will be detailed in the presentation.

100-kyr pacing of the East Asian summer monsoon over the last five glacial cycles inferred from land snails

Dr. Rui Bao [1], ***Dr. Xuefen Sheng*** [2]

1. Nanjing Normal University, 2. School of Earth Sciences and Engineering, Nanjing University, Nanjing 210023

The East Asian summer monsoon (EASM) transports moisture from the tropical Indo-pacific to the boreal, which constitutes the primary rainfall for the East Asia area and greatly influences regional hydrological conditions. The prevailing of the EASM is commonly thought to be mainly influenced by the orbital forcing and the effects of orbital forcing on the EASM after the Mid-Pleistocene transition are controversial. Different climatic proxies have different cycles, for example, Chinese cave δ18O records only show low-latitude ~20-kyr cycles, while pedogenic proxy records from Chinese loess are dominated by high-latitude 100-kyr cycles. This discrepancy may result from the multi-component origin of proxies, particularly for pedogenic signals in loess deposits, with the primary climatic signals modified by pedogenic smoothing, leaching, and changes in sedimentation rate. In this study, we used the carbon isotopic composition of land snail shells (δ13Cshell) in the loess deposition as an indicator of precipitation, which record the past 470 kyr EASM fluctuation in the central Chinese Loess Plateau. δ13Cshell is well correlated with magnetic susceptibility and δ13CIC (carbon isotope composition of carbonate) on orbital timescales, showing pronounced 100-kyr glacial-interglacial cycles, with more depleted values during inter-glacial compared to glacial periods. Cross-spectral analysis furtherly shows the δ13Cshell was coherent with pedogenesis proxies (especially magnetic susceptibility), within the eccentricity band (~100-kyr), suggesting that, like pedogenesis proxies, the δ13Cshell record variations of EASM precipitation. The absence of a precession signal in our records suggests that δ13Cshell is not significantly influenced by the sedimentation rate and that it exclusively captures the dominant 100-kyr signal of monsoon precipitation. Overall, δ13Cshell record is highly coupled with high northern latitude ice volume variations, possibly supporting the high-latitude forcing of EASM. We also found that at the end of marine isotope stage (MIS) 11, δ13Cshell-based precipitation remained at an interglacial level following the MIS 11 super-interglacial climate in the Northern Hemisphere, although on a global basis a glacial period had commenced. It is confirmed that the δ13Cshell should sensitively record the key climatic events of the East Asian monsoon.

North African Humid Periods over the past 800000 years – Timing, Amplitude and Forcing

Prof. Paul Valdes [1]***, Dr. Edward Armstrong*** [2]***, Dr. Miikka Tallavaara*** [3]***, Dr. Peter Hopcroft*** [4]

1. *School of Geographical Sciences, University of Bristol,* ***2.*** *Department of Geosciences and Geography of the University of Helsinki,* ***3.*** *Department of Geosciences and Geography, University of Helsinki,* ***4.*** *University of Birmingham*

The Sahara region has experienced periodic wet periods over the quaternary and beyond. The timing of these North African Humid Periods (NAHPs) is linked to astronomically pacing by precession which impacts the position of the African monsoon systems. However, many models do not correctly simulate the magnitude of these events and so the driving mechanisms remain poorly constrained. Here we present an 800kyr climate dataset produced using a convection updated version of the HadCM3B coupled climate model that simulates 20 AHPs over the past 800kyr which have good agreement with the timing of NAHPs identified in proxy data. Precession determines their pacing, however their amplitude is strongly linked to eccentricity via its control over ice sheet extent. During glacials, the thermodynamic effect of increased albedo weakens the West African Monsoon and alters the dynamics of the subtropical westerly jet which inhibits Saharan convective rainfall. This suppresses the amplitude of the NAHPs during glacial periods of precession minima. Our results highlight the importance of both precession and eccentricity, and the role of high latitude processes in determining the timing and amplitude of the NAHPs.

Ice volume and insolation forcing of abrupt strengthening of East Asian winter monsoon during glacial inceptions

The East Asian winter monsoon (EAWM), a major component of the East Asian monsoon circulation, is characterized by prevailing low-level northwesterly winds tightly linked to the high-northern-latitude climate via the Siberian-Mongolian High.Our current understanding of the EAWM dynamics during the glacial-interglacial cycles is mostly based on loess records on the Chinese Loess Plateau (CLP), which suggest that the EAWM intensity is closely linked to the volume of the Northern Hemisphere ice sheets (NHIS) on orbital timescale. However, unlike the ‘sawtooth’ pattern of global ice volume that shows a gradual build-up of the ice sheets (in ~9000 years) followed by rapid deglaciation (in ~1000 years) since the middle Pleistocene transition as documented by the benthic $\delta^{18}O$ records, the loess records of EAWM show distinct glacial and interglacial modes, with the transitions between them generally being quick. This dissimilar evolution pattern between the EAWM and the global ice volume (and NHIS) at the interglacial-glacial transitions means that some key information is missing regarding the dynamics of the EAWM during the glacial inceptions. By generating an independent chronology framework and integrating multi-proxy records from the loess sections on the central CLP, here we show that the rapid intensifying of the EAWM during glacial inceptions, previously demonstrated as a direct response to the build-up of NHIS, actually reflects millennial perturbations in the large-scale atmospheric circulation in East Asia caused by insolation-triggered abrupt North Atlantic cooling when NHIS reaches a critical large size. The role of NHIS is reinterpreted as preconditioning the teleconnection between North Atlantic and East Asia during glacial inceptions instead of directly controlling the intensity of EAWM. Our integrated multi-proxy records thus highlight the key role of ice volume in modulating the response of the EAWM to insolation-triggered North Atlantic cooling during the interglacial-glacial transitions.

North African aridity and humidity variability during the Plio-Pleistocene

Dr. Rick Hennekam [1], ***Dr. Katharine Grant*** [2], ***Prof. Eelco Rohling*** [2], ***Dr. Rik Tjallingii*** [3], ***Dr. David Heslop*** [2], ***Prof. Andrew Roberts*** [2], ***Prof. Lucas Lourens*** [4], ***Prof. Gert-Jan Reichart*** [1]

Records of North African climate are essential to get a mechanistic understanding of the link between insolation changes, monsoonal changes, and global climate variability. An established way to reconstruct North African climate and associated monsoon dynamics is by the use of the ratio of titanium to aluminum (Ti/Al) in sediment cores from the eastern Mediterranean Sea. During humid intervals these sediments contain an increased amount of aluminum-rich clays from North African rivers, while during arid intervals these sediments contain more titanium-rich dust from North African deserts. Therefore, high/low values of Ti/Al correspond to arid/humid conditions in North Africa, respectively. Here, we demonstrate how to obtain reliable Ti/Al data using X-Ray Fluorescence (XRF) core scanning; an analytical method that is fast and relatively inexpensive. As such, this method allowed us to produce a 5-Myr North African climate record from eastern Mediterranean Sea sediments (ODP Site 967). This near-continuous timeseries of the North African environment shows that (i) fluvial terrigenous sediment inputs doubled during Green Sahara Periods at ~3.2 million years ago, likely as a result of an abrupt non-linear North African landscape response, (ii) African environmental variability and associated monsoon dynamics were dominantly paced by low-latitude insolation alone to ~1.2 million years ago, and (iii) remote high-latitude climate left especially a notable imprint on North African aridity/humidity after the mid-Pleistocene transition (~1.2-0.7 Ma) when a threshold ice volume was reached during ice ages.

The spatial–temporal evolution of the Asian summer monsoon during the late Miocene and potential CO2 forcing: A data–model comparison

Dr. Zhilin He [1], *Dr. Zhongshi Zhang* [2], *Prof. Zhengtang Guo* [1], *Dr. Ning Tan* [1], *Mr. Zijian Zhang* [1], *Mr. Zhipeng Wu* [3], *Dr. Chunxia Zhang* [3], *Dr. Chenglong Deng* [4]

State Key Laboratory of Lithospheric Evolution, Institute of Geology and Geophysics, Chinese Academy of Sciences

The long-term evolution of the Asian summer monsoon and its drivers are important for understanding future Asian summer monsoon variations. Due to inconsistencies among proxy data and/or different interpretations, the long-term evolution and drivers of the East and South Asian summer monsoons (EASM and SASM) during the late Miocene still remain controversial. There are two main viewpoints involving an overall strengthening or weakening trend, which is typically attributed to uplift of the Himalaya–Tibetan Plateau or global cooling. Here, we compiled paleoenvironmental reconstructions for the EASM and SASM during the late Miocene and used numerical simulations to investigate their evolution and potential drivers. The synthesized results indicate that the late Miocene climate: (1) underwent an overall drying trend in northern China, but a wetting trend in the South China Sea and surrounding areas; and (2) became progressively drier on the northern Indian subcontinent, but not on the southern Indian subcontinent. The modeling results indicate that: (1) EASM circulation overall weakened, whereas SASM circulation weakened (strengthened) in the northern (southern) part of South Asian monsoon domain; (2) summer precipitation decreased (increased) in the northern (southern) part of East and South Asian monsoon domains, which is roughly agreement with the paleoclimate records. Our results suggest that a decline in atmospheric CO_2 may have been an important driver of the evolution of the EASM and SASM during the late Miocene.

Session 16: Linking paleoenvironmental proxies at different scales: potential, problems and limits

How to combine dental wear and pollen proxies for a better knowledge of past local environments?

Dr. Antigone Uzunidis [1]***, Prof. Florent Rivals*** [2]***, Dr. Juan Ochando Tomás*** [3]***, Dr. Tiffanie Fourcade*** [4]***, Prof. Maria Sanchez-Goñi*** [5]

1. *Institut Català de Paleoecologia Humana i Evolució Social (IPHES-CERCA), Zona Educacional 4, Campus Sescelades URV (Edifici W3) 43007 Tarragona, Spain,* ***2.*** *IPHES-CERCA, Institut Catala de Paleoecologia Humana i Evolucio Social,* ***3.*** *university of Rome Sapienza,* ***4.*** *University Bordeaux-Montaigne,* ***5.*** *Ecole Pratique des Hautes Etudes, Paris Science Lettres University*

Among the tools used to describe past local environments, those derived from the plant and animal remains are the most powerful. The study of pollen and dental wear in herbivores are commonly used for this purpose. They allow us to reconstruct local plant cover and infer the climatic context. These approaches, however, are rarely combined together. We present here the first study that integrate pollen records from caves and deep-sea cores and dental wear data (meso- and microwear) from archaeological sites.
Pollen spectra from caves reflect the composition of the local vegetation cover contemporaneous with the sedimentary layer from which they originate. Pollen from deep-sea cores gives an integrated image of the regional plant communities with a precision of a few hundred years. Dental wear allows the reconstruction of the animal diet, and in the case of herbivores, the plants available in the area. However, this approach is less detailed than pollen studies since it only discriminates between dicots and monocots. It addresses the local and regional environments through the prism of the sedimentary level but allows us to identify seasonal variations by comparing the dental meso- (a few years) and microwear (a few days) signals.
In addition to increase accuracy and resolution of the local environmental interpretations, the combination of these data could allow 1) improving the interpretation of past environments based on tooth wear by linking macro- and micro-trace patterns as directly as possible to non-analogue present-day plant communities; 2) combining the time scales accessible through the two approaches and detail definition of the amplitude of seasonal variations; 3) defining the specificities of a local environment in relation to regional trends by combining the geographical scales represented by deep-sea and archaeological sedimentary sequences.
Nevertheless, despite this promising perspective, the disparity of the data limits their integration and imposes a methodological questioning. For example, sedimentary layers provide, in comparison with deep-sea cores, imprecise ages. The time-span they cover generally encompasses several of the climatic events identified in the deep-sea cores. At the scale of the site, the different origin of the pollen and the teeth limit their statistical integration.

Multiproxy reconstruction of the Plio-Pleistocene ecological context of ungulates from the Ahl al Oughlam site (Morocco) based on tooth analysis

***Mr. Iván Ramírez Pedraza* [1], Prof. Florent Rivals [1], Dr. Carlos Tornero [2], Prof. Denis Geraads [3], Prof. Jean Paul Raynal [4], Dr. Abderrahim Mohib [5], Dr. David Lefèvre [6]**

***1.** IPHES-CERCA, Institut Catala de Paleoecologia Humana i Evolucio Social, **2.** Department of Prehistory, Autonomous University of Barcelona (UAB), **3.** CR2P-UMR 7207, CNRS, MNHN, Sorbonne Universités, **4.** Université de Bordeaux, CNRS, UMR 5199 PACEA, **5.** Institut National des Sciences de l'Archéologie et du Patrimoine (INSAP), **6.** Université Paul Valéry Montpellier 3, CNRS, UMR 5140 Archéologie des sociétés méditerranéennes, Campus Saint Charles*

The Sahara Desert was not always a natural barrier in the past and it experienced multiple green and humid phases, allowing dispersal episodes of fauna from Sub-Saharian locations to the North of Africa. High-resolution palaeoecological studies are underrepresented for the Plio-Pleistocene in Northern Africa. The aim of this work is to fill this gap reconstructing the paleoecology of the Ahl al Oughlam (AaO) ungulate communities by characterizing their diets and habitats combining two proxies, stable isotopes and dental wear.
AaO is located at the southeastern limit of the city of Casablanca (Morocco) at about 34° North and 105 m a.s.l. The site, rich in small and large vertebrates, is correlated to near the Plio-Pleistocene boundary (ca. 2.5 Ma) based on biostratigraphy of mammals.
A total of 87 samples of tooth enamel from ungulates were sampled for the stable carbon and oxygen isotope analysis and 64 and 45 molars were selected for microwear and mesowear analysis, respectively. These techniques provide dietary information on three different timescales: stable isotopes - first years of animal's life; mesowear - annual average of an animal's life and microwear - last days/weeks of an animal's life.
The carbon isotope results show the predominance of C_3 plants in the diet of all species. The difference in $\delta^{18}O$ between non-obligate and obligate drinkers has been used as a proxy for relative aridity. These differences in AaO taxa suggest an aridity similar to that of today's African savannah. The dental wear results show a wide spectrum of diets. Mesowear indicates low levels of abrasion related to browser diet for *Sivatherium*, *Gazella* and Alcelaphini, and a high level of abrasion related to grazer diet for *Hipparion*. Microwear reveals browse-dominated dietary traits for *Gazella* and *Sivatherium*, and mixed feeding dietary traits for *Anancus*, *Hipparion* and Alcelaphini. Unexpectedly, the AaO Alcelaphini show a dental wear pattern corresponding to a mixed and less abrasive diet than pure grazing diet of the modern Alcelaphini
In conclusion, the combination of proxies highlights niche partitioning among the ungulates recovered at AaO and the availability of different habitats such as open woodland and xeric C_3 grassland.

Dental Wear Analysis: The Diet of Deer and their Pleistocene Palaeoecology

Ms. Laura Hemmingham [1], ***Prof. Danielle Schreve*** [1], ***Dr. Spyridoula Pappa*** [2]

1. Royal Holloway, University of London, 2. Natural History Museum, London

During the Pleistocene, dramatic fluctuations in climate greatly shaped European environments, determining the available foliage for herbivores to consume. Previous research has identified a wide diversity of dietary signals of Pleistocene deer, with groups that have a stronger grazing signal, a stronger browsing signal, or a mixed feeding diet. Focusing on the later part of the Last Glacial Period, Marine Isotope Stage 3 (MIS 3, ~26-60 thousand years ago (kya)) until the end of the Pleistocene c.11.5 thousand years ago, this study utilises dental wear analysis to elucidate the dietary ecology of reindeer (*Rangifer tarandus*), red deer (*Cervus elaphus*) and giant deer (*Megaloceros giganteus*) from various Late Pleistocene sites. Dental wear analysis is comprised of two methods – dental microwear analysis and dental mesowear analysis. Dental microwear is a well-established technique of examining tooth enamel for distinctive microscopic scars made by certain food groups, which provides high-resolution insights into the organism's dietary behaviour during the final weeks to days before death. Dental mesowear is the macroscopic study of tooth cusp shape and relief, which is formed from the varying forces of abrasion and attrition in a diet over months to years, producing a more general signal of an individual's diet. By applying these methods to Late Pleistocene deer specimens, it can be determined that the dietary ecospaces of deer did not significantly overlap, indicating a degree of niche differentiation. It is further suggested that the disparity between microwear (short-term diet) and mesowear (long-term diet) in reindeer from certain sites may indicate seasonal flexibility in diet and the use of particular sites year-round. Therefore, by increasing our knowledge of species' dietary ecology in the face of past climatic change, we may further improve predictions of current species' responses to the rapidly changing globe.

Multi-proxy dietary reconstruction of derived Equinae from the Miocene through the Plio-Pleistocene of North America

Dr. Gina Semprebon [1], ***Prof. Florent Rivals*** [2]

1. *Bay Path Universitty,* ***2.*** *IPHES-CERCA, Institut Catala de Paleoecologia Humana i Evolucio Social*

Dietary proxies with different temporal resolutions were employed to provide a comprehensive dietary reconstruction of North American fossil equid taxa spanning from the late Miocene (Clarendonian) through the Pleistocene (Rancholabrean). Hypsodonty, mesowear and microwear trends were studied on derived Equinae. These results were then compared to three extensive extant ungulate tooth wear databases. Results show that in the early Miocene, derived Equinae underwent a consistent increase in hypsodonty and mesowear scores (abrasion indices) and continued this trend through the Pliocene and Pleistocene but declined slightly in the Recent. A microwear abrasion index, scratch texture, mirrored hypsodonty and mesowear trends, but microwear alone turns over rapidly enough to reveal the actual dietary reason for these shifts in abrasion. In the early Miocene, microwear scratch number results show that hypsodonty and mesowear trends toward greater abrasion were due to the derived Equinae engaging mostly on high-abrasion grass consumption but as grazers and mixed feeders. In the late Miocene, the derived Equinae continued with coarse microwear scratch textures and continued the trend toward engaging in both grazing and mixed feeding. This dietary trend continued into the Pliocene, but in the Pleistocene, only one species in the genus *Equus* studied here had microwear consistent with pure grazing, although deeper time mesowear and hypsodonty proxies had values that are more consistent with grazing in extant forms. High degrees of microwear pitting and gouging were more accelerated from the early Miocene onward indicating exposure to exogenous grit on food items and most likely explaining the extreme acquisition of hypsodonty and blunter mesowear cusps in equids compared to other North American ungulate families. This acquisition of hypsodonty set the stage for the Equidae to become the only hypergrazer North American family in the Recent. Results here underscore the vital importance of utilizing more than one dietary proxy to provide enough information to reconstruct paleodiet with assuredness.

A New View: Multidimensional and Time Transgressive Approaches to Ecometrics

Relationships between functional traits and environmental conditions are crucial for maintaining ecosystems through time, and ecometrics is a powerful approach for identifying those relationships. This approach analyzes the relationship between the functional traits of an entire community and the environmental conditions with which they are associated, serving as an alternative to taxon-based approaches that focus on individual species. For example, communities of herbivores with high crowned teeth (high hypsodonty) are likely to be found in arid areas with low precipitation because the high crowns facilitate ingestion of more grit and abrasive vegetation. Ecometrics enables us to test ecological and evolutionary processes that are responsible for the observed spatial distribution of traits. It can also be used to reconstruct paleoenvironments and assess the mismatch between expected and realized trait distributions within communities. Multiple ecometric relationships have been established for plants and animals but have not been thoroughly integrated across traits, taxonomic groups, or continents. New paleoclimate data and recent descriptions of new ecometric traits provide an opportunity to develop a more multidimensional and time transgressive approach. Here, we consider ways to expand these suites of ecometric traits and how to integrate a comprehensive set of traits into a multi-trait, multi-taxonomic framework. This integration serves as the next step in advancing our understanding of community-level relationships with the environment and thoroughly examining ecometric fit through time.

A review of the woolly rhinoceros Pleistocene record in Poland

Prof. Kamilla Pawłowska [1]

1. *Adam Mickiewicz University, Poznań, Poland*

The woolly rhinoceros (*Coelodonta antiquitatis* Blumenbach 1799) was widely distributed across northern Eurasia, including Poland, during the Pleistocene. Polish evidence for this is provided in the form of over a hundred sites, which were however identified over sixty years ago (Kowalski, 1959), and some succeeding loose findings. We have thus no knowledge of the details of the woolly rhinoceros' presence; in particular, we do not know in geographical terms how widely it was distributed across Poland. Equally important as the distribution is the location of the sites which, as can be expected, will correspond to the position of the ice sheet in its several phases and the presence of the mammoth steppe, which was preferred by the woolly rhinoceros. We do not know either if its presence was permanent, temporary, or periodic. Further, none of the studies conducted so far have addressed the ancient DNA, which could shed light on ancient populations.

As the history of the woolly rhinoceros in Poland has not received sufficient attention, we will focus in this presentation on this key representative of megafauna, and one that is also well recognized in Europe.

This study was performed under a grant from the National Science Center, Poland (2021/43/B/ST10/00362) awarded to Kamilla Pawłowska.

Building ecometric models using small mammal hypsodonty to estimate paleoprecipitation across East Africa

Ms. Julia Schap [1]***, Dr. Jenny McGuire*** [1]***, Dr. Michelle Lawing*** [2]***, Dr. Rachel Short*** [3]

1. *Georgia Institute of Technology,* ***2.*** *Texas A&M University Department of Ecology and Conservation Biology,* ***3.*** *South Dakota State University*

By examining the relationships between fauna and climate through time, we can better anticipate how communities will respond to climatic changes. Ecometric analyses examine the relationships between functional traits and environment at the community level. Traits used in these studies directly influence how an organism interacts with its environment. Previous studies using ecometrics have explored relationships between hypsodonty (tooth crown height) and precipitation and temperature. Many studies in large mammals find that high hypsodonty is associated with low precipitation. However, recent work finds that hypsodonty in North American small mammal communities is also correlated with mean annual temperature with these communities showing more *in situ* changes in response to climate. Here, we examined community-level hypsodonty of African rodents and lagomorphs to test if the same relationship exists across geographic space. With projected warmer and drier climates, Africa's rich biodiversity is expected to see changes in community composition in the near future. To investigate this trait-environment relationship in Africa, categorical hypsodonty values (brachydont, mesodont, and hypsodont) were gathered from the literature and museum collections for 92 modern African taxa (86%). Equidistant 50-km points were used to generate community lists by sampling IUCN range maps. There was a stronger linear correlation between small mammal community-level hypsodonty and annual precipitation (r^2=0.61, p<.001) than mean annual temperature (r^2=0.05, p<.001) possibly due to less variation in temperature than precipitation across Africa. We use maximum-likelihood to construct ecometric spaces that predict paleoprecipitation for seven well-sampled Quaternary fossil localities from East Africa. We placed the fossil sites into our ecometric spaces based on their trait composition. One site had a non-analog community occupying trait space not represented by modern communities, meaning an estimate of precipitation is not possible using this model. Fossil communities had relatively lower mean tooth crown heights than most modern communities and, thus, often plotted on the wetter end of the range of trait space, suggesting higher precipitation during the Quaternary. For each site, small mammal hypsodonty ecometrics demonstrates how communities are shifting in trait space and in response to climatic change by revealing the direction and magnitude of change over time.

Interglacial or interstadial, difficulty in correlating local and global data during the middle Pleistocene at the Arago Cave.

***Dr. Loïc Lebreton* [1], *Dr. Cyril Viallet* [2]**

***1.** Institut Català de Paleoecologia Humana i Evolució Social (IPHES-CERCA), Zona Educacional 4, Campus Sescelades URV (Edifici W3) 43007 Tarragona, Spain, **2.** Paléotime - UMR 7194 HNHP "Histoire naturelle de l'Homme préhistorique" MNHN-CNRS-UPVD, Département Homme et Environnement du Muséum National d'Histoire Naturelle, 1 rue R. Panhard 75013 Paris*

Middle Pleistocene is marked by the settlement of achelean and their diversification after the MIS 12. The Arago cave regroup numerous human settlements correlate to MIS 12, 13 and MIS 14 making it an important site for the comprehension of the Lower Paleolithic in Southwestern Europe. It's also an important site for the understanding of paleoenvironments and paleobiodiversity as it has yielded rich faunal associations. The faunal associations allow to observe three climatic stages within this recording: two cold ones and a mild one. The small vertebrates, with their abundance and their diversity, are particularly useful for the observation of these period, which historically have been correlated to glacial or interglacial stages. If the first cold phase, dated 438+/- 31ka is correlated to the Marine Isotopic Stage 12 (MIS 12), the correlation of the following phases to isotopic stages can be discussed. They may correspond to climatic variations of the MIS 12. Indeed, the latest studies about paleoclimatic reconstitution which allow to define the evolution of the paleo-temperature show that these differences are relatively small. Therefore, instead of a correlation to MIS 12, 13 and 14, the medium complex of the Caune de l'Arago could belong solely to MIS 12. The correlation of these environmental change to other global data, notably isotopic curve, is challenging because there are various local factors influencing faunal association. We propose here to present both hypotheses and to discuss the various factors which influence the distribution and the representation of the small vertebrate species present on the site.

Molluscs and Microfossils as indicators of early Holocene Palaeoenvironmental reconstruction of the Grand Erg Occidental, North-Western Algerian Sahara

***Dr. Mennad Saci* [1], *Prof. Bouhameur Mansour* [2], *Dr. Bachiri Nourreddine* [1], *Dr. Nassima Yahiaoui* [3], *Prof. Paula Reimer* [4], *Prof. Mahammed Mahboubi* [1]**

1. Université Oran 2, 2. Université d'Oran 2,, 3. UUniversité Oran 2, 4. Centre for Climate, The Environment and Chronology (14CHRONO), School of Natural and Built Environment, Queen's University, Belfast

The witness hill in the sabkha El Mahouche of Grand Erg Occidental (North-Western, Algerian Sahara), revealed the existence of an Early to Mid-Holocene paleo-lake is located in the Northwestern Algeria Sahara 600 km away from the Mediterranean. The present study aimed to reconstruct the palaeoenvironmental changes of The outcrop, SMI (3.3 m) in length contained eight lithologic units, is almost completely composed of the mollusc shell five gasteropoda (Biomphalaria pfeifferi, Bulinus truncates, Hydrobia sp., Potamides conicus, Melanoides tuberculatus), and bivalve *Cerastoderma glaucum*, ten of fresh-brackish water ostracods, three benthic foraminifer species. The association indicates a fresh-brackish water lake with temporary inflows of freshwater, in order to reconstruct the palaeoenvironmental history of this outcrop. Which is subdivided into many ecological stages: The first stage consists of very shallow conditions, plant remains and rare freshwater ostracods indicate slightly brackish, and gastropods probably a swampy wetland which had established due to humid climate conditions. The second stage consists high abundance of fresh-brackish water ostracods and gastropods, and indicates a lake-level rise .The first development of a permanent water body points to a variable salinity, and therefore to unstable conditions of the lake's early phase.

The third stage includes gastropods (B. pfeifferi, B. truncates, Hydrobia sp.), and microfossil taxa communities are dominated by taxa tolerant in salinity conditions, followed by a relatively stable salinity level, which characterizes a fully established, relatively large water body. Indicates stable environmental conditions of a permanent fresh- saline lake.

The fourth stage begins while the prevailing ostracods Cyprideis torosa and Loxoconcha elliptica, together with the molluscs C. glaucum, Hydrobia sp., and P. conicus. The high number of foraminifers indicates an increase in salinity level point to a lake-level drop until the formation of gyps (last stage). About 7782 14C yr BP; the appearance of C. glaucum is evidence of the onset to aridification. As a consequence, the lake gradually begins to vanish.

Late Holocene mangrove dynamics of the Doce River delta, southeastern Brazil: Implications for the understanding of mangrove resilience to sea-level changes and channel dynamics

Prof. Marlon Franca [1], ***Mr. Fernando Silva*** [2], ***Prof. Marcelo Cohen*** [2], ***Prof. Luiz Pessenda*** [3], ***Prof. Frank Mayle*** [4], ***Dr. Neuza Fontes*** [2], ***Dr. Flavio Lorente*** [5], ***Dr. Antonio Alvaro Buso*** [5], ***Prof. Marisa Piccolo*** [5], ***Prof. José Bendassolli*** [5], ***Prof. Kita Macario*** [6], ***Mr. Nicholas Culligan*** [7]

1. *Federal Institute of Espírito Santo, Brazil,* ***2.*** *Graduate Program of Geology and Geochemistry, Federal University of Pará, Brazil,* ***3.*** *C-14 Laboratory - Centre for Nuclear Energy in Agriculture - University of São Paulo,* ***4.*** *University of Reading,* ***5.*** *Center for Nuclear Energy in Agriculture, University of São Paulo, Brazil,* ***6.*** *LAC-UFF AMS Laboratory-Fluminense Federal University, Niteroi, Brazil,* ***7.*** *Department of Oceanography and Coastal Sciences, College of the Coast and Environment, Louisiana State University, Baton Rouge, LA 70803, United States of America*

This work aims to understand mangrove resilience to changes in a wave-influenced delta in southeastern Brazil during the late Holocene using an integrated analysis of palynology, sedimentology, and geochemistry ($\delta^{13}C$, $\delta^{15}N$, C:N and C:S ratio), and radiocarbon dating on two sediment cores. The data indicated three mangrove succession phases: 1) an estuarine point bar/tidal flat occupied by a mixture of mangrove species (~2660 - ~2050 cal yr BP); 2) a tidal flat dominated by *Laguncularia* mangroves (~2050 - ~900 cal yr BP); and 3) tidal flats with *Laguncularia* mangroves upstream and establishment of *Rhizophora/Avicennia* mangrove at the river mouth (~900 cal yr BP until present). The geochemical results suggest a dominance of C_3 terrestrial plants with a mixture of C_4 plants and organic matter of marine/estuarine origin throughout the late Holocene. *Laguncularia* and *Rhizophora* trees were established since ~2660 cal yr BP as pioneers, followed thereafter by *Avicennia*. Currently, tidal flats upstream are occupied by mangroves mainly represented by *Laguncularia*. *Rhizophora/Avicennia* mangroves occur at the mouth of the river. The relative sea-level fall during the late Holocene, as well as the channel dynamics, caused the development of tidal flats and mangrove succession inland. The succession of *Rhizophora*, *Laguncularia,* and *Avicennia*, followed by the permanence of only *Laguncularia*, is likely related to the resilience of each mangrove genus to habitat disturbance (e.g., salinity and sediment grain size fractions) caused by sea-level changes and channel dynamics. Our results show that mangroves may be resilient to the effects of Atlantic sea-level fluctuations, but the floristic structure in the past is different from that of today.

Complex vegetation response to glacial-interglacial cycles on the Loess Plateau of China over the past 800,000 years

Prof. Bin Zhou [1]***, Mr. Xuehan Zhou*** [1]***, Prof. Michael Meadows*** [2]***, Ms. Yang Pang*** [1]***, Mr. Zhe Wang*** [1]

1. *School of Earth Sciences and Engineering, Nanjing University,* ***2.*** *School of Geography and Ocean Sciences, Nanjing University,*

Reconstructing the paleo-vegetation on the Chinese Loess Plateau (CLP) is important to understanding the coupled relationship between vegetation and climate. However, the evolution of vegetation on the CLP during glacial and interglacial cycles of the Quaternary remains subject to controversy. Here we analyze $\delta^{13}C_{TOC}$, *n*-alkanes preserved in sediments from a 60-meter section, Lingtai, on the central CLP, as well as records of atmospheric temperature and monsoon precipitation based on the branched glycerol dialkyl glycerol tetraether (br-GDGT) membrane lipids and magnetic susceptibility (MS), to reconstruct vegetation and climatic factors over the last 800 ka. Based on increasing ratios of *n*-alkanes, a general increase in shrubland after 420 ka, with more grass generally in the past 250 ka is revealed. During the transition periods from glacial to interglacial, the appearance of $\delta^{13}C$ peaks, with values of >-21‰, along with higher ratios of $C_{31}/(C_{27}+C_{29}+C_{31})$ and $(C_{27}+C_{33})/(C_{29}+C_{33})$, indicate an increase in both C_4 grasses and C_3 shrubs. Depleted $\delta^{13}C$ values and lower $C_{31}/(C_{27}+C_{29}+C_{31})$ imply a greater contribution from C_3 trees during some interglacial periods, including in the lower paleosol layer of S5 (MIS13). During the transitions from late interglacial and early glacial, an increase in C_3 grasses is indicated by depleted $\delta^{13}C$ values and higher $C_{31}/(C_{27}+C_{29}+C_{31})$ ratios. In comparison with $\delta^{13}C$ records from the CLP along a SE-NW transect since the last glacial, the increase in C_4 plants is consistent with increasing temperature as indicated by br-GDGT proxies during the transition periods from glacial to interglacial, but occurs earlier than the intensified monsoon that is indicated by higher MS in paleosol layers. This implies that increasing abundance of C_4 plants is associated with the transitional periods from glacial to interglacial under conditions of higher temperature and drier climate in the central and southeast CLP. Lower $\delta^{13}C$ values (<-23‰) and lower $C_{33}/(C_{33}+C_{29})$ values (<0.3) correspond to periods of lower MAT and relatively depleted $\delta D_{wax,}$ implying that a moderately warm and wet climate is favorable to C_3 trees in this region. To conclude, rather than strictly following changes in monsoon intensity within a simple glacial-interglacial pattern, vegetation evolution on the CLP responds to complex hydrothermal dynamics.

Application of the Landscape Reconstruction Algorithm in the Northern French Alps to assess Holocene land cover changes

Ms. Andréa Julien [1], *Dr. Erwan Messager* [1], *Dr. Charline Giguet-Covex* [1], *Dr. Fabien Arnaud* [1], *Dr. Florence Mazier* [2], *Dr. Laurent Marquer* [3]

1. Laboratoire EDYTEM UMR CNRS 5204 Université Savoie Mont Blanc, 2. GEODE, UMR 5602 CNRS, Toulouse, 3. Department of Botany, University of Innsbruck

Major trends in Holocene vegetation changes in the Alps are known based on palaeoecological studies. However, in the detail, disparities are observed both at regional and local scales. This is mainly due to the spatial variability of the mountain landscapes, e.g. different valleys and altitudes are characterized by different plant abundance/composition, resulting from a combination of factors such as soil characteristics, the natural distribution of plant taxa and local human activities. In the aim of assessing the spatial extent of past plant abundances and vegetation composition through time, there is still a critical need to disentangle the local from the regional vegetation changes.

Pollen-based vegetation modelling approaches have been developed to meet this challenge. However, such works are still few in mountain environments. In the present project, we aimed at reconstructing the spatial variability in regional and local plant abundances in a mountain region by applying the Landscape Reconstruction Algorithm (LRA) to reconstruct the spatial distribution of the vegetation in the Northern French Alps over the last 5 millennia.

Here, we present our methodological approach to calibrate models from modern vegetation and evaluate the performances of the LRA to assess both regional and local vegetation in a mountain region. 45 sites, including lakes and peat bogs were sampled in a region of 45 km^2 located between the Mont Blanc, the Lake Annecy and the Lake Geneva. Pollen and *seda*DNA analyses have been carried out on each top of these sediment cores. Current and historical regional vegetation maps are used to evaluate the performance of the REVEALS model (i.e. regional component of the LRA). Regarding the performance of the LOVE model (i.e. local component of the LRA), we use for the evaluation, the current vegetation units surrounding each site (within a 10km radius) based on vegetation maps and botanical surveys. The vegetation maps and the LRA runs are performed for specific time slice during the Holocene. This research aims at improving the use of the LRA to reconstruct past vegetation and land-use changes from a local to a regional scale in mountain regions, in general.

Age-mixing harmonizes apparent differences in extinction chronologies between fossil and eDNA records

Dr. Joshua Miller [1], *Dr. Carl Simpson* [2]

1. University of Cincinnati, 2. University of Colorado Boulder

Environmental DNA (eDNA) collected from stratigraphic sections routinely identify megafauna DNA from sediments that are several thousand years younger than species' last fossil occurrences. While such records have been used to propose the survival of mammoths and other species well into the Middle Holocene, a unique challenge for using eDNA records to estimate extinction timing is that organisms can contribute DNA to sediments long after their deaths. eDNA archives mix undatable DNA from both living and dead individuals, thus the durations that bones and other biological tissues persist on landscapes impart important controls on the scale of temporal mixing within eDNA samples. To characterize how the duration of bone persistence changes due to environmental settings, we aggregated data from the literature on the oldest radiocarbon-dated surface-collected bones from different ecosystems. We included bones that we are reasonably confident persisted without being completely buried ("never buried"), and bones for which exhumation at some point cannot be confidently excluded ("potentially never buried"). We supplemented these data with AMS radiocarbon dated bones from Arctic Alaska and temperate North America. Pairing bone persistence with mean annual temperatures from their sample localities, we find a strong link between local temperature and the logged duration of bone persistence (never buried bones, $R^2 = 0.94$, $p < 0.01$; potentially never buried bones, $R^2 = 0.95$, $p < 0.01$). Using published data on Arctic mammoths as a test case, we find that the gap between the most recent fossil occurrence and the most recent sediments containing mammoth DNA (~7 kyr) is within expectations of the predicted duration of bone persistence for Siberian temperatures. Particularly in cold, high-latitude systems, decay rates of bones and other tissues are extremely slow and remains on landscape surfaces can be ubiquitous. Bones in these settings are frozen for much of the year and even highly weathered specimens, including those exhumed from permafrost millennia after initial burial, can release viable DNA. Rather than millennial-scale extensions to species survival, DNA from sediments that significantly postdate last fossil occurrences likely identify temporal mixing in eDNA and highlight commingling of the dead with the living.

Session 18:
Dansgaard-Oechger events in climate models and the real world

The regional imprints of Dansgaard-Oeschger events on land and marine environments

Prof. Maria Sanchez-Goñi [1]***, Dr. Tiffanie Fourcade*** [2]***, Dr. Coralie Zorzi*** [3]***, Dr. Dunia Urrego*** [4]***, Dr. Nils Weitzel*** [5]

1. Ecole Pratique des Hautes Etudes, Paris Science Lettres University, 2. University Bordeaux-Montaigne, 3. University of Bordeaux, 4. University of Exeter, 5. University of Tübingen

One of the most important challenges of the IPCC is documenting the regional impact of the present-day global warming. Yet, identifying the regional expression of global changes is the first and necessary step to understand the mechanisms behind them. The best examples of past global warming events, comparable in velocity and magnitude to those expected in the 21st-century, are those associated with the Dansgaard–Oeschger (D–O) cycles that punctuated the last glacial period, ~115,000-27,000 years ago (115-27 ka). Reasonably well-chronologically constrained deep-sea and terrestrial records of D-O cycles provide an excellent opportunity for documenting the nature (shape, amplitude, timing and duration) of the vegetation, fire and oceanic regional responses to past rapid global warming events. Building on the ACER (https://doi.org/10.1594/PANGAEA.870867) and Paleo-Jump (https://www.tipes.dk/paleojump-a-tipes-database-for-research-on-rapid-climate-transitions/) databases, I will present a new compilation of D-O records from geochemical, sedimentological and micropaleontological data. I will pay particular attention to one of the best dated event, the D-O 8, centered at ~38,000 years ago (38 ka). It followed the Heinrich Stadial 4 cold phase (~40 -38 years ago), and occurred during a period of minima in precession and intermediate ice volume (Marine Isotope Stage 3). Compared to the other D-O events, D-O 8 was marked by strong Greenland warming, ~10°C, and strong increase in atmospheric CH_4 and CO_2 concentrations, by at around 150 ppb and 20 ppm, respectively, and was associated with a vigorous resumption of the Atlantic Meridional Overturning Circulation. D-O 8 warming has also the advantage to be relatively recent and, therefore, one of the best recorded all around the world.

The long and winding road to solving the enigma of DO-events

Prof. Peter Ditlevsen [1]

1. *Physics of Ice, Climate and Earth, Niels Bohr Institute, University of Copenhagen*

The DO-events are the most profound expressions of rapid natural climate transitions observed in the Pleistocene climate record. They were first discovered in ice core records more than 30 years ago, but are only now in the infancy of being reproduced in climate models. This points to a complex sequence of events necessary for triggering the sudden warming and more gradual cooling events. These involving arctic sea blocking deep water formation, changing the Atlantic meridional overturning, influencing the transport of heat and salt etc. A lot of these processes are only partly known from the sparse paleoclimatic records. In order to guide the modelling, we shall focus on the high-resolution ice core record from Greenland and extract as much information as possible on the underlying dynamics from this one timeseries. By analysis the structure of the fast fluctuations in the record and the statistics of durations of DO-events we can make inferences on the causes and predictability of the transitions.

Modeling glacial climate variability with comprehensive Earth System Models – Advances and Challenges

Dr. Marie-Luise Kapsch [1]***, Dr. Chetankumar Jalihal*** [1]***, Dr. Clemens Schannwell*** [1]***, Dr. Marlene Klockmann*** [2]***, Dr. Uwe Mikolajewicz*** [1]

***1.** Max Planck Institute for Meteorology,* ***2.** Helmholtz Centre HEREON*

Rapid climate changes during the last glacial cycle are evident in marine and terrestrial records. However, as observations are spatially confined and differ in their temporal resolution and extent, the underlying processes triggering abrupt climate changes have not been fully understood. In order to improve the process understanding, a great advance has been made throughout the last years in developing and setting up comprehensive Earth System Models (ESMs) for simulating climate changes on glacial time scales.

The German paleo-climate modeling initiative PALMOD facilitated these efforts and allowed for the development of three ESMs with interactive ice sheets and solid Earth dynamics for the examination of climate changes and variability during different stages of the last glacial cycle, such as the last deglaciation and Marine Isotope Stage 3 (MIS3). Both periods exhibit abrupt climate events in observational records, such as Dansgaard-Oeschger (D-O) and/or Heinrich events (HEs).

A set of coordinated sensitivity experiments within PALMOD allowed to assess whether the ESMs are generally capable of simulating D-O events under realistic MIS3 boundary conditions. Comparing the independent ESMs and the boundary conditions necessary to trigger D-O like oscillations highlights the limitations of simulating abrupt events with comprehensive ESMs under realistic boundary conditions but helps to improve our understanding of the underlying mechanisms.

Anatomy of past abrupt warmings recorded in Greenland ice cores

Several model-based mechanisms have been suggested to explain the abrupt climate variability evidenced in Northern Hemisphere paleoclimate reconstructions during the Last Glacial. However, because of the limited temporal resolution achievable in most climatic archives and relative dating uncertainties between paleoclimate records, it remains challenging to test the proposed processes with data allowing a subcentennial-scale investigation of the anatomy – the duration and temporal phasing – of the changes in different parts of the world.

Here, we overcome these limitations by using new and existing high/resolution records from the Greenland NGRIP and NEEM ice cores across the Last Glacial to map the pluriannual-scale evolution of tracers ($\delta^{18}O$, d-excess, Ca^{2+}, Na^{+}, annual layer thickness) which contain signatures of climatic changes in different regions of the Northern Hemisphere.

We highlight the absence of a systematic pattern in the anatomy of abrupt changes as recorded in different ice parameters. This diversity in the sequence of changes seen in ice-core data is also observed in climate parameters derived from numerical simulations which exhibit self-sustained abrupt variability arising from internal atmosphere-ice-ocean interactions. Our analysis of two ice cores shows that the diversity of abrupt warming transitions represents variability inherent to the climate system and not archive-specific noise. Our results hint that during these abrupt events, it may not be possible to infer statistically-robust leads and lags between the different components of the climate system because of their tight coupling.

A multiproxy record of Dansgaard-Oeschger events from 120 to 72 ka based on cave stalagmites from south-east France

Dr. Ellen Corrick [1]***, Prof. Russell Drysdale*** [2]***, Dr. John Hellstrom*** [2]***, Dr. Isabelle Couchoud*** [3]***, Dr. Didier Cailhol*** [4]***, Mr. Henri Wong*** [5]***, Prof. Hai Cheng*** [6]***, Dr. Stéphane Jaillet*** [3]***, Mr. Stéphane Tocino*** [7]

1. *School of Earth, Atmosphere and Environment, Monash University, Clayton, Victoria, Australia,* ***2.*** *University of Melbourne,* ***3.*** *Laboratoire EDYTEM UMR CNRS 5204 Université Savoie Mont Blanc,* ***4.*** *Inrap and TRACES - UMR5608, Jean Jaurès - Toulouse University,* ***5.*** *Australian Nuclear Science and Technology Organisation, Lucas Heights, Australia,* ***6.*** *Xi'an Jiaotong University,* ***7.*** *Grand Site Aven d'Orgnac*

Dansgaard-Oeschger (D-O) events are one of the best examples of naturally occurring abrupt climate change. D-O events are clearly recorded in Greenland ice core records with coincident changes detected in marine and terrestrial palaeoclimate records spanning a range of climate zones. Cave stalagmites provide some of the best terrestrial records of D-O events as they preserve decadal resolution records, have multiple climate sensitive proxies, are widely distributed and, importantly, can be accurately and precisely dated by uranium-thorium dating. Cave stalagmites therefore offer the opportunity to improve our understanding of global climate tele-connections during D-O events and to improve the chronology of event timing. Here we present a stacked, multiproxy ($d^{18}O$, $d^{13}C$, Mg/Ca and Sr/Ca) stalagmite record providing near continuous coverage from 120 to 72 ka (MIS 5d-a). The stacked record is composed of four stalagmites from Saint-Marcel Cave and two stalagmites from Orgnac Cave. Both caves are in south-east France. Proxy variations are replicated well between temporally overlapping sections of the stalagmites. This provides confidence in the interpretation of the proxy variations as reflective of climate and environmental changes outside of the cave. Dating of each stalagmite is focused on the abrupt transitions to optimise the chronological determination of the timing of these events. A composite depth-age model is constructed based on the age measurements from individual stalagmites. The stacked record clearly records almost all D-O events spanning from Greenland Stadial 26 to Greenland Interstadial (GI) 19.2, demonstrating a strong sensitivity of rainfall and temperature changes at the site to climate changes in the North Atlantic region. In addition to recording the main D-O events, sub-millennial events, such as GI 23.2, GI 24.1b and GS 24.2, which are poorly studied outside of Greenland, are also recorded. This stacked record, based on six well dated stalagmites, provides improved understanding of the response to millennial and sub-millennial changes in western Europe, and refined chronological constraint for the timing of abrupt events throughout the early last glacial period.

Regionally coherent patterns of organic deposition in Japanese lakes track millennial scale variability in the East Asian Monsoon during Marine Isotope Stage 3

Dr. Jonathan Tyler [1]***, Mr. Alexander Francke*** [1]***, Dr. Danielle McLean*** [2]***, Dr. Richard Staff*** [3]***, Prof. Yusuke Yokoyama*** [4]***, Prof. Minoru Ikehara*** [5]***, Prof. Fujio KUMON*** [5]***, Prof. Takeshi Nakagawa*** [6]

The nature and timing of millennial scale variability across the East Asian Monsoon (EAM) during the last glacial cycle remains a point of debate, particularly in the maritime affected regions of eastern Asia. Here we infer regional scale hydroclimate variability between 50-10 thousand years before present (ka B.P.), based on three remarkably similar lake sediment total organic carbon (TOC) records, from Lake Suigetsu, Lake Nojiri and Lake Biwa, Japan. The three records were chronostratigraphically tied to the precise varve and radiocarbon chronology of Lake Suigetsu using common tephra layers, and by re-calibrating radiocarbon dates from Lakes Biwa and Nojiri using IntCal20 (and by extension, Lake Suigetsu) as the calibration reference. Based on this chronological alignment, TOC in the three cores correlates to a high degree ($R^2 > 0.6$), revealing a common, regional scale climate driver over environmental change on a centennial-millennial timescale.

Collectively, these records are interpreted to reflect regional scale hydroclimatic change, which is linked to variability in the EAM. Carbon isotope and C/N ratios from the Lake Suigetsu sediments indicate that variations in TOC are driven by changes in the flux of terrestrial organic matter to the lake. The Japanese lake TOC records exhibit marked similarities with speleothem, loess, marine and ice core records from across Asia, lending strength to the hypothesis of a linked winter and summer monsoonal cycle. In particular, several records highlight a period of markedly enhanced precipitation between 40-35 ka. There is no consistent correlation between millennial scale variability in Japan and Greenland ice core $d^{18}O$. However, a variable correlation exists between Japanese hydroclimate and Antarctic ice core $d^{18}O$, with a fluctuating sign and strength of correlation that appears to vary on an orbital timescale. We therefore support the hypothesis that a climate teleconnection with Southern Hemisphere and Pacific Ocean temperature had a major effect on precipitation in Japan during the last glacial period, possibly subject to modulation by the cross-equatorial insolation gradient.

Global patterns of climate change during Dansgaard-Oechger warming events in MIS3

Dr. Colin Prentice [1], ***Ms. Mengmeng Liu*** [2], ***Dr. Sandy P. Harrison*** [3]

1. Georgina Mace Centre for the Living Planet, Department of Life Sciences, Imperial College London, Silwood Park Campus, Buckhurst Road, Ascot SL5 7PY, UK, 2. School of Archaeology, Geography & Environmental Science, Reading University, Whiteknights, Reading, RG6 6AH, UK

Quantitative information on climate changes during Dansgaard-Oeschger cycles is necessary if we are to understand better how these rapid events were expressed globally, how they impacted land ecosystems and biogeochemical cycles, and how well they are simulated by climate models. There are now many long terrestrial records covering the last glacial period, yet there has been no recent assessment of the implied climate signals. Only a few quantitative climate reconstructions have been attempted, and those available were derived using different methods. Here we use pollen samples from 73 sites globally, covering part or all of Marine Isotope Stage 3 (MIS3), to reconstruct changes in seasonal temperatures and moisture availability during Dansgaard-Oeschger warming events (D-O 12 through 5) using a partial least-squares calibration technique, based on the unimodal model of taxon abundances, that accounts both for sampling frequency (downweighting heavily sampled regions of climate space) and for the tolerance breadths (upweighting pollen taxa with narrow ranges) of the taxa in the (global) surface-sample training data set. We show large increases in both summer and winter temperatures in the northern extratropics, and these warmings are associated with significant changes in moisture availability. Seasonal warming is negligible in the tropical records, however, where changes in moisture availability dominate. Temperature changes in the southern extratropics were large, but in some cases anti-phased with those in the northern extratropics.

Matrix profile analysis of Dansgaard-Oeschger events in paleoclimate time series

Dansgaard-Oeschger (DO) events are one of the most striking examples of abrupt transitions observed in paleoclimatic records, particularly from Greenland. The identification of DO events in an observational record, which has typically low resolution and significant high-frequency variability, cannot rely on visual identification alone, requiring robust non-subjective approaches. Of particular interest are data-driven methods that can be applied to diverse proxy records (ice cores, speleothems, marine and lake sediments), in a consistent and objective way.

In this study we apply a purely data-driven time series method, the Matrix Profile approach, which is an algorithmic approach depending only on the prescribed length of sub-sequences within a time series. The identification of similar patterns within a time series is based on the calculation of nearest neighbours between sub-sequences, estimated through z-normalized Euclidean distances. Here the Matrix Profile approach is applied in order to identify similar events within time series and also across multiple time series, using the NGRIP Greenland ice core and the CENOGRID marine proxy records. We show that the matrix profile approach is able to identify abrupt transitions and similarity in terms of shape patterns between events in an objective and consistent way.

Identifying the mechanisms of DO-scale oscillations in a GCM: A salt oscillator triggered by the Laurentide ice sheet

Dr. Edward Armstrong [1], ***Dr. Kenji Izumi*** [2], ***Prof. Paul Valdes*** [2]

1. Department of Geosciences and Geography of the University of Helsinki, 2. School of Geographical Sciences, University of Bristol

The driver mechanisms of Dansgaard-Oeschger (DO) events remain uncertain, in part because many climate models do not show similar oscillatory behaviour. Here we present results from glacial simulations of the HadCM3B coupled atmosphere-ocean-vegetation model that show stochastic, quasi-periodical variability on a similar scale to the DO events. This variability is driven by variations in the strength of the Atlantic Meridional Overturning Circulation in response to North Atlantic salinity fluctuations. The mechanism represents a salt oscillator driven by the salinity gradient between the tropics and the Northern North Atlantic. Utilising a full set of model salinity diagnostics, we identify a complex ocean-atmosphere-sea-ice feedback mechanism that maintains this oscillator, driven by the interplay between surface freshwater fluxes (tropical P-E balance and sea-ice), advection, and convection. The key trigger is the extent of the Laurentide ice sheet, which alters atmospheric and ocean circulation patterns, highlighting the sensitivity of the climate system to land-ice extent. This, in addition to the background climate state, pushes the climate beyond a tipping point and into an oscillatory mode on a timescale comparable to the DO events.

An oscillating Atlantic Meridional Overturning Circulation during the last glacial period

Mr. Yvan Romé [1], ***Dr. Ruza Ivanovic*** [1], ***Dr. Lauren J. Gregoire*** [1], ***Dr. Sam Sherriff-Tadano*** [1]

1. *School of Earth and Environment, University of Leeds*

Abrupt climate changes over the last glacial period (~ 115 to 12 thousand years ago) are often associated with reorganisation of the Atlantic Meridional Overturning Circulation (AMOC). It has been suggested that the AMOC can exist in more than one stable mode, but the mechanisms leading to switches between different regimes are still not understood. It is also unclear how disruptions of the ocean circulation are connected to millennial-scale climate variability, such as Dansgaard-Oeschger events or abrupt transitions during the late last deglaciation.

Most attempts at theorising glacial millennial-scale variability have involved looking at heat and salt transfers between the subtropical and subpolar gyres. This is often referred to as the 'salt oscillator' mechanism, which in turn controlled the intensity of the North Atlantic current. We propose that the salt oscillator is in fact part of a larger motion combining harmonic and stochastic dynamics spanning through all components of the climate system when triggered by an initial excitation. Only under certain combinations of boundary conditions and forcings can multiple stable states coexist, sometimes leading to the activation of a pseudo-oscillating regime for thousands of years.

Based on a new set of last glacial maximum (~21 thousand years ago) simulations that oscillate when forced with snapshots of the early last deglaciation meltwater history, we propose a new way of visualising the stability of the AMOC and its shifts between different stable modes. We provide a detailed analysis of the heat and salinity tendencies in a comprehensive description of the different oscillating modes. Finally, we discuss how the freshwater forcing framework fits into the broader theory of glacial abrupt climate changes.

Effect of Climatic Precession on Dansgaard-Oeschger-Like Oscillations

Mr. Yuta Kuniyoshi [1], ***Prof. Ayako Abe-Ouchi*** [2], ***Dr. Sam Sherriff-Tadano*** [3], ***Dr. Wing-Le Chan*** [1], ***Dr. Fuyuki Saito*** [4]

1. *Atmosphere and Ocean Research Institute, The University of Tokyo,* ***2.*** *The University of Tokyo,* ***3.*** *School of Earth and Environment, University of Leeds,* ***4.*** *Japan Agency for Marine-Earth Science and Technology*

Using the climate model MIROC4m, we simulate self-sustained oscillations of millennial-scale periodicity in the climate and Atlantic meridional overturning circulation under glacial conditions. We show two cases of extreme climatic precession and examine the mechanism of these oscillations. When the climatic precession corresponds to strong (weak) boreal seasonality, the period of the oscillation is about 1,500 (3,000) years. During the stadial, hot (cool) summer conditions in the Northern Hemisphere contribute to thin (thick) sea ice, which covers the deep convection sites, triggering early (late) abrupt climate change. During the interstadial, as sea ice is thin (thick), cold deep-water forms and cools the subsurface quickly (slowly), which influences the stratification of the North Atlantic Ocean. We show that the oscillations are explained by the internal feedbacks of the atmosphere-sea ice-ocean system, especially subsurface ocean temperature change and salt advection feedback with a positive feedback between the subpolar gyre and deep convection.

Ocean-sea ice dynamics in the Nordic Seas across a stadial-interstadial transition – a modelling and data perspective

Dr. Chuncheng Guo [1], ***Dr. Bjørg Risebrobakken*** [1], ***Mrs. Wanyee Wong*** [1], ***Dr. Marlene Klockmann*** [2], ***Dr. Guido Vettoretti*** [3]

1. *NORCE Norwegian Research Centre, and Bjerknes Centre for Climate Research,* ***2.*** *Helmholtz Zentrum Geesthacht,* ***3.*** *Physics of Ice, Climate and Earth, Niels Bohr Institute, University of Copenhagen*

We will present results of ABRUPT, a project in which we simulate and reconstruct the sea ice conditions, ocean hydrography and climate of the Nordic Seas, over two targeted Dansgaard-Oechger events. Multi-model output from three transient glacial GCM simulations (NorESM, CESM, MPI-ESM) and high-resolution reconstructions from an eastern Nordic Seas transect (from the Faeroe-Shetland Channel to the Fram Strait) show that ocean-atmosphere-sea ice processes and dynamics during the transition from H4 to GI8 are strongly coupled.
Both model results and reconstructions suggest subsurface ocean warming and polynya events in the southern- and northernmost Nordic Seas during the cold stadial. For a short time during the stadial to interstadial transition, a corridor of open water and hence sea ice-free conditions existed from the southern Nordic Seas all the way to the Fram Strait. The breakup of the sea ice cover is likely caused by the overshoot of AMOC during the transition and the associated enhanced ocean heat transport into the Nordic Seas. After the transition, winter sea ice grows back in the Fram Strait during the interstadial state, but the Southern Nordic Seas remain ice-free.

Climate feedbacks can be constrained by Dansgaard–Oeschger events

Ms. Mengmeng Liu [1], ***Dr. Colin Prentice*** [2], ***Dr. Laurie Menviel*** [3], ***Dr. Sandy P. Harrison*** [4]

1. *Department of Life Sciences, Imperial College London, Silwood Park Campus, Ascot SL5 7PY, UK,* ***2.*** *Georgina Mace Centre for the Living Planet, Department of Life Sciences, Imperial College London, Silwood Park Campus, Buckhurst Road, Ascot SL5 7PY, UK,* ***3.*** *Climate Change Research Centre/ESSRC, The University of New South Wales,* ***4.*** *School of Archaeology, Geography & Environmental Science, Reading University, Whiteknights, Reading, RG6 6AH, UK*

There are large uncertainties in the estimation of the magnitude of biospheric feedbacks to climate: there are large differences between the estimates produced by Earth System Models and observations also have large ranges. The rapid warmings during the last glacial period, the Dansgaard–Oeschger (D-O) events, are comparable in both rate and magnitude to present-day warming and can provide a better constraint. We have successfully used these events to quantify greenhouse-gas climate feedbacks, using the global mean temperature change obtained from a climate model (LOVECLIM) simulation of D-O events and the radiative forcing brought about by greenhouse gases, calculated by their concentration changes in ice core records. We derive feedback estimates of 0.155 ± 0.035 W m^{-2} K^{-1} for CO_2, 0.114 ± 0.013 W m^{-2} K^{-1} for CH_4 and 0.106 ± 0.026 W m^{-2} K^{-1} for N_2O. These estimates are consistent but more tightly constrained than previous estimates.
This methodology can be applied to estimate other biospheric climate feedbacks, including land-surface albedo. Land-surface albedo can be predicted as a function of snow cover, vegetation height and maximum fAPAR (the fraction of Absorbed Photosynthetically Active Radiation). We reconstructed changes in vegetation height and maximum fAPAR using pollen data from individual sites covering the D-O events and derived snow cover changes from a climate model (LOVECLIM) simulation, then we applied a 3D variational technique to produce a global gridded map for each event from these site-based albedos. These values are then used to calculate the corresponding radiative forcing in order to estimate the land-surface albedo feedback in the same way as greenhouse-gas climate feedbacks.

Atmospheric CO2 impact on spontaneous Dansgaard–Oeschger type oscillations: oscillatory sweet-spot for three climate models

Dr. Irene Malmierca-Vallet [1]***, Dr. Louise Sime*** [1]

1. *British Antarctic Survey*

Greenland ice core records feature Dansgaard–Oeschger (DO) events; abrupt warming episodes followed by a gradual cooling phase during mid-glacial periods. Here, we analysis spontaneous self-sustained D-O type oscillations reproduced in three climate models: CCSM4, MPI-ESM and HadCM3. The three models show D-O type oscillatory behaviour in a remarkably similar, narrow window of atmospheric CO2 concentrations between approximately 185 to 230 parts per million (ppm). This CO2 range also compares particularly well with Marine Isotopic Stage 3 (MIS 3 - between 27.8 – 59.4 thousand of years BP, hereafter ka) atmospheric CO2 values (233-187.5 ppm), when D-O events occurred with most regularity.

In all three models, the oscillatory experiments with higher CO2 show an increased built-up of stadial salinity in the upper ocean in the subtropics, especially in the eastern edge of the North Atlantic Current, compared with the ensemble mean: the tendency to re-invigorate the Atlantic Meridional Overturning Circulation (AMOC) is increased and so the system spend less time in the stadial phase. CO2 also affects North Atlantic and Arctic sea ice, determining interstadial and stadial duration. Similar sensitivity CO2 experiments performed with other climate models may help in further constraining the here-identified range of atmospheric CO2 (185-230 ppm) bounding this D-O sweet-spot.

Carbon fluxes during Dansgaard-Oeschger events as simulated by an Earth System Model. (Jochum, Chase, Nuterman, Pedro, Rasmussen, Vettoretti, Zheng)

Prof. Markus Jochum [1]

1. *TeamOcean*

The CESM with biogeochemistry is configured to simulate glacial climate. The integration shows transitions from interstadials to stadials and back. The amplitude of the associated Greenland and Antarctica temperature changes and the atmospheric CO2 signal are consistent with ice-core reconstructions, and so are the time lags between termination of a stadial, Antarctic temperature reversal, and the decline of the atmospheric CO2 concentration. The present model results stand out because the transitions occur spontaneously (without forcing changes like hosing) and because they reproduce the observed features above in a configuration that uses the same parameterizations as climate simulations for the present day (i.e., no retuning has been done). During stadials, precipitation shifts lead to reduced growth on land, which dominates the CO 2 increase; the ocean acts as a minor carbon sink during the stadials. After the end of the stadials, however, the sudden reversal of the stadial anomalies in temperature, wind, and precipitation turns the ocean into a carbon source, which accounts for the continued rise of CO2 for several hundred years into the interstadial. The simulations also provide a novel possible interpretation for the observed correlation between CO 2 and Antarctic temperature: rather than both being controlled by Southern Ocean processes, they are both controlled by the North Atlantic Ocean, and most of the extra CO 2 may not be of Southern Hemisphere origin. If the stadials are prolonged through North Atlantic hosing, the upper ocean comes to an equilibrium, and the CO 2 response is dominated by a single process: reduced export production in the North Atlantic as result of the collapsed overturning circulation. This is in contrast to the unforced simulation where the net ocean carbon flux anomaly is the sum of several regional responses of both signs and similar magnitudes. Reducing the aeolian iron deposition by half, to account for the observed reduction of Southern Hemisphere dust fluxes during stadials, reduces biological productivity and export production so that the Southern Ocean emerges as an important carbon source, at least for the three centuries up until a new equilibrium for the upper ocean is reached.

Session 19: Global characterization of the Neogene–Quaternary (Pliocene–Pleistocene) transition

Benthic δ18O and δ13C record from the Monte San Nicola section (Gelasian GSSP, Sicily)

Dr. Elena Zanola [1], ***Prof. Luca Capraro*** [1], ***Prof. Patrizia Ferretti*** [2], ***Prof. Eliana Fornaciari*** [1], ***Prof. Simone Galeotti*** [3], ***Prof. Alessandro Incarbona*** [4], ***Dr. Patrizia Macrì*** [5]

1. University of Padova - Department of Geosciences, 2. Department of Environmental Sciences, Informatics and Statistics, Ca' Foscari University of Venice, 3. University of Urbino - Department of pure and applied sciences, 4. University of Palermo - Department of Earth and Sea Sciences, 5. Istituto Nazionale di Geofisica e Vulcanologia, Rome (Italy)

The Central Mediterranean region is traditionally acknowledged as a key reference area for investigating the global climate variability over the last few million years. In particular, the expanded open marine successions exposed along the coastline of Southern Italy and Sicily preserve a manifold array of paleoclimatic proxies, which can be tightly constrained in time by means of a detailed biomagnetostratigraphic framework (Cita et al. 2008; Capraro et al., 2017, 2022). In this context, the Monte San Nicola area (Southern Sicily) offers a spectacular stratigraphic succession that was employed for defining the GSSP of the Gelasian Stage (ca. 2.58 Ma; Rio et al., 1998). The section has been recently redefined as the basal Pleistocene Stage (Head et al., 2008), because the triplet of glacial episodes found immediately above the Gelasian GSSP (i.e., the MIS 100 - MIS 98 - MIS 96 glacials) is considered correlative to the definitive onset of the Northern Hemisphere Glaciation (NHG; Zachos et al. 2001). Recent studies on both the historical Monte San Nicola section, where the Gelasian GSSP is located, and adjacent profiles (Capraro et al., 2022) provided information on the long-term climatic evolution across the Gelasian and the MIS 100 glacial in particular (Becker et al., 2005). Nonetheless, documentation across the Piacenzian/Gelasian boundary is still sparse.

We are currently committed to reconstructing a continuous and chronologically sound benthic $\delta^{18}O$ and $\delta^{13}C$ record across the "Mandorlo" section of Capraro et al. (2022), with a specific focus on the interval straddling the Piacenzian/Gelasian boundary. Results achieved so far proved critical for pinning the Gauss-Matuyama geomagnetic reversal and establishing the relative positions of the main guiding criteria for recognizing the boundary, as well as new insights on the oceanographic and climatic evolution of the central Mediterranean at the beginning of the Northern Hemisphere Glaciation.

Paleomagnetic and oxygen isotopic analyses on a boring core drilled through the base of Quaternary from the marine sedimentary succession Chikura Group in the southern Boso Peninsula, Japan

Prof. Makoto Okada [1], Mr. Joan Songeons [1], Mr. Daiki Nagatomo [1], Dr. Yusuke suganuma [2]

1. Ibaraki University, 2. National Institute of Polar Research

The Chikura Group is a Pliocene-Pleistocene marine sedimentary succession distributed in the southernmost part of the Boso Peninsula. This sedimentary succession is characterized by a strong and stable magnetic signal in addition to abundant marine microfossils. Due to this nature, the Chikura Group is suitable for paleomagnetic and paleoceanographic studies. To obtain a detailed paleomagnetic record of the Gauss-Matuyama geomagnetic reversal boundary, which is the stratigraphic guide to indicate the base of the Quaternary System, we conducted a drilling campaign to take an oriented-boring core (GM-1 core) through the base horizon of the Quaternary in the Chikura Group. As a result, we have successfully collected a core consisting of almost continuous sandstone-siltstone alternation over 51 m long. Oxygen isotope measurements of benthic foraminifera, done at every 1m stratigraphic interval, confirmed that the GM-1 core covers MIS (Marine Isotope Stages) 102-G1. At MIS 103, preliminary paleomagnetic measurements confirmed a VGP path across the equator with a paleointensity trough corresponding to the Gauss-Matsuyama boundary. We will discuss the geomagnetic field variation during the geomagnetic reversal by reconstructing a detailed paleomagnetic record around the G-M boundary and comparing them with the results of ^{10}Be measurements currently being conducted.

GELSTRAT: an international program reinvestigating the Neogene–Quaternary boundary at the type locality of Monte San Nicola, near Gela, Sicily

Prof. Martin Head [1], ***Prof. Antonio Caruso*** [2], ***Prof. Adele Bertini*** [3], ***Prof. Patrizia Maiorano*** [4], ***Prof. Maria Marino*** [4], ***Dr. Wieslawa Radmacher*** [5]

__1.__ Department of Earth Sciences, Brock University, ***2.*** *Dipartimento di Scienze e Tecnologie Biologiche, Chimiche e Farmaceutiche, Università di Palermo, Italy,* ***3.*** *Dipartimento di Scienze della Terra, Università degli Studi di Firenze, Via La Pira 4, I-50121 Firenze, Italy,* ***4.*** *Department of Earth and GeoEnvironmental Sciences, University of Bari,* ***5.*** *Institute of Geological Sciences, Polish Academy of Sciences*

The Global boundary Stratotype Section and Point (GSSP) at Monte San Nicola, near Gela, Sicily, Italy was proposed in 1996 to define the base of the Gelasian Stage, then the uppermost stage of the Pliocene Series, in recognition of the intensification of Northern Hemisphere glaciation. This GSSP acquired elevated significance upon its approval in 2009 to define also the base of the Quaternary System and redefine the base of the Pleistocene Series. It is placed at the base of the marly layer immediately overlying the prominent, laminated, reddish, sapropelic Nicola bed, and has an astronomically tuned age of 2.58 Ma. The Nicola bed is assigned to Mediterranean Precession-Related Cycle 250 and aligns with an obliquity maximum representing Marine Isotope Stage 103 which, together with the Gauss–Matuyama paleomagnetic reversal, facilitates global correlation. Fine details of the stratigraphy nonetheless remain uncertain, including the precise position of the Gauss–Matuyama relative to the GSSP. GELSTRAT was inaugurated in September 2021 during an INQUA-SQS International Field Workshop focused on the reinvestigation and reanalysis of the Gelasian GSSP using modern methods and a broad range of proxies. Sampling across the boundary interval at the type section in September 2021 was supplemented by further fieldwork in April–May 2023 and resulted in the collection of 404 samples across a ~18 m stratigraphic interval spanning the GSSP and ranging from the top of bed A1 to ~10 m above the top of the Nicola bed (A5). Samples were collected at ~5 cm intervals. Pervasive fine-scale tectonic fracturing of the Monte San Nicola outcrop, coupled with the brittle nature of the dominant marl lithology, makes closer-interval sampling challenging although several narrow blocks of the finely laminated Nicola bed were collected for additional microstratigraphic analysis. GELSTRAT is an international collaborative program in which approaches planned or in progress include: calcareous nannofossils, foraminifers, pollen, dinoflagellate cysts, macrofossils, ichnofossils, foraminiferal stable isotopes, organic geochemistry, clay mineralogy, magnetostratigraphy, and ^{10}Be analysis. A refined characterization of the Gelasian GSSP will enhance its utility for the precise recognition of the base of the Quaternary on a global scale.

Paleoclimate evidences from calcareous plankton assemblages at the Pliocene-Pleistocene transition (Monte San Nicola section, Sicily)

Dr. Marina Addante [1], ***Prof. Angela Girone*** [1], ***Prof. Patrizia Maiorano*** [1], ***Prof. Maria Marino*** [1], ***Prof. Giovanna Scopelliti*** [2], ***Dr. Samanta Trotta*** [1], ***Prof. Antonio Caruso*** [3]

1. Department of Earth and GeoEnvironmental Sciences, University of Bari, 2. Dipartimento di Scienze della Terra e del Mare, Università di Palermo, Italy, 3. Dipartimento di Scienze e Tecnologie Biologiche, Chimiche e Farmaceutiche, Università di Palermo, Italy

The present work is part of the GELSTRAT project, inaugurated in September 2021 during an INQUA-SQS International Field Workshop and focused on a high-resolution investigation of the Pliocene-Pleistocene transition (PPt), in the marly succession of Monte San Nicola - MSN (Gela, Sicily). The section represents a chronostratigraphic reference, as it contains the Global Stratotype Section and Point (GSSP) of Gelasian (ca. 2.58 Ma), the chronostratigraphic boundary that actually marks the base of the Quaternary System. Within the GELSTRAT project, the MSN succession was sampled in great detail, providing a temporal resolution of one sample every ~ 1 ka, from the top of sapropel A1 to ~10 m above the top of sapropel A5 (Nicola bed). The study interval is placed at the transition between the end of a relatively warm climatic phase, the so-called Pliocene Warm Period, around the 3 Ma, and the progressive intensification of the North Hemisphere Glaciation (NHG). It includes MIS 100, considered as one of the first pronounced glacial stage at the onset of NHG. Recent studies have been performed on the same section or on complementary outcrops, mainly focusing on the long-term stratigraphic features of the whole stratotype section or detailed isotopic studies on specific interval such as MIS 100 revealing climate evidences very similar to those observed during the Late Pleistocene Dansgaard–Oeschger and Heinrich events. However, more extended high-resolution studies on paleoclimate signal, as recorded by calcareous plankton across the transition, are still very scarce. The present contribution provides preliminary high-resolution quantitative results on calcareous nannofossil and planktonic foraminifera assemblages revealing significative glacial-interglacial and higher frequency paleoenvironmental changes, which improve the recognition and interpretation of climate variability across the PPt.

Assessing vegetation change and climate variability across the onset of Northern Hemisphere glaciation in the central Mediterranean area: The Monte San Nicola section

Mr. Houssem Tabbabi [1], ***Mr. Gabriele Niccolini*** [2], ***Prof. Adele Bertini*** [3]

1. Dipartimento di Scienze della Terra, Università di Firenze, Italy, 2. Department of Earth and GeoEnvironmental Sciences, University of Bari, 3. Dipartimento di Scienze della Terra, Università degli Studi di Firenze, Via La Pira 4, I-50121 Firenze, Italy

In the frame of the international program GELSTRAT, devoted to revisiting and documenting the Gelasian GSSP at high temporal resolution, using a multi-proxy approach (sedimentology, magnetostratigraphy, beryllium-10, marine and terrestrial biostratigraphy and paleoecology, geochemistry), pollen investigations are in progress on the samples collected at the type locality of Monte San Nicola (near Gela, Sicily). Here, across the ~18 m stratigraphic interval, including the GSSP, from the top of bed A1 to ~10 m above the top of the Nicola bed (A5), 440 samples were collected in marls and sapropels. Pollen samples were processed at the palynological laboratory of the university of Florence. Many of them, especially from the base up to the top of A4, exhibit low to very low pollen concentrations. However higher concentrations characterized the interval at the Piacenzian/Gelasian transition. The high-resolution pollen analysis documents cyclic behavior of flora and vegetation at the beginning of the Northern Hemisphere glaciations. Subtropical humid forest taxa are overall scanty with the exception of *Cathaya*. On the other hand, deciduous temperate forest (especially deciduous *Quercus*), altitudinal coniferous forest (*Picea* and *Abies*) as well as open, herbaceous vegetation are quite well expanded documenting temperature and humidity changes, during the successive glacial/interglacial cycles. Current state analysis shows that open vegetation and especially steppe taxa (e.g., Amaranthaceae, *Artemisia*, *Ephedra*) exhibit an increasing trend, which becomes more evident above A5. Dry conditions seem especially expanded after 2.58 Ma; on the other hand, just before, humid and cold phases are frequent as attested by the increase of montane coniferous taxa (especially *Picea*), e.g. in the sapropel A4/5 (MIS 104).

The flora composition, vegetation structure, and the glacial/interglacial patterns at Monte San Nicola (southern Sicily) are compared with those from the coeval pollen records from several Mediterranean sites according to E-W and N-S transects. This also contribute to a better depiction of the Gelasian GSSP, enhancing its utility for global correlation as well as to an accurate detection of the base of the Quaternary on a global scale.

Session 20: Subglacial erosion, transport, and deposition: from landform and sediment evidence to modeling

Quantifying Subglacial Processes associated with soft bedded glaciers

Prof. Jane Hart [1], ***Dr. Nathaniel Baurley*** [1], ***Prof. Kirk Martinez*** [1]

1. *University of Southampton*

Understanding subglacial processes are vital in predicting modern sea level rise as well as reconstructing the formation of subglacial tills. We examine a series of modern soft-bedded glaciers in maritime locations and use a range of techniques (including *in situ* Glacsweb probes and web-connected GPS systems) to examine their subglacial seasonal behaviour, during summer and winter. We investigate different subglacial hydrological patterns. We are able estimate the relatively sliding and deformation associated with different subglacial water pathways and relate this to till deposition.

Glacial erosion: controls and global distribution

1. *University of Victoria,* ***2.*** *Dalhousie University,* ***3.*** *Institute of Environmental Geoscience,* ***4.*** *Dartmouth College,* ***5.*** *University of Alberta,* ***6.*** *The University of British Columbia,* ***7.*** *Pennsylvania State University*

Glacial erosion has often been parameterized as proportional to glacier sliding velocity, while the role played by local geology, hydrology and climate remain largely unquantified. As a result, our understanding of the links between global climate, tectonics and glacial erosion is limited. To address this shortcoming, we present a comprehensive synthesis of previously published Quaternary glacial erosion rates from six different measurement techniques integrated over 10^{-2} to 10^{6} years: (i) instrumental measurements beneath active glaciers, (ii) sediment fluxes derived from meltwater streams or (iii) ice-marginal deposits, (iv) terrestrial cosmogenic nuclide dating (TCN), (v) luminescence thermochronometry, and (vi) relief generation of chronologically constrained surfaces. Our synthesis includes 1065 empirical data points and 465 erosion rates from ice sheets, ice caps, and topographically confined glaciers that range over six orders of magnitude, between 10^{-4} and 100 mm yr^{-1}. Using a filtered dataset of contemporary erosion rates, we apply machine learning tools, using available environmental, glaciological, and geological datasets to assess the dominant controls on subgroups of nominal data categories. On a global scale, while glacial sliding velocity is an important control, we also discover equally strong or stronger correlations between other glaciological, environmental, and lithological parameters and glacial erosion rate, some of which have not been previously documented.

Discriminating substrate geology and ice flow velocity controls on subglacial streamlined landforms and surfaces under a paleo ice stream in central Canada

Dr. Naki Akçar [1], ***Prof. Nick Eyles*** [2], ***Mr. Syed Bukhari*** [2], ***Dr. Roger Paulen*** [3], ***Dr. Shane Sookhan*** [2]

1. Institute of Geological Sciences, University of Bern, 2. Department of Physical and Environmental Sciences, University of Toronto at Scarborough, 3. Geological Survey of Canada

The Peterborough Drumlin Field (PDF: 5000 km^2) in Southern Ontario, Central Canada contains some 3000 streamlined bedforms. LiDAR mapping and statistical analyses show continuums between drumlins, grooved drumlins, and megascale glacial lineations, that previous work showed to be erosional in origin, cut below a soft-bedded terrestrial paleo ice stream flowing off the Algonquin Highlands south to the interlobate Oak Ridges Moraine during the final stages of the last glaciation c. 12000 years before present. Using the curvature-based relief separation method for mapping the morphology of these bedforms we identified eight morphotypes and in addition, six types of streamlined surfaces characterized by specific assemblages of morphotypes recording a progressive reduction of bed relief and roughness by subglacial erosion. Initial statistical analysis shows that more elongated morphotypes and streamlined surfaces are grouped into distinct flow sets suggesting the primary importance of variation in flow velocity across the ice stream in shaping and smoothing the bed. This study tests this hypothesis by exploring the specific role of substrate geology in bedform evolution established by observations and facies analysis of sediments exposed in numerous road cuts and quarries. This exercise confirms previous suggestions that bedform geology is unchanging and consists largely of an older till (Northern Till) deposited during the Last Glacial Maximum of the Laurentide Ice Sheet which was subsequently eroded by faster flowing streaming ice during deglaciation leaving a thin upper till cap. Confirmation of the primacy of ice flow velocity in controlling morphotypes and surfaces now allows glaciodynamic modeling and recognition of specific ice flow velocities from streamlined morphotypes and surfaces on ancient ice stream beds.

LiDAR mapping of drumlinoids formed by erosion below a deforming subglacial erodent layer at Saskatchewan Glacier, Canadian Rocky Mountains

Mr. Syed Bukhari [1], *Prof. Nick Eyles* [1], *Dr. Niko Putkinen* [2], *Dr. Roger Paulen* [3], *Dr. Naki Akçar* [4]

1. Department of Physical and Environmental Sciences, University of Toronto at Scarborough, 2. Geological Survey of Finland, 3. Geological Survey of Canada, 4. Institute of Geological Sciences, University of Bern

Saskatchewan Glacier is the longest (12 km) outlet glacier of the Columbia Icefields in the Canadian Rocky Mountains of Alberta, Canada and attained its maximum Little Ice Age (LIA) extent in 1853. Unusually, for valley glaciers in the region which flow for the most part over hard rock beds, the retreat of Saskatchewan Glacier is exposing an extensive (10 km^2) till bed with numerous low relief drumlinoids revealed by high resolution (+10, 000 pts/m^2) LiDAR mapping. These are cored by antecedent sediment (glaciofluvial outwash, glaciolacustrine silt, and valley side alluvial fan debris) draped erosively by a thin (< 1 m) clast-rich LIA till. Drumlinoid surfaces have been extensively striated by individual clasts and clast clusters being swept across underlying sediments within a clast-rich subglacial traction carpet (erodent layer) now preserved as a thin (< 1 m) 'traction till.' Drumlinoid surfaces closely resemble slickensided fault planes. Larger boulders being driven across drumlinoids d left plough marks in their wakes and crescentic ramps of thickened till wrapped around their leading edges. Subglacial debris was driven to the ice margin and swept forward during winter and episodic multi-year still stands, into hummocky push moraines. Soft till was also squeezed into irregular ridges at the base of crevasses, and molded in the lee of large, lodged boulders into longer flutes that propagated in length downglacier. LiDAR and outcrop data confirm that drumlinoids are the product of erosional streamlining of overridden sediment by a deforming subglacial clast-rich 'erodent layer' between ice and its bed. The same fundamental erosional stratigraphy, where a thin till cap truncates older streamlined sediments occurs widely below the beds of other retreating LIA glaciers indicating the global relevance of the erodent layer model. The work reported here underscores the need to expand high resolution LIDAR mapping of Little Ice Age and Pleistocene glacier beds.

Murtoos and subglacial meltwater dynamics: examples from the Fennoscandian Ice Sheet area

Prof. Antti Ojala [1], ***Dr. Joni Mäkinen*** [1], ***Dr. Jussi Hovikoski*** [2], ***Dr. Jukka-Pekka Palmu*** [2], ***Dr. Elina Ahokangas*** [1], ***Mr. Kari Kajuutti*** [1], ***Ms. Juulia Kautto*** [1], ***Prof. Mark Johnson*** [3], ***Dr. Gustaf Peterson Becher*** [4], ***Mr. Christian Öhrling*** [4], ***Dr. Adam Hepburn*** [5], ***Prof. Christine Dow*** [5]

1. *Department of Geography and Geology, University of Turku,* ***2.*** *Geological Survey of Finland,* ***3.*** *Department of Earth Sciences, University of Gothenburg,* ***4.*** *Geological Survey of Sweden,* ***5.*** *Geography and Environmental Management, University of Waterloo*

The present paper summarizes the main characteristics of murtoos found from the Fennoscandian Ice Sheet area with remote sensing and numerous murtoo excavations in Finland and Sweden. By using examples of their spatial and temporal relationships with other glacial landforms, subglacial meltwater routes and lithofacies analyses, we describe three main observations. First, murtoos are formed subglacially, which is seen from their orientation parallel to ice flow and associations with eskers and subglacial meltwater routes. For example, murtoos are sometimes overlain by eskers, glacial lineations and De Geer moraine ridges. Some murtoos are also covered by loose diamicton (flow till) that was deposited in the final phase of deglaciation. Second, the morphometric diversity of murtoos and murtoo-related landforms in the Fennoscandian Ice Sheet area is significant, with triangle-type murtoos the most representative and distinctive examples of murtoo landforms. Thie murtoo continuum describes the complexity of subglacial processes, including changes in ice flow velocity, water pressure and ice-sediment coupling, during deglaciation. Third, murtoos are depositional landforms composed of silt/clay-poor, sandy and gravelly diamictons interbedded with sorted glaciofluvial sediments. We provide a general structure of murtoos and typical sediment lithofacies found in murtoos and murtoo-related landforms. We suggest murtoo sediments are produced by pulsed, highly sediment concentrated flows during deglaciation concurrent only weak glaciotectonic deformation. Importantly, murtoos potentially represent a transition form from non-channelized to channelized subglacial drainage networks, which is important from the viewpoint of glacial hydrology and ice-sheet dynamics. Murtoos may thus provide new information for glacial modelling approaches by introducing the missing link between inefficient and efficient subglacial drainage, and thereby also increase our understanding on how current glaciers will behave in the warming climate.

A model of ice-marginal sediment-landform development at Lake Tekapo, Southern Alps, New Zealand

Dr. Jenna Sutherland [1], ***Dr. David Evans*** [2], ***Prof. Jonathan Carrivick*** [3], ***Prof. James Shulmeister*** [4]

1. *Leeds Beckett University,* ***2.*** *Durham University,* ***3.*** *University of Leeds,* ***4.*** *University of Canterbury*

The extent of the Southern Alps icefield in New Zealand is well-constrained chronologically for the last glacial cycle. The sediment-landform imprint of this glacial system, however, offers insight into ice-marginal processes that chronological control cannot. We present the first detailed investigation of sediments along the south-western shores of Lake Tekapo, South Island. We identify seven lithofacies, from which a five-stage palaeo-glaciological reconstruction of depositional glaciotectonic events is proposed: (i) ice-marginal advance and deposition of outwash gravels in lithofacies (LF) 1; (ii) ice-marginal recession and the development of an ice-contact lake, manifest in rhythmite deposition and iceberg rafting of dropstones (LF 2), followed by a depositional hiatus; (iii) ice-marginal recession recorded in ice-proximal aggradation of glaciofluvial hyperconcentrated flows (LFs 3, 4); (iv) ice-marginal advance documented by glaciotectonic disturbance and localized hydrofracturing, coeval with the deposition of delta foresets and a subglacial diamicton/till (LFs 5, 6); (v) final stages of ice-marginal recession and deposition of outwash gravels in LF 7. Two infrared stimulated luminescence ages were obtained from the glaciolacustrine sediments and, whilst the dating has some limitations, the sediments pre-date both the global and local Last Glacial Maximum. This reveals that the sediments do not relate to the age of the landforms stratigraphically above them and suggests perhaps that more recent glacial advances lacked capacity to erode the underlying pre-existing sediments deposited during the penultimate cycle, thereby reducing the accommodation space in the valley overdeepening. Overall, this outcrop records phases of valley aggradation throughout multiple glacial cycles which is preserved in substantial volumes. Such findings are not new features of the Quaternary stratigraphy in New Zealand; extensive *in-situ* sediments that have survived subsequent ice re-advances are consistent with sediment fills recorded elsewhere across South Island.

Genesis of glaciofluvial hummocks in subglacial meltwater corridors of the Slave Geological Province, Canada.

Dr. Brent Ward [1], ***Mr. Patrick Desrosiers*** [2], ***Mr. David Sacco*** [2], ***Ms. Anna Haiblen*** [3]

1. Simon Fraser University, 2. Palmer Environmental Consulting, 3. Groundwater Consulting

The Slave Geological Province in Northern Canada was affected by the Laurentide Ice Sheet during the last glaciation. A distinctive record of this is a network of 'subglacial meltwater corridors' (SMCs), consisting of relatively continuous, narrow, sub-linear tracts where till has been eroded, bedrock is commonly exposed, and glaciofluvial landforms were deposited. SMCs are parallel to sub-parallel with deglacial ice flow directions and have undulating longitudinal profiles. Till dominates in intervening areas. Here we discuss the origin of SMC's and genesis of the landforms within them.

Eskers make up a small proportion of the glaciofluvial features in most SMCs, more common are scour zones and variably shaped depositional landforms referred to as 'hummocks,' composed of sandy diamicton. Hummocks typically occur in groups of tens but can number in the hundreds. Features range from individual mounds to irregular complexes with multiple high points. Sample transects from unmodified till into the SMC's indicate the hummocks are much sandier than the regional till. In some SMCs, the hummocks are streamlined. Limited morphometric analysis shows that individual features have a mean length-to-width ratio of 1.8. The average mound elongation direction usually parallels the final ice flow that affected the area.

These results and mapping relationships suggest the corridors were formed from subglacial meltwater flow. SMCs likely formed late during deglaciation because in most areas, the hummocks and eskers that they contain do not appear significantly affected by ice flow. In SMCs that contain both eskers and hummocks, depositional relationships indicate esker ridges were deposited after the glaciofluvial hummocks. We hypothesize that transient, sheet-type subglacial meltwater flow events resulted in erosion and transport of till to form the SMC's. Glaciofluvial hummocks formed from the rapid deposition of eroded till while eskers likely formed further downflow during the waning stages of these flow events. SMC's and related landforms likely formed in short segments in a time transgressive manner. Meltwater could have been sourced from supraglacial lakes that drained in catastrophic pulses. It is possible that SMCs are the Quaternary landscape record of lake-drainage events similar to those that occur presently in Southwest Greenland.

Session 21: Records of climate change from MIS 3 and MIS 2 in the Southern Hemisphere: The Lynda Petherick Memorial Session

The Last Glacial Maximum on Minjerribah – North Stradbroke Island: Lynda Petherick's contribution to understanding of Australia's late Quaternary environments.

Prof. Patrick Moss [1]***, Prof. Hamish McGowan*** [2]

1. *University of Queensland,* ***2.*** *The University of Queensland*

Lynda Petherick's research on the last glacial environments of Minjerribah (North Stradbroke Island), Southeast Queensland, Australia provided important impetus in developing the island as a crucial location for understanding eastern Australian Sub-Tropical Quaternary environments, particularly in a global context. Lynda focussed on two sites, Native Companion Lagoon and Tortoise Lagoon, with an emphasis on analysis on dust to examine climate dynamics during the Last Glacial Maximum (LGM), as well as pollen and charcoal analysis to understand landscape processes. This presentation will provide an overview of this research, as well as examining new research that has built on the significant foundations that Lynda's research has provided. In particular, a focus will be on landscape change over the last 45,000 years for the southeast coastal dunes of Minjerribah. This region has evidence of continuous human occupation from beyond the LGM to present, and the Native Companion Lagoon site provides important insight into the regional landscape change for this locality. Furthermore, a new LGM site, Jumping Grass Marsh, situated near the settlement of Dunwich will be discussed. This site provides new information on LGM environments through pollen and charcoal analysis that can be related to both Native Companion and Tortoise Lagoons and builds on the previous work undertaken by Lynda on LGM environments for sub-tropical eastern Australia.

A glacial chronology from sub-Antarctic Marion Island for MIS 3 and MIS 2

Dr. Elizabeth Rudolph [1]***, Prof. David Hedding*** [2]***, Prof. Dominic Hodgson*** [3]***, Prof. Werner Nel*** [4]

1. *University of the Free State,* ***2.*** *University of South Africa,* ***3.*** *British Antarctic Survey,* ***4.*** *University of Fort Hare*

It is increasingly apparent that local and regional factors, including geographic location, topography, and climatic variability, strongly influence the timing and extent of glaciation across the Southern Hemisphere. Glacial chronologies of sub-Antarctic Islands can provide valuable insights into the nature of regional climatic variability and the localised response(s) of glacial systems during periods of climatic change. On Marion Island, southern Indian Ocean, new cosmogenic 36Cl exposure ages confirm a local Last Glacial Maximum was reached prior to ~35 ka. Ice retreated throughout MIS 2 with minor standstill events between ~33-26 and ~20-17 ka, with limited evidence of ice re-advances during the Antarctic Cold Reversal or Holocene cooling periods. In this talk we compare Marion Island's glacial chronology with other sub-Antarctic islands (e.g. the Kerguelen archipelago, Auckland and Campbell islands, and South Georgia) and continental mountain glaciers (e.g. Patagonia and New Zealand) and review the evidence for a Southern Hemisphere glacial maximum in late MIS 3 (~41 ka), and glacier responses to cooling periods around ~32 and 21 ka. At a regional scale, sea surface temperatures and the position of the Southern Westerly Wind belt are recognized as key controls on ice accumulation due to their influence on air-temperature and precipitation regimes and the equilibrium-line altitude. At a local island scale, geomorphological mapping shows that deglaciation of individual glacier lobes was a-synchronous due to local physiography and topographical factors controlling the island's micro-climate.

Wood charcoal from Knysna Eastern Heads Cave 1: Evidence for the impact of the Last Glacial Maximum climate on woody vegetation and people of the Palaeo-Agulhas Plain, southern Africa

Dr. Bongekile Zwane [1], ***Dr. Lynne Quick*** [1], ***Dr. Naomi Cleghorn*** [2]

1. Botany Department & African Centre for Coastal Palaeoscience, Nelson Mandela University, Gqeberha, *2. Department of Sociology and Anthropology, University of Texas at Arlington*

The Last Glacial Maximum (LGM) is important for understanding the change from the Middle Stone Age (MSA) to Later Stone Age (LSA) in southern Africa. Evidence for this transition is often found in archaeological sites from the interior of the subcontinent. However, coastal sites hold unique evidence for the effects of glacial MIS 2 climates on the coastal landscapes and the resources on which people depended. The Knysna Eastern Heads Cave 1 (KEH-1), situated on the coastal margin of the southern Cape, is one of very few sites which preserve the continuity of life in the southern Cape across the MSA and LSA. It is currently being investigated to better understand the effects of the 26- thousand years old (ka) orbital forcing on southern Africa's coastal ecosystems. The glacial conditions of the LGM prompted an approximately 120 meters of sea level drop which opened more than 80 km2 of coastal plain, the Palaeo-Agulhas Plain (PAP), in the southern Cape of South Africa. This now-extinct landscape expanded the Cape Floristic Region (CFR) of South Africa and diversified the resource base for the human populations during MIS 2. KEH-1 accommodated some of these human populations who first invented the LSA lithic tool industry. Their adaptation to the LGM environment is partially visible in the archaeological and palaeoenvironmental record of the cave. Here, we present the preliminary results for the analysis of wood charcoal from three stratigraphic units (Dark Brown Spally, Dark Shelly and Dense Hearth Aggregate) of KEH-1 that are dated between >45 and 22 ka. This charcoal assemblage represents the subset of woody vegetation which grew in the vicinity of the site including parts of the PAP. We use the occurrence and diversity of the vegetation communities represented by this charcoal, to discuss the climate and its significance to the wider southern Cape ecosystem. We also use this vegetation subset to reconstruct the pattern of KEH-1 occupation by people and contextualise their foraging strategies spanning the MIS 3- 2 period.

Sedimentology and Luminescence Chronology of Glaciation in the Upper Clutha River Drainages, South Island, New Zealand

Prof. Glenn Thackray [1], *Prof. Tammy Rittenour* [2], *Prof. James Shulmeister* [3]

1. Idaho State University, 2. Utah State University, 3. University of Canterbury

Southern Hemisphere glaciation bears similarities and contrasts with its Northern Hemisphere counterparts. In New Zealand, the last glaciation featured early maxima that shifted northward through MIS 3-2 (60-15 ka). The upper Clutha River region fills a spatial gap in data from the South Island, revealing five glacial advances.
Sediments document three advances during MIS 3. The earliest occurred ca. 60 ka, as reflected in distal outwash at Beacon Point on Lake Wanaka. Distal outwash at Beacon Point and 7 km downvalley at the Cardrona River indicate extensive ice ca. 42 ka. A third advance ca. 32 ka is well-documented through rapidly aggraded outwash gravel at Beacon Point and deformed ice-terminal diamicton and gravel in a moraine at Kirimoko Crescent.
Two additional ice advances mark MIS 2. At Glendhu Bay, a terminal ice lobe deposited proglacial gravels, deformed by ice overrun, and delta foresets, dated to 29 and 28 ka, respectively. Correlative 29 ka sandy lacustrine strata at Deans Bank, near the Lake Wanaka outlet, also document the advance. The youngest advance is documented in extensive exposures at Lake Hawea, 12 km NE. Basal outwash dates to 20-19 ka, overlain by diamicton and lake sediments suggesting that the terminal moraine impounded the drainage, with lake floor gravel-sand deposits documenting subglacial lacustrine water discharge. Downstream, correlative outwash at Reko's Point Conservation Area on the Clutha River dates to 22 ka. The youngest dated glacigenic deposits are two outwash units dated to 18 and 17 ka at Deans Bank.
MIS 3-2 glaciation in the Clutha shows similar advance timing as other regional records. The ca. 40 and 32 ka advances correlate closely with advances in the Rangitata Valley, and the 32 ka advance correlates with CRN-dated advances at Lake Ohau and elsewhere. The 60 ka advance is indistinguishable from 65 ka advances at Lake Pukaki and the Rangitata Valley, together documenting an early glacial maximum in the southern half of the South Island. Cumulatively these results demonstrate that ice extended to or beyond ”LGM limits during several intervals in MIS 3 and early MIS 2.

Glacial to millennial variability in the Southern Hemisphere westerlies

Dr. Timothy Shanahan [1], ***Dr. Paul Augustinus*** [2], ***Dr. Natallia Piatrunia*** [3]

***1.** The University of Texas at Austin,* ***2.** University of Auckland,* ***3.** Department of Geological Sciences, The University of Texas at Austin, USA*

The Southern Hemisphere westerly winds (SHWW) play an important role in the global climate system through interhemispheric ocean and atmospheric linkages. It has been proposed that changes in the position of the westerlies on millennial to orbital timescales, may have an influence on Southern Ocean carbon storage, thereby acting as a critical feedback mechanism for driving changes in atmospheric CO_2 and global climate. However, climate model simulations and proxy records of past changes in the position of the southern westerlies provide an inconsistent view of SHWW behavior. Here, we use measurements of leaf wax hydrogen isotopes and the MBT'_{5me} paleotemperature index to reconstruct climate variability in the southern mid-latitudes over the past 50 k from a maar lake system on the North Island of New Zealand. We interpret leaf wax hydrogen isotope variability as reflecting changes in the position of the SHWW – an interpretation that is grounded in the analysis of modern precipitation isotopes. Our results indicate that the SHWW shifted in phase with the ITCZ on a range of timescales (e.g., orbital to millennial, including during the during the Holocene) throughout the record, and reflect the dominant role of interhemispheric temperature gradients in driving global atmospheric circulation response to climate forcing. Conversely, temperature changes reflect a southern high latitude signal, with orbital to millennial-scale variability synchronous with reconstructions from Antarctic ice cores. These results show that millennial-scale warming (i.e., during AIM events) was not restricted to the high-latitudes but reached at least as far equatorward as the Southern Hemisphere subtropics. However, despite the SH polar signal dominance on temperature, our reconstructions show that precipitation and SHWW behavior was controlled by changes in the Northern Hemisphere high latitudes.

Southern Ocean mechanisms of CO2 draw down and release on glacial-interglacial timescales

Ms. Madison Shankle [1]***, Dr. Molly Trudgill*** [2]***, Mr. Romain Euverte*** [2]***, Dr. Elisabeth Michel*** [2]***, Dr. William Gray*** [2]***, Dr. Andrea Burke*** [1]***, Dr. James Rae*** [1]

1. University of St Andrews, 2. LSCE-IPSL, Laboratoire des Sciences du Climat et de l'Environnement (CEA-CNRS-UVSQ), Paris-Saclay

The Southern Ocean is a major regulator of global climate, connecting the world's ocean basins as well as the atmosphere and deep ocean through both lateral and vertical exchanges of heat and carbon. Despite the importance of this region to global climate, however, its response to future climate change remains uncertain. Studying how the Southern Ocean operated under past climate states offers an opportunity to better understand the processes governing its role in climate today. For example, the Southern Ocean is widely believed to have played a driving role in the atmospheric CO_2 swings of the ice ages, ventilating carbon-rich deep waters to the atmosphere during interglacial periods and facilitating abyssal ocean carbon storage (by limiting this deep-surface exchange) during glacial periods. However, direct evidence of this abyssal carbon storage during glacial times – and the processes responsible for it – remains limited.

Here we present a suite of geochemical proxy records providing new insights into Southern Ocean circulation and carbon cycling, documenting abyssal ocean carbon storage as a mechanism of atmospheric CO_2 draw down over the Last Glacial Cycle. Trace element and stable isotope ($d^{13}C$, $d^{18}O$, $d^{11}B$) compositions of benthic foraminiferal calcite from the Indian Ocean sector of the Southern Ocean show how carbon was sequestered in the deep ocean over the course of glaciation and subsequently released to surface waters during deglaciation. These dynamics are captured by geochemical records reflecting temperature, pH, productivity, and circulation changes in the Southern Ocean over the Last Glacial Cycle, providing crucial insights to the processes responsible for this carbon cycling. Comparison to Earth system model output provides further context for the dynamics evinced by the proxy data. These results together form a more comprehensive picture of Southern Ocean carbon cycling over the Last Glacial Cycle and provide a foundation from which to develop a better mechanistic understanding of the Southern Ocean's role in past and future climate change, including processes such as advection and mixing, ocean-ice interactions, and productivity and nutrient dynamics.

Monsoonal variations during MIS 3 and 2 in the Kimberley, north-western Australia

Ms. Teresa Dixon [1], ***Dr. Justine Kemp*** [2], ***Dr. Rachel Rudd*** [3], ***Ms. Charmaine Howie*** [1], ***Prof. Patrick Moss*** [4], ***Prof. Hamish McGowan*** [1]

1. *The University of Queensland,* ***2.*** *Australian Research Centre for Human Evolution, Griffith University, Queensland,* ***3.*** *Max Planck Institute of Geoanthropology, Jena, Germany / The University of Queensland, Brisbane, Australia,* ***4.*** *University of Queensland*

The climate of the Kimberley region in north-western Australia is characterised by the Indo-Australian Summer Monsoon (IASM). Variations in the strength and position of the monsoon are caused by its interaction with other regional climate drivers and have significant control on the vegetation of the region. Since the arrival of humans to Sahul, large-scale climatic variability in response to Heinrich and Dansgaard–Oeshger events and the Last Glacial Maximum have influenced tropical Australia. There are several intervals during Marine Isotope Stages 3 and 2 during which the response of the IASM to these global events is unclear or debated, owing partly to the scarcity of records extending through the late Quaternary from northwest Australia.

We present pollen, charcoal and geochemical records from the eastern Kimberley extending around 72 ka, beyond the first known arrival of humans to the continent around 60 ka ago. A sediment core collected from the northern edge of the Tanami Desert in a low-relief, seasonally inundated floodplain is consistent with regular sedimentation, and captures an environmental signal from the present-day southern edge of monsoonal influence. To the north, 60 km south of the Joseph Bonaparte Gulf, a second core was collected in the back plain of the Bullo River, well within the zone of monsoonal influence. The cores' collective results permit interpretation of variations in both the strength and latitudinal migration of the IASM.

The results of this research show variations in the regional environment of both locations, although the southern core appears to reflect more stable conditions. Geochemical and pollen results indicate intervals of stronger and weaker monsoon activity, which span timeframes where either few studies exist, or there is debate surrounding the interpreted environmental conditions.

Session 22: Mountain glaciations and their diversity: Perspectives in geomorphology, geochronology, palaeoglaciology, and palaeoclimatology

Glaciers and ice caps under climate change since the Little Ice Age

Prof. Jonathan Carrivick [1], ***Prof. Jacob Yde*** [2], ***Dr. Jenna Sutherland*** [3], ***Dr. William James*** [1], ***Mr. Ethan Lee*** [4], ***Mr. Michael Grimes*** [1], ***Dr. Clare Boston*** [5]

1. *University of Leeds,* ***2.*** *Western Norway University of Applied Sciences,* ***3.*** *Leeds Beckett University,* ***4.*** *Newcastle University,* ***5.*** *University of Portsmouth*

Mountain glaciers and ice caps are undergoing rapid mass loss but rates of contemporary change lack long-term (centennial-scale) context. Future projections of glacier changes require spin up to present day conditions and thus baseline ice extents and ice volumes are a prerequisite for model validation. Here, we review reconstructions of the Little Ice Age maximum glacier extent and ice surface of glacier around the World.

We focus on Jostedalsbreen, which is the largest ice mass in mainland Europe, but make comparison with our other published analyses of changes to mountain glaciers and ice caps since the LIA to show that Jostedalsbreen is unusual in not exhibiting an acceleration in mass loss since the LIA. Indeed, we have reported a 23 % acceleration of glacier mass loss in NE Greenland and a doubling for the Southern Alps of New Zealand. Others have reported a doubling of the rate of mass loss for the Vatnajökull ice cap and for Patagonia since the LIA. We have recently reported a ten-fold increase in glacier mass loss for ~ 15,000 glaciers across the Himalaya. We will present emerging results of our study across Greenland. A synthesis of these long-term analyses reveals a latitudinal effect, regional climate effects and local controls on long-term glacier mass balance. For example, local rates of loss across the Himalaya were enhanced with the presence of surface debris cover (by 2 times vs clean-ice) and/or a proglacial lake (by 2.5 times vs land-terminating).

Overall, we highlight the utility of geomorphological-based reconstructions of glaciers for understanding and quantifying long-term (centennial-scale) responses of mountain glaciers and ice caps to climate and hence for understanding of meltwater production and proglacial landscape evolution.

Catastrophic glacier volume loss on Juneau Icefield driven by non-linear processes

Dr. Bethan Davies [1]***, Dr. Robert McNabb*** [2]***, Dr. Jacob Bendle*** [3]***, Prof. Jonathan Carrivick*** [4]***, Dr. Jeremy Ely*** [5]***, Dr. Tom Holt*** [6]***, Dr. Lindsey Nicholson*** [7]***, Prof. Mauri Pelto*** [8]

__1.__ Newcastle University, __2.__ Ulster University, __3.__ Geological Survey of Norway, __4.__ University of Leeds, __5.__ Department of Geography, University of Sheffield, __6.__ Aberystwyth University, __7.__ Department of Geology, Innsbruck University, Austria, __8.__ Nichols College

Plateau icefields are sensitive to climate change due to the non-linear controls their topography imparts on their response to climate change. We used geomorphological mapping and structure-from-motion to reconstruct the extent, volume and velocity of Juneau Icefield during the “Little Ice Age” (1770), 1948 and 1979, and every ~10 years from 1979 to 2020 AD.

The study area included 1158 glaciers in 1770AD, covering 5405.91 ± 104.62 km^2 (1589.57 km^2 greater than in 2019). Total icefield volume loss (LIA to 2020AD) was 176.14 ± 27.22 $km^{3,}$ with the disappearance of 108 glaciers. Rates of recession 1770-1948 were -6.27 km^2 a^{-1}, volume loss was -0.12 ± 0.05 km^3 a^{-1}, and 97.14% of glaciers receded. From 1948-1979, glaciers receded at -5.53 km^2 a^{-1}, icefield-wide volume loss was -0.88 ± 0.20 km^3 a^{-1} and 31.84% of glaciers advanced. Several glaciers thickened slightly, with an advance of 1,486 m for Taku Glacier.

From 1979-1990, recession accelerated, reaching -7.95 km^2 a^{-1}, and 8.53% of glaciers advanced. Recession was -17.19 km^2 a^{-1} (1990-2005) and accelerated sharply after 2005, reaching -23.69 km^2 a^{-1} (2005-2015) and then -45.69 km^2 a^{-1} (2015-2019). This indicates an eight-fold increase in recession from 2015-2019 relative to 1948-1979, and a fivefold increase relative to 1979-1990.

Icefield-wide volume loss from 1979-2000 reached -3.00 ± 0.18 km^3 a^{-1}, -3.08 ± 1.01 km^3 a^{-1} (2000-2010), and -5.91 ± 0.80 km^3 a^{-1} (2010-2020). Thinning is now apparent at elevations of 1725 m asl on Gilkey Glacier and 1670 m asl on Meade Glacier, and thinning has now reached the plateau accumulation area. This has resulted in increasing glacier fragmentation, with disconnections between accumulation and ablation areas occurring with rapidly increasing frequency after 2005 AD, due to the ELA rising to areas of thin, steep, heavily crevassed ice. This study shows a glaciological threshold response to a warming climate and a rising ELA. Thinning on the plateau area is inducing rapid and accelerating recession of glacier tongues and fragmentation of the icefield. The non-linear behavior observed is highly concerning for the future viability of the icefield.

Glaciers in the Sierra Nevada, California are likely unprecedentedly small in the Holocene

Mr. Andrew Jones [1], ***Dr. Alan Hidy*** [2], ***Dr. Susan Zimmerman*** [2], ***Mr. Andrew Gorin*** [3], ***Dr. Brent Goehring*** [4], ***Prof. Douglas Clark*** [5], ***Prof. Jeremy Shakun*** [6], ***Dr. Greg Stock*** [7], ***Ms. Julia Demarines*** [3], ***Dr. Shaun Marcott*** [1]

Glaciers in the Sierra Nevada, California, USA are thought to have disappeared in the early to mid-Holocene (~10,000–3,000 years ago) during peak Holocene summer warmth before subsequently reforming and advancing during late Holocene 'Neoglacial' cooling. The degree to which modern retreat is anomalous in the Holocene frames our understanding of climate change in California this century, with implications for water resources that affect biodiversity loss, agriculture, and human consumption. Here, we synthesize evidence from moraine surface exposure ages, distal lake sediment records, and new proglacial bedrock exposure ages that suggest Sierra Nevada glaciers existed through the Holocene and are only now disappearing.
We measured paired *in situ* ^{14}C and ^{10}Be concentrations in proglacial bedrock between modern ice and the Little Ice Age moraine at Conness, East Lyell, and Maclure glaciers, all in or bordering Yosemite National Park, California. Bedrock nuclide concentrations at the terminus of Conness Glacier (n=6) are near AMS system-blank levels for both ^{10}Be and ^{14}C measurements, suggesting that Conness was larger than its modern size (2018 CE) for the entire Holocene until present. ^{10}Be bedrock concentrations from the terminus of Maclure Glacier (n=3) are similarly near blank levels, suggesting it too has receded to an unprecedented minimum size in the Holocene. ^{10}Be exposure ages from bedrock at East Lyell Glacier (n=6) range from near-blank levels to ~1,700 years, incompatible with full deglaciation from 10–3 ka. Bedrock samples are from various locations of the glacier forefield, likely relating to the scatter in ages. ^{14}C ages for Lyell and Maclure Glaciers are forthcoming and will be presented at the meeting. At all three sites, moraine boulder ^{10}Be ages (n = 29) and lake sediment records suggest late Holocene glacier growth, which we use to explore plausible Holocene glacier length histories via numerical modeling of bedrock nuclide concentrations.

Holocene glacier chronology of the Southern Alps/New Zealand - A re-assessment based on Schmidt-hammer exposure-age dating (SHD) and geomorphological analysis

Prof. Stefan Winkler [1]

1. *University of Würzburg*

The investigation of Holocene glacier chronologies has been recognised as one key element of research on mountain glaciations in the light of current global change because they can be utilised as high-resolution palaeoclimatic archives. During the past few decades considerable progress has been achieved, in particular due to substantial improvements of the ability to accurately date glacial landforms essential for subsequent analysis in the context of glacier advance/retreat periods. The Southern Alps of New Zealand are among the few suitable study sites for the investigation of Holocene glacier chronologies in the mid-latitudinal Southern Hemisphere that consequently have drawn attention.

Although a decent number of studies on this topic have been carried out in the Southern Alps so far, reviewing recent publications still reveals some problems related to the specific characteristics of this geomorphologically and climatically dynamic mountain region: (1) complex geomorphology of glacier forelands and their landforms affected by strong paraglacial modification, (2) influence of frequent mass movement events on moraine formation and (possibly) glacier response, (3) limited information on representativeness of local glacier records and resulting questions about the justification of amalgamated records, (4) few modern glaciological studies hampering proper palaeoclimatic interpretation and postulated Early Holocene glacier advances that do not really fit existing parallel records of other palaeoclimatic proxies, and (5) comparison of different approaches and their limited assessment in relation to older studies. As a result, even more recently published Holocene glacier chronologies from the Southern Alps do not necessarily pass critical assessment.

During a current research project several glacier forelands in the region were geomorphologically mapped/analysed along an extensive application of Schmidt-hammer exposure-age dating (SHD). Based on previously published age information local SHD calibration curves have been calculated and applied to extent the regional basis for the reconstruction of a reliable regional Holocene glacier chronology. Preliminary findings partly contrast to existing data, in particular do they generally point towards a reduced number of Holocene glacier advance periods (neoglacial events) than some studies previously claim. The complex geomorphology of many forelands requires a more careful interpretation of chronological data than often presented in related studies.

Cold control then precipitation control for Alpine glaciers (Le Tour and Argentière, Mont Blanc massif) in the Younger Dryas and early Holocene

Mrs. Julia AGZIOU [1]***, Dr. Jean-Louis Mugnier*** [1]***, Mrs. Lea Courtial-Manent*** [1]***, Dr. Jean-François Buoncristiani*** [2]***, Dr. Julien Carcaillet*** [3]***, Dr. Riccardo Vassallo*** [1]

1. ISTerre, Université Grenoble Alpes, CS 40700 38058 GRENOBLE Cedex 9, 2. Biogéosciences, 3. ISTerre, CNRS, Université Grenoble Alpes

The last glacial Younger Dryas (YD) stadial outcome seems to be followed by an abrupt heatwave with augmenting temperatures that have reached 8 ± 7 C°, however, numerous moraines were actually formed afterward. Their construction is the result of readvances spatially and temporally closed from those belonging to the YD. To better understand this paradox, we studied the paleo-glacial margins from the haute Arve valley through geomorphological and geochronological methods to constraint the extents in a first time. In a second time, we defined climate conditions associated to different paleo-glacial extents with the help of a "Precipitation Degree Day" (PDD) model adjusted with a mass-balance law for 2 stadial : the Younger Dryas-Early Holocene transition (YD-EH) and the Early Holocene (EH).

A simple scenario is proposed, which is coherent with 35 10Be dating samples (including 20 news) and 2 14C ages : Argentière and Tour glaciers still formed the haute Arve valley glacier after the abrupt temperatures change after ~11.7 (i.e. they were still joined). The margin is defined by the moraines system of La Joux (10.7 ± 0.5 ka). They then retracted, coupled with the formation of proglacial/juxtaglacial lakes at the ancient confluence zone. Sediments of the lake were covered by the moraine of Tré le champs le bas where new samples are dated (9.6 ± 0.6 ka), belonging to the Holocene. Furthermore, this advance was less important than the YD one, and preceded by a glacial retreat around 12.180-10.834 ka Cal. BP (14 C, Intcal20).

The PDD model parameters were calibrated using the Tour and Argentière mass-balances in order to look for precipitation x temperatures combinations and reconstruct the climate conditions of two stadials : La Joux and Tré le champs le bas in order to evaluate how it evolved during a transition between glacial and interglacial periods. The results suggest extents of alpine glaciers in the Mont Blanc massif has been consecutively controlled by a persisting cold post YD more intense comparing to today's, followed by an increase of precipitations during the Holocene, superimposed to cold peaks less intense than YD.

Insights on a wet Alpine Younger Dryas: new data from the Italian Dolomites (southern Eastern Alps)

Dr. Sandro Rossato [1]***, Prof. Paolo Mozzi*** [2]***, Prof. Susan Ivy-Ochs*** [3]***, Dr. Giovanni Monegato*** [4]***, Prof. Matteo Spagnolo*** [5]***, Dr. Christof Vockenhuber*** [3]***, Prof. Silvana Martin*** [2]

1. *CNR - IGG / Univ. Padova - Dept. Geosciences,* ***2.*** *University of Padova, Department of Geosciences,* ***3.*** *ETH Zurich,* ***4.*** *CNR - IGG,* ***5.*** *School of Geosciences, University of Aberdeen, Aberdeen, UK*

The Alpine Lateglacial was punctuated by mild interstadials and cold stadials, the youngest (12.8-11.7 ka, in the European Alps) being the Younger Dryas (YD) and corresponding to the last glacier readvance before the Holocene. Temperature reconstructions suggest the YD being 3-5°C colder than today. Paleoprecipitation patterns during YD are debated, but there is agreement on a 20-30% lowering in the central part of the Alps. However, no data are available for the whole eastern side of the Alps, where our study area is located.

We studied the YD glacial deposits in the Venegia Valley (Italian Dolomites), where a small glacier still survives (Travignolo glacier). During the YD, this glacier was merged with two others, forming a 6 km-long tongue. At its front, it built a well-expressed morainic arc, made of at least three main ridges. The shape and size of the glacier, as well as cosmogenic dates obtained from boulders on the frontal moraines, confirm these arcs to be YD in age. We reconstructed both the YD and LIA glacier extents, obtaining also the associated ELAs using the GlaRe GIS toolbox. These data allow for an inference of paleoprecipitations occurring at the YD by means of the empirical diagram developed by Ohmura and Boettcher, and utilising independent summer temperature reconstructions. Results suggest precipitations were relatively high at the study site during the YD, though it remains unclear whether this was in terms of annual or seasonal (snowy) precipitation.

Late-glacial and Holocene glaciers and snowpack in the High Atlas Mountains, Morocco

Prof. PHILIP HUGHES [1]***, Dr. Benjamin Bell*** [1]***, Dr. David Fink*** [2]***, Dr. Henk Cornelissen*** [1]***, Dr. William Fletcher*** [1]***, Dr. Roger Braithwaite*** [1]***, Prof. Ali Rhoujjati*** [3]

1. *The University of Manchester,* ***2.*** *ANSTO,* ***3.*** *Université Cadi Ayyad*

Pleistocene glaciations of the Last Glacial Cycle in the High Atlas Mountains are well documented and widespread, extending into lower valley areas below altitudes of 2000 m. In the Toubkal Massif (4167 m) of the Marrakech High Atlas, glaciers reached 5-10 km in length and formed plateau icefields over the drainage divides. In the Late-glacial and Younger Dryas, cirque glaciers persisted. Today, only a few snowpatches survive summer melting though perennial snowpatches and potentially, small niche glaciers, were far more widespread during the 19th and 20th century. Evidence for these former snowpatches and niche glaciers has been mapped, and ^{36}Cl and ^{10}Be terrestrial cosmogenic nuclide exposure dating has been applied to successive moraines from the cirque headwalls and down-valley. A key focus is to compare the extent and climatic significance of Holocene glaciers with Late-glacial and earlier Pleistocene counterparts. It is unclear presently whether the largest Holocene glaciers and perennial snowpatches belong to the Early-Mid Holocene or the Little Ice Age. Available palaeoenvironmental evidence from sediment sequences from nearby marsh and lake records at Oukaïmeden and on the Yagour Plateau, respectively, can complement the geomorphological and exposure dating record. In the High Atlas, the Little Ice Age was characterised by wetter conditions than today and coupled with slightly cooler summer conditions. This may have favoured the survival of perennial snowpatches and niche glaciers. However, other cool/wet episodes are recorded through the Holocene based on the continuous sediment record from the Yagour Plateau. The relationship between snowmelt and climate is reconstructed using degree-day modelling. It is clear from this that the reconstructed regional equilibrium line altitude for glaciers throughout the Holocene, and also today, is above the highest peaks. Hence niche glaciers and indeed perennial snowpatches, would have all existed under strong topoclimatic controls and valley-to-valley microclimatic differences, where large potential melt was offset by shading and avalanching snow. This topoclimatic complexity was combined with other influencing factors such as localised cooling over perennial snow/ice surfaces in topographic hollows and also debris cover.

Late Pleistocene glacial history of the Black Forest, southern Germany, and implications for past atmospheric circulation patterns

Mr. Felix Martin Hofmann [1]***, Prof. Frank Preusser*** [2]

1. *University of Freiburg, Faculty of Environment and Natural Resources, Institute of Earth and Environmental Science,* ***2.*** *Albert-Ludwigs-Universität Freiburg*

During the Late Pleistocene, an ice cap and its up to 25 km-long outlet glaciers temporarily covered the highest summit of the Black Forest, Feldberg (1493 m above sea-level) and the surrounding region. During deglaciation, the ice cap disintegrated into valley glaciers with independent accumulation areas. Valley glaciers finally evolved into cirque glaciers. Despite recent efforts, the chronology of Late Pleistocene glacier fluctuations in the Black Forest is not sufficiently understood. In particular, the timing of glacial re-advances or standstills at the end of the deglaciation remains largely unknown. The onset of glacier retreat from the Late Pleistocene maximum ice extent has hitherto not been successfully dated.

This study addresses these issues by applying ^{10}Be cosmic-ray exposure (CRE) dating to moraines at three sites. Newly acquired chronological data imply that glacier retreat from the moraines of the marine isotope stage (MIS) 2 maximum advance was underway by 21 ka at the latest when glacier recession in the Swiss Alpine Foreland had already begun. Recalculated ages for the Bavarian Forest suggest that glaciers in the Bavarian Forest and in the Black Forest might have withdrawn simultaneously from their MIS 2 maximum positions. Within the limits of available data, CRE ages suggest that glaciers in both regions attained their MIS 2 maximum extent when a westerly atmospheric circulation re-established over Central Europe. To confirm these hypotheses, additional data for the Black Forest is needed. Ages of moraines at two sites fall into the Lateglacial.

Glaciers and equilibrium line altitudes (ELAs) during moraine formation were reconstructed for paleoclimatic inferences. ELA-based reconstructions of paleoprecipitation for the youngest ice-marginal positions were undertaken with data from two independent summer temperature records. Unrealistically high annual precipitation during the Lateglacial would have been required to balance summer temperatures at the ELA. Even if all potential errors of the reconstruction are taken into account, it seems unlikely that glaciers still existed in the Black Forest after the abrupt rise in summer temperature at ~14.6 ka. Therefore, deglaciation was likely completed during this climatic event or before.

Synchronous Last Glacial Maximum advances of large and small palaeoglaciers in the Maritime Alps

Mr. Lukas Rettig [1], ***Dr. Sarah Kamleitner*** [2], ***Prof. Susan Ivy-Ochs*** [2], ***Dr. Giovanni Monegato*** [3], ***Prof. Paolo Mozzi*** [1], ***Prof. Adriano Ribolini*** [4], ***Prof. Brice Rea*** [5], ***Ms. Lucy Ashpitel*** [5], ***Prof. Matteo Spagnolo*** [5]

1. *Department of Geosciences, University of Padova,* ***2.*** *Laboratory of Ion Beam Physics, ETH Zürich,* ***3.*** *CNR IGG, Padova,* ***4.*** *Department of Earth Sciences, University of Pisa,* ***5.*** *School of Geosciences, University of Aberdeen*

The Maritime Alps represent the southernmost sector of the Western European Alps (NW-Italy, SE-France). During the Last Glacial Maximum (LGM), this mountain range hosted both large valley glaciers in the order of several hundred km^2, but also smaller glaciers that remained confined to side valleys or cirques. Owing to their location, in close proximity to the Gulf of Genoa, the glaciers in the Maritime Alps were strongly influenced by Western Mediterranean atmospheric circulation. Reconstructing their past extents and Equilibrium Line Altitudes (ELAs) can therefore be used as a proxy to track changes in this circulation over time.

During the past decades, multiple geomorphological surveys have been carried out in the Maritime Alps to map glacial features and to constrain LGM ice advances through numerical dating methods. However, these studies have primarily focused on the large glacial systems in the Stura and Gesso valleys. The evolution of smaller (and likely more responsive) palaeoglaciers and their ELAs, on the other hand, are less well constrained. Additionally, it remains unclear if these smaller glaciers advanced synchronously with the larger Stura and Gesso systems.

To address these questions, we present new data from three small LGM mountain glaciers, located on both northern and southern sides of the Maritime Alps. Palaeoglacier 3D geometries and ELAs were reconstructed using GIS-tools based on previous geomorphological surveys, while age control is provided through new ^{10}Be cosmogenic exposure dating of moraine boulders. We demonstrate that moraines in the Maritime Alps record a two-fold LGM advance and that, within the dating uncertainties, the small glaciers advanced synchronously to the larger valley systems both in the Maritime Alps and beyond. Additionally, reconstructed ELAs are discussed in the context of the LGM palaeoclimate of the southern side of the Alps and the wider Western Mediterranean region.

Mountain glacier fluctuations in the Glen of Imaal, Ireland, during the Last Glacial Maximum and Heinrich Stadial 1

Dr. Margaret Jackson [1]***, Dr. Gordon Bromley*** [2]***, Dr. Brenda Hall*** [3]***, Dr. Shaun Eaves*** [4]***, Ms. Adrienne Foreman*** [2]

1. *Geography, School of Natural Sciences, Trinity College Dublin,* ***2.*** *Geography and Palaeoenvironmental Research Unit, University of Galway,* ***3.*** *School of Earth and Climate Sciences, University of Maine,* ***4.*** *Victoria University of Wellington*

Projecting accurately the sensitivity of Earth's ice sheets to future warming is dependent on our understanding of past ice sheet response to climate shifts. Recent work focused on offshore and near-shore glacial sediments in the northeastern North Atlantic provides insight into the dynamics, and ultimate demise, of the ice sheet that once covered Britain and Ireland during the Last Glacial Maximum. However, ground-truthed chronologic information on the terrestrial pattern of British-Irish Ice Sheet (BIIS) retreat remains relatively sparse, thus limiting our ability to reconstruct ice sheet response to Quaternary climate changes. Ireland hosts an array of glacial landforms that attest to the former terrestrial extent of both the BIIS and to the numerous mountain glaciers that remained after the ice sheet itself had receded. Here we report a new glacial chronology from the Glen of Imaal, in Ireland's Wicklow Mountains, constrained with cosmogenic beryllium-10 surface-exposure ages of moraines and erratic boulders. These data provide direct chronologic constraint on the extent and timing of mountain glacier fluctuations at the Glen of Imaal and indicate that mountain glaciation was most extensive at the site approximately 23 ka, after which protracted retreat began. Our data also suggest that glaciers may have disappeared from the catchment entirely during Heinrich Stadial 1. Because mountain glaciers can exist only in the absence of an overlying ice sheet, the ages of these mountain glacier moraines place a minimum limiting age on the timing of ice sheet retreat in the southern Wicklow Mountains. These data offer new insight into the response of Ireland's cryosphere to past climate change and provide discrete terrestrial targets for ice sheet and glacial modelers investigating the response of these ice masses to changing climate conditions.

Past debris-charged plateau icefields in the Godeanu Mountains, Southern Carpathians, Romania

Ms. Cristina Balaban [1], ***Prof. David Roberts*** [1], ***Dr. David Evans*** [1], ***Dr. Stewart Jamieson*** [1]

1. *Durham University*

Reconstructing the extent, style, timing and drivers of past mountain glaciation is crucial in both understanding past atmospheric circulation and predicting future climate change. Unlike in high-elevation mountains situated in maritime and continental climates, less is known of past glaciation in mid-altitude mountains, located in transitional climates, such as the Southern Carpathians of Romania. Despite these mountains harbouring a rich glacial geomorphology, this has never been systematically mapped according to well-established morphological criteria, nor confidently related to former styles of glaciation. Therefore, filling this gap is important for not only accurately identifying glacial extents, but also for establishing past glaciation styles and relating them to past ice dynamics and climate. Here, we aim to devise the first glacial landsystem model for the Southern Carpathians (the debris-charged plateau icefield landsystem) to enhance our understanding of the glaciation style and dynamics of past mountain glaciers in temperate-continental climates. Using a geomorphologically-rich mountain range, the Godeanu Mountains in the Southern Carpathians, as a case study, we will first present a remote- and field-based geomorphological map of the study area, whereby we identify and interpret between mountain landforms of glacial, periglacial and paraglacial origin. Secondly, we will infer both the origin and the transport pathways of selected, ground-truthed glacial landforms, by analysing their sedimentology. Furthermore, we hypothesise the relationship between the mountain geomorphology and glaciation style and dynamics, based on the spatial linkages between the landforms in the study area, through the glacial landsystem model. Finally, we assess the implications of the glacial landsystem model for the geomorphology and ice dynamics in other areas of the Southern Carpathians and beyond.

Paleoglacier and -climate reconstructions on the Eastern Black Sea Mountains, obtained from Parallel Ice Sheet Model (PISM)

Prof. Mehmet Akif Sarıkaya [1]***, Dr. Adem Candaş*** [2]***, Dr. Ömer L. Şen*** [3]

1. *3Eurasian Earth Science Institute,* ***2.*** *Istanbul Technical University,* ***3.*** *Eurasia Institute of Earth Sciences, Istanbul Technical University, Turkiye*

Investigating disappearing glaciers due to recent climate changes and examining their past records provide feedback for future climate predictions. In recent years, the efforts to investigate the existence of paleoglaciers in Turkey have been increasing. Dating studies using cosmogenic isotopes provide significant information about the timing of paleoglaciers, especially for the Last Glacial Period. These studies have shown that the Anatolian paleoglaciers mostly reached their largest extents during the Last Glacial Maximum (LGM, ~ 21 ka ago) and then retreated to their successive positions. However, in some regions, the maximum conditions have occurred much earlier. One of them is the Eastern Black Sea Mountains of Turkey. In this study, a physical glacial flow model was used to understand why the Eastern Black Sea Mountains behaved differently. The study area covers the most rugged and glaciated part of the Black Sea region. We used an open-source software called Parallel Ice Sheet Model (PISM), to model the paleotemperature and paleoprecipitation conditions during the last glaciation. First, we changed the current climatic conditions in the region, and then three-dimensional glacier reconstructions were created using manipulated ice mass balance conditions in PISM. The paleoglacier extents obtained in previous studies via elevation of lateral and terminal moraines, and trim lines were compared with the model results to determine the paleoclimatic conditions of the glaciers. Here, the preliminary results of our project funded through a TUBITAK grant (#121Y507) will be presented.

Glacial chronology north of Lake Issyk-Kul in the Kyrgyz Tian Shan using cosmogenic nuclide dating

Dr. Shasta Marrero [1]***, Prof. Fred Phillips*** [2]***, Dr. Jacob Selander*** [3]***, Prof. Michael Oskin*** [4]***, Prof. Bodo Bookhagen*** [5]***, Dr. Richard Shanks*** [6]

***1.** School of Earth and Environmental Sciences, Cardiff University, **2.** New Mexico Institute of Mining and Technology, **3.** Highline College, **4.** Earth and Planetary Sciences, UC Davis, **5.** Department of Earth Sciences, University of Potsdam, **6.** Scottish Universities Environmental Research Centre, East Kilbride, UK*

There is ongoing debate over the mechanisms driving glaciation in the Tian Shan in Central Asia. Quantitatively dated glacial chronologies provide critical information for models exploring possible influencing factors. Compared to other glaciated regions of the world, the Tian Shan has relatively few dated glacial features, with significant discrepancies present between existing studies.

This study presents dates on glacial features in Chon-Koi-Su Canyon located in the Tian Shan north of Lake Issyk-Kul. Using cosmogenic chlorine-36, 25 samples from moraines in the valley showed three distinct advances. The Last Glacial Maximum (LGM) advance was extensive (>8km downvalley) when many other glacial chronologies in the area do not identify a significant/any advance at this time. The dates from the oldest moraine aligns well with youngest of three 10Be-dated terraces nearby, potentially extending the glacial chronology to even older events. This well-dated glacial chronology, including an extensive LGM advance, contributes a new dataset in a previously undated area of the Tian Shan, providing new insight into the ongoing debate over the factors controlling glaciation in the Tian Shan.

Asymmetries within the Pyrenees and correlation across the westernmost European mountain ranges. Glaciation typologies

Mr. Valenti Turu [1], ***Dr. Jose-Luís Peña-Monné*** [2], ***Dr. Guy Jalut*** [3], ***Dr. Rosa M. Carrasco*** [4], ***Ms. Laia Turu-Font*** [5], ***Dr. Marc Oliva*** [6]

__1.__ Fundació Marcel Chevalier, __2.__ Departamento de Geografía y Ordenacion del Territorio and IUCA, Universidad de Zaragoza, Zaragoza, __3.__ Fundació Marcel Chevallier, Edifici Socio-Cultural de la Llacuna, AD500 Andorra la Vella,, __4.__ Universidad de Castilla-La Mancha, __5.__ Departament Ciències de l'Antiguitat i l'Edat Mitjana, Universitat Autònoma de Barcelonade, __6.__ Department of Geography, University of Barcelona

In the last glacial cycle, glacier expansion started as early as MIS 5d in the Mediterranean region, followed by a notably abrupt cooling in MIS 4 that lasted no more than about ~10 ka, in contrast with the ~16 ka of MIS 2, within which the Last Glacial Maximum (LGM) phase took place centred at 22.1 ± 4.3 ka. Noticeable from the Pyrenees was a last maximum ice extent (LMIE) predating the LGM from northern ice sheets, a pioneering European mountain area underlining this asymmetry. Besides, we point to several distinctive traits encompassing chronology and glacial dynamics. I - A Penultimate glacial cycle during MIS 6 and older glacio-fluvial terraces beyond the range of the luminescence dating method. II – An early glacial advance in MIS 5d (~97 $_{-15}\backslash^{+19}$ ka) followed by glacier retreat during MIS 5c (< 91 ± 9 ka). III – The last maximum ice extent (LMIE) is from the early MIS 4 (~74 ± 4.5 ka). IV – Glaciers thinned during the second half of MIS 3 (~39 $_{-6}\backslash^{+11}$ ka). V – During the MIS 3 – MIS 2 transition, glaciers were highly sensitive to climate fluctuation. VI – The Last Glacial Maximum (LGM) is always back an end moraine built previously and, in some cases, was characterised by the construction of nested moraines. Our research unravels the main glacial phases in the Pyrenees, a region in SW Europe of significant relevance in connection with the last glacial cycle (LGC). By comparing our results with those from other mountain ranges in Portugal, Spain, and France, we recognise patterns highlighting portions of the LGC or all of it and outlined above, as follows: (A) areas where glaciers were relevant during MIS 2, some of them (B) including a far-flung end moraine produced in previous glacial phases (early Würm or Riss), (C) areas showing a pseudo-pleniglacial condition, (D) multi-phase glacier advances, (E) those showing the relevant presence of glaciers during Termination-I.

Moisture control on LGM atmospheric lapse rates: a model – data comparison in the American Cordillera

Dr. Pierre-Henri BLARD [1]***, Mr. Etienne Legrain*** [2]***, Dr. Masa Kageyama*** [3]***, Dr. Guillaume LEDUC*** [4]***, Dr. Stella BOURDIN*** [5]***, Dr. Julien Charreau*** [1]***, Dr. Lukas Kluft*** [6]

Reconstructing spatial and temporal variations of the vertical atmospheric temperature gradient (lapse rate, "LR") is key to anticipate the future climate of high-altitude regions. This parameter may amplify or mitigate the future warming at high elevation, implying contrasted impacts on the stability of glaciers. Several regional studies suggested that the tropical LR was steeper than today during the last glacial maximum (LGM) (Loomis et al., 2017; Blard et al., 2007), while other studies concluded that the LGM lapse rate was similar than today (Tripati et al., 2014). Here we present a new compilation of glacier-based temperature reconstructions at high elevation (> 2500 m) for the LGM, which are compared to synchronous changes of sea surface temperatures (Pacific Ocean), along the American Cordillera, from 40°S to 40°N.

This new reconstruction confirms that lapse rates were steeper in the regions that were drier than today during the LGM. This corresponds to an amplification of cooling at high altitude during the LGM. To further analyze this observation, we also use the IPSL global climate model PMIP4 results (Kageyama et al., 2021), which, in agreement with the reconstructions, yields a steeper tropical lapse rate in its LGM simulation, compared with the pre-industrial one. Next, we disentangle the impacts of the lower atmospheric CO_2 concentration and of lower humidity using a single column radiative-convective equilibrium model (Kluft et al., 2019), and show the strong impact of changes in humidity in the tropical lapse rate steepening at the LGM.

Submarine gas hydrate systems are increasingly recognised to be associated with seafloor features recording the venting of gas-rich fluids to the deep ocean. The Amazon deep-sea fan contains a gas hydrate system characterised by a discontinuous bottom simulating reflection (BSR) forming elongate patches that follow the crests of thrust-folds within an upper slope (500-2250 m) compressional belt related to the gravitational collapse of the fan. Multibeam hydroacoustic data have previously shown the upper slope to be associated with dozens of water column gas flares, most rising from high backscatter seafloor mounds from two of which gas hydrates have been sampled. Here we present examples of seafloor features observed using bathymetry derived from extracts of a commercial 3D seismic volume (10 m grid resolution). In places, the data reveal fields of sub-circular morphological features up to tens of meters in relief and hundreds of meters in width. The features include a variety of positive and negative morphologies, including mounds, depressions, and mounds within depressions. The morphology of the mounds allows them to be interpreted as small mud volcanoes, some with crater-like depressions at their summits; some mud volcanoes sit within larger depressions interpreted to represent calderas due to localised subsidence. A few unfilled depressions are observed and may be calderas or large pockmarks. Seismic profiles show the seafloor features to be underlain by chaotic vertical columns consistent with plumbing systems, which pass through the BSR patches to root in subjacent thrust-folds. Some seafloor features, or groups of features, are associated with 'pluming' BSRs that indicate the rise of warm fluids; however, only a few coincide with water column gas flares previously identified on multibeam imagery, possibly reflecting episodic activity. The surprising variety of relatively small extrusive morphologies observed on the upper Amazon fan underscores the potential of high resolution seafloor datasets to provide new insights into the processes and products of deep-sea fluid venting.

REE and trace elements behavior in shallow hydrothermal vents sourrounding Panarea island (Italy)

Dr. Fabio Sposito [1]***, Dr. Francesco Italiano*** [2]***, Dr. Manfredi Longo*** [2]***, Dr. Lorenzo Brusca*** [1]

1. *Istituto Nazionale di Geofisica e Vulcanologia (INGV),* ***2.*** *Istituto Nazionale di Geofisica e Vulcanologia (INGV), Palermo*

Exploration of Shallow Hydrothermal Vents (SHV_s) is usually focused on analysis of major chemical species while contents of trace and Rare Earth Elements play an important role as tracers both of natural and anthropic geochemical processes.

Here we show progresses concerning trace elements and REE geochemistry in natural system focusing on their geochemical behavior in SHVs (shallow hydrothermal vents) in the surrounding area of Panarea Island (Eolian Islands, Italy).

Samples were collected from submerged vents at different depth (5-40m) and analyzed for Al, V, Mn, Fe, Ni, As, Ba, Pb and REE from June 2015 to July 2022.

Physical-chemical parameters span in a wide range of values: pH 2.7–8.2 and -235–186 mV for pH and Eh respectively; this variability is responsible of the variations in concentrations of Fe, Al, Mn and total REE concentration (REE_s) as an inverse correlation in observed between pH and Fe-Al-Mn and between pH and REE_s.

The pH values play a controlling role on the precipitation/dissolution of solid phases, inducing a fractionation of REE. The positive correlation between REE_s and Fe-Al-Mn in fluid samples shows the simultaneous variations of these elements linked to co-precipitation and adsorption onto the surface of oxide and oxyhydroxide of Fe, Al and Mn involving process of REE scavenging controlling their abundance dissolved in hydrothermal fluids.

REE Patterns show two different trends and according to the pattern shapes, waters could be classified in two groups: group-1 ($LREE_n/HREE_n>1$) showing decreasing trend from La to Lu (carbonate complexation of REE) and group-2 ($LREE_n/HREE_n<1$), characterized by Light REE depletion (adsorption to Al, Fe and Mn-oxyhydroxides).

Plotting $LREE_n/HREE_n$ vs REE_s, a hyperbolic array is composed by two end-members: EM1 characterized by higher $LREE_n/HREE_n$ and low Fe, Al and Mn concentrations; EM2 with Lower $LREE_n/HREE_n$ and high Fe, Al and Mn concentrations.

All these evidences demonstrate that the contamination of discharging fluids and consequent formation of Fe, Al and Mn-bearing minerals controls the fractionation of REE and trace elements. As a result, the fate of trace metals and REE is mainly conveyed by both processes of scavenging onto newly forming Fe-Mn-Al-oxyhydroxides and carbonate complexation.

Submarine geomorphology offshore Crotone (Calabrian Accretionary Prism): the contribution of fluid expulsion and sediment mobilization

Dr. Andrea Argnani [1], Dr. Claudio Pellegrini [1], Dr. Marzia Rovere [1]

1. CNR-ISMAR Bologna

Accretionary prisms originate at active subductive margins and grow mainly through the piling of sediments scraped from the subducting plate. During this process these sediments are progressively buried and squeezed, leading to fluid expulsion and often sediment mobilization. As a result, fluid venting, mud volcanoes and mud diapirs are common features in accretionary prisms worldwide. Subduction zones are present within the Mediterranean region, involving residual portions of the Tethyan oceans that have survived Aftica-Europe continental collision. One of these subduction zones is located underneath Calabria and give rise to the narrow Calabrian Arc accretionary prism, that covers most of the Ionian Sea and is confined on either side, east and west, by the Apulian and Malta escarpments, respectively. Mud volcanoes are known from long time to populate the inner Calabrian accretionary prism, and it is likely that their number is still largely underestimated. Few of these mud volcanoes have been extensively studied, revealing the occurrence of thermogenic gas and of microfossil assemblages ranging from Late Cretaceous to Recent. The Ionian Sea offshore of the Crotone promontory offers examples where the expressions of fluid expulsion and sediment mobilization are visible both in the subsurface and at the seafloor. The analysis of morphobathymetries at variable resolution and public domain and proprietary seismic data, including 3D seismic cubes, allows to characterize systems of mud diapirs, both active and fossil, and their relationships with trains of pockmarks. Mud pools and pockmarks are direct expression at the seafloor of fluid expulsion but in some instances they also contribute to destabilize the uppermost sedimentary strata, triggering small landslides. A fossil mud diapir-mud pool system has also been identified; it is sealed by relatively undeformed sedimentary strata, allowing to constrain a minimum age range for the onset of fluid expulsion and sediment mobilization.

Integration of morphobathymetric data and ROV observations for the study of fluid-related features offshore Scoglio d'Affrica islet (Northern Tyrrhenian Sea)

Dr. Martina Pierdomenico [1]***, Prof. Daniele Casalbore*** [2]***, Dr. Daniele Spatola*** [3]***, Ms. Denise Petronelli*** [2]***, Dr. Alessia Conti*** [4]***, Mr. Stefano Graziani*** [5]***, Prof. Francesco Chiocci*** [6]

1. *Institute of Anthropic Impacts and Sustainability in marine environment, National Research Council (IAS-CNR), Italy,* ***2.*** *Department of Earth Sciences, Sapienza University of Rome,* ***3.*** *1. Department of Earth Sciences, Sapienza University, Rome, Italy,* ***4.*** *Institute of environmental geology and geoengineering, National Research Council (IGAG - CNR), Italy,* ***5.*** *Department of Earth Sciences, Sapienza University of Rome, Italy,* ***6.*** *university of Rome Sapienza*

Fluid seepage from the seafloor is a common process that has been reported worldwide from coastal to deep-sea environments. Scoglio d'Affrica islet is located in the southernmost part of the Elba-Pianosa Ridge, a north-south elongated morpho-structural high separating the Tuscany margin from the Corsica Basin in the northern Tyrrhenian Sea. Submarine fluid emissions have been documented in this area since late '60, including a violent gas outburst occurred in 2017 offshore Scoglio d'Affrica islet. High-resolution bathymetric surveys performed after the event revealed the widespread occurrence of fluid-related morphological features, encompassing several mud volcanoes with different size and shape and hundreds of pockmarks. In this work, we present the results of the integration of morphobathymetric data with ROV observations collected in the area in 2017 and 2021. ROV videos showed a large variability in the seafloor characteristics of the mud volcanoes across the study area. A prevalent sandy seafloor with local accumulation of mud breccia characterized the top of larger edifices, while in other cases the videos recorded the presence of large boulders partially or totally covered by *Posidonia oceanica* meadows, which was widespread in the area. Active seepage via both continuous and intermittent bubble release from the seafloor was observed on videos, with venting points distributed over different features and seafloor types. The integration of morphobathymetric data with small scale information from video footage provides insights into the seafloor-shaping processes linked to fluid seepage around Scoglio d'Affrica islet. This is a particularly relevant issue considering both the paucity of studies on shallow-water mud volcanoes as well as the hazard associated with violent gas outbursts in such settings.

Session 25: Islands and their relationship with the continent to investigate time and mode of their colonization by terrestrial vertebrates and Homo dispersal

Coastline evolution in Sicily using archaeological data between 15 and 7 ka cal BP

Dr. Fabrizio Antonioli [1], Prof. Luca Sineo [2], Dr. Claudia Speciale [3], Dr. Vincenza Forgia [4]

***1.** CNR IGAG, **2.** STEBICEF Lab di Antropologia, Palermo University, **3.** Prehistoric Archaeology Göteborg University,, **4.** Dipartimento Culture e Società, Università di Palermo*

The peculiar paleo-geographic evolution of Sicily, the main Mediterranean island, makes it a perfect environment to study the relationship among early peopling, marine environment and coastal changes through the last millennia. One of the main issue debated from ancient topographers and archaeologists dealing with human mobility, ancient viability and paleo environmental studies is the actual morphology of the coastline depending from relative sea level-change that deeply changed from 15 ka cal BP (-101 m), 11 ka cal BP (-56.6) and 7 ka cal BP (-10.3 m) (Lambeck et al., 2011) directly influencing palaeocostlines, topographic and historical interpretations. Our research aims at filling this gap, offering valid variables to territorial models eventually combining archaeological survey and excavation data with the actual ancient coastal morphology and the related distance from archaeological sites: all decisive factors for a precise palaeoenvironmental contextualization of the archaeological data and the reconstruction of littoral resource exploitation patterns, human occupation, and mobility patterns along the coasts.

In order to achieve our scope we have georeferred the main archeological sites along the modern coastline of Sicily with a chronology spanning from the documented early peopling of the island (~ 17 ka cal BP) to the Neolithic. Then we take into consideration morphobathymetric, lithological and sea level change (both isostatic and tectonic), in order to reconstruct the ancient coastal morphology, the distance and altitude of sites from and on the sea and, in some cases, the eventual existence of submerged archeological deposits or features at five specific case study: Grotta del Tuono and Cala del Genovese (Egadi, Trapani), Baia dell'Uzzo (San Vito Lo Capo, Trapani), Grotta dell'Arco di Capo Zafferano (Bagheria, Palermo) and Riparo del Castello (Termini Imerese, Palermo).

SEAcross: A tool to measure the performance of large mammals in crossing sea straits

Dr. Christine Hertler [1], ***Dr. Mika Puspaningrum*** [2], ***Mr. Iwan Pramesti Anwar*** [2], ***Mr. Jan-Olaf Reschke*** [1], ***Dr. Alexandra van der Geer*** [3], ***Mr. Emmanuel Kipruto Ngetich*** [1]

1. ROCEEH Research Centre, Senckenberg Research Institute, Frankfurt/M, 2. Bandung Institute of Technology, 3. Naturalis Natural History Museum Leiden

Reconstructing dispersals of paleo-species often suffers from low data coverage, leaving wide gaps in space and time. Data often is extremely punctual. In such cases, simulation-based approaches like agent-based modelling may support testing hypotheses about course, speed and/or range of specific dispersal events. We developed the SEAcross ABM to test dispersal performances of terrestrial mammals in archipelagos. The agents cover sea straits by quadrupedal paddling, a swimming style accomplished by all terrestrial mammals. Body mass and size of the agents determine their swimming performance, particularly range and speed of movement in water. Additionally, the agents may differ in their hydrophobia score, i.e. their preparedness to start a crossing attempt, and the group size required to rate crossing attempts as successful. The model also allows to accommodate sea straits of different width, and current speed and direction.
We applied the SEAcross ABM in a suite of experiments, mainly focusing on Southeast Asia and Wallacea, to demonstrate its flexibility. It can be applied to examine dispersal routes and ranges of individual species, for instance the dispersal of stegodons across insular Southeast Asia and Wallacea. In this case, a shrinking model is included to accommodate for island dwarfing, because size critically influences dispersal performances. As a result, we were able to identify potential routes, and compare the range with the known fossil record. Moreover, it can also be applied to examine the fossil record of mammalian taxa in specific islands, where the faunas are composed of a mixture of migrants originating from mainland Southeast Asia and Meganesia. Data emerging from the SEAcross ABM can then be validated by the fossil record. Some of the results will be introduced and discussed here.

New insights into the Late Pleistocene climate of Malta: Microfaunal analysis from Għar il-Fkieren

Ms. Rochelle Lorraine Xerri [1], ***Dr. Mathew Stewart*** [2], ***Prof. Nicholas Vella*** [1], ***Dr. Patrick Roberts*** [3], ***Prof. Eleanor Scerri*** [2]

1. *University of Malta,* ***2.*** *Max Planck Institute for Geoanthropology,* ***3.*** *isoTROPIC Research Group, Max Planck Institute for Geoanthropology*

The Maltese Islands are known to have hosted a much more vibrant and biodiverse range of species during the Pleistocene than they do today, such as pygmy elephants, giant swans, and large dormice. However, most of what is known about Malta's Pleistocene fauna originates from excavations undertaken at the Għar Dalam cave site using rudimentary methods over a century ago. Għar il-Fkieren, a newly-discovered Quaternary site replete with faunal remains, now provides the opportunity to gain independent insights into the climate conditions, faunal complexes, and biogeographical history of the Maltese islands during the Late Pleistocene. Here we present a study on the microfauna from this site with a special focus on rodents. Microfauna, with their small home ranges, restricted habitat, and high reproductive rates, are excellent proxies for local environments and environmental change. While their use as proxies has long been recognised, microfauna have not yet been studied with a view to understanding climate history in Maltese contexts. We combine here microfauna taxonomy, morphometry, and stable isotope analysis to provide an unprecedented insight into the environmental and climatic conditions during the Late Pleistocene on the Maltese Islands.

Island time. Exploring human-animal interactions during the Pleistocene in the Wallacean Islands

Dr. Sofia Samper Carro [1]

1. School of Culture, History and Language, College of Asia and the Pacific, Fellows Rd., The Australian National University, Acton

Research in the Wallacean islands, the biogeographic region separating the Asian and Australian continental shelves, has provided insights into the antiquity of human occupations, migratory routes, navigation techniques, and artistic manifestations. Furthermore, recent genetic studies, as well as evidence of the diversity of cultural practices, illustrate the research potential of this region.

Human-animal interactions in these insular environments are sometimes difficult to assess. Differences in the type of existing vertebrate fauna prior to AMH occupations, as well as the depauperated terrestrial fauna in some of these environments, requires systematic and individualized research approaches. The rich Pleistocene terrestrial fauna in islands like Java, Flores, Sulawesi or Kalimatan contrasts with the limited terrestrial resources available for AMH survival in Timor, Alor and Kisar. Additionally, most of the archaeological sites identified in these islands are located in cave systems, which contribute to difficulties to interpret the agent responsible for some of the faunal assemblages documented.

In this presentation, I will provide a brief overview of recent advances in the study of human-animal interactions in the Wallacean Islands during the Pleistocene. This talk will demonstrate how geometric morphometrics, osteometric, geospatial and taphonomical methods can contribute to achieve a better understanding of AMH animal resources management and interaction with their environment when they reached these islands on their way to the Sahul continental shelf.

Interactions between humans and dwarf elephants: a chronological perspective

***Dr. Victoria Herridge* [1], *Prof. David Richards* [2], *Dr. Christopher D. Standish* [3], *Dr. Dan Nita* [4], *Prof. Edward Rhodes* [5], *Dr. Gabriella Mangano* [6], *Prof. Adrian Lister* [1], *Mr. John Borg* [7], *Prof. George Iliopoulos* [8]**

***1.** Natural History Museum, **2.** School of Geographical Sciences, University of Bristol, **3.** University of Southampton, **4.** Babes-Bolyai University, **5.** Landscape Dynamics, Department of Geography, University of Sheffield, Sheffield S10 2TN, UK, **6.** Museo della Fauna, Messina, **7.** Natural History Unit (Heritage Malta), National Museum of Natural History, **8.** Department of Geology, University of Patras*

Multiple examples of insular dwarfism, such as that observed in the fossil record for Pleistocene elephants, provide one of the most intriguing ‘natural experiments’ in parallel evolution. The corollary to this, which has received less focus, is that it also provides a study system for examining the drivers of extinction. Critically, the turnover events (faunal extinction, followed by renewal) observed across several hundred thousand years on islands such as Sicily, Malta, Crete and Cyprus provide an opportunity for assessing a baseline extinction risk for vulnerable populations. Human activity has been invoked as the main driver of extinction for *Palaeoloxodon (Elephas) cypriotes* on Cyprus. However, the extinction of pre-Holocene insular forms is largely assumed to have occurred in the absence of humans. One key issue here is that the evidence for interactions between humans and insular endemic species are largely inferred from chronological overlap, yet the chronologies are far from robust. Here we will present an overview of our current best understanding of the geochronology of Mediterranean dwarf elephant, deer and hippopotamus, and place this in the context of human activity on those same islands, and the neighbouring mainland. In doing so, we will highlight the degree to which we can be confident that these endemic fauna and humans did –and did not– overlap, and what this means for our understanding of human impact on both the evolution and extinction of mammalian fauna.

The Acheulean settlement of Lesbos Island: An Edaphics Approach

Dr. Peny Tsakanikou [1], ***Dr. Simon Kübler*** [2], ***Prof. George Iliopoulos*** [3], ***Prof. Nena Galanidou*** [1]

1. Department of History and Archaeology, University of Crete, 2. Department of Earth and Environmental Sciences, Ludwig Maximilians University, Munich, 3. Department of Geology, University of Patras

The Aegean Sea has for long been envisioned in Pleistocene geography as a natural water barrier and as a 'cul de sac' in the discussion about the early hominin out of Africa dispersals. Recent work on the submerged landscapes of the Aegean led to the production of reliable palaeogeographical reconstructions for the past 400 Ka revealing a completely different picture. Large parts of the Aegean seabed now lying underwater, were subaerially exposed during the glacial lowstands most possibly since the Late Pliocene/Early Pleistocene and throughout the Pleistocene. Extended terrestrial environments created land bridges connecting western Asia to the Greek mainland and W Europe via the Aegean. Only recently this aspect started to gain ground in the discussion about the early Eurasian settlements, highlighting the biogeographical significance of the Aegean at the crossroads between three continents.

Robust archaeological evidence from Lesbos Island, NE Aegean, attributed to the Acheulean, attests to such crossings of hominin groups from W Asia to the Aegean. Absolute chronology methods (pIRIR, palaeomagnetism) offer minimum ages for the presence and activity of hominins on Lesbos between 476 and 164 Ka, in the second half of the Middle Pleistocene, while relative chronology (techno-typological comparisons) shows clear affinities with Early Middle Pleistocene Acheulean assemblages from C Anatolia, Israel and E Africa. The rich, and unique in NE Mediterranean, Palaeolithic Lesbos lithic assemblage, both excavated from fluvio-lacustrine deposits and collected from the surface of the Kalloni basin, reveal Acheulean variants covering the wide chronological span of this tradition. Hominin groups were returning recurrently to S Lesbos during the Middle Pleistocene. What attracted them there?

Here we apply an edaphics approach to S Lesbos to shed light on the hominin-landscape interaction. We examine the inputs of complex topography, volcanic landscape resources, including hot springs, and permanent and ephemeral water bodies to the Acheulean settlement and land use. The distribution of soil nutrients, vital for sustaining plant and animal populations over the modern landscape, is used as a proxy to decipher the ecological value of the Middle Pleistocene landscape and its affordances, through the identification of attractive/unattractive areas.

A Quaternary Galapagos: Mediterranean Islands in the Pleistocene and Holocene

Dr. Victoria Herridge [1] ***, Prof. Eleanor Scerri*** [2]

1. *Natural History Museum,* ***2.*** *Max Planck Institute for Geoanthropology*

The Mediterranean region connects three continents, Europe, Africa and Asia. Changes in sea level meant that, at times, islands connected to the mainland, and formed stepping stones that circumvented longer coastal routes to link different regions of the Mediterranean. In turn, periods of sea level rise often drove intense processes of selection on islands, with biogeographic legacies sometimes lasting into the present day. These dynamic connections and periods of isolation have created a theatre of evolution that was ultimately interrupted by successive waves of humans and periods of climatic changes. Endemic species began to go extinct, in some instances replaced by analogous species translocated by humans from different mainland regions. This talk synthesises the available 'big picture' data on the Quaternary of Mediterranean Islands, using recent advances to coalesce the state of knowledge into a series of key questions. These concern long-term patterns of landscape change, tectonics and sea level rise, ecosystem resilience, the directionality and timing of faunal exchanges, processes of evolution, and ultimately, the transition to human dominated landscapes. These island transitions at the nexus of three continents are then used as lessons for understanding broader questions relating to the Anthropocene and today's biodiversity crisis.

Plants and animals use on islands. Limits, strategies, and adaptation from an archaeobotanical and archaeozoological perspective

Dr. Claudia Speciale [1]***, Mr. Fabio Fiori*** [2]***, Dr. Jacob Morales*** [3]***, Dr. Salvatore Pasta*** [4]***, Dr. Llorenç Picornell Gelabert*** [5]***, Mr. Vito Giuseppe Prillo*** [6]

1. *IPHES-CERCA, Catalan Institute of Human Paleoecology and Social Evolution, Tarragona (Spain); Department of Historical Studies, University of Gothenburg (Sweden),* ***2.*** *Department of History, Cultures and Societies, University of Bologna (Italy),* ***3.*** *Department of Historical Studies, Universidad de Las Palmas de Gran Canaria (Spain),* ***4.*** *Institute of Biosciences and BioResources, Unit of Palermo, National Research Council, Palermo (Italy),* ***5.*** *Department of Historical Sciences and Theory of the Arts, University of the Balearic Islands (Spain),* ***6.*** *Department of Cultural Heritage, University of Padova (Italy)*

Islands have been considered models for archaeological research because of their nodal role within the wider networks of coastal and maritime sites. The limitedness of their area and resources and the need to forefront short- or long-distance voyages to reach them make islands more or less isolated, at least for some natural and cultural processes, particularly affecting local terrestrial plant and animal assemblages. This physical separation from the mainland often makes island ecosystems follow their own peculiar dynamics, and consequently humans had to cope with these constraints. Island human communities all over the world and through different chronological phases have then adopted special subsistence strategies to live in these territories, sometimes more successfully and other times ending their occupation with the abandonment. Here we present to present the most recent results of ongoing archaeobotanical (anthracological and carpological) and archaeozoological analyses on some Mediterranean (mostly Ustica, Aeolian Islands, Pantelleria) and northeastern Atlantic (Canary) Islands. Our goal is to compare islands of different size, distance from the mainland or other islands, geologic origin, reachability through sailing, plant and animal diversity to detect the patterns of adaptation of human communities to island features. We will focus on:

-the process and integration/impact of faunal (mammal) species introduction to the island environments

-the specific strategies of management of insular wood resources, i.e. the adaptation of human communities to cope with some specific features of local vegetation

-the selection of domestic animal breeds and size for sustainability

-the displacement of native animals from/to the mainland or other islands

-the genetic isolation of and use of storage systems

-the import of plant staple resources

-the specific exploitation of local wild fauna

-the indicators of local climate changes and adaptation

-the ethnobotanical evidence of centennial/millennial local agricultural customs.

Session 27: Resilience versus collapse: Human responses to climate change in the Quaternary

Towards an improved understanding of Late Pleistocene and Holocene vegetation dynamics, resource exploitation and the resilience of human communities in the south-central Peruvian Andes

We present new palaeoenvironmental data from three wetlands located in the south-central Peruvian Andes. Laguna Runtoccocha is a lake basin formed within a small moraine at 4150 m (Apurimac) with a sedimentary sequence spanning the last ~15,500 years. Ayapampa is a small peatland (Apurimac; 3400 m) and Laguna Tocsaccocha (Ayacucho; 2290 m) is a partially infilled lake basin; both located in the Chicha-Soras Valley. They have sedimentary records spanning the last ~3500 and ~1600 years respectively. The pollen-stratigraphic data from Laguna Runtoccocha suggests that the Late Pleistocene landscape was characterised by open puna grassland as well as discontinuous montane taxa. We believe that the vegetation was responding to increased moisture availability on the puna resulting in an upslope shift in ecotonal boundaries possibly during the Lateglacial Interstadial (~14,700-13,000 cal yrs BP). An expansion of puna taxa, especially grassland, and a decline in arboreal taxa, denoted the transition to the Early Holocene. Together with the higher incidence of wildfires suggested by the charcoal concentrations, collectively this indicates an environmental response to Early Holocene climate warming and possibly lower precipitation. The Middle Holocene was characterised by a rise in xerophytic taxa suggesting a broader environmental response to higher temperatures and/or lower precipitation. The onset of the Late Holocene appears to be a change in the earlier aridification trend with evidence for increased moisture availability. Peat accumulation rates increase at Laguna Runtoccocha and sedimentation initiated at Ayapampa and Laguna Tocsaccocha. These records have permitted an evaluation of the relationships between climate variability, environmental change and cultural development, especially during the Late Holocene. During this period, human activities, especially those associated with terrace agriculture, transformed the landscape and environment. The records provide unequivocal evidence for the cultivation of *Zea mays*, and possibly other taxa, during the Middle Horizon, late Late Intermediate Period and Late Horizon cultural periods. We argue that land-use changes during these periods indicate agricultural intensification against a background of variable precipitation. In contrast, abandonment of terrace agriculture in the study area during the Late Intermediate Period suggests a possible failure to adapt to aridification coincident with a major cultural transformation.

Holocene climate-vegetation-land use interactions in the lowlands of Northern Greece

More than 8000 years ago, the agricultural innovations that laid the foundations for modern societies spread from the Near East over Greece, the Balkans, and other Mediterranean routes. This process, named ‘Neolithisation’, involved the shift from a nomadic hunter-gatherer lifestyle to sedentary farming. Alongside the adoption of an agrarian economy, humans drastically increased their impact on the environment and the biosphere, for instance through the introduction, propagation, reduction, or extirpation of species, as well as through increased fire occurrence, erosion and eutrophication. During the initial wave of Neolithisation into Europe, past human societies had to deal with, and adapt to, environmental forcing, chiefly a major climatic shift centered around 8200 years ago.

The ERC-Synergy project EXPLO (‘EXPLOring the dynamics and causes of prehistoric land use change in the cradle of European farming’) aims at investigating key questions regarding the interaction between past human ways of life, land use, climate, and the wider environment through a unique combination of archaeological, biological, climatic and dynamic landscape modelling approaches. Within this general framework, the primary goal of our paleoecology sub-project is to gain, for periods of particular interest, continuous high-precision and high-resolution proxy records of vegetation, fire, land use, aquatic productivity, and species diversity from pollen, spores, charcoal, macrofossil, elemental, and pigment analysis. Results of these analyses will be compared with paleoclimatic reconstructions to assess societal, biosphere and geosphere responses. Our study site Limni Volvi close to the Mediterranean coast is a unique site to investigate the environmental impact of the Neolithisation on the lowlands of Northern Greece. Our results will contribute to filling the existing knowledge gap about the Holocene dynamics of mesomediterranean (partially evergreen broadleaved) vegetation in Northern Greece.

Deciphering human-environment interactions at the onset of farming in Europe with a continuous high-resolution palaeoecological record from Limni Zazari, Northern Greece

Institute of Archaeological Sciences & Oeschger Centre for Climate Change Research, University of Bern

More than 8000 years ago, agriculture was first introduced to Northern Greece from Western Asia, starting the European Neolithisation process. The establishment of early farming societies with their crops and livestock changed the natural biomes and environments of Europe forever. New land use practices had a notable impact on vegetation and fire regimes. However, these first farmers were highly dependent on their natural environment and had to adapt their practices to changes in climate and vegetation. The interplay between Neolithisation, vegetation and climate is complex and still not well understood. Continuous, high-resolution multi-proxy time series of past vegetation dynamics and fire histories are needed to understand the long-term relationships between the first Neolithic European farmers and their environment.

We analysed sediments from Limni Zazari, a small lake in Northern Greece, to study the interactions between climate, land use, fire and vegetation. We present a new continuous high-resolution vegetation, environment and fire history record spanning the Late Mesolithic and the Neolithic (ca. 10,000-5,000 cal BP), reconstructed by using pollen, spores, microscopic charcoal, XRF and Hyperspectral Imaging (HSI) scanning.

During the Mesolithic, mixed deciduous oak forests interspersed with open grassland communities covered the surroundings of Limni Zazari. Around 8,500 cal BP, a significant decline in forests occurred, together with an increase of steppe vegetation, that lasted for about 400 years. The synchronous increase in anthropogenic indicators suggests the start of agriculture in the area during this period. Early Holocene climate instability possibly facilitated the start of Neolithic farming in Northern Greece. Subsequently, after the establishment of several Neolithic settlements nearby at ~7,500 cal BP, forests experienced regular disturbances. Even though forests were resilient and recovered quickly from these disturbances, vegetation composition slowly changed.

Our study describes the interactions between vegetation, climate and the first European farming communities, with an emphasis on primeval forest response dynamics. A better understanding of the processes and mechanisms of past societal and ecosystem adaptation to climate change and disturbance may provide useful insights for a future under global change conditions.

Archaeobotanic insights into the spread of Jura lake pile dwelling wheat diversity

Dr. Caroline Schaal [1]***, Prof. Pierre Pétrequin*** [2]***, Dr. Anne-Marie Pétrequin*** [2]***, Dr. Sabine Karg*** [3]

Ledoux, UAR 3124, CNRS & Bourgogne Franche-Comté University, Besançon, France Centre de recherche archéologique de la vallée de l'Ain, CRAVA, Gray France,* ***3.*** *Free University of Berlin, Institute for Prehistoric Archaeology, Berlin, Germany*

Around 3900 BC, the first farmers in the Jura chose the lake shores of Chalain and Clairvaux to construct their villages in humid environments. Usually built on dry land, the houses and granaries were adapted to the waterlogged lands. The most classic case is that of villages with raised floors on stilts. According to ethnographic comparisons and approaches to social functioning, Neolithic farmers built their villages in naturally defensive positions, to shelter men and crops.

The installation of the settlements in wetlands has as an important archaeological consequence: the extraordinary preservation of organic material of plant origin such as textile, architectural timbers, wooden artefacts, textiles and vegetal remains. Furthermore, the chronological framework in wetland sites reaches an unprecedented precision, based on the dendrochronological datation of the piles and timbers. The plant macroremains are quite remarkable finds for undertaking original research. These wetland sites in the French Jura mountains thus offer archaeologists the opportunity of exploring questions on demography, social organizations and cultural practices during almost one millennium.

With hundreds of thousands of plants remains that correspond to several hundred plant species, these sites offer outstanding conditions for different issues such as the paleoenvironment, the economics and the history of anthropo-ecosystems. In the light of new studies on the origin and diffusion of agriculture, we would like to focus on the emblematic species: wheat (*Triticum spp*.), as these cultivated plants reached France, either along the river Danube or along the Mediterranean coast. The crops had to adapt to new biogeographic, climatic and cultural conditions. By focusing on wheat as a model species, it is possible to reconstruct evolutionary trajectories in response to natural factors and changes in economic and cultural practices.

Ancient Maya responses to climate change in the tropical lowlands of MesoAmerica.

Dr. Joanna Tindall [1]***, Dr. Shawn O'Donnell*** [2]***, Prof. Sarah Metcalfe*** [1]***, Prof. Bronwen Whitney*** [2]***, Dr. Julie Hoggarth*** [3]***, Prof. Jaime Awe*** [4]***, Dr. Elizabeth Rushton*** [5]***, Dr. Haydar Martinez Dyrzo*** [1]

The ancient Maya of MesoAmerica continue to be of great interest because of cultural disruptions occurring in the late PreClassic (Abandonment), Classic (Hiatus) and particularly in the Terminal Classic (Collapse), when several large settlements were abandoned (ca. 800 – 1000 CE). Drought has been implicated as a potential driver of these periods of change, although a range of other causes have been suggested, including environmental degradation caused by human activity. The timing and scale of change was, however, highly variable suggesting differential resilience of both natural and human systems.
We combine elemental, geochemical, palynological and charcoal data from the New River Lagoon and Ambergris Caye (Belize) and Laguna Esmeralda (Mexico) to track changes in climate, vegetation cover, key cultivated crops (e.g. *Zea mays)* and fire histories with available evidence from the archaeological record to explore the interactions between humans and climate.
The New River Lagoon (NRL) is a large open system, with the important Maya settlement of Lamanai on its western shore. There is limited evidence for drought in the Terminal Classic and Lamanai was not abandoned. The Ambergris Caye site lies close to the PostClassic settlement of Basil Jones, but records much longer human disturbance across the island. Laguna Esmeralda lies in an area with no evidence for large Maya settlements. Drier conditions seem to be recorded at the time of the Abandonment, Hiatus and Collapse and early cultivation apparently had little impact on forest cover. Evidence for climate change, the timing of maximum human impact and economic strategies varies across these sites, suggesting variations in the resilience of both natural and human systems.
Comparison with other key climate records such as those from Yok Balam and Macal Chasm provides further insights into interactions between people, climate, and their environment over the late Holocene.

Collapse of the pre-Columbian Monumental Mound Culture in the Bolivian Amazon

The Llanos de Mojos (LM) of Amazonian Bolivia is a mosaic of tropical rainforests and seasonally-flooded savannas, home to the Monumental Mound Culture (MMC) – perhaps the most complex pre-Columbian (pre-AD1492) society to have developed in Amazonia. In a region which is today sparsely populated and used mainly for cattle ranching, the MMC built a complex network of artificial earthworks, comprising > 150 monumental habitation mounds (HM) interconnected by canals and causeways. Little archaeological and palaeoecological research has yet been undertaken, but it points to a densely populated, stratified society, based upon intensive maize agriculture. This project addresses a fundamental question: ‘When and why did the MMC collapse?’

Emerging archaeological evidence suggests that the MMC disappeared ca. AD1400, ~150 years before European arrival, challenging the paradigm of post-Contact collapse. However, whether this chronology of site abandonment is representative of the MMC is unknown. The limited palaeoecological research shows temporal correlation between archaeological earth-work occupation and charcoal peaks in sediment cores of neighbouring lakes and bogs. The latter leads us to infer, that changes in charcoal abundance serve as a proxy for changes in human population density.

We use a palaeoecological approach to determine the spatiotemporal pattern of abandonment of the HM across the MMC region. We present high-resolution fossil charcoal and cultigen pollen records, from cores of 8 lakes and palaeo-river channels, with Bayesian age-depth models spanning the past 1-2 millennia. The palaeo-channels, adjacent to the HM, capture land-use change on individual HM, while lake records, capture land use at coarser-grained spatial scales.

Based on the premise that long-term declines in charcoal signify site abandonment, we test the following hypotheses: the collapse of the MMC preceded (H1) *versus* post-dated (H2) European arrival; collapse of the MMC was sudden and simultaneous across the region (H3) *versus* spatially heterogeneous and time-transgressive (H4).

Analyses of these fossil records are ongoing. However, preliminary data from 3 sites (Lagunas San Jose, Peroto, Loma Suarez) is consistent with H1. Once our analyses are complete, we will cross-correlate our charcoal and cultigen pollen data with speleothem records from the region to examine the possibility of climate-driven collapse.

From microscopic biodiversity to macroscopic similarities between past and present environmental dynamics: the case study of the Terramara S. Rosa di Poviglio (N Italy)

Changes in plant species richness and composition have been triggered by the interaction's dynamics between human societies, ecosystems, and climate. The environment and human populations influence each other: changes in the cultural landscape occur in response to different climatic conditions, and the development of societies modulates ecosystems. In such context, Palynology, being a trans- and inter-disciplinary science, can explore biodiversity changes in a long-term perspective with the aim of obtaining functional answers to interpret current environmental and social dynamics.

Here, we present a palynological investigation carried out in the Po Plain, the main floodplain of northern Italy, focusing on the interaction between human–water systems during the Holocene. Three terrestrial cores were collected in the framework of the SUCCESSO-TERRA Project (PRIN-20158KBLNB) in the area surrounding the Terramara S. Rosa di Poviglio, a Middle Bronze Age settlement belonging to the Terramare culture, which has been investigated for almost 40 years.

Pollen spectra describe a long-term picture of large-scale vegetation changes as a dual result of climatic oscillations and human overprints. We noticed a shift towards a permanent and extensive impact on biodiversity during the Middle Bronze Age, from the establishment of the Terramara culture until its societal crisis. The latter was triggered by extensive and intensive agricultural and livestock overgrazing. Our data are further evidence that the prolonged and intense exploitation of a territory transformed the natural environment into a cultural landscape with the development of new conditions untenable for civilisations without taking subsistence adaptations.

A multiproxy record of human and climatic impacts on disturbance and vegetation in the Southern Rocky Mountains, USA

Dr. Paul Henne [1], ***Dr. Susann Stolze*** [2], ***Dr. Natalie Kehrwald*** [1], ***Dr. Sarah Spaulding*** [1], ***Dr. Rebecca Brice*** [3], ***Dr. Ellis Margolis*** [1]

1. *United States Geological Survey,* ***2.*** *Colorado School of Mines,* ***3.*** *U.S. Geological Survey*

Human populations have a long history of ecological impacts on forests in the mountains of the Southwestern United States. Networks of tree-ring archives demonstrate shifts in regional fire regimes associated with Native American land use followed by Spanish and American colonization. However, tree-ring records fade before ca. 1400 AD, which limits understanding of long-term interactions among humans, climate, disturbance, and vegetation in this fire-prone region. We are addressing this limitation with a multi-proxy record of environmental change from Santa Fe Lake, New Mexico (3532 m a.s.l.), the southernmost lake in the Rocky Mountains. We are reconstructing vegetation dynamics with pollen analysis, fire histories with sedimentary charcoal, paleohydrology with diatom analysis, and the presence of humans in the watershed with fecal sterols. Sediment began accumulating at Santa Fe Lake ca. 13,755 cal yr BP. An abundance of pollen types transported from lower elevations, (e.g., *Artemisia* up to 50%) indicate an open landscape existed near the lake at this time. Increasing *Picea* pollen after 12,000 cal yr BP record the regional expansion of subalpine forests. Stomates and needles of *Picea* and *Abies* document the arrival of the upper treeline at the lake by 10,000 cal yr BP. *Pinus* also increases at this time, probably due to expansion by *Pinus ponderosa* at lower elevations. Increasing *Abies* and *Pinus aristata*-type pollen after 7000 cal yr BP may indicate an expansion of the upper treeline ecotone above the lake. Preliminary data suggest that agriculture became established in the region after 1200 AD (750 cal yr BP), when maize pollen first appears in the record. The largest peak in microscopic charcoal accumulation also occurs at this time, which suggests an increase in regional burning, perhaps related to the establishment of permanent Puebloan settlements. We are further exploring these long-term human impacts using fecal sterols and charcoal analysis.

Session 28: Timing and structure of freshwater ecosystem response to external forcing: evidence from high-resolution multi-proxy lake and peat bog records

Climate synchronicity in Tasmanian terrestrial and aquatic ecosystem over the Holocene

Dr. Kristen Beck [1], ***Prof. Michael Fletcher*** [2], ***Dr. Michela Mariani*** [3], ***Dr. Feli Hopf*** [4]

***1.** University of Lincoln, **2.** University of Melbourne, **3.** University of Nottingham, **4.** Australian National University*

PowerPoint Presentation

Climate is the most important driver of aquatic ecosystem change, effecting changes to nutrient status, productivity, and ecosystem health and function. Aquatic ecosystems are affected by two climatic forces *energy* and *mass*. *Energy* encompasses the direct climate influences of heat, wind, and irradiance. Whereas *mass* fluxes are the indirect climate influences of *energy* on the terrestrial environment, catchment, and aquatic ecosystem through avenues of changing vegetation, soil development, and catchment dynamics that alter aquatic ecosystems. While there is a greater understanding of climate impacts on freshwater systems, and a growing understanding of the complex indirect relationships climate has on these environments; the patterns related to *energy* and *mass* on longer timescales and larger spatial scales are not particularly well-known. Tasmanian freshwater systems show tight coupling to the terrestrial environment with changing climate over the Holocene. Climate related shifts in fire regimes, vegetation, and catchment dynamics indirectly drive aquatic ecosystem change including changes in species assemblage, pH, nutrient status, and light availability. While there is evidence of both *energy* and *mass* climate influences on the terrestrial and aquatic ecosystem of Tasmania, the timing (synchronicity) and consistency (coherence) in these responses have not been evaluated on a regional scale. Using five multiproxy lake records from western Tasmania of pollen, charcoal, aquatic remains, and generalise additive modelling we aim to answer the following questions:

Q1- Are Tasmanian terrestrial and aquatic environments responding synchronously or asynchronously to Holocene climate?

Q2- Do terrestrial and aquatic ecosystems show consistent patterns (coherence) of direct and indirect responses to climate over the Holocene?

Preliminary findings show synchronicity between rainforest and aquatic ecosystems changes at ca. 3.5 ka, with the exception of an early response at one site (Paddy's Lake) at ca. 6 ka. During the early Holocene, sites are responding to *mass*, but with onset of drying sites have a mixed *mass* and *energy* response due to differing biogeography. Synchronicity and coherence is unexpected in sites driven my *mass* where more variability in anticipated, however, there is evidence of synchronicity and coherence in the terrestrial and aquatic ecosystems across western Tasmania.

A palaeoecological evaluation of Typha as a potential tool for wetland management in New Zealand. Part 1: ecological perspectives

Prof. Rewi Newnham [1]***, Dr. Xun Li*** [2]***, Dr. Marcus Vandergoes*** [2]***, Dr. Valerie van-den-Bos*** [2]***, Dr. Rose Gregersen*** [1]***, Dr. Jamie Howarth*** [1]***, Dr. Andrew Rees*** [1]***, Dr. Susanna Wood*** [3]

1. *Victoria University of Wellington,* ***2.*** *GNS Science,* ***3.*** *Cawthron Institute*

Palaeoecology can inform a process-based understanding of ecosystem function and resilience, that can in turn help guide restoration strategies. The potential for this 'past-present-future' approach is especially high in the case of wetlands, which can provide a range of critical 'ecosystem services' but have been vastly depleted in recent decades. Here we investigate the ecological roles played by the wetland plant *Typha orientalis* (raupō) in New Zealand prehistory and consider the important implications for future freshwater wetland management. In the context of recent pervasive wetland degradation throughout New Zealand, this iconic yet enigmatic plant can be viewed as an invasive threat or as a valuable ecological and economic resource and a natural, indigenous agent for bioremediation. As this New Zealand species shares the same intrinsic ecological and morphological attributes of the ~40 species or hybrids of *Typha* that span most of the planet, this work may find resonance in many other regions as well.

Our preliminary investigation presented here reconstructs the history of *Typha* over the past ~1000 years, based on interrogation of 91 new pollen records along with a range of ecosystem health indicators generated from lake sites across New Zealand. These new records build upon previous work showing that *Typha* consistently responded to disturbance, accentuated by human activity, but in different ways. At almost every site (82%) where *Typha* is present naturally, its expansion is promoted to varying extents during - and presumably because of - periods of human activity and in particular forest clearance and associated sediment and nutrient flux. These multiple patterns of response over time point to a range of hydrological, trophic and cultural scenarios that are conducive for *Typha* expansion. Intriguingly, independent proxies point to stable or even improved water quality conditions during the *Typha* expansion phase at some sites, raising important questions about its potential role in mitigating the ecological impacts of disturbance. In a separate presentation at this congress we show that *Typha* expansion also provided new opportunities for its use as a valuable food and material resource, prompting further questions as to the extent it was deliberately managed by prehistoric populations.

Identifying the Homerian Climate anomaly through high resolution analysis of annually laminated sediments from Holzmaar, Germany

Dr. Maria Lujan Garcia [1], *Ms. Stella Birlo* [1], *Prof. Bernd Zolitschka* [1]

1. University of Bremen, Institute of Geography, Geopolar, Germany

Paleoclimatic reconstruction helps to place contemporary climate change into perspective of natural climatic variability and thus increases our understanding of the climate system. Previous studies have identified cold and wet periods for the past millennia across Europe. Yet and due to the lack of high temporal resolution datasets, the climatic mechanisms controlling these events remain unclear. Here, environmental archives with annually laminated (varved) sediments come into play, since they permit a calendar-year chronology and allow calculation of precise sediment accumulation-rates. One of the most widely used biological proxy for lake records are diatom assemblages, as their species composition is related to climate variability and anthropogenic impact. As an overview, we performed multiproxy analyses of a sediment record from Holzmaar (West-Eifel Volcanic Field, Germany) that covered the last 16,000 years. In addition to diatom assemblages, we analysed physical (magnetic susceptibility) and geochemical proxies (biogenic silica, elemental composition) to assess the main trends of paleoenvironmental change with a centennial resolution for the 14 m-long composite record. In this contribution, we focus on the Homerian Climate Anomaly (ca. 2750 cal. BP) with high decadal temporal resolution. This short and wet event not only coincides with a period of low solar radiation, but also with the most pronounced biostratigraphic shift from the Subboreal to the Subatlantic and the transition from late Bronze Age to early Iron Age settlements. We aim to provide insights into diatom biodiversity patterns during this period. With the support of other proxies this helps to disentangle climatic variations for this transition. For example, a distinct increase in windiness is documented by diatom blooms of *Stephanodiscus minutulus*. We expect our contribution to be the starting point for similar analyses of sediments from different other varved Central European lakes in search of the Homerian Climate Anomaly. The overarching aim is to correlate this event in space and time and eventually establish a regional assessment of this climate anomaly.

Evidence for natural lake anoxia events during abrupt climate change in the last 130 ka in Eurasia

Nutrient excess in lakes causes an increase in aquatic primary productivity, often leading to the establishment of hypolimnetic anoxia. Under these anoxic conditions, redox-sensitive elements such as iron, manganese and phosphorous may be redissolved from the sediment and released into the lake water. These elements increase primary productivity, prolonging lake anoxia and establishing positive chemical feedback mechanisms.

Studies have shown that (natural) eutrophication leading to the establishment of anoxia can be found even in pre-anthropogenic times. However, links between climate change, eutrophication, and the development of hypolimnetic anoxia are still poorly understood. Furthermore, it is unknown whether such successions of anoxic events were entirely or only partly reversible and how long it took for natural lake ecosystems to recover. Thus, we aim to compare (i) the reaction of morphometrically similar lakes to the same climatic perturbation, e.g., Dansgaard-Oeschger Events (DOE), and (ii) the reaction of individual lakes to a sequence of similar climatic perturbations. We investigate high-resolution lake sedimentary records from volcanic lakes in the Eifel, Germany, covering the last 130 ka and compare them to Swiss, Italian, and Chinese lakes.

Using a multi-proxy approach, we apply scanning XRF to detect elemental composition and hyperspectral-imaging pigment detection to estimate primary productivity and hypolimnetic anoxia. Additionally, we use HPLC for qualitative pigment determination to trace shifts in the community of primary producers. Furthermore, we use sequential extraction of redox-sensitive elements (Fe, Mn, P) to trace evidence of anoxia, related redissolution processes and internal cycling of nutrients.

Preliminary results suggest that, because of rapid climate warming, the succession starts with excessive nutrient delivery from the catchment, causing an increase in primary productivity composed of green algae. When anoxia develops, anoxic phototrophic green and purple sulphur bacteria partially replace the green algae. Additionally, the redox-sensitive and reactive P, Fe, and Mn fractions decrease in the sediment, indicating redissolution and internal P recycling. Thus, the internally fertilized lake continues in a high productivity mode.

Our results establish a link between climate change and biogeochemical responses of lakes, which are essential for future projections, e.g., lake ecosystem protection strategies or water resource management plans.

Understanding the role of palaeoclimatic drivers on cyanobacteria bloom development in shallow lakes

Mr. David A. Hatton [1], ***Prof. Helen Roe*** [1], ***Prof. R. Timothy Patterson*** [2], ***Prof. Peter R. Leavitt*** [3], ***Prof. Eduard G. Reinhardt*** [4], ***Mr. Ethan T. McCann*** [5], ***Dr. David R. McMullin*** [5], ***Dr. Nawaf A. Nasser*** [2], ***Mr. Matthew G. Marshall*** [6]

Department of Earth Sciences, Carleton University

Harmful cyanobacterial algal blooms (CyanoHABs) have garnered increased public and scientific interest due to the potentially devastating impacts of their toxic secondary metabolites on biota. This has created significant impetus to understand the spatial and temporal drivers associated with their development. While anthropogenic nutrient enrichment and climate-related processes are recognised as important controls on CyanoHABs in modern lake environments, few studies have explored the mechanistic links between specific climatological stressors (e.g. storm events) and past episodes of CyanoHAB development.

This multi-proxy palaeolimnological study is examining the relationships between past toxic algal bloom events, climatological controls (especially historic storms) and catchment-related disturbances in recent (ca. last 500 yr), shallow lake sediment records from New Brunswick, Canada, a maritime region which has seen an increased frequency of lake CyanoHABS in response to land-use change and historic storms.

Palaeo-climatological shifts were investigated in three dated sediment cores using End-member Mixing Analysis (EMMA) of grain-size data, which aids in the determination of depositional pathways associated with hydrological processes (e.g. heavy precipitation) and Itrax X-Ray Fluorescence (XRF), which is useful for detecting palaeo-precipitation and palaeotempest signals. Cyanobacterial responses were inferred from fossil sedimentary pigments and microcystin congeners (cyanobacteria-specific metabolites that preserve in sediments). Ongoing stable isotope analyses ($\delta^{13}C$; $\delta^{15}N$) will further aid in understanding lake productivity shifts and changes in lake sediment provenance.

Our results show that toxigenic metabolites increased by several orders of magnitude in the uppermost (<5 cm) core sediments from all the study lakes. This coincides with fossil pigment shifts, increases in sedimentary phosphorus, and increases in XRF-derived storm air mass signals. In one site (Harvey Lake) notable changes in the upper 2 cm of the record are linked to a major 2014 storm which triggered a significant CyanoHAB event. In another lake, four staggered zones of microcystins may indicate periodic phases of toxigenic cyanobacteria throughout the 0.35 m record.

The mosaic of palaeolimnological proxies being applied in this study will be critical for untangling the complex ecological, sedimentological and geochemical responses of these CyanoHAB-impacted lakes to climate-related stressors. This, in turn, will be integral for understanding their resilience to future change.

Aquatic community response to a century of environmental change and human impacts in Searsville Reservoir, CA

Dr. Maria Viteri [1]***, Dr. M. Allison Stegner*** [1]***, Prof. R. Scott Anderson*** [2]***, Mr. SeanPaul La Selle*** [3]***, Dr. Brian Sherrod*** [3]***, Dr. Anthony D. Barnosky*** [1]***, Dr. Elizabeth A Hadly*** [1]

1. Stanford University, 2. Northern Arizona University, 3. United States Geological Survey

Aquatic invertebrates are critical components of lake ecosystems. They are foundational to lacustrine food webs and often act as bioindicators for aquatic health. Microcrustaceans such as ostracods and cladocerans are particularly sensitive to changes in lake conditions including vegetation shifts, water depth fluctuations, and pollution inputs. Microcrustacean remains preserved in sedimentary records therefore have the potential to record environmental change and human impacts over time.

We analyzed the composition and abundance of freshwater microcrustaceans in a high-resolution sediment core from Searsville Reservoir (Woodside, California, USA) to track environmental change, including human impacts, over the last ~130 years. We paired this with a pollen analysis to examine concurrent shifts in algae and aquatic vegetation, providing context for microcrustacean community change. Searsville's high sedimentation rate – 12 cm/yr on average – provides a rare opportunity to explore community assembly at the ~yearly level following the creation of this anthropogenic system. Sediment samples were collected from Searsville core JRBP2018-VC01A for the analysis of ostracod valves and cladoceran ephippia as well as pollen, spores, and non-pollen palynomorphs. Representative specimens of each ostracod taxon were photographed using a scanning electron microscope (SEM) and the remaining microcrustaceans were identified under a compound microscope. We then used stratigraphically constrained hierarchical cluster analysis (CONISS) to assess whether there were significant shifts in microcrustacean community composition across the core.

CONISS revealed multiple shifts in the microcrustacean record, which we interpreted with the aid of the pollen record and detailed historical documentation. Increases in microcrustacean relative abundances were correlated positively with wetland rooted aquatics and negatively with algae. In addition, historical records of pesticide inputs to Searsville correspond with dramatic shifts in the microcrustacean community. Together, this multiproxy approach records the stabilization of the reservoir sediments, the proliferation of rooted aquatics, the shallowing of the lake over time, and especially the heavy use of herbicides in the 1950s.

This work adds an important microcrustacean record to California and contributes to the environmental record of this watershed. Microcrustaceans play an important role as tracers of anthropogenic pollutants in the Anthropocene.

Lake recovery pathways: testing ecosystem resilience from historic lake settlement impacts

Cultural eutrophication is one of the most widespread pressures on lake systems, with profound impacts on ecological structure, function and overall biodiversity. Probably the first impacts to lakes worldwide occurred as people settled around lake shores, and here we focus on specific lake dwelling sites, both artificially built and natural, called crannogs. Our studies concentrate on Scottish and Irish crannogs, constructed in the Iron Age and Medieval periods, which provide point source inputs into relatively small lakes, typically resulting in cultural eutrophication. These impacts can be quite specific spatially, and we use cores from near the crannogs, in addition to open water (lake central) cores to consider local vs lake wide impacts. The lake sediment cores have been well dated, and analysed for a wide range of proxies, including aquatic subfossil indicators, pollen, sedimentary ancient DNA (sedaDNA), and geochemical analyses. We collate these datasets to assess aquatic ecosystem responses (diatoms, chironomids, macrophytes) against a range of drivers, including land use change, animal abundance and associated processes, and other catchment changes.

While we, broadly, have a good knowledge of the mechanisms by which freshwater lakes can collapse to a degraded state, we have relatively little understanding of the nature and pace of their recovery to a resilient state. We measure resilience in terms of structural change (as opposed to frequency analyses of time series) through a suite of recently developed metrics, and here we use our datasets to test these new metrics across lake recovery from crannog impacts. Our data show that as the crannogs are abandoned, and point source inputs reduced, the lakes typically start to recover. We will use our data to consider whether the lakes respond through different recovery pathways, and/or whether they only achieve partial recovery against the backdrop of continued external, often diffuse, pressures. Furthermore, we will consider how different trophic levels respond to recovery as the ecosystem networks readjust to hysteresis on a timescale of decades to centuries.

Tracking historical human disturbances on remote islands using a multiproxy approach: Lake Ginjal record (Terceira Island, Azores)

The discovery and occupation of remote oceanic islands drastically modified their ecosystems, and the Azores was no exception. One of the first impacts of human arrival was changes in vegetation due to land clearance practices, an increase in soil erosion, introduction of exotic species, and homogenization of these unique ecosystems. Here, we provide the first environmental reconstruction based on multiproxy analysis (pollen, diatoms, cladocera, chironomids, charcoal, and organic matter) from Terceira Island spanning the last 650 years. We distinguished four main phases in Lake Ginjal: ca 1420-1500 CE (PI), 1500-1650 CE (PII), 1650-1950 CE (PIII), and 1950-modern (PIV). Phase I coincides with the official dates of Portuguese discovery and subsequent settlement of the archipelago. The absence of native forest species, the very low relative abundances of trees and shrubs throughout the record, and the dominance (> 90 %) of herbaceous plant pollen, clearly suggest a firmly already established open grassland. Furthermore, the continuous occurrence of coprophilous dung fungal spores and macro-charcoal particles and the presence of *Cerealia* sp. also support this point. This pressure on the terrestrial environment was also exerted on the lake. Abundance peaks in aerophilic diatoms (e.g., *Pinnularia borealis)*, plus the presence of chironomids associated with low oxygen requirements (e.g., *Chironomus* spp.), indicate a high lake trophic state. From ca. 1500 CE all proxy-based records changed significantly, coinciding with a marked growth in the human population on Terceira island. The sharp rise in the dominance of macrophyte-associated taxa, such as *Tabellaria flocculosa*, and lower TOC/TN values indicate a rise in lake trophic state. Phase III starts with a significant decrease in Cladocera and chironomids influx and an expansion of eutrophic diatoms such as *Fragilaria tenera*. This pattern is similar and coeval to those observed in other Azorean lakes, with the introduction of exotic fishes, which intensify internal nutrient release in the lake, leading to an increase in eutrophication. The last phase is characterized by changes in biological assemblages from more open-water (*F. tenera*) to macrophyte-associated taxa (*Alonella nana*), suggesting a shallow lake level trend due to near-complete sedimentary infilling and the subsequent development of a paludification process.

Session 29: Escaping the trap: frontiers of trapped charge dating

Finding Quaternary Seismogenic Activity along the Eastern Periadriatic Fault System: Dating of Fault Gouges using Trapped Charge Methods

Mr. Erick Prince* [1], Dr. Sumiko Tsukamoto [2], Dr. Christoph Grützner [3], Prof. Marko Vrabec [4], Prof. Kamil Ustaszewski [3]

__1.__ Institute for Geosciences, Friedrich-Schiller University Jena, Germany, __2.__ LIAG, __3.__ University of Jena, __4.__ University of Ljubljana

The Periadriatic Fault System (PAF) is among the most important and largest post-collisional structures of the Alps; it accommodated between 150-300 km of right-lateral strike-slip motion between the European and Adriatic plates from about 35 until 15 Ma. Recent GPS data suggest the Eastern Alps are still accommodating Adria-Europe convergence. However, according to instrumental and historical seismicity, seismotectonic deformation is mostly concentrated in the adjacent Southern Alps. In this contribution, we aim to show which segments accommodated seismotectonic deformation during the Quaternary by applying Electron Spin Resonance (ESR) and Optically Stimulated Luminescence (OSL) dating to fault gouges produced by the fault system. The method is especially useful for dating shear heating during earthquake activity at near-surface conditions due to its dating range (a few decades to ~1 Ma) and low closure temperature (below 100°C). For ESR, we measure the signals from the Al center in quartz following the single aliquot additive (SAAD) and single aliquot regenerative (SAR) protocols, focusing on the 100-150 µm grain size fraction. For OSL, we use the SAR protocol and measure the infrared stimulated luminescence (IRSL) signals at 50°C and 225°C on potassium feldspar aliquots of the 100-150 µm grain size fraction. Our ESR results indicate the PAF system accommodated seismotectonic deformation during the last 1 Ma, while the minimum ages obtained via OSL suggest that the events are not likely younger than 0.4 Ma.

Luminescence chronology and thermometry studies of plant opal phytoliths

Prof. Joel Spencer [1], ***Prof. David Sanderson*** [2]

1. Department of Geology, Kansas State University, 2. Scottish Universities Environmental Research Centre

In this work we have been investigating luminescence properties of plant opal phytoliths to assess their suitability for determination of age and thermometric information from soil and sediment sequences. Opal phytoliths form when monosilicic acid from soil-waters is taken up by plants and altered to silica, producing intra- or extra- cellular structures giving grasses and stems their strength. Opal phytoliths are usually considered non-crystalline and referred to as mineraloid structures, with ~4-9% water, <5% other elements, and specific gravity ranging from ~1.5-2.3. They are known to be resistant to degradation and preserved in soil or sediment after decomposition of organic matter. Earlier work examined a <2.37 g/cm^3 density fraction in parallel with quartz grains from samples from fluvial terraces and soil pits on Konza Prairie Biological Station native tall grass prairie a few km from Kansas State University. We observed similar luminescence characteristics from the phytolith fractions to quartz, with bright blue OSL signals and good single-aliquot regenerative-dose characteristics. In two hours the OSL signal is ~90% bleached by white light, whereas red fluorescence lab lighting has a negligible effect over the same exposure time. TL data suggested the presence of feldspatic-like minerals or perhaps thermal degradation of the phytoliths during measurement; the phytolith fractions were also stimulated by $IRSL_{50}$ perhaps also indicating contaminant minerals. SEM analyses identify what appear to be weathered silica grains, but also highly weathered, pitted concretions with silicate-like structures from element mapping but actual mineral identification is unclear.

Recently we have begun analyzing samples collected from a suite of stratified paleosols from the mid-continent stream type-site of Claussen, Mill Creek, Wabaunsee County, Kansas. This site has documented phytolith examples and a radiocarbon framework. We are continuing characterization studies, incorporating screening of prepared fractions with SEM and $IRSL_{50}$ evaluation, and pulsed time domain analysis measurements are being explored.

We think luminescence from opal phytoliths shows great promise as an alternative target to quartz or feldspar, but moreover as a sensitive recorder of climatic change or fire exposure on plant communities. This presentation will review earlier work and discuss most recent findings from the Claussen site.

Detection of ancient heating in archaeological sediments: Not as simple as it looks!

Prof. Simon Armitage [1]***, Ms. Finley Jones*** [2]

__1.__ Centre for Quaternary Research, Department of Geography, Royal Holloway University of London, Egham, UK, __2.__ Center for Quaternary Research, Department of Geography, Royal Holloway University of London

A number of single-grain dating studies of archaeological sediments have documented samples where the luminescence properties differ from those of the surrounding sediments. This phenomenon has been attributed to heating in antiquity. Similarly, single-grain sensitivity distributions from experimentally heated quartzes have been used to infer ancient heating of geological materials, thereby allowing them to be dated by luminescence techniques. However, although firing is a probable explanation of otherwise anomalous differences between the luminescence properties of adjacent samples/grains, relatively few studies have measured the effect of firing upon individual mineral grains. A fuller understanding of thermally induced changes in luminescence properties, particularly the sensitivity of quartz, could allow a) detection of hearths or burning features in archaeological sediments and b) identification of post-depositional resetting of luminescence signals by hearths constructed in overlying sediments.

In this study we present luminescence data from samples obtained during an experimental archaeology field season conducted near Blombos Cave, South Africa, by researchers from the SapienCE Centre of Excellence. Fires were constructed and burned upon a modern sand substrate obtained from coastal dunes near Blombos Cave. Temperature was continuously recorded at the sand/fire interface, and at 5 and 10 cm depth, yielding samples with a well-documented firing history. Burn times ranged from 1 to 10 days. The natural single-grain sensitivity distributions and abbreviated thermal activation characteristics (observation before and after a single controlled episode of heating) were measured for quartz extracted from fourteen samples with known firing histories. The effects of firing can be detected in both datasets, but samples with similar firing histories yielded different sensitivity distributions. Exposure in a UVACube 400 solar simulator also modified sample sensitivity distributions. This observation suggests that firing is best detected when the sample has not been exposed to sunlight, even if there is no intention to measure the sample's equivalent dose. The implications of our observations for identifying ancient heating in data obtained during routine equivalent dose measurements will be discussed.

Single-grain luminescence signal from modern fluvial feldspar sediments to investigate fluvial transport

Dr. Anne GUYEZ [1] ***, Prof. Stéphane BONNET*** [1] ***, Prof. Tony Reimann*** [2] ***, Dr. Sebastien Carretier*** [1] ***, Prof. Jakob Wallinga*** [3]

1. Géosciences Environnement Toulouse (GET), Université de Toulouse, UPS, IRD, CNRS, 31400, Toulouse, France, 2. Institute of Geography, University of Cologne, 3. Netherlands Center for Luminescence Dating & Soil Geography and Landscape group, Wageningen University, Wageningen

Luminescence in single-grain was developed to date sand deposits in which grains were heterogeneously bleach by sunlight before deposition, which is common in fluvial context.

In this study, we measured the single-grain post-infrared luminescence (SG-pIRIR) signal from modern flood-plain deposit from the Rakaia and the Waimakariri braided rivers running in the Canterbury Plains in the South Island of New Zealand. As suggested in publications from the last decade (McGuire and Rhodes, 2015; Gray et al.,2018; Sawakuchi et al., 2018), we used luminescence signal to quantify transport processes and transient storage of particles in floodplains in those rivers. We found for both rivers that the percentage of saturated grains and the mean D_e of the D_e distribution follow exponential decays with distance along the river. On the opposite, the quantity of well-bleached grains of the D_e

distribution increase exponentially towards downstream.

To get information on transport and storage from those trends, we developed a numerical model that simulate the successive displacement and D_e evolution of grains along a river. The code includes three main processes that repeat until each grain reach the river outlet: (1) displacement of a distance set with an exponential probability density function (PDF); (2) temporary storage for a period R_t between two displacements in the floodplain, set with a PDF that follows a Pareto law (exponent=-2). During R_t, D_e can increase proportionally to the dose rate; (3) bleaching of grains during displacement (fluvial transport) or storage (if exposed at the surface of the floodplain during Rt) according to a probability P_{Bl}. To first order, this simple model simulates well natural observations from Canterbury Plains rivers. This very simple transport model allows to decipher SG-pIRIR data and to estimate the mean transport length between 2 and 10 km and mean resting time between 20 and 150 years of sand-sized fluvial particles. Future works should consider testing these tools on other tectono-climatic or different flow styles contexts.

Using infra-red stimulated luminescence to understand sediment transport during flood events

Ms. Tessa Spano [1], ***Prof. Edward Rhodes*** [2], ***Prof. Rebecca Hodge*** [3]

1. Department of Geography, University of Sheffield, Sheffield, UK, 2. Landscape Dynamics, Department of Geography, University of Sheffield, Sheffield S10 2TN, UK, 3. Durham University

Understanding sediment transport dynamics provides key insight into frequency and magnitude of flood events in fluvial systems. Accurate prediction of high flow events has important implications for disaster preparedness, transmission of water-borne diseases, and our understanding of landscape evolution. Multiple elevated temperature infra-red stimulated luminescence (MET-IRSL) has great potential to provide detailed information on the movement of sediment grains through time and space. MET-IRSL stimulates grains using infra-red at a series of elevated temperatures to access multiple charge populations with different bleaching behaviours. Past light exposure and storage times can be determined by the relative difference between signals of a single grain or aliquot. The distribution of light exposure and storage through time can constrain the frequency and magnitude of high flow events.

We present field data from Scotland, California and Malawi, combined with a numerical modelling approach to understanding fluvial sediment transport and flow dynamics using MET-IRSL. A combination of single grain and multiple grain techniques are used to determine downriver changes in luminescence characteristics of grains, which reflect alternating high and low energy conditions. Downriver changes in luminescence are simulated using optimised bleaching and growth functions, to forward model the characteristic transport and flow regimes for these systems. This represents one of a set of tools we are developing to understand risk of water-borne disease outbreak associated with sediment transport during high flow or flood events in Malawi.

Coupling dosimetric methods (luminescence and ESR) with hydrosedimentary connectivity to unravel source-to-sink dynamics in the Strengbach catchment (Eastern France)

UMR HNHP 7184 (CNRS-MNHN-Université de Perpignan)

Sediment routing systems in fluvial catchments are primarily governed by intertwined climatic, tectonic and man-induced drivers at the centennial/millennial timescales. Among the various geomorphicical and geochemical approaches developed to trace sediment dynamics, the scientific community has recently explored the potential of (palaeo-)dosimetric methods, which are extensively used to date e.g. Quaternary alluvial environments. Recently, optically Stimulated luminescence (OSL) and Electron Spin Resonance (ESR) signals have been successfully transposed to decipher sediment provenance and transport in fluvial catchments. In parallel, the index of connectivity has been growingly used to quantitatively assess catchment-scale hydrosedimentary connectivity over the last decade.

Against this framework, the French ANR QUARTZ research project aims at using quartz grains as an ubiquitous marker of sedimentary dynamics to understand (i) how each quartz grain holds a source-specific signature, and (ii) how this signature evolves along sediment routing systems. This study specifically focuses on the second aim. Longitudinal measurements of OSL and ESR signals from modern river borne sediments are performed together with the assessment of the catchment-scale index of connectivity. It is argued here that coupling both information can help to quantitatively unravel source-to-sink sedimentary dynamics. More precisely, the longitudinal evolution of ESR and OSL residual doses in quartz sediments is reconstructed. Whilst a downstream decrease of residual doses is expected owing to increasing duration to light exposure with increasing transport distance, sediment inputs from tributaries can blur this signal. Here, this relation between bleaching evolution of quartz and sediments inputs is investigated via the index of connectivity.

A first campaign was performed in the Strengbach catchment in the Vosges Mountains (Eastern France) as it represents an ideal natural laboratory. Firstly, the geochemical composition of the source materials has been studied for more than thirty years. Secondly, it contains various quartz-bearing formations, i.e. plutonic, metamorphic and sedimentary. Finally, it displays a simple geomorphic configuration with (i) well-identified sources in the Vosges Mountains, (ii) a deeply-incised main valley with absence of significant intermediate storage (e.g. no terrace system) and (iii) a clear, single sink (Upper Rhine Graben). This allows representative computation of the index of connectivity (or dysconnectivity).

Quartz ESR Thermochronometry to constrain neotectonic movements on the Central and Eastern Alps

Dr. Valentina Argante [1]***, Dr. Sumiko Tsukamoto*** [2]***, Prof. Christoph von Hagke*** [3]***, Dr. Christian Brandes*** [4]***, Dr. David C. Tanner*** [5]

1. *Leibniz Institute for Applied Geophysics (LIAG),* ***2.*** *LIAG,* ***3.*** *University of Salzburg,* ***4.*** *Institut für Geologie, Leibniz Universität Hannover,* ***5.*** *Leibniz Institute for Applied Geophysics*

Low temperature thermochronology is a useful tool to reconstruct the tectonic deformation of the upper crust. It is a suitable tool to investigate deformation associated with cooling and exhumation of the lower crust in orogenic settings. Quartz is the most common mineral in the crust, and it occurs in magmatic as well as sedimentary and metamorphic rocks. The potential of quartz electron spin resonance (ESR) as a radiation dosimeter has been well documented, and many studies applied the method to date sediments and heated rocks (e.g. tephra). In this study we apply quartz ESR dating as an ultralow-temperature thermochronometer, characterized by a closure temperature of 30° - 90°, and dating range of 10^3-10^7 years. We show the first results of ESR thermochronometry on quartz applied to rocks from crustal scale faults in the Eastern Alps. Here, the lower crust has been tectonically exhumed associated with exhumation of the Tauern Window. Several low-temperature thermochronological data are available from this area, such as fission tracks or U-Th/He data on zircon and apatite. Results of the first ESR measurements of 15 samples crossing the Brenner and Salzachtal faults (northern and western border of the Tauern Window) show that the ESR ages of quartz get younger toward the central part of the Tauern Window, in accordance with fission track and (U-Th)/He ages. Moreover, we are able to show that the ESR ages fit with the normal tectonic movement of the Brenner Fault. These first results are promising to establish ESR as an ultra-low thermochronometer using the most common mineral in the crustal rocks, quartz.

Session 30: A multiscale geoarchaeological approach for the interpretation of palaeo-landscapes and human activities

Finding Suitable Grounds: Multiscale geoarchaeological tracing of the start of crop cultivation in submerged and buried landscapes of the Netherlands.

***Prof. Hans Huisman* [1], *Dr. Kim M. Cohen* [2], *Ms. Elena Familetto* [2], *Dr. Wim Hoek* [2], *Dr. Mans Schepers* [1], *Ms. Ana Smuk* [1], *Dr. Nico Willemse* [3], *Prof. Esther Stouthamer* [2]**

***1.** Groningen Institute of Archaeology, University of Groningen, **2.** Dept. of Physical Geography, Faculty of Geosciences, Utrecht University, **3.** RAAP Archaeological Consultancy, Zutphen*

We present a new project ("Finding Suitable Grounds") that focusses on buried and submerged Mesolithic and Neolithic landscapes in the Netherlands. The exceptional conservation of the natural surfaces from the age of the "neolithization window (6000 – 4000 cal. Yr. BC)" provides unequalled opportunities for studying the agricultural transition, and its impact on the natural environment. We will investigate in detail where, how and when humans in the Dutch lowlands first managed to clear suitable grounds and started crop cultivation.
We use newly collected and digitally archived (legacy) sedimentary, palynological and archaeological surveying data as well as new geophysical survey data to identify and target the most suitable areas for crop cultivation in the drowned and submerged landscapes. On new core samples we will use an approach that combines soil micromorphology, 14C dating and multi-proxy palaeobotanical analyses. These will reveal in minute detail how the various landscape niches were used by hunter-gatherers and how this use changed due to the adoption of crop cultivation, as well as by the rising sea level.
The introduction of farming (including crop cultivation) was a major development in the history of human society, abandoning the hunter-gatherer mobile life styles for more settled ones. Discussions on the mode and speed of this change have been a major topic among archaeologists and anthropologists. The 'neolithization debate' between those who advocate a quick adoption, and those who regard the process as one of gradual inclusion is still not resolved.
Geoarchaeology has until now played a (too) limited role in this debate. This is unfortunate, as geoarchaeological data, proxies and research methods at a range of different scales - from region to microscope - are essential for understanding the potential for crop cultivation of different landscape features and for their spatial delineation. Moreover, they make it possible to identify past cultivation practices and for contextualizing and focusing multi-proxy palaeobotanical studies into human subsistence and ecological impact.

Multi-disciplinary geophysical and geoarchaeological investigations indicate a Mid-Holocene environmental shift at Neolithic wetland site of Pestenacker (South Germany)

Ms. Anne Köhler [1]***, Dr. Ulrike Werban*** [2]***, Mr. Marco Pohle*** [2]***, Mr. Johannes Rabiger-Voellmer*** [3]***, Dr. Birgit Schneider*** [1]***, Mrs. Anneli Wanger-O'Neill*** [4]***, Ms. Stefanie Berg*** [4]***, Prof. Peter Dietrich*** [2]***, Prof. Christoph Zielhofer*** [1]

1. *Institute of Geography, Leipzig University,* ***2.*** *Helmholtz Centre for Environmental Research, Leipzig,* ***3.*** *Physical Geography, Institute for Geography, Leipzig University, Germany,* ***4.*** *Bavarian State Department for Cultural Heritage*

Reconstructing past human and environmental interaction is a substantial component of understanding 'great transitions' within these complex systems and their interdependencies.

We focus on the reconstruction of the Late Neolithic wetland occupation history at Pestenacker, an UNESCO world heritage site in the northern Alpine forelands of central Europe. We aim to recover and understand potential interactions between supra-regional climate forcing and local socio-ecological response mechanisms. In this context, we used larger scale geophysical prospection methods (Electromagnetic Induction, Electrical Resistivity Tomography and Direct Push sensing with two different probes) in combination with small-scale driving core drillings and results of archaeological excavations to create a high-resolution stratigraphic record of the valley. In addition, we compare the stratigraphical data with the dendroarchaeological and radiocarbon data sets to reconstruct the human environmental interactions at the study site during the Holocene.

Changing climatic patterns induced a shift of hydrosedimentary conditions around the prehistoric settlement site of Pestenacker during the Mid-Holocene. Decreased temperatures and increased precipitation, resulted in the formation of a stream course and therefore a drainage of the fen at the valley floor. This probably indicates a regional hydrological tipping point and subsequently favours conditions for valley floor settlement during the Late Neolithics.

Multi-scale formation processes of open-air Middle Paleolithic sites in the arid Negev desert, Israel – A conceptual model

Ms. Maya Oron [1]***, Dr. Joel Roskin*** [2]***, Dr. Yoav Avni*** [3]***, Dr. Naomi Porat*** [4]***, Prof. Erella Hovers*** [5]

1. *Institute of Archaeology, Hebrew University, Jerusalem; Israeli Antiquities Authority,* ***2.*** *Department of Geography and Environment, Bar Ilan University, Ramat-Gan, Israel,* ***3.*** *Geological Survey of Israel, 32 Yesha'ayahu Leibowitz, 9692100 Jerusalem, Israel,* ***4.*** *Geological Survey of Israel,* ***5.*** *Department of Prehistory, Institute of Archaeology, Hebrew University of Jerusalem*

Open-air anthropogenic accumulations of material cultural residues are often perceived as partial, distorted, and potentially time-averaged archaeological records, where it is difficult to distinguish underlying anthropogenic vs. geogenic factors and the temporal span of formation processes, and how these affected the integrity of archaeological records. In this study we analyze the depositional histories of three Middle Paleolithic archaeological open-air sites in the arid Negev desert of Israel, by combining archaeological and geomorphological methods to create a conceptual model of multi-scale effects on the archaeological remains. We rely on the long research history in archaeology and geomorphology in the Negev desert and show that integration of archaeological and geomorphological methodologies provides nuanced insights to our understanding of the archaeological record. Further, when applying a multi-scale analysis of the regional and local processes that affected each site, the links established between regional and local geomorphic processes and lithic taphonomy allow back-tracking environmental processes from flint taphonomic attributes. Placing each site within the range and scope of regional and local processes of exposure and burial by using informed and critically-evaluated data helps to create a more robust regional archaeological data base. We suggest that our approach is useful in other arid zone contexts and may have implications for understanding Pleistocene population movements across such regions.

Reassessing the lower stratigraphical complex of Grotta Romanelli (Lecce, southern Italy)

Grotta Romanelli (Lecce, southern Italy) is one of the most important Quaternary caves in Italy, known since the end of the 1800s. The long stratigraphic sequence preserves an extraordinary archaeological and paleontological archive for the understanding of palaeo-landscapes evolution and human-environment interactions from the Middle Pleistocene to the early Holocene.

The recent systematic research, resumed in 2015, together with the new geoarchaeological approach and the revision of the collections belonging to previous excavations, provide a large amount of new data on the chronostratigraphic framework, the paleoenvironmental setting, the faunal spectrum, and the techno-economic behaviors.

Here, we present new data on the lowermost stratigraphic units inside the cave (ISU), which are much older than previously thought. According to a recent litho-, morpho-, and chrono-stratigraphical re-assessment, supported by new U/Th dates, the ISU1 and ISU2 (levels K and I *sensu* Blanc 1920) were referred between MIS 9 and MIS 7, whereas the ISU 3 (level G *sensu* Blanc 1920) was attributed to MIS 5e.

The revision of the lithic collections, coupled with the study of the artefacts from new excavation, highlighted an expedient lithic technology mainly focused on the production of undifferentiated flakes on local limestone. Vertebrate assemblage is mainly composed of birds, megaherbivores, suids, bovines, cervids, rabbits and few carnivorans. The small vertebrate assemblage is characterized by the presence of small mammals (rodents, bats and insectivores), fishes, reptiles and amphibians.

Additionally, we discuss this lithic and fossil record in the new chrono-stratigraphic and paleoclimatic setting as well as in the penecontemporaneous cultural framework of the southern part of the Italian peninsula.

Submerged Palaeolandscapes of the Southern Hemisphere (SPLOSH) – What is emerging from the Southern Hemisphere

***Dr. Ingrid Ward* [1], *Dr. Alex Bastos* [2], *Dr. Diego Carabias* [3], *Dr. Hayley Cawthra* [4], *Dr. Helen Farr* [5], *Prof. Andrew Green* [6], *Prof. Fraser Sturt* [5]**

The study of submerged coastal landscapes and human occupation records has rapidly emerged as a key topic in Quaternary science in the last decade aided by new and higher-resolution technologies and focused research programs. These are only beginning to be translated into the Southern Hemisphere where with its wide range of latitudes (from ~12ºN to ~56ºS) and climatic and biogeographic contexts, present a whole suite of different challenges and opportunities. Funded by INQUA for 2020 – 2023, Submerged Palaeolandscapes of the Southern Hemisphere (SPLOSH) focus group was set up to raise awareness and to help strengthen the importance of submerged landscape research in this region. We provide an overview of current knowledge in South America, Southern Africa and Australasia and explore how new palaeogeographic and palaeoecological research, alongside related coastal archaeology, is helping to map out future directions for submerged cultural landscape research in these regions. A common theme across is the need to raise awareness of submerged cultural resources and the multi-disciplinary approach needed to understand the unique landscapes in which they are preserved.

The "Lake of Olympia": Geoarchaeological evidence of a mid- to late Holocene lake environment in the vicinity of ancient Olympia (western Peloponnese, Greece)

Mrs. Lena Slabon [1]***, Prof. Andreas Vött*** [2]***, Dr. Lea Obrocki*** [1]***, Prof. Franziska Lang*** [3]***, Prof. Hans-Joachim Gehrke*** [4]***, Dr. Birgitta Eder*** [5]***, Dr. Erofili-Iris Kolia*** [6]***, Dr. Oliver Pilz*** [7]***, Ms. Sarah Bäumler*** [8]***, Dr. Dennis Wilken*** [9]

Ancient Olympia is located at the northern fringe of the Makrisia basin at the confluence of the Kladeos and Alpheios rivers. The entire area was affected by strong tectonic uplift of minimum 13 m to 30 m since the mid-Holocene. Our study presents evidence of a large lake environment near Olympia. The "Lake of Olympia" covered large parts of the Makrisia basin, with the ancient site of Olympia directly located at the northern shore. The Alpheios River, flowing through the lake, was naturally dammed at a narrow breakthrough valley across the hills of the nearby Drouva ridge.

Limnic sediments were retrieved at various locations in the Makrisia basin, i.e., at the western and southern fringes as well as in the immediate surroundings of ancient Olympia. These findings are supported by Direct Push sensing and geochemical data. Additionally, micropalaeontological studies reveal the existence of fresh-water ostracods within these limnic sediments. Based on radiocarbon ages, the "Lake of Olympia" existed at least until the late Bronze Age and again during several periods in Antiquity. The fluctuating water level was primarily controlled by the natural bedrock sill of the Drouva ridge. Water level was influenced by tectonic processes, and anthropogenic control at the narrow breakthrough situation may be assumed.

We suppose that the "Lake of Olympia" was used to provide adequate water supply during summer months for the visitors of the ancient Olympic Games as well as the livestock needed as supply for food and sacrifices. Furthermore, shallow water conditions at the eastern fringe of the lake would easily allow to cross the large valley of the Makrisia basin.

Postglacial environmental and human habitation dynamics in the north-eastern lowlands of Romania, derived from a new peat archive and archaeological data

Ms. Anișoara Filip [1], *Prof. Marcel Mindrescu* [1], *Mr. Gheorghe Badaluta* [1], *Mrs. Anca Petras* [1], *Dr. Gabriela Florescu* [1]

1. Stefan cel Mare University of Suceava

Anthropogenic activities have impacted global land cover and climate for millennia and climatic and environmental conditions have always been the main factors for human settlement dynamics. This study builds on the first record of environmental history at the western extremity of the Eastern European forest-steppe zone (NE Romanian lowlands), derived from the Dersca-Lozna fen archive, that could explain postglacial human habitation dynamics in this understudied area. To assess fen development and erosion dynamics at the local scale, we derived downcore lithostratigraphic information, bulk density, and humidity values over a continuous time window that spans the last ca. 12000 years. Pollen and charcoal analysis were added to reconstruct regional vegetation history and the role of fire in land-use change. To reconstruct the dynamics of human habitation, we surveyed published archaeological studies and traces of human settlement. The archaeological sites database was subjected to morphometric analysis based on relevant factors (slope, proximity to major waterways, and relief) underlining the evolution of preferred environmental conditions for settling. The main results of spatial distribution analysis converge to conclude the following: three hotspots of human habitation throughout millennia have been identified in the study area; as the population number grew, the number of settlements and the altitude range of the populated landscape increased (particularly in the Bronze Age); the sites' expansion followed the accessibility of the valleys and proximity to water resources. These outputs overlap the preliminary paleoenvironmental picture inferred from the peat stratigraphy, revealing a long-term human impact on the landscape. Thus, two major shifts in erosion and vegetation dynamics are apparent in the peat record: the first coincides with the Bronze Age settlement expansion (ca. 3300 years ago), whereas the second corresponds to a new settlement expansion in the Medieval Warm Period (ca. 900-1200 years ago). The Cucuteni-Trypillia Neolithic culture, inhabiting this area for millennia, left no visible traces in the palaeoenvironmental record. Our study has the potential to fill in the gaps regarding habitation dynamics and human-landscape interactions in this area with a long history of human presence and a white spot on the palaeoenvironmental map of Eastern Europe.

Think globally, act locally: A probabilistic model for climate impacts to coastal resources along the Delaware Bay, USA

Dr. Heather Wholey [1]***, Dr. Daria Nikitina*** [1]

1. *West Chester University of Pennsylvania*

The future projections of the global mean sea level (GMSL) reported by the IPCC are based on a range of greenhouse gas emissions scenarios and state that 70% of all coastlines will experience a rise in sea level by 2100 and will continue to rise beyond 2100. However, GMSL projections are insufficient for local assessments, adaptation, and action plans. The probabilistic sea-levels for 21st and 22nd centuries use a global network of tide gauge sites and three Representative Concentration Pathway (RCP) scenarios of gas emissions. Regional and localized probability distributions of sea level rise (SLR) and storm surges can be developed by assimilating GMSL rise and regional tide gauge observations and applying the Sea, Lakes, and Overland Surges from Hurricanes (SLOSH) model. We use a GIS-based interdisciplinary approach to examine and assess the impacts of SLR and storm surges to Delaware Bay coastal zone. This region includes nearly 1600 documented cultural heritage resources; more than half could be damaged or lost by the year 2100 due to SLR, storm surges, and coastal erosion. The archaeological and historic record indicate tremendous cultural diversity for the area, spanning the past 13,000 years, including Indigenous settlements; African diaspora sites; 17th-century European colonies; 18th century industry; maritime endeavors; subsistence and commercial farming; 19th-century prototype resort towns; and sites associated with the Revolutionary and Civil Wars and World War II. Many align with national narratives and world heritage themes; damage will result in loss of historical information, scientific evidence, and cultural heritage. Our integrated geo-database allows for the visualization of impacts to specific locations and landscapes, and temporal and cultural categories of resources. The probabilistic SLR and SLOSH models offer robust predictions of future trends in the Delaware Bay, and the ability to develop localized vulnerability parameters and pro-active management or preservation strategies for threatened sites and landscapes. The results are of interest to historic preservation and natural resources planners, cultural resources managers, Indigenous community leaders, scholars, and the public, illustrating how our actions today play a role in sustaining cultural heritage for the future.

The rock art sites-landscape nexus: the case-study of the Valcamonica

Dr. Dario Sigari [1], ***Dr. Luca Forti*** [2]

1. CNRS - UMR 5608 TRACES, 2. Department of Earth Sciences, University of Milan

Valcamonica, an Alpine valley in Northern Italy, has one of Europe's largest concentrations of open-air rock art, representing a preferential case study to investigate the rock art-landscape-settlements relationships.

The rupestrian heritage of Valcamonica extends for c. 90 km along the whole length of the valley, on both sides with areas of primary clusters. The long chronology of human occupation, which spans from the Upper Palaeolithic upto historical times, reflects human behaviour in giving special meaning and values to certain places that lasted and changed over millennia.

Understanding how much this attitude had been influenced by the landscape, according to its natural resources richness, visibility, accessibility, location of the rocks and how the cultural variable might have played is a new research field into which the project PARC-Paesaggi dell'Arte Rupestre Camuna (Landscapes of Valcamonica Rock Art) wants to investigate.

For this work, authors consider the two selected clusters of Luine hill in the lower valley and Paspardo territory in the mid-valley so to access the relationship with the environmental resources, the landscape features and the cultural choices along all the different rock art chronologies of the valley, using a multi-scale analysis. Specifically, for the Luine hill, a geomorphological investigation correlated to the palaeoenvironmental reconstruction of the post-LGM landscape allows us to estimate the Palaeolithic settlement-rock art sites-landscape nexus. For the Paspardo area, the study of archive aerial images, together with the geomorphological and spatial analysis of the sites, according to the different rock art chronologies, and the comparison with the actual high resolution satellite images highlights the possible cultural driven choices in the selection of the rock art sites in the past and the impact on the preservation of the rock art.

Contribution of Sediment flow Connectivity Index (SfCI) application to landscape archaeology investigations

Dr. Marina Zingaro [1] ***, Prof. Domenico Capolongo*** [1] ***, Prof. Paola Palmentola*** [2] ***, Dr. Alberto Refice*** [3] ***, Dr. Giovanni Scardino*** [1] ***, Dr. Marco La Salandra*** [1] ***, Dr. Rodolfo Roseto*** [1] ***, Prof. Giovanni Scicchitano*** [1]

1. *Department of Earth and GeoEnvironmental Sciences, University of Bari,* ***2.*** *Department of Ancient and Late Antique Studies, University of Bari,* ***3.*** *Institute for the Electromagnetic Sensing of the Environment—Italian National Research Council (IREA-CNR)*

The integration of the geomorphological analysis in archaeological investigation is essential to describe physical geography and land morphology, to understand the interrelation of natural and anthropogenic surface-occurring phenomena over time and thus to reconstruct the evolution of the relationship between environment and human activities. On the other hand, a better analysis of landforms and the geomorphological processes helps to connect the historical evidences to landscape reconstruction by supporting the archaeological interpretation. Comparative evaluation of archaeological data with other information sources provides several information for a preliminary analysis of sites, for planning and unfolding of field surveys, for understanding of the post-depositional processes and for the description of palaeo-landscapes.

The Sediment flow Connectivity Index (SfCI) is a powerful geomorphic indicator for defining the most sensitive areas to geomorphological modifications in a catchment, in order to reconstruct the palaeo-landscape. The index describes the connection paths of the sediment in lateral and longitudinal directions to the catchment outlet, by considering the connectivity as the connection by sediment transport. The index computation is based on a mapping approach that is the result of the gradient-based flow accumulation of a sediment mobility index, which is in turn a function of rainfall, geotechnical properties of soil and land use by integrating functional aspects within a structural component. As demonstrated by the previous SfCI applications, the index can be used to correlate the effects of the various events that occur in a catchment, since water and sediment displacement conditions, and in turn is conditioned by the morphological evolution.

We present the experimental application of SfCI for a landscape archaeological analysis in order to assess the contribution of the index to potentially recognize and to interpret the historical evidences in the reconstruction of landscape evolution. The investigation was performed in a test area of Apulia (southern Italy) by exploring an interdisciplinary approach that could open innovative research scenarios.

The Holocene fluvial evolution of the Egyptian Nile Valley and its impact on ancient society

Dr. Jan Peeters [1], Dr. Angus Graham [2], Dr. Willem Toonen [3], Dr. Benjamin Pennington [4], Dr. Julie Durcan [5], Mr. Tim Winkels [6], Dr. Kathryn Adamson [7]

***1.** Kelsey Museum of Archaeology, University of Michigan, **2.** Department of Archaeology and Ancient History, Uppsala University, Uppsala, Sweden, **3.** Dept. Earth Sciences, Vrije Universiteit Amsterdam, **4.** Geography & Environment, University of Southampton, **5.** School of Geography and the Environment, University of Oxford, **6.** Dept. of Physical Geography, Faculty of Geosciences, Utrecht University, **7.** Manchester Metropolitan University*

Responses of the Egyptian Nile to Holocene climate change are largely unknown, despite the Nile's central role in the emergence of Ancient Egyptian culture. Over the last decade, to try to rectify this situation, the Theban Harbours and Waterscapes Survey (THaWS) has drilled more than 250 boreholes in cross-valley transects at ancient Thebes (Luxor, Egypt) to study the architecture of the Holocene Nile alluvium and its geomorphological elements; e.g. channel belts, levees, flood basins, fluvial terraces. The work also critically informs on human-environment interactions at this UNESCO World Heritage Site, which includes Karnak and Luxor temples.

Here, we present a novel framework for the Holocene evolution of the Egyptian Nile Valley, based on our geological transects and a high-resolution chronology based on 48 OSL dates and >10,000 pottery fragments that were gathered from fluvial contexts. Our reconstruction reveals a history of dramatic changes in fluvial style, hitherto unknown, but on par with major hydroclimatic changes over the Nile Basin. Valley-wide channel incision and phased fluvial terrace formation occurred from the early Holocene until ~4 ka BP. This progressive valley entrenchment coincides with relatively wet conditions over the Nile Basin of the African Humid Period.

Around 4 ka BP this trajectory changed quickly into rapid floodplain aggradation with progressively the establishment of a single-channel river planform around 2 ka BP – the modern river Nile. Between 4-2 ka BP the Nile was a multi-channel system with high rates of overbank deposition that relocated its branches through the process of avulsion. The 4 ka BP transformation coincides with progressive regional aridification. It is assumed that reduced vegetation cover in the Ethiopian Highlands was the main driver for a pivotal increase in fine-grained sediment supply to the trunk valley, triggering a major response in fluvial style.

Whilst it is known that Ancient Egyptian culture was strongly interconnected with the fluvial landscape, our research highlights the potential role that climate change and river dynamics may have had on settlement patterns, the ritual landscape, and the regional agro-economy.

Millennial scale mid-latitude ice cores from ice patches: a novel proxy for accessing the paleoecology of alpine biomes, the timing of warming events, and the contemporaneity of archaeological records.

Dr. Craig Lee [1]

1. Montana State University

Ice patches are areas of permanent snow and ice that survive the summer months as a result of drifted, wind-blown snow. In general they are not massive enough to become glaciers, although snow in these locations can turn into névé and eventually firn ice through freeze-thaw cycles and compaction. As in other parts of the world, global warming is causing perennial ice patches in the Rocky Mountains to melt, resulting in the release of ancient archaeological materials that until recently were in frozen stasis. The emergence of cultural materials from these environments is the foundation for the field of ice patch archeology, a sub-field of cryospheric archaeology—the archaeology of the frozen world—which is under threat globally due to warming climate. To better understand the nature and potential of the ice patch record, ice patches in the Greater Yellowstone Area and Glacier National Park, USA were cored to recover accumulations of organic materials (lags) that form as debris covered surfaces during melt periods. This paper shares the methods employed. The macrobotanical analysis of the recovered lag contents demonstrate the potential for more than 10,000 years of preserved material to exist in these locations based on *terminus ante quem* radiocarbon dates from the deepest lags recovered. This paper compares the ages of the recovered lags between three ice patches and compares those ages with the ages of the archaeological materials recovered at ice patches. Indigenous partners participated in the planing and execution of these projects and the plant communities recorded in the lags were shared with interested Indigenous and scientific communities, e.g., botanists.

On the Way to the Fluvial Anthroposphere—Current Limitations and Perspectives of Multidisciplinary Research

***Dr. Lukas Werther* [1], *Prof. Natascha Mehler* [1], *Prof. Gerrit Jasper Schenk* [2], *Prof. Christoph Zielhofer* [3]**

***1.** Institute of Prehistoric and Medieval Archaeology, Department of Medieval Archaeology, Tübingen University, Tübingen, **2.** Institute of History, History of the Middle Ages, Technical University of Darmstadt, Darmstadt, Germany, **3.** Institute of Geography, Chair of Physical Geography, Leipzig University, Leipzig*

Floodplains represent a global hotspot of sensitive socioenvironmental changes and early human forcing mechanisms. In this presentation, we focus on the environmental conditions of preindustrial floodplains in Central Europe and the fluvial societies that operated there. Due to their high land-use capacity and the simultaneous necessity of land reclamation and risk minimisation, societies have radically restructured the Central European floodplains. According to the current scientific consensus, up to 95% of Central European floodplains have been extensively restructured or destroyed. Therefore, question arises as to whether or when it is justified to understand Central European floodplains as a 'Fluvial Anthroposphere'. The case studies available to date show that human-induced impacts on floodplain morphologies and environments and the formation of specific fluvial societies reveal fundamental changes in the medieval and preindustrial modern periods. This presentation aims to contribute to disentangling the questions of when and why humans became a significant controlling factor in Central European floodplain formation, and how humans in interaction with natural processes and other chains of effects have modified floodplains. As a conclusion, we superimpose emerging fields of research concerning the onset of the Fluvial Anthroposphere and provide specific thematic objectives for future multidisciplinary work.

Holocene pedosedimentary archives of the Kassala region of Sudan: first insights into the archaeo-environmental history of an underrepresented land

Dr. Stefano Costanzo [1]

1. *Università degli Studi di Napoli "L'Orientale"*

Studies upon past climates, natural landscapes, and paleoenvironments of archaeologically pivotal regions of northern Africa have been of paramount interest in the past decades. For some of those regions, the human-environmental nexus, intended as the inseparable mutual agency between people and nature, has been a long-standing research question; yet, for some others, while purely archaeological endeavours have been ongoing for decades, the environmental record is still an archive to be explored. In this study, newly found archaeo-environmental sites from the easternmost stretches of the Sahelian belt, in the Kassala region of Sudan, are presented. Therein, pedosedimentary features that encase rich archaeological evidence and the climatic history of the region are found within a landscape characterized by emerged naked granitoid plutons dotting a vast gravelly pediplain cut by year-round dry riverbeds and colonized by xerophytes and thin ephemeral grass. By means of regional-scale survey, remote sensing, physico-chemical lab analyses, micromorphology, and radiometric dating, the uppermost portion of the Quaternary record was investigated in order to contextualize the Holocene prehistoric, protohistoric, and later archaeological record of the region. The main identified features include (i) African Humid Period buried isoumic soil horizons (mollisol profiles) in lower flat grounds - legacy of water-reliant prairie environments -, (ii) later accretional dusty aeolian deposits intermingled with colluvial gravels and rich archaeological surfaces close to the plutons' foothills - testimony of a climatic deterioration towards aridity -, and (iii) diffuse hydric erosion of the delicate dusty deposits, with consistent soil loss and displacement - outcome of anciently established hyper seasonality leading to present day weather anomalies. In a current environmental context characterized by severe and rapid soil erosion processes that are irredeemably altering the pristine accretional archives, these multi-scalar results are of great importance as a contribution to a more holistic understanding of past human economies of the region, as well as representing newly added tiles to the recent climatic history of the continent.

Characterizing stratigraphic markers of Late Quaternary Mediterranean landscapes (Southeastern France): an integrated approach revealing detailed sedimentary processes and potential archeological taphonomies.

Ms. Naïs SIRDEYS [1]***, Dr. Vincent OLLIVIER*** [2]***, Prof. Olivier BELLIER*** [1]***, Prof. Jean-Pierre BRACCO*** [2]

1. *Aix Marseille University, CNRS, IRD, INRAE, College de France, CEREGE, Aix-en-Provence, France,* ***2.*** *LAMPEA (UMR 7269; CNRS-Aix Marseille Université, Ministère de la Culture et de la Communication), MMSH 5 rue du Château de l'Horloge, 13094 Aix-en-Provence, France*

The great spatial and geographical disparities in Mediterranean human occupations require a better understanding of climatic events, cultural knowledge, morphogenesis and landscape evolution for the study of archeological records. In southeastern France, the Upper Paleolithic, the Mesolithic, the Early and Middle Neolithic periods have few open-air archaeological sites, resulting in a lack of understanding of the complex relationships between human occupations and adaptations to environmental changes (climatic, geomorphological, natural resource availability). Apart from the interpretative bias related to potential cultural habits, it questions the potential and significant impact of environmental parameters on conservative and destructive properties in open-air sites distribution. To overcome this problem, an integrated multi-disciplinary geoarcheological approach has been developed on targeted sedimentary markers of temperate periods suitable for archeological findings and dated from 50 to 3 ka within detrital sequences and calcareous tufa. It combines geochronological methods (^{14}C, OSL), elemental analysis (pXRF), granulometry, calcimetry and spectrocolorimetry with paleoenvironmental (malacology, anthracology) and existing archeological data. The aim is to detect sedimentary indicators of stable *versus* dynamic phases (in the conservation/destruction of sites) within sensitive sedimentary systems from micro- (elemental to stratigraphic) to landscape- scales for more than 15 sites throughout the southeastern France. For the Upper Pleistocene, its applications yield a consistent high-resolution detection and characterization of almost 10 paleosols covering 13 Greenland interstadials some of which dated between 50 ka and 26 ka. Elemental compositions, taphonomic processes and paleoenvironmental data display evidences for stable environment and slow sedimentation dynamics. In postglacial and Holocene calcareous tufa sequence periods of stability match with chalky phases typical of low hydrodynamism and detritism. The final phases of the studied sequences show significant carbonate signals and noisy detrital components translating globally stable environments associated with short and local disturbances. These environmental destabilizations, potentially climato-anthropic, raise questions about archaeological potential. A correlation between these stable phases and archeological potentials and taphonomies is proposed. The high-resolution reading of sedimentary processes close to and off-sites of sequences improve our understanding of some specific continental archives for a better perception of the impact of diachronic multiscale (climatic, geomorphological) environmental changes on human occupations in Mediterranean domain.

Landscape evolution at the Bronze Age tell site Toboliu (Bihor, Romania)

Mrs. Mirijam Zickel [1], ***Dr. Astrid Roepke*** [2]

1. *Institute of Geography, University of Cologne, Cologne,* ***2.*** *Astrid Röpke*

The interdisciplinary project ‘Living together or apart? Unravelling the development, internal organization and social structure of a complex Bronze Age tell settlement at Toboliu, western Romania’ (see Găvan et al. 2021) aims to analyse Bronze Age settlement activity at Toboliu, which is situated in the eastern part of the Pannonian Basin. Associated land use and landscape development are important key features, and therefore a focus of the paleogeographic landscape reconstruction of the tell’s surroundings. Since the topography is strongly overprinted by current and past agricultural activity the interpretation of archaeological sediments, but also palaeoenvironmental analysis is challenging. To cope with this, requires moving on different methodological scaling levels within the scope of a close archaeological-geoscientific collaboration. For instance, several extensive drainless depressions which surrounds the tell show some characteristics of periglacial relict forms as well as of prehistoric extraction pits. These were sampled in the field with core drillings, analysed geophysically and -chemically, but also investigated for spatial relationships using a high-resolution digital elevation model and magnetographic imagery. The first radiocarbon sample of one depression bottom dates back to the Copper Age. In addition, optically stimulated luminescence (OSL) dating is under preparation to gain information on sedimentation rates.

From site observation to regional interpretation, the influence of multi-scalar approach on soil properties and their archaeological implication: Kurdistan (Iraq)

Mr. Mathias Bellat [1], *Dr. Tobias Rentschler* [1], *Dr. Benjamin Glissmann* [1], *Dr. Ruhollah Taghizadeh-Mehrjardi* [1], *Prof. Paola Sconzo* [2], *Prof. Peter Pfälzner* [1], *Prof. Thomas Scholten* [1]

1. CRC1070 ResourceCultures, Eberhard Karls University of Tübingen, Gartenstr. 29, 72070 Tübingen, Germany, 2. Department of Culture and Society, University of Palermo

Soils are incorporating many different chemical and physical properties and this numerous information is a useful tool for geoarchaeologists and archaeologists. Indeed, soils can give information on climate, human activities, vegetation, and geological or geomorphological features in the present and past times. The different components of soil can be described as punctual observations or mapped at micro-, meso-, and mega scale throughout computing process (machine learning and interpolation) after *in situ* observations. Gathering information from punctual observations or mapping an area is different and will give different interpretations and results on the soil properties. Indeed, archaeologists and geoarchaeologists are looking for answers to their questions, and soil scientists need to know which approach fits the best with the question asked. This presentation aims to clarify the different uses of soil properties for soil scientists and geoarchaeologists who intend to answer archaeological questions.

This study was conducted on two different campaigns in Iraqi Kurdistan in 2019 and 2022. The first one focused on the sampling of 76 soil profiles near former human settlements (24), while the second expedition was designed to map the soil properties of the Selevani plain with 101 profiles and 453 samples taken. Each mission had a different goal, in one case it was to specify the activity in the nearby area of soil sampling, and in the other, it was to map the different soil properties at a regional scale to use them afterwards for GIS analysis linked with settlement patterns. If the performed analyses on soil samples are the same, the interpretation of the results differs, because objectives are different. While the punctual observation will answer a specific local question, the mapping strategy will help for future surveys or statistical observations over the study area. With this case study, we will give two examples of concrete interpretations from these distinct strategies.

Palaeoenvironment and landscape history of ancient complex society in southern Nigeria: a multiscale view

Dr. Kingsley Daraojimba [1], *Dr. Federica Sulas* [1]

1. University of Cambridge

Geoarchaeology has been transforming our understanding of human-environment interactions across tropical environments, revealing new histories of human landscapes and social complexity. West African environments remain somewhat peripheral to these developments, despite a rich archaeological record. This paper presents the results of new dataset at Igbo-Ukwu, southern Nigeria's earliest complex society dating to the early first millennium CE. Whilst Igbo-Ukwu is world-famous for returning some of the finest intricately crafted metal objects and rich material culture in West Africa, little is known about the environmental settings sustaining such developments. Recent work, integrating landscape-scale geoarchaeological survey, soil bulk and palynological analyses has produced the first records of buried soils and archaeological sediments. pH and particle size distribution analyses offer some preliminary insights on the character of the soil cover at Igbo-Ukwu, mineral sources and processes of soil formation and transport, and implications for preservation of organic and inorganic artefacts. At micro-scale, the presence of illuvial clay, dung, coprophilous fungal spores, and charred material in buried soils is indicative of open vegetation, animal browsing, and domestic activities associated with the ancient settlement. Our integrated multiscale approach has enabled the recovery and correlations of environmental and anthropic records across Igbo-Ukwu's cultural landscape, while also showing the relevance and feasibility of examining buried soil sequence to understand human-environmental interplay in tropical West Africa.

The Early to Mid-Holocene geoarchaeological landscape of Shaqat Jadailah (Southern Rub al Khali, Sultanate of Oman)

Dr. Maria Pia Maiorano [1], ***Dr. Mohammed Al Kindi*** [2], ***Dr. Tara Beuzen-Waller*** [3], ***Dr. Vincent Charpentier*** [4], ***Prof. Martin Pickford*** [5], ***Mr. Federico Borgi*** [6]

1. Goethe University Frankfurt, 2. Earth Sciences Consultancy Centre, 3. University of Tübingen, 4. INRAP, 5. Muséum national d'Histoire naturelle, CNRS, Sorbonne Université, 6. University of Milan

During the Early and Middle Holocene, the currently hyperarid region of Southern Rub al Khali experienced phases of favourable climate with increased rainfall that resulted in playa lakes and the proliferation of vegetation. From the first phases of the Holocene, human groups occupied the area close to the village of Maitan (not far from the border junction between Oman, Yemen and Saudi Arabia) with temporary and long-lasting encampments. This paper presents the results of the geoarchaeological survey and geomorphological investigations carried out in the interdunal area and open-air palimpsests of Shaqat Jadailah. The fieldwork focused on the environmental, socio-economic, and technological changes that stimulated cultural variability and technological innovation in Southeastern Arabia in the Early and Middle Holocene. Here, the identification of Late Palaeolithic and Neolithic sites yields new insights into the ancient landscapes and human mobility patterns across the region. The presence of abundant lithic artefacts, together with grinding slabs, grindstones, fossilized animal bones and ornaments (some from far off marine environments), speaks for the prolonged occupation of the area during prehistoric times. The deflated sediments in the region indicate the prevalence of predominantly arid and hyper-arid conditions, with brief intervals of relatively humid conditions. The sites in Shaqat Jadailah reveal new archaeological horizons for the transition between Early and Middle Holocene, in intimate connection with the palaeoenvironmental record, even when poorly preserved. The rich and diverse lithic record indicates a complex mosaic of population movements, clustering, and connections. Such diversity patterns and occupational strategies suggest a branched vision of cultural evolution in the hunter-gatherers-herders' groups of the region as opposed to linear models. The prominent cultural variability highlighted in the area was compared to data from other parts of Oman, Yemen, Saudi Arabia and the United Arab Emirates, and shows a high and dynamic human presence in this area, which nowadays appears so inhospitable.

Hunting strategies and land uses in the Early Upper Paleolithic (EUP) in the Mt. Ashitaka area, Central Japan

Prof. Takuya Yamaoka [1]***, Dr. Jun Takakura*** [2]***, Prof. Nobuyuki Ikeya*** [3]***, Mr. Motoki Miyoshi*** [4]***, Mr. Hideharu Maejima*** [5]

1. *Faculty of Humanities and Social Sciences, Shizuoka University,* ***2.*** *l Archaeological Research Center, Hokkaido University,* ***3.*** *Center for Obsidian and Lithic Studies, Meiji University,* ***4.*** *Hyogo Construction Technology Center for Regional Development,* ***5.*** *Numazu City Board of Education*

Mt. Ashitaka is located at the center of the main island of Japan. The Mt. Ashitaka area is a representative research field of the EUP (ca. 38,000 – 29000 cal BP) in the Japanese Islands. Volcanic ashes (Pleistocene tephras) from neighboring volcanos had accumulated in the area and formed the Ashitaka Loam Formation. The Upper Paleolithic (UP) assemblages were found in the Upper Member of the Formation. It consists of alternate eolian depositions of reddish-brown scoria (SC) layers and ten buried paleosol layers, called Black Bands (BB). Clear and high-resolution stratigraphic sequences provide geological contexts for establishing a detailed and reliable UP chronology in the area. The UP is divided into 5 phases in the area and Phases 1 and 2 belong to the EUP. More than 95 archaeological horizons of the EUP from more than 30 sites have been excavated and reported.

Research in soil science clarified that Black bands (BB) in the Mt. Ashitaka area are the Kurobokudo layers (black humic volcanic ash soil) and estimated that they have developed under semi-grassland vegetation resulting from human activities such as burning and deforestation to make man-made ecosystems because they appeared after emergence of the oldest EUP site and climax forests were generally formed even in the late Pleistocene in the area. Archaeological research in the area also clarified that the Kurobokudo layers were only found in a limited range and their distributions roughly coincide with the distributions of the EUP sites. Besides it, recent archaeological research revealed that hunter-gatherers in the Layer BB V period in Phase 1 employed projectile technology, and hunter-gatherers in the Layer BB III period in Phase 2 used trap pits for hunting. Distributions of sites relating to hunting activities are different between both periods. Such information seems to support the hypothesis of artificial modifications of vegetation during the EUP and suggests that such vegetative alterations could have been associated with land uses for hunting (and other activities). Based on them, this paper presents that the Mt. Ashitaka area has a high potential for the study of niche construction by hunter-gatherers in the Late Pleistocene.

Late Pleistocene and Holocene sand dune formation in the Carpathian Basin

Dr. György Sipos [1]***, Dr. Tímea Kiss*** [2]***, Mr. Gergő Magyar*** [1]***, Mr. Dávid Filyó*** [1]***, Dr. Botond Buró*** [3]***, Dr. Gábor Négyesi*** [4]***, Prof. Slobodan Marković*** [5]***, Dr. Milivoj Gavrilov*** [5]***, Mr. Rastko Marković*** [6]***, Dr. Tamás Bartyik*** [1]

Aeolian sand dunes provide a sensitive archive for the reconstruction of Late Pleistocene and Holocene environmental change and human impact. This is especially true for the Carpathian Basin, where large rivers, such as the Danube, built extensive alluvial fans which were abandoned later, and aeolian processes could reshape their surface in dryer periods of the Late Pleistocene and even of the Holocene, during which human impact continuously intensified in these areas. Though dune fields represent a dynamic environment, the periodical reactivation of aeolian processes led to the development of several dune generations.

Earlier, the timing of aeolian periods was assessed on the basis of geomorphological analysis and a limited number of radiocarbon data. In the past one and a half decades, however, a growing number of OSL data has been published from these areas. The primary objective of the present research was, therefore, to review published and unpublished OSL ages, to assess the temporal and spatial pattern of aeolian activity in the past 20 ka in the Carpathian Basin, and to make regional comparisons.

In the present study, we summarized OSL data obtained from 6 dune fields. In total, nearly 200 ages were considered from 20 sites. In the case of four dune fields, representative dunes were sampled in detail (crest, slope, foredune depression). Thus, the general framework of aeolian history could be outlined, and region-specific features could be identified. Besides, by analysing all the available data, the magnitude and spatial extension of climate and human-induced aeolian activities were also assessed.

Soil-stratigraphic archives and evidence for late Pleistocene Indigenous land use from a dune-dammed endorheic basin in the Sonoran Desert, Arizona, USA

Mr. Jason Windingstad [1], Prof. Craig Rasmussen [2], Dr. Vance Holliday [1]

1. The University of Arizona, 2. Department of Environmental Science, University of Arizona

Drainage networks in the Sonoran Desert section of the Basin and Range physiographic province of southern Arizona have been fully integrated with the lower Colorado river since the early Pliocene (>5 Ma). However, topographically closed basins have developed where migrating eolian sand or basalt flows impede mountain piedmont and/or axial valley drainages. One such basin is located along the eastern margin of the Mohawk Valley in southwestern Arizona. Here, the Mohawk Dune Field has created a linear ~2 x 25 km endorheic basin along the distal Mohawk Mountain piedmont. The recent characterization and dating of eolian, alluvial, and dry playa soil-stratigraphic archives and archaeological remains preserved in this basin (and adjacent areas) are bringing to light an important record of wet-dry cycles and indigenous land use dating back to the latest Pleistocene. Local valley-axis alluvial records document groundwater discharge, low-energy sheetflooding, and major channel incision at ~21-23, 15.5-21 ka, and 10 ka, respectively (cal ^{14}C). Within the basin proper, intensified piedmont flooding and dry playa inundation occurred > 8 ka and again at 2.7-2.9 ka. Compound crescentic dunes developed in the Holocene at 0.08, 0.2, 0.5-0.6, 1.9, and 7 ka (OSL). Older dunes with well-developed soils have yet to be dated but have been assigned to the late Pleistocene. Dune development is linked to the renewal of sand sources along the Gila River and local distal alluvial fan sheetflood deposits using mineralogical methods. Correlation with paleoclimatic proxies suggests episodes of increased flooding in the Holocene are linked to extra-tropical cyclones and atmospheric rivers from 8-10 ka and intensified El Niño-Southern Oscillation climatic patterns after 5-6 ka. Clovis (~13.3-12.8 ka) occupation of the basin occurred adjacent to a small playa presently marked by a mesquite bosque. Although not directly associated with the Clovis locality, the fossil remains of horse, camel, and bison have been identified in the area suggesting large game was likely present during Clovis times. Unfortunately, Clovis-age alluvium along axial drainages was removed by erosion shortly after 10 ka. Future coring work will target late Pleistocene stratigraphic successions that are preserved in the endorheic basin playas and dunes.

Pre-Holocene Human Presence in the Caribbean: Supporting Archaeological Inference with Geochemical Data

Prof. William Buhay [1], *Dr. Yadira Chinique de Armas* [1], *Prof. Mirjana Roksandic* [2]

1. The University of Winnipeg, 2. University of Winnipeg

The oldest date of human presence in the insular Caribbean determined so far is between 7,430 and 7,330 years before present (BP). However, charcoal-bearing sediments adjacent to two cave paintings (pictographs), discovered in Cueva El Fustete II in southeastern Cuba, have recently provided three Late Pleistocene age dates. These extraordinary dates, between 17,500 and 13,500 years BP, are within the ranges of other pre-Clovis dates obtained recently from both North and South American archaeological sites, and are significantly older than any of the dates currently available for the Caribbean. If confirmed, these dates would provide new support for coastal migration through the Pacific sea route (the Kelp Highway) into North and South America, and would serve to generate new ideas regarding how humans spread in the Americas, and how, when, and why they first reached the Caribbean. In order to ascertain that these dates come from the charcoal, the Cueva El Fustete II charcoal bearing sediments need to be thoroughly characterized. The main objective of this research is to validate the accuracy of these dates using radiocarbon and uranium-series dating methods. Once proven, they will have strong repercussions on our understanding of the early peopling of the insular Caribbean.

Session 31: Processes and feedbacks during glacial terminations

Perspective on ice age Terminations from absolute chronologies provided by global speleothem records

Dr. Nikita Kaushal [1], ***Prof. Heather Stoll*** [2]

1. Department of Earth Sciences, University of Oxford, 2. (5) Department of Earth Sciences, ETH Zürich, Zürich, Switzerland

Glacial Terminations represent the largest amplitude climate changes of the last several million years. Over ~ 10 ky timescale, large northern hemisphere ice sheets retreat and sea level rises, and atmospheric CO_2 and global temperatures make a full transition from glacial to interglacial levels. Several possible orbital-insolation triggers have been described to initiate and sustain glacial Terminations, and feedbacks between ice sheet retreat, ocean circulation and ocean carbon storage are invoked to explain the unstoppable progression.

Because of the availability of radiocarbon dating, the most recent termination (TI) has been extensively characterized. Yet, it is widely discussed whether this sequence of feedbacks and millennial events, and rate of warming is recurrent over previous Terminations or is unique. Beyond the limit of radiocarbon dating, the chronologies of climate records from ice and marine cores are often developed by tuning to orbital parameters which limits their use in understanding climate dynamics, particularly the response to orbital forcing.

Speleothems provide absolute age control and high-resolution proxy measurements. This archive therefore provides unique records of climate change across Terminations, and additionally may provide the opportunity to tune ice and marine core archives. However, speleothem climate signals are encoded in a number of proxies. Unlike proxies in other archives like ice or marine cores, the climatic interpretation of a given proxy can vary quite significantly among different regions.

In this study, we

- synthesise the available speleothem records providing climate information for Terminations: TII, TIII, TIV and TV.
- present the records based on the aspect of climate encoded in the available records.
- where multiple records are available for a given region, we evaluate the scale of regional coherency in the proxy interpretation.
- examine the effects of different ice volume corrections on the final climate proxy record.
- evaluate whether there are consistent leads and lags in the manifestation of Terminations across different aspects of the climate systems and different regions.
- examine the expression of millennial events during Terminations.
- we speculate on suitable tuning targets among marine and ice core proxies, and discuss what model ouputs maybe most suitable for comparison.

Mean Ocean Temperature during Terminations I-IV and their subsequent interglacials

Mr. Markus Grimmer [1], *Dr. Daniel Baggenstos* [2], *Dr. Jochen Schmitt* [1], *Dr. Sarah Shackleton* [3], *Dr. Jeffrey Severinghaus* [4], *Prof. Hubertus Fischer* [1]

1. *Climate and Environmental Physics and Oeschger Centre for Climate Change Research, University of Bern, Switzerland,* ***2.*** *Australian Antarctic Division, Kingston TAS, Australia,* ***3.*** *Princeton University,* ***4.*** *Scripps Institution of Oceanography*

Deglaciations are the largest natural global warming events across the Quaternary. During these large-scale reorganizations of the climate system, the planet takes up vast amounts of energy. This energy is largely partitioned between Earth's two dominant surface energy reservoirs on glacial-interglacial time scale: the ocean and the latent heat used to melt continental ice sheets. Thus, global ocean heat content (OHC), in combination with global sea level, are the two key metrics for the determination of Earth's energy imbalance during the Quaternary.
Ratios of noble gases and N_2 trapped in polar ice cores are a proxy for past mean ocean temperature (MOT), which is directly linked to OHC. Since noble gases are inert, their atmospheric abundances on glacial-interglacial time scale are solely dependent on their well understood temperature-dependent solubilities in ocean water. As the atmosphere is well-mixed, a single ice core sample is sufficient to obtain a snapshot of the global ocean's noble gas content, and, through the temperature-dependent solubilities, its heat content. Thanks to high precision mass spectrometry, the 1σ uncertainty of recent MOT reconstructions is on the order of 0.4°C. Consequently, MOT has proven to be a novel powerful proxy for the past climate.
Here we present a new MOT dataset for Terminations II-IV and their subsequent interglacials, based on noble gas ratios in the EDC ice core. In combination with published data on Termination I (Baggenstos et al., 2019), the EDC MOT record now spans the last four Terminations. We find the largest glacial-interglacial change in OHC of about $1.7\cdot10^{25}$J across Termination II, equivalent to 3.0°C temperature change. OHC changes during Termination I, III, and IV were somewhat smaller with $1.4\cdot10^{25}$J (2.6°C), $1.3\cdot10^{25}$J (2.4°C), and $1.2\cdot10^{25}$J (2.2°C), respectively. Our new Termination II data is in good agreement with the recently published Taylor Glacier Last Interglacial (LIG) record of Shackleton et al., 2020, giving further confidence in the robustness of our results. In accordance with Shackleton et al., we find an overshoot in MOT at the onset of the LIG. A similar, albeit stronger overshoot in MOT can also be found at the end of Termination IV.

Evolution of the phase relationship between Antarctic climate and atmospheric CO2 concentrations across the last five terminations

Mr. Etienne Legrain [1]***, Dr. Emilie Capron*** [1]***, Dr. Antoine Grisart*** [2]***, Dr. Frédéric Parrenin*** [1]***, Dr. Amaelle Landais*** [3]***, Mr. Gregory Teste*** [1]***, Mr. Frederic Prie*** [2]***, Dr. Roberto Grilli*** [1]***, Dr. Lucas Silva*** [4]***, Prof. Hubertus Fischer*** [4]***, Prof. Thomas Stocker*** [4]

1. Université Grenoble Alpes, CNRS, IRD, Grenoble INP, IGE, 2. LSCE-IPSL, Laboratoire des Sciences du Climat et de l'Environnement (CEA-CNRS-UVSQ), Paris-Saclay, 3. LSCE, 4. Climate and Environmental Physics and Oeschger Centre for Climate Change Research, University of Bern, Switzerland

Antarctic ice cores are a favoured archive to study past climate and carbon cycle changes from orbital to multi-centennial timescales. They record variations in local temperature through water stable isotopes in the ice phase and provide direct reconstructions of atmospheric composition in the gas phase. Understanding the climate- carbon cycle interactions over glacial terminations is important as they represent the largest global climate changes across the Quaternary. Studies investigating the evolution of the phase relationship between Antarctic climate and atmospheric CO2 changes have mostly focused on the last two terminations because of (i) the scarcity of high-resolution paleoclimatic records covering older terminations and (ii) the uncertainties attached to estimates of the age difference between the ice and the entrapped air, reaching several centuries in the Antarctic ice cores.

Here, we present a new atmospheric CO2 record from the EPICA Dome C (EDC) ice core measured with the IGE experimental set-up spanning between 260 and 190 ka, hence including Termination III. With an average temporal resolution of ~300 years, our new record improves by a factor of three the reference CO2 record over this period that was measured on the Vostok ice core. Also, we improved the resolution of δ15N of N2 record in EDC ice core, a gas-phase proxy for changes in surface climatic conditions in Antarctica, across TIII, TIV and TV measuring new samples at LSCE. Additionally, we used new and previously published CO2 record over TII, TIV and TV measured with the Bern experimental set-up.

By combining those CO2 and δ15N records, we quantify with one coherent methodology the phase relationship evolution between Antarctic climate and atmospheric CO2 concentrations without relative chronology uncertainties over the last five terminations. Our analysis suggests a synchronous change in atmospheric CO2 and Antarctic climate at the onset of terminations, while Antarctic climate leads atmospheric CO2 changes by few centuries at the end of terminations. Finally, we use low-latitude climate tracers measured in the EDC ice core gas phase (CH4, δ18Oatm) to investigate at a global scale the possible mechanisms controlling those changes in the phase relationship between carbon cycle and Antarctic climate.

An improved North Atlantic benthic δ18O stack demonstrates precession pacing of Late Pleistocene glacial terminations

Mrs. Bethany Hobart [1]***, Dr. Lorraine Lisiecki*** [2]***, Mr. Devin Rand*** [1]***, Dr. Taehee Lee*** [3]***, Dr. Charles Lawrence*** [4]

1. *University of California, Santa Barbara,* ***2.*** *Department of Earth Science, University of California, Santa Barbara, CA 93106, USA,* ***3.*** *Harvard University,* ***4.*** *Brown University*

The mechanism responsible for ~100-kyr cyclicity in Late Pleistocene glaciations is one of the most enduring questions in paleoclimate. Characterizing the response of the climate system to orbital forcing requires precisely dated and continuous paleoclimate archives with small, well-defined uncertainties. Distinguishing whether one orbital cycle is more important than another for triggering ~100-kyr glacial terminations requires both an accurate, non-orbitally tuned age model and a statistical measure of orbital influence. Because precession is the shortest cycle, its apparent influence is disproportionately diminished by age model uncertainties and noise in climate proxy records. Untuned Late Pleistocene age estimates for benthic δ^{18}O stacks (e.g., Huybers and Wunch, 2005; Lisiecki, 2010) have uncertainties of ~10 kyr (i.e., half a precession cycle) beyond the range of radiocarbon dating.

We investigate the roles of precession and obliquity in triggering terminations by measuring the orbital phases associated with termination onset in North Atlantic benthic δ^{18}O records. Non-orbitally tuned ages are generated by correlating North Atlantic ice-rafted debris peaks to well-dated weak monsoon intervals in Chinese speleothems, with age uncertainties less than +/- 4 kyr. Multiproxy probabilistic stacking software, called BIGMACS, is used to generate a 650-kyr stack of eight North Atlantic benthic δ^{18}O records, enhancing the signal-to-noise ratio of the proxy signal. The effects of precession and obliquity on termination timing are evaluated using the Rayleigh's *R* statistic for the orbital phases of terminations, as in Huybers and Wunsch (2005). The stack yields a statistically significant values for both precession and obliquity, with precession having a higher *R* value (0.76) than obliquity (0.66). Thus, we conclude that precession is at least as important as obliquity in triggering glacial terminations.

The last two glacial terminations simulated by an ice sheet – climate coupled model: similarities and differences

***Dr. Aurelien Quiquet* [1], *Dr. Didier Roche* [2]**

1. Laboratoire des Sciences du Climat et de l'Environnement, 2. LSCE-IPSL, Laboratoire des Sciences du Climat et de l'Environnement (CEA-CNRS-UVSQ), Paris-Saclay

Glacial terminations are marked by a large-scale ice sheet collapse and a re-organisation of all the components of the climate system. These periods are characterised by some abrupt events, both in terms of sea level rise and in terms of climate shifts. The glacial terminations thus provide an unique opportunity to study the interplays between ice sheet and climate changes within a multi-millenial gradual warming context.
Here we use an ice sheet model synchronously coupled to an Earth system model of intermediate complexity to explicitly take into account the different feedbacks at play. We follow a similar methodology to simulate the last two terminations in order to explore the sensitivity of the climate and ice sheet trajectory to the forcings.
We show that the simulated ice sheet geometry evolution is in overall good agreement with available global reconstructions for the last termination. Large-scale grounding line instabilities are simulated both for the Eurasian and North American ice sheets even though the past abrupt sea level rises are underestimated, possibly because the climate model underestimates the millenial-scale temperature variability. In our model, Atlantic oceanic circulation is strongly sensitive to freshwater flux from ice sheet melting and abrupt warming phases in Greenland are linked to oceanic circulation recoveries. The penultimate deglaciation resembles the last deglaciation with a more rapid ice sheet collapse because of stronger insolation forcing. Our model produces a Greenland ice sheet contribution to sea level rise during the last interglacial of about 2 m of sea level equivalent, in agreement with most recent estimates.

Coupled climate-ice sheet simulations of the last two glacial maxima: why were the Northern Hemisphere ice sheets so different?

Ms. Violet Patterson [1], ***Dr. Lauren J. Gregoire*** [1], ***Dr. Ruza Ivanovic*** [1], ***Dr. Niall Gandy*** [2], ***Prof. Paul Valdes*** [3], ***Dr. Jonathan Owen*** [1], ***Dr. Sam Sherriff-Tadano*** [1]

1. *School of Earth and Environment, University of Leeds,* ***2.*** *Department of Natural and Built Environment, Sheffield Hallam University,* ***3.*** *School of Geographical Sciences, University of Bristol*

The past two deglaciations (~138-128 ka and ~19-11 ka) had very different histories of climate change, for example in the timings and magnitudes of their abrupt temperature and ocean circulation changes. A key contribution to these differences is the contrasting configurations of the Northern Hemisphere ice sheets during the glacial maxima immediately preceding the deglaciation (the Last Glacial Maximum, LGM, ~21 ka; and the Penultimate Glacial Maximum, PGM, ~140 ka). These vast ice sheets exerted an important control on the initial climate state for the deglaciation through their topographic, energy balance and meltwater influences, and hence on the subsequent chain of events, thus impacting the climate, ocean and sea level evolution during deglaciation. In this context, it is extremely useful to be able to examine the complex physical interactions between the climate and ice sheets in order to understand how and why the different configurations of North American and Eurasian ice sheets formed in the two time periods, the commonalities between these two glacial maxima states, and the ice sheets' intrinsic vulnerabilities to changing climate.

Here, we present the results from coupled climate-ice sheet simulations of the PGM and LGM performed using the fast general circulation model FAMOUS coupled to an ice sheet model; FAMOUS-ice (Glimmer-CISM and BISICLES). The simulations follow the PMIP4 glacial maxima protocols (Ivanovic et al., 2016; Menviel et al., 2019), but have dynamically evolving Northern Hemisphere ice sheets. Embracing the uncertainty in choices for model input (including parameter values), we have adopted a large ensemble approach, producing a range of physically consistent ice sheet and climate states for the glacial maxima. We have developed a set of metrics based on a synthesis of climate and ice sheet data, against which we are able to evaluate the model performance and filter out any implausible LGM and PGM conditions. We can thus estimate the uncertainty in our results, examining the relative importance of uncertain model parameters for each time period and their effect on the simulated processes and feedbacks between the climate and ice sheets.

Abrupt climate changes in the last two deglaciations simulated with different Northern ice sheet discharge and insolation

Dr. Takashi Obase [1]***, Prof. Ayako Abe-Ouchi*** [1]***, Dr. Fuyuki Saito*** [2]

1. *The University of Tokyo,* ***2.*** *Japan Agency for Marine-Earth Science and Technology*

There were significant differences between the last two deglaciations, particularly in Atlantic Meridional Overturning Circulation (AMOC) and Antarctic warming in the deglaciations and the following interglacials. Here, we present transient simulations of deglaciation using a coupled atmosphere–ocean general circulation model for the last two deglaciations focusing on the impact of ice sheet discharge on climate changes associated with the AMOC in the first part, and the sensitivity studies using a Northern Hemisphere ice sheet model in the second part. We show that a set of abrupt climate changes of the last deglaciation, including Bolling–Allerod warming, the Younger Dryas, and onset of the Holocene were simulated with gradual changes of both ice sheet discharge and radiative forcing. On the other hand, penultimate deglaciation, with the abrupt climate change only at the beginning of the last interglacial was simulated when the ice sheet discharge was greater than in the last deglaciation by a factor of 1.5. The results, together with Northern Hemisphere ice sheet model experiments suggest the importance of the transient climate and AMOC responses to the different orbital forcing conditions of the last two deglaciations, through the mechanisms of mass loss of the Northern Hemisphere ice sheet and meltwater influx to the ocean.

Sensitivity of millennial-scale climate oscillations to boundary conditions in HadCM3 glacial simulations

Ms. Brooke Snoll [1]***, Dr. Ruza Ivanovic*** [1]***, Dr. Lauren J. Gregoire*** [1]***, Dr. Sam Sherriff-Tadano*** [1]***, Mr. Yvan Romé*** [1]

***1.** School of Earth and Environment, University of Leeds*

Romé et al. (2022) present a new set of long-run Last Glacial Maximum experiments with millennial-scale climate oscillations between cold and warm modes. These oscillations are triggered by different snapshots of ice-sheet meltwater derived from the early stages of the last deglaciation. The overall characteristics of the oscillating events share similarities with $\delta^{18}O$ records of the last glacial period. We test the robustness of these oscillations under different climate conditions, such as those resembling Marine Isotope Stage 3 when multiple abrupt climate transitions, called Dansgaard-Oeschger events, occur. We present the results of multiple sensitivity experiments with modifications to the original simulations including adjustments of atmospheric CO_2 concentration, orbital parameters, and ice sheet geometry to those more comparable to Marine Isotope Stage 3. These experiments were run with intentions to better understand the range of conditions the oscillations can be sustained within the model and provide additional insight into the triggering mechanisms that control abrupt climate changes. The results also show how the adjusted climate conditions effect the time and periodicity of the oscillations and how this could relate to the changing periodicity of observed Dansgaard-Oeschger events.

Multi-millennial scale climate variability driven by bi-polar seesaw

Dr. Sam Sherriff-Tadano [1]***, Prof. Ayako Abe-Ouchi*** [2]***, Dr. Wing-Le Chan*** [1]***, Mr. Yuta Kuniyoshi*** [1]***, Dr. Takashi Obase*** [2]***, Dr. Akira Oka*** [2]

1. *Atmosphere and Ocean Research Institute, The University of Tokyo,* ***2.*** *The University of Tokyo*

Millennial time-scale climate variability, which appears during glacial periods including the deglaciation, is characterized by an abrupt warming over Greenland and a gradual cooling over Antarctica, which are called the bi-polar seesaw. These climate changes and the bi-polar seesaw are often related to the drastic strengthening of the Atlantic Meridional Overturning Circulation (AMOC). Despite its importance on the evolution of ice sheets, carbon cycles and human beings, the driving mechanisms of DO cycles remains elusive. Here, from an analysis of intrinsic oscillation of Atlantic Meridional Overturning Circulation (AMOC) obtained from a comprehensive climate model and from nudging sensitivity experiments, we show that gradual changes in the amount of brine rejection from sea ice over the Southern Ocean due to the bi-polar seesaw can drive the AMOC variability. The strengthening of the AMOC gradually increases the brine rejection and its freshwater transport over the Southern Ocean. This change in sea ice then causes a weakening of AMOC by increasing the stratification of the deep ocean and by reducing salinity of Antarctic Intermediate Water that flows into the North Atlantic Deep Water formation regions. Our results suggest the important role of bi-polar seesaw in driving multi-millennial time scale climate variability.

Ross Ice Shelf retreat and ocean dynamics during the Last Glacial Termination: insights from the Joides Basin, Ross Sea, Antarctica

Quaternary glacial terminations are periods of rapid warming during which climate and carbon cycles experience large-scale reorganization. The last glacial termination (ca. 18-11.5 Ka), in particular, is the temporally closest timeframe from which we can gather information regarding processes and feedbacks that lead to such climatic reorganization. Here we present results from the Southern Ocean, a region which during the Last Deglaciation was affected by strong CO_2 outgassing in relation to the resumption of the thermohaline circulation and ice shelves retreat. Our study focuses on a series of sedimentary cores collected in the JOIDES trough, Ross Sea. The studied area is characterized by complex ice shelf-ocean dynamics and represents one of the sites of Antarctic Bottom Water (AABW) formation which originates from a mixture of cold Ice Shelf Waters (ISW) and impinging modified Circumpolar Deep Water (mCDW) from the outer shelf.

Sea ice and open water dynamics, including information on trophic levels and paleo-seawater temperatures, were reconstructed using a suite of organic biomarkers that includes Highly Branched Isoprenoids (e.g. $IPSO_{25}$ and HBI III), sterols (Brassicasterol and Cholesterol) and Glycerol Dialkyl Glycerol Tetraethers (GDGTs). Biomarker profiles were also compared to bulk organic carbon and stable carbon isotope data ($\delta^{13}C$), as well as sedimentary facies reconstructed from grain-size information, XRF analyses and IRD presence.

Our results depict a coherent and rapid transition from a sub-ice shelf environment (during the Last Glacial Maximum, LGM) to a distal ice shelf system, evolving then into an open marine system. At the LGM the coring site was covered by the paleo-Ross Ice Shelf. Impinging warm waters at the onset of the deglaciation likely caused the paleo - Ice Shelf to retreat southward, freeing the JOIDES trough from the thick ice cover and allowing pelagic primary productivity. Enhanced upwelling of warm and nutrient-rich waters (presumably paleo mCDW) caused persistent blooming of the open water organisms during the whole deglaciation, stabilizing during the Holocene.

Collectively, our datasets illustrate the value of combining environmental organic proxies with sedimentary facies for the reconstruction of rapid changes in glacio-marine environments.

Multi-proxy agreement on Atlantic circulation dynamics during the last deglaciation

Dr. Frerk Pöppelmeier [1]***, Dr. Aurich Jeltsch-Thömmes*** [1]***, Prof. Fortunat Joos*** [1]***, Dr. Jörg Lippold*** [2]***, Prof. Thomas F. Stocker*** [1]

1. *Climate and Environmental Physics and Oeschger Centre for Climate Change Research, University of Bern,* **2.** *Institute of Earth Sciences, Heidelberg University*

Uncertainties persist in the understanding of the Atlantic Meridional Overturning Circulation (AMOC) and its response to external perturbations such as freshwater or radiative forcing. Abrupt reduction of the AMOC is considered a climate tipping point that may have been crossed when Earth's climate was propelled out of the last ice age. However, the evolution of the AMOC since the Last Glacial Maximum (LGM) remains insufficiently constrained due to model and proxy limitations. Here we leverage information from both multi-proxy data and climate model simulations to constrain the Atlantic circulation over the past 20,000 years. This is facilitated by the explicit implementation of the ocean proxies $\Delta^{14}C$, $\delta^{13}C$, εNd, and $^{231}Pa/^{230}Th$ in our model, allowing for a direct model-data comparison. We find a coherent picture of a shallow and weak AMOC during the LGM that reconciles long-standing conflicting proxy evidence. Model-data assimilation of the last deglaciation, with fully transient simulations starting from this new, multiple constrained LGM state, indicate a muted AMOC response during Heinrich Stadial 1. The relatively small changes from the LGM to the Heinrich Stadial 1 in AMOC are therefore in conflict with the proposal that an AMOC collapse triggered the early deglacial rise in atmospheric CO_2 and instead favor mechanisms associated with the Southern Ocean/Pacific. We further find that the water mass geometry did not fully adjust to the strong AMOC reduction during the comparably short Younger Dryas period. Our results thus demonstrate that even relatively small freshwater fluxes can substantially perturb the AMOC, which implies an increasing risk for its future stability under anthropogenic climate warming.

An abrupt temperature and hydroclimate transition in eastern Africa during Termination V

Ms. Briana Ramirez [1], Dr. Isla S. Castañeda [2], Dr. Jeffrey Salacup [1], Dr. Thomas Johnson [1]

1. Department of Geosciences, University of Massachusetts, Amherst, MA, USA, 2. Department of Geosciences at the University of Massachusetts

Over the last few million years, the climate over much of Africa exhibits a long-term drying trend with episodes of high climate variability coinciding with the intensification of glacial-interglacial cycles. Of particular interest, is a shift to drier and more variable conditions noted in the Olorgesailie Formation (Kenya) between 500 and 300 thousand years ago (ka) in which Potts et al. (2018) observed a turnover of ~85% of large-body mammalian fauna to smaller-body related taxa and suggested that the shift was an evolutionary response to better adapt to the changing climate. However, an erosional gap in the Olorgesailie record during this time interval means that the cause of this faunal shift is still an outstanding question. To understand East African climate variability during the Mid-Pleistocene, we analyze Lake Malawi drill core MAL 05–1 (~11ºS, 34ºE) to investigate if a specific climatic event stands out as a possible driver of the dramatic change observed in the East African mammal community. We use organic geochemical proxies including branched glycerol diaklyl glycerol tetraethers (brGDGTs; the MBT'_{5ME} index) and leaf wax carbon and deuterium isotopes to develop high-resolution temperature, vegetation, and precipitation records, respectively, between 600 and 200 ka. Results show an abrupt temperature increase of ~9°C occurring in less than 3000 years during Glacial Termination V, which is the Marine Isotope Stage (MIS) 12 to MIS 11 transition at ~430 ka. Preliminary leaf wax deuterium isotopic values show an enrichment that coincides with deglacial warmings suggesting a shift to more arid conditions during interglacial than in glacial periods. This change from a cold/wet glacial to a warm/dry interglacial contrasts with the cool/dry pattern of the Last Glacial Maximum (LGM) in East Africa which transitioned to a warm/wet Holocene. Leaf wax carbon isotopes are presently being analyzed to understand past shifts in C_3 vs C_4 vegetation type, which can be related to climatic conditions. We propose that the major warming and drying during Termination V in East Africa represents a significant abrupt change in the climate of eastern Africa and was a likely driver of the major faunal turnover noted in the region.

Glacial-interglacial carbon cycle dynamics of the past 800 kyr in an isotope-enabled Earth system Model of Intermediate Complexity

Dr. Markus Adloff [1]***, Dr. Aurich Jeltsch-Thömmes*** [2]***, Dr. Frerk Pöppelmeier*** [3]***, Prof. Thomas Stocker*** [3]***, Prof. Fortunat Joos*** [2]

1. *Climate and Environmental Physics and Oeschger Centre of Climate Change Research, University of Bern, Switzerland,* ***2.*** *Climate and Environmental Physics and Oeschger Centre for Climate Change Research, University of Bern,* ***3.*** *Climate and Environmental Physics and Oeschger Centre for Climate Change Research, University of Bern, Switzerland*

Marine sediment and ice cores preserved biogeochemical evidence of carbon transfers between land, ocean, and atmosphere in connection with the temperature and sea ice fluctuations of past ice age cycles. These carbon transfers and the underlying sensitivities of these carbon reservoirs to radiative changes remain poorly understood. Numerical studies proved the potential of several physical and biogeochemical processes to alter atmospheric CO_2 under steady-state glacial conditions. Yet, it is unclear how much they actually affected carbon cycling transiently during repeated glacial cycles. Addressing this uncertainty, we produced a simulation ensemble of various physical and biogeochemical carbon cycle forcings over the repeated glacial inceptions and terminations of the last 800 kyr with the Bern3D Earth system model of intermediate complexity. With this ensemble, we assessed the potential and pathways of different physical and biogeochemical Earth system changes to affect carbon and carbon isotope partitioning between atmosphere, ocean, and sediments. We will present results of the simulated Earth system dynamics during repeated glacial cycles and a comparison with multiple carbon, climate, and circulation proxy time series. Our analysis shows that low glacial atmospheric CO_2 concentrations can be obtained through enhanced C storage in various reservoirs: the deep Pacific and Atlantic, sediments or C burial to the lithosphere. Yet, the associated timing of CO_2 shifts, and patterns of carbon isotope and carbonate preservation change differ and suggest an opportunity to distinguish them in reconstructed changes of $\delta^{13}C$ and sediment composition. In our simulations, the radiative effects of glacial-interglacial orbital, greenhouse gas concentration, and ice albedo changes result in larger carbon transfers between ocean and sediments than atmosphere and ocean, particularly during deglaciations when carbon deposition in sediments is temporarily enhanced. Additional ocean circulation changes have large effects on regional carbon cycling, but they cause smaller fluctuations of atmospheric CO_2 and $\delta^{13}C$ than shown in proxy data. Biochemical controls on the organic matter and carbonate pumps in the ocean have the largest potential to shift carbon between atmosphere, ocean, and sediments and alter their isotopic composition, but no individual process produces data-consistent carbon fluxes in isolation, and their effects add non-linearly when combined.

How much did weathering fluxes change during the last deglaciation? Implications for transient runs with Earth System Models

Dr. Fanny Lhardy [1]***, Dr. Bo Liu*** [1]***, Dr. Matteo Willeit*** [2]***, Dr. Nathaelle Bouttes*** [3]***, Dr. Takasumi Kurahashi-Nakamura*** [4]***, Dr. Stefan Hagemann*** [5]***, Dr. Tatiana Ilyina*** [1]

During the last deglaciation (ca. 19-11 ka BP), the Earth's climate transitioned from cold and arid to comparatively warmer and wetter conditions. Simultaneously, large ice sheets melted and led to a significant rise of sea level (ca. +120 m), which reduced the size of the exposed continental shelves. Loess deposits were also gradually eroded. These changes influenced the chemical weathering of rocks because weathering rates depend on climate variables (runoff and temperature), land-sea distribution and lithology. Since weathering consumes CO_2 and releases ions (e.g. bicarbonate ions), which increase the river loads of carbon, nutrients and alkalinity, deglacial changes in weathering rates are expected to have consequences for the global carbon cycle. In particular, as a source term in the alkalinity budget, river fluxes can disequilibrate the global ocean inventory, a critical driver of carbon sequestration into the ocean, which is often assumed constant in Earth System Models. In this study, we calculate weathering fluxes using reconstructed lithological maps, and model results from transient runs of the last deglaciation and/or time-slice runs of the Last Glacial Maximum and pre-industrial period. For different models (MPI-ESM, CLIMBER-X, iLOVECLIM, CESM), we compare their evolution and spatial distribution. We show that while the increase of runoff during deglaciation enhances weathering, the rise of sea level and the erosion of loess deposits tend to have a counterbalancing effect on the river loads. As a result, our model ensemble tends to show inconsistent deglacial changes of river loads (e.g. for phosphorus), depending both on runoff biases and on the representation of land-sea distribution. Still, all models indicate a decrease of river alkalinity from the LGM to the pre-industrial. Based on these findings, we discuss the implications of an explicit representation of weathering fluxes for the global carbon cycle in transient runs with Earth System Models.

Carbonate compensation in the glacial Pacific constrained from paired oxygen and carbonate system reconstructions

Dr. Molly Trudgill [1], ***Dr. William Gray*** [1], ***Dr. Nathaelle Bouttes*** [1], ***Dr. Guy Munhoven*** [2], ***Mr. Nathan Colle*** [1], ***Dr. Didier Roche*** [1], ***Mr. Romain Euverte*** [1], ***Dr. James Rae*** [3], ***Dr. Elisabeth Michel*** [4], ***Dr. Arnaud Dapoigny*** [1]

1. *LSCE-IPSL, Laboratoire des Sciences du Climat et de l'Environnement (CEA-CNRS-UVSQ), Paris-Saclay,* ***2.*** *Université de Liège,* ***3.*** *University of St Andrews,* ***4.*** *LSCE*

The response of the deep ocean carbonate system and $CaCO_3$ dissolution to changes in the carbon cycle ('*carbonate compensation*') is a first order control on atmospheric CO_2 on timescales of ~10^3 to 10^5 years. Although carbonate compensation could account for up to ~*half* of the glacial drawdown of CO_2, quantitative estimates of changes in ocean alkalinity are lacking. As such, the role of carbonate compensation in driving glacial-interglacial CO_2 variations remains poorly understood.

Here, we combine reconstructions of dissolved oxygen from the infaunal-epifaunal benthic foraminiferal $\delta^{13}C$ proxy ($\Delta\delta^{13}C$) and carbonate system reconstructions from boron proxies (B/Ca, $\delta^{11}B$) in benthic foraminifera to quantify changes in both respired CO_2 storage within the deep Pacific during the last glacial, and the response of the carbonate system to this addition/removal of respired CO_2. Our results provide the first quantitative estimates of the amount and timing of alkalinity changes in the deep Pacific over the last deglaciation. Our results indicate an increase in deep ocean alkalinity during the Last Glacial Maximum, and indicate the buffering of the deep ocean occurs substantially faster than the canonical timescale of ~5 kyr (Broecker and Peng, 1987). We also present results from a series of sensitivity experiments and long-term simulations using the recently coupled iLOVECLIM-MEDUSA climate/carbon-cycle/sediment model, with implications for our understanding of carbonate compensation in both glacial times, and the long-term future.

Session 32: Paleo perspectives on a warmer and wetter future Arctic

Speleothem record of warmer and wetter past interglacials in northeast Greenland

Ms. Anika Donner [1]**, *Prof. Gina E. Moseley*** [1]**, *Mr. Werner Kofler*** [2]**, *Dr. Laurent Marquer*** [2]**, *Ms. Lena Friedrich*** [1]**, *Prof. Christoph Spotl*** [1]**, *Prof. R. Lawrence Edwards*** [3]

1. *Institute of Geology, University of Innsbruck,* **2.** *Department of Botany, University of Innsbruck,* **3.** *Department of Earth Sciences, University of Minnesota*

Improving understanding of the Arctic's amplified response to climate warming and the subsequent global consequences can be achieved through investigation of past interglacial periods. While excellent and reliable palaeoclimate records exist for some areas in the Arctic, others are under-investigated, for instance Greenland prior to 130 ka. Northeast Greenland is one of the regions where the effects of Arctic amplification are most intense within the observational period as well as modelled future scenarios. In this study, we investigate speleothems from caves situated in northeast Greenland (80°N), where the current arid climate (ca. 200 mm per year) and frozen ground prevent speleothem deposition. The presence of extensive speleothem deposits in northeast Greenland thus indicates at least one period of wetter and warmer climate in the recent geological past. Based on reproducible ^{230}Th/U disequilibrium dating, the most recent significant speleothem deposition occurred during marine isotope stage 11 (MIS11), an unusually long interglacial with a similar orbital composition as the Holocene, rendering it a good analogue for future climate evolution. Prior to this, the extended MIS13-15 interglacial period was a period of exceptionally prolific speleothem deposition. δ^{18}O and δ^{13}C variability during these two growth phases display large centennial-scale excursions. Furthermore, preliminary investigations into pollen preserved in MIS11 speleothem samples suggest the presence of boreal coniferous species such as *Picea*, *Abies* and *Pinus* as well as others such as *Corylus*, *Alnus*, Ericaceae, Cyperaceae, and Poaceae. These results indicate an environment vastly different to today, where the landscape is largely barren except for a few small alpine plants and shrubs, however, they agree with a record of MIS11 vegetation in a marine core off the coast of south Greenland. While still being under investigation, this could imply that the reconstructed forestation of south Greenland during MIS11 reached further north. The speleothems additionally contain floral macrofossils and large amounts of spores indicating potential for further investigations of environmental conditions in northeast Greenland during a warmer and wetter past.

Overshooting the critical threshold for the Greenland ice-sheet

Mr. Nils Bochow [1], *Ms. Anna Poltronieri* [1], *Dr. Alexander Robinson* [2], *Prof. Martin Rypdal* [1], *Prof. Niklas Boers* [3]

1. Arctic University of Tromso, 2. Complutense University of Madrid, 3. Technical University of Munich

Global sea-level rise due to the melting of the Greenland ice sheet poses a severe threat to human society in the 21st century (IPCC, 2021). Modelling and paleoclimatic evidence suggest that rapidly increasing temperatures in the Arctic can trigger positive feedback mechanisms, and the ice sheet is hypothesised to exhibit multiple stable states. Consequently, there are tipping points when the global mean surface temperature crosses specific thresholds (Robinson et al., 2012). Given the current efforts to reduce global emissions of greenhouse gasses, it becomes increasingly unlikely that we will reach the 1.5°C goal by the end of the century. Simultaneously, crossing a critical threshold for the Greenland ice sheet becomes inevitable, and the first early-warning signals of a possible transition have already been found (Boers & Rypdal,2021). However, a short-term overshooting of a critical threshold is possible without prompting a change in the system state (Ritchie et al., 2021). In this study, we use a complex ice sheet model to investigate the effects of different carbon-capture scenarios after crossing the first critical threshold for the Greenland ice sheet. We outline a stability diagram for several emission scenarios and show that temporarily overshooting the temperature threshold may lead to catastrophic consequences in specific scenarios.

About 19 ky ago, the global climate transitioned from the cold and dry conditions typifying the Last Glacial Maximum (26 – 20 ky Before Present, BP) to the warmer and wetter conditions of the Holocene (11.7 ky BP to Present). In this period, the Northern Hemisphere witnessed a 3.5 °C warming, the demise of the Arctic ice sheets, a 130 m sea level rise, and a profound reorganization of the Arctic permafrost systems that lost about 1000 Petagrams of organic carbon (Pg OC). Simultaneously, the concentration of greenhouse gases rose with sharp fluctuations, the latest and most abrupt of which occurred at the Younger Dryas (YD) – Preboreal (PB) transition (ca. 11.6 ky BP) when natural methane (CH_4) emissions suddenly increased of about 220 parts per billion by volume (ppbv). The abrupt release of petrogenic CH_4 and the destabilization of marine and subglacial methane hydrates were invoked as possible drivers, hypotheses that were challenged by studies targeting the isotopic fingerprint of CH_4 from ice cores. These studies rather proposed a nearly contemporaneous – moderately ^{14}C-depleted – OC source for CH_4 emissions identified in organic matter respired in wetlands. Additionally, the studies discarded relevant contribution from old permafrost OC, but they couldn't constrain the permafrost carbon complexities as permafrost carbon can exhibit a continuum of radiocarbon ages. With this study, we used the Siberian shelf as receptor of permafrost destabilization during the YD-PB transition to help resolving the permafrost carbon complexity during abrupt warming. We targeted lipid biomarkers (lignin phenols and cutin acids) and the C isotope composition (d^{13}C and D^{14}C) of terrigenous OC from shelf sediments deposited off the paleo-delta of the Lena River (Arctic Ocean), which integrates the signal of a vast area dominated by permafrost and sensitive to climate perturbations. Preliminary results warn against seemingly non-negligible contribution to CH_4 emissions from nearly contemporaneous permafrost OC. This study aids in understanding how permafrost systems may respond to current man-induced rapid climate warming, including the possible release of additional CH_4 that would amplify anthropogenic climate change.

Analysis of Early-Warning Signals for Arctic Summer Sea Ice Loss

Ms. Anna Poltronieri [1], *Mr. Nils Bochow* [1], *Prof. Martin Rypdal* [1]

1. Arctic University of Tromso

The rapid loss of Arctic sea ice in the last decades is one of the most evident manifestations of anthropogenic climate change. A transition to an ice-free Arctic during summer would impact climate and ecosystems, both regionally and globally. The identification of early-warning signals for the loss of the Arctic summer sea ice could provide important insights into the state of the Arctic region.

We collect and analyze CMIP6 model runs that reach Arctic sea-ice-free conditions (area below 10^6 km^2) in summer. Despite the high inter-model spread, with the range for the date of an ice-free summer spanning around 100 years, the evolution of the Arctic summer sea ice area right before reaching ice-free conditions is strikingly similar across the CMIP6 models.

When looking for early-warning signals for Arctic summer sea ice loss, we observe a significant increase in the variance of the sea ice area before reaching ice-free conditions. This behavior is detected in the majority of the models, and also averaged over the ensemble. We find no increase in the 1-year-lag autocorrelation in model data, possibly due to the multiscale characteristics of climate variability, which can mask changes in serial correlations. However, in the satellite-inferred observations, increases in both variance and lag-1 autocorrelation have recently been revealed.

Not gone with the Wind: coastal lake sediment sequence from southern tip of Svalbard records Holocene changes in storminess on human-relevant timescales

Mrs. Zofia Stachowska-Kamińska [1]***, Dr. Willem van-der-Bilt*** [2]***, Dr. Mateusz Czesław Strzelecki*** [3]***, Ms. Zofia Owczarek*** [3]

1. *Institute of Marine and Environmental Sciences, University of Szczecin, Szczecin, Poland,* ***2.*** *Department of Earth Science, University of Bergen; Bjerknes Centre for Climate Research, Bergen, Norway,* ***3.*** *Alfred Jahn Cold Regions Research Centre, Institute of Geography and Regional Development, University of Wrocław, Wrocław, Poland*

The Arctic warms faster than anywhere else on Earth. This amplified response to on-going climate change is most visibly demonstrated by a dramatic decline in sea-ice extent. As larger areas become ice-free for longer periods of time, winds can interact more with open water – increasing wave height. The ensuing increase in storminess may accelerate coastal erosion and complicates trans-Arctic shipping. But despite these consequences, the magnitude of changes in storminess remain highly uncertain. By extending scarce and sparse instrumental records into past analogues for near-future conditions, continuous and well-dated geological archives of coastal change can close this gap. Here, we present such evidence from a coastal lake sediment sequence retrieved from Svalbard‘s southern tip – an area exposed to the dominant westerly winds. Steinbruvatnet, the targeted lake, is sheltered by a bedrock barrier and experienced little isostatic uplift, so that the distance between basin and coast remained stable since deglaciation. ^{14}C ages derived from terrestrial plant macrofossils reveal that the analyzed ~1m sediment sequence covers the entire Holocene. Employing a novel multi-proxy approach, we provide independent lines of geochemical (XRF), visual (3-D CT) and granulometric evidence for the input of wind-driven sea-spray and clastic input. Our findings suggest a strong coupling between Holocene climate change and the frequency and magnitude of storm events in the region.

The research is supported by the Polish National Science Centre grant ‘ASPIRE - Arctic storm impacts recorded in beach-ridges and lake archives: scenarios for less icy future’ No. UMO-2020/37/B/ST10/03074.

Storegga tsunami or storm? Palaeoclimate, palaeoglacier and sea-level inferences from Ringgåsvatnet, Nordaustlandet, Svalbard Archipelago.

Mr. Joseph Buckby [1]***, Dr. Mark Furze*** [1]***, Prof. Jostein Bakke*** [2]***, Prof. Henriette Linge*** [2]

***1.** Dept. of Arctic Geology, The University Centre in Svalbard, Longyearbyen, Svalbard,* ***2.** Department of Earth Science, University of Bergen, Bergen, Norway*

Analysis of detailed Arctic lacustrine records spanning the Holocene can provide vital information on evolving climate, sea level, and ice sheet behaviour during internals considered analogous to anthropogenically-forced project future climate. Records from climatically sensitive high Arctic settings are of value given their sensitivity to changing environmental conditions. Ringgåsvatnet on Nordaustlandet, NE Svalbard Archipelago is such a case.

The lake situated above 80ºN was cored in 2017. Cores have subsequently undergone analysis to reconstruct their glacier, sea-level and palaeoclimate history. The ice cap of Ahlmannfonna resides within the main catchment of Ringgåsvatnet with meltwater delivery to the lake likely also from the northwest margin of the Austfonna ice cap during deglaciation. The cores record the post-glacial emergence of Ringgåsvatnet with initial isolation of the basin dated to the Early Holocene based on AMS ^{14}C radiocarbon ages on terrestrial macrofossils and foraminifera. Marine and lacustrine sedimentation in Ringgåsvatnet and its post-glacial emergence denote a clear shift in the climate during the Holocene. Within the isolation phase there is a unique sandy layer that is not replicated elsewhere in the core stratigraphy. Based on the current geochronology it is suggested that this may be the first evidence of the Storegga tsunami recorded on Svalbard.

Following lake isolation, a lacustrine environment is dominated by minerogenic input with several phases of sediment variability interpreted as glacial activity. There appears to be no prolonged period of glaciogenic absence from Ringgåsvatnet during the Holocene, suggesting that Ahlmannfonna remained throughout, although it may have remained in a heavily reduced state during the mid-Holocene. This northernmost lacustrine record from the Svalbard Archipelago provides key inferences to Holocene paleoclimates and events in an area where there is sparse prior knowledge.

Unravelling Holocene sea-level and surging glacier histories in central Spitsbergen: a case study from the Erdmannflya lowland

Dr. Mark Furze [1]***, Mr. Joseph Buckby*** [1]***, Dr. Thomas Lakeman*** [2]***, Mr. Guy Walker-Springett*** [3]***, Ms. Ammandine Missana*** [4]***, Prof. Michael Retelle*** [5]***, Ms. Amélie Roche*** [1]***, Prof. Sönke Szidat*** [6]

School of Ocean Sciences, Bangor University, Bangor, Gwynedd, Wales, 4. Dept. of Physical Geography, Stockholm University, Stockholm, 5. Earth & Climate Sciences, Bates College, Lewiston, Maine, 6. Department of Chemistry, Biochemistry and Pharmaceutical Sciences, University of Bern, Bern

Detailed reconstructions of Holocene Arctic palaeoenvironments are essential for generating deeper time perspectives on landscape adjustments to changing climate and providing analogues for a postulated warmer future.

Here, as part of the SHERBET project (Svalbard Holocene Emergence and Raised Beach Environments and Timing) we present the latest findings from ongoing work on Erdmannflya, a glacially influenced coastal lowland on the northwest coast of Isfjorden in central Spitsbergen, Svalbard. Detailed UAV and TLS mapping of the area has provided, for the first time, a high resolution understanding of raised beach ridge morphological variation in response to changing wave, current, and tidal conditions through the Holocene of Isfjorden. A new chronology constrained by molluscan and cetacean radiocarbon dates underpins the sea level reconstructions and challenges the assumption that much of western Spitsbergen experienced a Mid Holocene transgression. Further, moraines emplaced within and atop the raised beach sequences, along with high resolution lacustrine cores, permit the elucidation of a history of glacier surges extending well beyond historical records.

Taken together, this environmental-scale reconstruction of Holocene change using a linked raised marine – glacial landsystems approach, shows that a nuanced portrait of landscape evolution can be achieved. That is despite the complexities of rapid isostatic rebound, changing sea ice and wave conditions, climatically or dynamically forced glacial variability, and evolving atmosphere and ocean circulation. The record provides a valuable window into conditions in Isfjorden throughout the Holocene, and challenges a simple interpretation of the early Holocene as an analogue for a future warm Svalbard.

Session 33: Quaternary Glaciations: Processes, Sediments and Landforms

Evidence from geomorphological mapping and paired terrestrial cosmogenic nuclides for a relict cold-based landscape preserved under the Keewatin Ice Divide, Nunavut, Canada

Dr. Isabelle McMartin [1]***, Dr. Pierre-Marc Godbout*** [1]***, Dr. John Gosse*** [2]***, Ms. Janet Campbell*** [1]***, Mr. Tommy Tremblay*** [3]***, Prof. Martin Roy*** [4]***, Dr. Joerg M. Schaefer*** [5]

1. *Geological Survey of Canada, Natural Resources Canada,* ***2.*** *Dalhousie University,* ***3.*** *Canada-Nunavut Geoscience Office,* ***4.*** *Geotop-Université du Québec à Montréal, Montréal, Canada,* ***5.*** *Lamont-Doherty Earth Observatory, Columbia University*

Relict weathered terrains were recently identified and mapped in large areas formerly covered by the northern portion of the Keewatin Ice Divide, central Laurentide Ice Sheet (LIS), based on high-resolution imagery (Arctic-DEM and Landsat 8), ground-based observations, and surface materials composition. A gradual transition in the preservation of these relict terrains is reflected by changes in geomorphology, weathering, elevation, drainage network, and lake density. Over the Wager Plateau north of Baker Lake, extensive areas of uplands form a continuum ranging from abundant weathered diamictons, bedrock and blockfields, with little evidence of glacial erosion, to terrains with moderate glacial erosion, patchy weathering, sporadic streamlined landforms, a well-developed network of ice-marginal channels, and discontinuous eskers. In the large ice divide migration zone south of Baker Lake, a palimpsest glacial record (striations, landforms and dispersal trains) and stacked till sheets of different provenance reflect persistent warm-based conditions and mobile outflow centres during the last glacial cycle(s). Our classification of these terrains is supported by relative terrestrial cosmogenic nuclide (TCN) abundances in bedrock, till, and boulder samples. Paired ^{10}Be and ^{26}Al abundances are relatively high in relict terrains and apparent ^{10}Be ages of surface bedrock vary from 21.9 ± 0.5 ka to 61.9 ± 1.2 ka (n = 10; LSDn Age ±1σ interior). The pattern of the apparent ages suggests that TCNs produced prior to burial were preserved through incomplete erosion under a polythermal ice divide. The presence of occasional erratics over the weathered bedrock suggests full glacial coverage with sporadic warm-based conditions. In the fully warm-based terrains, apparent ^{10}Be ages on striated outcrops and wave-washed bedrock marine limits vary between 6.9 ± 0.5 ka and 9.0 ± 0.6 ka (n=10) and indicate no exposure inheritance or burial. These exposure ages are not well constrained by other geochronological measurements, and generally suggest that deglaciation occurred at least 1 ka earlier than radiocarbon-based reconstructions. The research captures the deglacial record of the LIS during a critical time and helps to reduce risk to mineral exploration in polythermal glaciated terrain by removing barriers to the use of TCN to quantify glacial erosion and sediment production.

Ice flow dynamics of the northwestern Laurentide Ice Sheet during the last deglaciation

Mr. Benjamin James Stoker [1], ***Ms. Helen Dulfer*** [2], ***Dr. Martin Margold*** [3], ***Prof. Chris Stokes*** [4], ***Prof. chris clark*** [5], ***Prof. Colm O'Cofaigh*** [6], ***Dr. David Evans*** [6], ***Dr. Sophie L. Norris*** [7], ***Dr. Duane Froese*** [8]

1. *Faculty of Science, Charles University,* ***2.*** *Department of Physical Geography and Geoecology, Charles University, Prague,* ***3.*** *Charles University,* ***4.*** *Department of Geography, Durham University, Durham, DH1 3LE, UK.,* ***5.*** *Department of Geography, University of Sheffield,* ***6.*** *Durham University,* ***7.*** *University of Victoria,* ***8.*** *University of Alberta*

Ice streaming exerts a strong influence on the mass balance of contemporary ice sheets, accounting for ~90% of the dynamic mass loss of the Antarctic Ice Sheet. Uncertainty in ice stream dynamics limits our ability to predict the future of ice sheets under anthropogenic climate change. Palaeo-ice sheets provide an opportunity to investigate ice stream and ice flow activity over long timescales. A recent ice sheet-wide reconstruction of changes in ice streaming activity for the Laurentide Ice Sheet identifies a number of palaeo-ice streams in the northwest of the Laurentide Ice Sheet where the spatial evolution through deglaciation is poorly constrained and the influence of changing ice source areas during deglaciation is uncertain. According to numerical modelling studies and empirical chronological constraints, this region of the Laurentide Ice Sheet experienced a period of rapid retreat driven by the collapse of the ice saddle with the Cordilleran Ice Sheet during the Bølling-Allerød interval. However, our understanding of the ice drainage network configuration during this period of remains poor and whether saddle collapse influenced the past ice flow dynamics has not been investigated.

Here we use a new glacial geomorphological map based on the ArcticDEM (2 m spatial resolution) to reconstruct the past ice flow dynamics of the northwest Laurentide Ice Sheet following the well-established approach of flowset mapping and the glacial inversion model. The rich detail of the geomorphological record mapped from high resolution data allows us to resolve the configuration and evolution of ice streaming over time. During deglaciation, the northwest Laurentide Ice Sheet experienced dramatic reorganisations with rapid switching of ice flow directions which allow us to understand the changing ice source areas associated with ice saddle collapse. The ice stream network was dominated by a series of time-transgressive ice streams (approx. 50 km to 300 km long), which switched on and off during deglaciation, as opposed to an extensive, long-term-operating ice stream network. This reconstruction provides a possible analogue for future changes in ice streaming in modern ice sheets under a warming climate.

Submarine landforms reveal past Antarctic Ice Sheet grounding-line retreat of kilometers per year

Dr. Christine Batchelor [1], ***Prof. Julian Dowdeswell*** [2], ***Dr. Aleksandr Montelli*** [2], ***Dr. Dag Ottesen*** [3], ***Dr. Frazer Christie*** [2], ***Mrs. Evelyn Dowdeswell*** [2], ***Dr. Jeffrey Evans*** [4]

The ice sheet grounding line is the environmentally sensitive boundary between grounded and floating ice, and its position determines the rate of ice-mass loss to the ocean. Despite advances in the temporal and spatial resolution at which the grounding line can be detected from satellite measurements, it is not known whether the ~50-year satellite record has captured the full range of potential variability in rates and styles of grounding-line retreat. Glacial landforms produced during the last glacial-interglacial cycle and preserved on mid- and high-latitude continental shelves can provide information about ice-sheet behaviour over longer timescales.

Here, we present a stunning assemblage of glacial landforms imaged at sub-metre resolution from an autonomous underwater vehicle in Larsen Inlet, eastern Antarctic Peninsula. The most striking features are a series of transverse-to-flow ridges that are <1.5 m high and spaced 20-25 m apart. We interpret these 'corrugation ridges' to be formed by the squeezing up of soft sediment during the rise and fall of the retreating ice sheet grounding line during successive tidal cycles.

We infer from the spacing of these ridges that the grounding line retreated at a rate of 40-50 m/day (>10 km/year) during regional deglaciation of Larsen Inlet about 11 ka. Although high, our inferred retreat rates for the last deglaciation align with newly acquired satellite observations of rapid contemporary grounding-line retreat in West Antarctica (11.7 km/year). This implies that the maximum magnitude of grounding-line retreat during past and ongoing periods of climatic warming may in fact be even greater than ~50 m/day.

Late Glacial-Holocene glacier fluctuations on sub-Antarctic Kerguelen Archipelago (49°S) based on surface exposure dating with in situ Cl-36, Be-10, Al-26 and C-14

Ms. Talin Tuestad [1], ***Prof. Henriette Linge*** [1], ***Dr. Philip Deline*** [2], ***Dr. Shasta Marrero*** [3], ***Prof. Jostein Bakke*** [1], ***Dr. Ludovic Ravanel*** [2], ***Dr. Fabien Arnaud*** [2], ***Mr. Lars Evje*** [1], ***Dr. Delia M. Gheorghiu*** [4], ***Dr. Richard Shanks*** [4], ***Dr. Anne Sofie Søndergaard*** [5], ***Prof. Jesper Olsen*** [6]

The Kerguelen Archipelago (49°S) is a group of sub-Antarctic volcanic islands located within the Southern Hemisphere's westerly wind belt in the southern Indian Ocean. The islands demonstrate significant evidence of widespread ice cover such as U-shaped valleys, fjords, erratic boulders and moraines. Nonetheless, Kerguelen has been subjected to very few studies of its Quaternary glacial history. Since glaciers are highly sensitive to changes in temperature and precipitation, glacial fluctuations on Kerguelen may provide insight into the past behaviour of the westerly wind regime. The Cook Ice Cap (CIC) covers a significant part of the western part of the islands, reaching over 1000 m a.s.l. Recent studies have demonstrated significant retreat of the CIC since the 1960s, which has been attributed to atmospheric drying due to the poleward shift of the Southern Ocean's westerly wind belt. The interdisciplinary project SOUTHSPHERE seeks to establish a baseline of the past behaviour of this atmospheric regime by reconstructing Late Glacial-Holocene glacial fluctuations, both spatially and temporally, using lake core records and glacial landforms from region northeast of the CIC.

Geomorphologic mapping of the region outlines several moraine systems associated with CIC outlet glaciers as well as local glaciers, located around 10 km north of the ice cap. Our investigation seeks to substantially improve the Late Glacial-Holocene glacial chronology on Kerguelen through surface exposure dating using *in situ* ^{36}Cl, ^{10}Be, ^{26}Al and ^{14}C. Surface exposure dating of glacial landforms on Kerguelen has previously been done primarily using *in situ* cosmogenic ^{36}Cl given the islands' volcanic origin. During an expedition in 2019, 110 rock samples for surface exposure dating were collected from moraines, scoured bedrock and erratic boulders. This study will produce the first multi-nuclide ^{10}Be, ^{26}Al and ^{14}C analysis of hydrothermal quartz on Kerguelen, which also provides a means of validating nearby *in situ* ^{36}Cl ages. A multi-nuclide analysis is particularly advantageous in this setting, as it exhibits highly active surface processes, strong weathering and high erosion rates. Such an analysis will allow for larger scale investigations of exposure histories, erosion rates, and overall landscape dynamics in the region.

Reconstruction of Late Pleistocene-Holocene East Antarctic Ice Sheet variations through the integrated analyses of marine sedimentological indicators from Terra Nova Bay, Ross Sea.

Asymmetrical glacigenic structures known as Grounding Zone Wedges, emerging from the Ross Sea continental shelf, owe their origin to the Antarctic Ice Sheet erosive action and transport capability. Those deposits, mainly constituted by glacial till, overlain by glaci-marine and marine sedimentary sequences, witness episodes of sea-level still-stands which are possibly linked to climatic variations.
Our study area, within Terra Nova Bay, is located offshore the Western sector of Ross Sea, where numerous studies have been carried out regarding the post-Last Glacial Maximum deglaciation patterns and the consequent Grounding Line retreat path of the East Antarctic Ice Sheet.
Two sediment cores retrieved from the topset of an exposed, well-preserved Grounding Zone Wedge near Adélie Cove constitute the basis of this research, which comes as a part of the broader DISGELI-PNRA project.
The lithological and textural composition of the analyzed sediment, together with semi-quantitative geochemical data obtained through XRF analyses and organic carbon data derived by CHN analyses, allowed to trace the recent behavior of the East Antarctic Ice Sheet in terms of depositional environment shifts. Radiocarbon dating performed on the bulk organic matter allowed to obtain a time constrain for the basal till deposits found in sediment cores, overlain by meltwater deposits and regular open-marine sedimentation.
Multi-disciplinary studies of glaci-marine sedimentary sequences constitute an effective method to provide a connection between submarine deposits and recent climatic events, highlighting minor changes occurred during the Quaternary.

Large canyons and sedimentation changes indicate extensive early-Quaternary glaciations of the Barents Sea

Climate proxies reveal a decrease of 4-6º C in global temperature associated with the onset of the Northern Hemisphere glaciations in the early Pleistocene. Sedimentary records of these early glaciations are sparse on paleo-shelves, yet sedimentary trough mouth fans formed on adjacent continental slopes provide a continuous record of the ice-sheet and climate development throughout the Quaternary. Here, we interpreted new high-quality 3D seismic reflection data combined with borehole and chronostratigraphic information from such a location in the western Barents Sea to study meltwater and sediment input to the deep ocean focusing on the on-set of glaciation on the Arctic margins. Sandy deposits were brought to the slopes of the high-latitude Bear Island Fan by a contourite-turbidite system prevailing at the onset of the Quaternary, about 2.6-2.4 Ma. From 2.1-0.9 Ma, muddy sediments were delivered from turbidites and debris flows originating from six canyons measuring up to 12 km in width and 200 m in depth. The large canyons on the shelf and associated downslope deposits document an increased meltwater input to Bear Island Fan during the obliquity-dominated Milankovitch cycles. During the subsequent eccentricity-dominated cycles, rapidly-deposited glacigenic debris flows and mega-scale glacial lineations document a reduced meltwater contribution. This study shows that this Arctic shelve was extensively glaciated in the early Quaternary, with increasingly enhanced meltwater and sediment contribution from the shelve to the slope.

Palaeo-ice margin oscillations in the area of Pleistocene continental glaciations (northern Poland) inferred from combined OSL and Be-10 dating

Ice sheets and glaciers are good indicators of climate changes. They tend to stay in equilibrium with the mean regional climate, but they also react to any long-term variations of temperature and precipitation by their mass balance adjustment. However, our knowledge about interactions of the Pleistocene palaeo-ice sheets with past climatic fluctuations is limited, as glacial geological record is fragmentary and in many cases difficult to date. In order to explore interactions between palaeo-ice sheets, such as the Fennoscandian Ice Sheet (FIS), and the Pleistocene climatic fluctuations, it is important to link available geological records with robust chronologies of palaeo-ice sheets advances and retreats.

Here we present the chronology and a reconstruction of the dynamics of palaeo-ice margin oscillations based on combined luminescence and Be-10 surface exposure dating. We focused on the southern fringe of the last FIS in northern Poland. The study area covers the region of a fresh glacial landscape shaped in the Late Pleistocene during the last FIS advance and retreat, which in this part of the north-central Europe occurred around 22–18 ka BP. The luminescence (OSL) method was used to date aeolian and outwash deposits intercalating basal till layers. The most likely age of the till layers was constrained by Bayesian modelling integrating sediments sequence with numerical dating controls. The Be-10 method was used to date erratic boulders left by the last FIS and which rest at the surface of a conspicuous moraines. We present 11 new OSL ages and 10 Be-10 ages (5 new and 5 already published).

Our results show highly dynamic oscillations of the palaeo-ice margin with at least three ice advances and three ice retreats in the period between ca. 19-17 ka BP. We attempt to correlate these oscillations with the north-central European glacial stratigraphy, and with paleoclimatic records available from global and regional archives, such as: ice cores, marine sediments, lake sediments and loess sequences.

Surging palaeo-ice lobes of Latvia

Dr. Kristaps Lamsters [1], ***Ms. Inese Grinbauma*** [2]

1. *Faculty of Geography and Earth Sciences, University of Latvia,* **2.** *Faculty of Oceanography and Geography, University of Gdańsk*

This study focuses on palaeo-ice lobe dynamics and possible surge behaviour in Latvia reconstructed from the glacial landform record. The availability of the 1-m-resolution LiDAR digital elevation model (DEM) has promoted the identification and mapping of previously undetected geometric ridge networks interpreted as crevasse-squeeze ridges (CSRs), which have been widely used nowadays to identify the modern and recently also the Pleistocene glacier surges. We have found the spectacular and well-preserved patterns of CSRs in two Latvian lowlands (Kursa and Eastern Latvian) characterized by fast-flowing/surging ice lobes. Both locations have CSRs across almost the whole width of ice lobes superimposed on mega-scale glacial lineations (MSGLs) and have experienced rapid ice-lobe shut-down and downwasting during the deglaciation, and formation of vast proglacial lakes. The internal structure of CSRs suggests bottom-up squeezing of glacier bed substrate (mostly subglacial till) into the transverse, slightly oblique, and occasionally even criss-cross pattern basal crevasses. Furthermore, the zig-zag pattern of even more than 10-km-long continuous CSRs has been recognized. These CSRs consist of ridges with connected segments oriented even 90 degrees to each other. Altogether more than 13 000 CSRs were mapped, and the average height of CSRs is only 1,5 m but the average length is 0.15-0.22 km. The glaciofluvial landform record allowed to access meltwater-related processes. In the case of the Kursa Lowland, meltwater-related landforms are rare except of proglacial lake sediment-covered plains, but the Eastern Latvian Lowland comprises meltwater channels, tunnel valleys, sandur plains, only some eskers and vast proglacial lake plains suggesting abundant meltwater that what was drained after the surge events. The repeated surging activity was also determined in the Eastern Latvian Lowland, which has at least four end moraine complexes related to the Lubāns Ice Lobe marginal positions during deglaciation. We provide one of the first evidence of possibly surging behaviour of ice lobes in the SE sector of the FIS, Latvia, from the record of CSRs and other glacial landforms and rise the important question that should be answered in further studies – what was the mechanism and timing of palaeo-ice stream/ lobe surging?

Unravelling the Early Pleistocene Glacial Landscape in the Swiss northern Alpine Foreland

Dr. Catharina Dieleman [1], ***Dr. Marcus Christl*** [2], ***Dr. Christof Vockenhuber*** [2], ***Mr. Philip Gautschi*** [2], ***Prof. Fritz Schlunegger*** [1], ***Dr. Naki Akçar*** [1]

1. Institute of Geological Sciences, University of Bern, 2. ETH Zurich, Laboratory of Ion Beam Physics, Zurich, Switzerland

The Early Quaternary in the Swiss northern Alpine Foreland was characterized by a transient and low relief landscape, when about four to eight glacier advances sculptured the northern Alpine Foreland. Landforms related to these advances are absent and sediment packages are scarce, thus laterally and horizontally discontinuous. They are preserved in a succession of glaciofluvial gravels intercalated with glacial and/or overbank sediments, so-called Cover Gravels (*Deckenschotter* in German). This study underscores the Early Quaternary stratigraphy in the Swiss northern Alpine Foreland by exploring some 30 Deckenschotter sites in detail. The analysis of the origin, transportation mechanism, and depositional environment, and the application of the established cosmogenic ^{10}Be and ^{26}Al chronology revealed five Pleistocene glacier advances between ca. 2.5 Ma and ca. 250 ka. Three of these glaciations occurred during the Early Pleistocene prior to the Mid-Pleistocene Transition (MPT): the first one at ca. 2.5 Ma appearing to be synchronous with the onset of Quaternary glaciations in the northern hemisphere, the second at ca. 1.5 Ma, and the third at ca. 1 Ma. The younger advances took place during the Middle Pleistocene: one is attributed to the Most Extensive Glaciation (MEG) at ca. 500 ka, and the other after 250 ka. During the early Pleistocene, the occurrence of a complex cut-and-fill arrangement of gravel units suggests that the base level of the rivers draining the glacial meltwaters was at a nearly constant elevation during that time. The phase of cut-and-fill system was followed by a period of incision, which was likely induced by the MPT after ca. 1 Ma, and the relief was consequently lowered. Our study thus portrays a unique case for landscape evolution in forelands where changes in climate during the MPT was possibly an important driving force.

Overdeepened glacial basins as archives for Quaternary glaciations and subglacial processes: A detailed study the Alpine foreland of Northern Switzerland

Overdeepened glacial basins are typical yet poorly understood elements of glacial landscapes. The 10s to 100s of meters of unconsolidated sediment infilling the overdeepenings are a largely untapped terrestrial archive for Quaternary environmental change and landscape evolution. We present a detailed study on a group of Quaternary overdeepenings in the Alpine foreland of N Switzerland (W Rhine paleoglacier and adjacent lobes). Seismic data and drill cores (ca. 1800 m in total from 11 sites) allowed us to reconstruct the geometry and the depositional evolution of these overdeepenings and the connected downstream fluvial channels. The collected data give a detailed picture of when and how overdeepenings were eroded and infilled, and which subglacial processes were involved. The results contribute to a more complete reconstruction of the repeated extensive glaciation of the Alpine forelands in response to global climatic changes during the Quaternary.

8.2 ka event recorded by a glacier advance in the South Western Alps

Prof. Adriano Ribolini [1] ***, Prof. Matteo Spagnolo*** [2] ***, Dr. David Fink*** [3]

1. *Department of Earth Science, University of Pisa, Italy,* ***2.*** *School of Geosciences, University of Aberdeen, Aberdeen, UK,* ***3.*** *ANSTO*

Numerous climate proxies around the globe have recorded a short-lived (centennial-scale) climatic cooling event at 8.2 ka BP, superimposed on the millennial-scale warming trend that characterized the early Holocene. In the Mediterranean region, several paleoclimatic reconstructions based on marine, lake and speleothem records confirm that the 8.2 ka event was short (~150-200 years), cold, arid, and significantly impacted regional ecosystems. However, the relationship between this abrupt change in climate conditions and geomorphological processes is not always straightforward, mainly due to a lack of chronological constraints. This is particularly true in the European Alps where, unlike for other well-known Holocene glacial oscillations, the effect of the 8.2. ka cooling event (i.e the Kromer Stadial in the Alpine glacial chronology) is poorly documented, with no glacial deposits (eg moraines) associated with this change having been dated thus far.

We collected 5 samples from prominent boulders standing on the crest of a frontal moraine in the Maritime Alps, the southernmost part of the Alpine chain, just 40 km inland from the Mediterranean Sea. The moraine is located in a valley where the southernmost glaciers of the Alps (Gelas, Peirabroc, Maledia glaciers) are still preserved, and where the location and age of the Late Pleistocene and Little Ice Age moraines are known (i.e. LGM, Oldest Dryas, Younger Dryas). The ^{10}Be exposure ages of these blocks yielded 10Be exposure ages ranging between 7.9 ± 0.4 ka and 8.2 ± 0.4 ka (average value of 8.0 ± 0.4 ka). These ages consistently indicate that the 8.2 ka global event is registered as a glacial advance in this sector of the Alps.

The results therefore allow us to i) add a fundamental tile to the glacial chronological sequence of the SW Alps, ii) confirm that these marginal glaciers (i.e. close to the Mediterranean Sea) are sensitive to short-lived climatic events, making them ideal indicators of environmental change caused by large-scale far-field climate variability that occurred in the North Atlantic.

Marine ice sheet instability: collapse or steady retreat? Evidence from The Minch, NW Scotland

Mr. Neil McDonald [1]***, Dr. Tom Bradwell*** [1]***, Dr. S. Louise Callard*** [2]***, Prof. Jaime Toney*** [3]

***1.** University of Stirling, **2.** University of Newcastle, **3.** University of Glasgow*

The 6th IPCC Assessment Report (AR6) projects sea-level rise between ~0.5 and 0.9 metres by 2100. However, when ice sheet instability effects are considered, this figure may rise to near 2 metres. The deep uncertainties relating to marine ice sheet instabilities stem from a lack of long-term observations. Palaeo-ice streams and large marine-terminating glaciers provide long-term observations via their now-exposed sediment and landform record. IPCC AR6 identifies only two unambiguous examples of palaeo-ice streams which have undergone marine ice stream instability, one of which is the Minch ice stream (MnIS), NW Scotland. The MnIS drained much of the northern sector the last British-Irish Ice Sheet, before undergoing dynamic retreat and possible collapse. This research presents a new chronology from AMS radiocarbon (^{14}C) dates to constrain initial ice-stream retreat and subsequent collapse. This research also employs an innovative multi-proxy approach. This approach combines traditional marine geological techniques – including sediment strength, ice-rafted debris (IRD) grain counting (>2mm), particle size analysis <2 mm (using a Beckmann-Coulter LS230) and foraminifera identification – supplemented by more novel methods, including automated X-ray computed-laminography sediment characterisation and lipid biomarker analyses. The findings focus on the relative roles of climate-driven vs internally driven dynamics in triggering ice-stream collapse and the subsequent nature of this retreat. This work will also help to determine the relative impacts of ice-shelf presence / removal, sea-surface warming, air temperatures and bed topography in (de)stabilising the MnIS before its ultimate disappearance.

Glacial geomorphological mapping of a complex ice-marginal landscape in West Cumbria, UK

Ms. Sinead Birks [1]***, Dr. Christopher Coleman*** [2]***, Dr. James Lawrence*** [1]

1. Imperial College London, 2. Jacobs

West Cumbria in the north-west of England is located in a former ice confluence zone of the last British-Irish Ice Sheet (BIIS). The confluence of Irish Sea Ice Stream (ISIS), local Lake District glaciers and Scottish ice resulted in a geomorphologically complex ice-marginal landscape along the coastal plain. Previous glacial geomorphological investigations in West Cumbria have focused on the needs and requirements of the site descriptive models at the local nuclear licenced sites (Sellafield and Low Level Waste Repository (LLWR)) to support their respective environmental safety cases. This has mainly focused on developing a regional lithostratigraphy and 3D geological models from Quaternary sediments. The focus on the nuclear industry has resulted in limited research on the glacial geomorphology and the dynamics, patterns, and processes of the BIIS in this area.

Presented is a glacial geomorphological map of West Cumbria covering an area of approximately 100 km^2. Remote mapping was carried out using LiDAR derived digital elevation and terrain models (DEMs/DTMs), combined with optical satellite imagery. This was supported by field mapping and sedimentological analysis to provide a holistic assessment of the geomorphology. This has resulted in a wide range of new glacial and glaciolacustrine landforms being mapped including moraines, kames, kettle holes, proglacial lakes, and meltwater channels. The results have enabled the reconstruction of former ice marginal positions and potential confluence zones of the ISIS and Lake District glaciers during the last glacial events in West Cumbria. The map provides a geomorphological framework which can be used to support and improve the understanding of current and future 3D geological models of West Cumbria.

Greenland Ice Sheet retreat during the Holocene from the mapping of ice marginal landforms

Ms. Carla Huynh [1]***, Prof. chris clark*** [2]***, Dr. Tancrede Leger*** [2]***, Dr. Jeremy Ely*** [2]***, Dr. Sarah L Bradley*** [2]***, Ms. Sharman Jones*** [3]

***1.** University of Edinburgh, **2.** Department of Geography, University of Sheffield, **3.** Aberystwyth University*

Understanding past ice sheet retreat is important for constraining numerical models to project future sea level rise contributions. We present the first landform-based empirical reconstruction of Greenland Ice Sheet retreat during the Holocene. Using the 2-metre resolution ArcticDEM, 271,799 terrestrial landforms have been mapped, covering most of the ice-free land around Greenland's periphery. The timing of ice marginal retreat was constrained using published geochronometric dates to produce an ice sheet-wide margin reconstruction from 13 ka to 6 ka. This reconstruction is the highest resolution GrIS-wide chronology and will be used to constrain an ice sheet model.

The morphology, bathymetry and stratigraphic architecture of the Northeast Greenland Ice Stream pinning point in outer 79N fjord.

Prof. David Roberts [1], ***Prof. Colm O'Cofaigh*** [1], ***Prof. Jeremy Lloyd*** [1], ***Dr. S. Louise Callard*** [2], ***Dr. Catalina Gebhardt*** [3], ***Dr. Boris Dorschel*** [4], ***Dr. Torsten Kanszow*** [3]

1. Durham University, 2. University of Newcastle, 3. Alfred Wegener Institute Helmholtz-Centre for Polar and Marine Research, 4. AWI - Alfred Wegener Institute for polar and marine research

Pinning points and ice shelves are critical components in determining the stability of marine terminating outlet glaciers and ice streams. In the Arctic and around Greenland ice shelves and tongues are becoming scarce as accelerated thinning due to surface mass balance change and sub-shelf ocean warming drive buoyant lift-off and ice shelf disintegration. Yet the nature of the physical interaction between ice shelves and pinning points, or how such environments evolve in relation to bed architecture, bathymetry and ocean circulation is under researched. Here we explore the morphology, geometry and sedimentary architecture of Bloch Nunatakker (BN), a pinning point which has served as both an anchor point for the Northeast Greenland Ice Stream (NEGIS) grounding line during deglaciation, as well as a shallow pinning point for the edge of the Little Ice Age/contemporary ice shelf in front of 79N fjord.

The large- scale geometry of the BN pinning point complex is controlled by a tectonic shear margin and intrusive complex composed of dolerite swarms. The bathymetry varies from ~50 m to 500m bsl and the seafloor terrain is composed of undulatory bedrock topography draped and infilled predominantly by deglacial phase glaciomarine and marine sediments. Multibeam and sub-bottom profile data clearly show areas of subglacial areal scour and streamlining, grounding zone wedges and moraines. The sedimentary architecture can be categorized into five distinct acoustic facies with bedrock, stratified basinal infills, deformed sedimentary sequences, subaqueous debris flows and postglacial sub-shelf and aeolian sources all contributing to the unique architecture of this pinning point.

The disappearance of the 79N grounding line and ice shelf at the opening of the Holocene due to increased air and ocean temperatures will be mirrored in the near future as the Arctic region warms. The BN pinning point and the adjacent fjord walls will provide some continued marginal stability for the ice shelf, but this region of the seafloor is unlikely to provide ice shelf stability in future decades.

Insights into the glaciodynamic conditions of subglacial bedform formation from model-data comparison

Mr. Remy Veness [1], ***Prof. chris clark*** [1], ***Dr. Jeremy Ely*** [1], ***Ms. Rosie Archer*** [1]

1. *Department of Geography, University of Sheffield*

Subglacial bedforms (drumlins, ribbed moraines and mega-scale glacial lineations (MSGL)) are abundant across deglaciated terrain. The glaciological conditions under which they form remain poorly understood. This arises from the following conundrum. Subglacial bedforms are difficult to image beneath contemporary ice sheets, meaning we have few observations of them actively evolving. Conversely, in palaeo-landscapes there are a plethora of subglacial bedforms which are more easily accessed, but the ice that formed them is no longer present to link specific conditions to.

In this work, we constrain the conditions of subglacial bedform formation, by utilising a rich palaeo drumlin record in Britain and Ireland, coupled with a well constrained numerical model of the last British Irish Ice Sheet (BIIS). We use this ice sheet model as a substitute for observations of ice conditions and ask under what conditions do bedforms arise? However, linking the model timing to that of drumlin formation is complex. To achieve this, we conducted statistical model-data comparison, analysing 200 numerical simulations of the BIIS between 32 and 15 ka. We quantitatively compare the geometry of modelled ice flow against directions inscribed in 120 drumlin fields, 20 ribbed moraine fields, and all recorded MSGL, to identify potential phases of ice sheet evolution under which the drumlins were formed. We then extract the glacial conditions (e.g. velocity, thickness, shear stress and timing) corresponding to the potential landforming events.

We find that bedforms do not relate directly to a specific ice velocity, thicknesses, or shear stress ranges but instead, their development appears to best match with the cumulative basal velocity. In other words the quantity of ice that directly moves over a point on the glacier bed is the main factor we observe to control landform development. Furthermore we find evidence to suggest landform length may be a result of increased cumulative velocity.

Spatialized investigation of subglacial bedform evolution and bed deformation unravels ice-meltwater-bed interactions

Mr. Jean Vérité [1]***, Dr. Edouard Ravier*** [1]***, Dr. Olivier Bourgeois*** [2]***, Mr. Paul Bessin*** [1]***, Mr. Stéphane Pochat*** [2]***, Mr. Régis Mourgues*** [1]

1. *Laboratoire de Planétologie et Géosciences, UMR 6112, CNRS, Le Mans Université, Avenue Olivier Messiaen, 72085 Le Mans CEDEX 9,* **2.** *Laboratoire de Planétologie et Géosciences, UMR 6112, CNRS, Nantes Université, 2 rue de la Houssinière, BP 92208, 44322 Nantes CEDEX 3*

While they probably represent the most relevant proxies for reconstructing ice-meltwater-bed interactions and ice sheet dynamics, the formation and evolution of subglacial bedforms is nowadays made difficult by the inability to monitor active bedforming processes at high temporal and spatial resolutions. Based on an unprecedented data compilation (~250 000 bedforms) and new morphometric indices we revisit the theory and significance of the subglacial bedform continuum to propose a new model correlating the degree of bedform evolution with the quantity and direction of deformation accommodated by the subglacial bed. We build high-resolution maps of subglacial bed deformation to explore the complex ice-meltwater-bed interactions and unravel the role of ice flow velocity, bed deformability and meltwater routes in bedforming processes. The model and method we propose contribute to perform field-based palaeoglaciological reconstructions of ice domes, ice streams, sticky spots and subglacial drainage routes with unprecedented resolution.

Who is who in the glacial forefield: a macro-fabric based classification of glacial landforms

Mr. Christoph Kettler [1], *Dr. Jürgen Reitner* [1], *Prof. Daniel Le Heron* [2]

1. Geological Survey of Austria, 2. Department of Geology, University of Vienna

Modern day glaciated areas pose as a sandbox model for the description and interpretation of glaciogenic landforms, where cause and effect are well constrained and understood. The description of glaciogenic landforms- or features are usually based on the lithofacies (e.g. diamicton, graded sand, etc.) or on sedimentological processes (e.g. meltout till, push moraine). Certainly, this procedure is well established and suitable when dealing with recent landforms. When it comes to ancient glacially associated deposits or former glaciated areas that are isolated or the general context is vague, interpretation can be difficult or ambiguous. Apart from lithofacies and sedimentological properties, the arrangement and orientation of clasts and glacial debris can be used to classify distinct morphotypes that occur in a glacial setting. For this purpose, we studied ice parallel-, orthogonal- and joint landforms as well as amalgamated deposits in the proximity and direct ice contact of the retreating Gepatsch glacier and Mittelberg glacier in Tyrol, Austria that were analysed according to their clast macro fabric. Based on the data of the spatial distribution and orientation of clasts that are extracted from virtual outcrop models, UAV surveys and classical fieldwork approaches, the analysed features differ significantly according to their fabric patterns and allow a classification supporting the existing terminology that helps to provide an alternative for the understanding of glaciogenic landforms.

Three-dimensional micro-tomography characterisation of fractures in subglacial traction till – towards a holistic understanding of a key variable in engineering geology and hydrogeology

Subglacial traction till (STT) and related sediments cover over 30% of the Earth's surface and are crucial to our endeavours of building safe infrastructure and extracting clean groundwater. However, due to the large variability in, and seeming unpredictability of, the properties of STT across formerly-glaciated areas, including much of Europe, assessments of ground stability and water conductivity have regularly faced more extreme challenges than sediments deposited by other earth-surface processes. We here present the synthesis of four years of research dedicated to solving a crucial element of this puzzle, namely the role of microscale and macroscale cracks (or fissures and fractures, FF) in STT. While such fractures have been described before, they have never been analysed systematically. Our combined and interdisciplinary approach of macroscale and microscale structural measurements (using modern glaciers in the European Alps and Arctic Sweden and combining this with formerly-glaciated areas in northern Europe) aim to shed light on the role of these enigmatic features. We here present the results of macroscale sedimentological methods (e.g. clast fabric, novel structural measurements of fractures and fissures) alongside engineering geological applications such as X-ray micro-tomography analyses and triaxial load-cell analyses as well as hydrogeological field and laboratory tracer experiments.

Together, these demonstrate that FFs are crucial conduits of groundwater and preferential loci for sediment failure, thereby providing the main predictor of ground (in)stability.

Two clear findings emerge: Firstly, FF patterns are not randomly oriented as hitherto thought, but clearly linked to glacier dynamics (e.g. thermal regime and flow path). Secondly, FF are clearly and systematically linked at micro- and macroscale. We will explore the implications of these highly encouraging findings in this contribution from both pure and applied aspects for the first time here.

Internal composition of glacial curvilineations in NW Poland constrains their origin as erosional remnants of channelized meltwater flows

Dr. Piotr Hermanowski [1], ***Prof. Jan Piotrowski*** [2]

***1.** Institute of Geology, Adam Mickiewicz University, Poznań, **2.** Department of Geoscience, Aarhus University*

Glacial curvilineations (GCLs) were first identified in 2010 in northern Poland and since then they have been documented in numerous other regions overridden by the Scandinavian and Laurentide ice sheets. The origin of GCLs attracts a lot of attention as it sheds light at the subglacial processes and informs our understanding of glacial sediment transport and deposition. So far two contrasting hypotheses of GCLs formation have been formulated: (1) by channelized subglacial meltwater erosion and (2) by bank failures at the edge of tunnel valleys or subglacial lakes.

In this study we investigated geomorphology and internal composition of GCLs in one of the largest drumlin fields in the Central European Lowland, aiming to decipher the mechanism of their formation. Specifically, LiDAR data were used for the geomorphological analysis, and the internal composition was investigated in five trenches at the GCLs' crests and at the adjacent till plain. The area has a distinct NNW-SSE geomorphic trend given by the orientation of drumlins and mega-scale glacial lineations whereas the most prominent geomorphic element, a tunnel valley hosting the GCLs, is oriented NE-SW. All excavated trenches expose massive, matrix-supported diamictons interpreted as subglacial traction till and characterized by distinctly uniform clast fabrics not related to the orientation of the GCLs.

Overall, our data show that the GCLs and the neighbouring till plain are parts of a common antecedent landsystem. No evidence of gravitational sliding from the flanks of the tunnel valley was found. The GCLs are interpreted as erosional remnants of an older landscape carved by channelized subglacial meltwater flows.

The development of low-lying coastal cirques during the transitional phase of the Scandinavian Ice Sheet

Dr. Rachel Oien [1], ***Dr. Iestyn Barr*** [2], ***Prof. Brice Rea*** [3], ***Prof. Matteo Spagnolo*** [3]

1. *University at Buffalo, NY,* ***2.*** *Manchester Metropolitan University,* ***3.*** *School of Geosciences, University of Aberdeen, Aberdeen, UK*

It is well established that during the Quaternary Scandinavia experienced a wide variety of climates from warm, similar to present-day conditions, to full-scale ice sheet inundation during glacial maxima. Under these varying conditions, there would have been periods when all of the high alpine areas would have been covered by an ice sheet or ice cap and cirque glaciers could only have been found in low-lying coastal environments beyond the ice sheet margins.

In the northern part of Scandinavia near the Lofoten islands, 67.5-69.5°N 1732 cirques have been identified, with over 55% lying below 500 m a.s.l. Due to the large number of low-lying cirques, particularly along the coast, they most likely required a cold climate such that a substantial Scandinavian ice cap/ice sheet existed and was probably proximal to them. Therefore, the low-lying coastal cirques must have been occupied by "active" glacial ice just before and just after glacial maxima, compared to the high elevation cirques inland which must have been occupied by "active" glacial ice comparatively early and late during a glacial cycle. While the high-elevation cirques will have been glaciated for much longer it is unclear how long cirques in each location hosted "active" cirque modifying ice. We have identified and mapped 1004 cirques that are proximal to and beyond the YD ice sheet limits and 728 cirques located inside the extent of the YD margin. A statistical comparison between the low-lying coastal cirques, proximal to the ice sheet margin, and the high elevation inland cirques, of various cirque metrics (e.g. slope and aspect), is undertaken in order to elucidate if the low-lying cirques differ from the high elevation cirques. If so can this can be attributed to the duration of active ice occupation or the difference in ice flux or the role of non-glacial processes that were active for most of the glaciation in the low-lying cirques, while the high elevation cirques were covered by cold-based ice. It is hoped that this study can further understanding of glacial landscape evolution in relation to ice sheet geometries i.e. proximal to the ice margin or the ice divide.

Late Pleistocene cirque glaciation in the Simien Mountains, Ethiopia

Dr. Clare Boston [1], ***Prof. Tim Barrows*** [2], ***Dr. Harold Lovell*** [1], ***Dr. Stephanie Mills*** [2], ***Dr. Nick Pepin*** [1]

1. *University of Portsmouth,* ***2.*** *School of Earth, Atmospheric and Life Sciences, The University of Wollongong, Wollongong, NSW 2522, Australia*

High-mountain tropical glaciers have been receding significantly in recent decades as a result of either rising temperature or falling precipitation. The sensitivity of these glaciers to changes in temperature and precipitation is spatially variable and depends on their location within the tropics and height above the 0° C isotherm. In tropical East Africa, Late Pleistocene glaciation was restricted to mountain ranges in Ethiopia, Kenya, Tanzania and Uganda. Regional differences in the timing of glacier advance and recession have previously been linked to differences in glacier sensitivity and variability in climatic conditions across these mountain ranges. To better understand the magnitude of climate change and its cause, we investigate Late Pleistocene glaciation in the Simien Mountains, Ethiopia. We present glacier reconstructions, ELA estimates and new ^{36}Cl ages on moraines. We find evidence for at least two stages of glaciation within the last glacial cycle, with initial ELA estimates between 4000 m and 4200 m asl. The results are compared with other sites across East Africa with respect to timing and glacier sensitivities.

Megaflood and GLOF research opportunities – a personal perspective

Prof. Paul A. Carling [1]

1. *University of Southampton*

A focus on adaptation to anthropogenic climate change and the effects on the global hydrological cycle, not least glacial recession worldwide, has led to a burgeoning interest in glacial lake outburst floods. For example, the number of scientific papers citing the terms 'megaflood', 'catastrophic flood' or 'glacial lake outburst flood' (GLOF) in the titles has more than doubled in the last decade. Research outputs relate to recent GLOFs, as well as the identification of prehistoric exceptional floods, many dating to the Pleistocene termination. Former dam sites and the associated sedimentary sequences relate to exceptional floods worldwide. Notable has been the acceleration of research on sites in China and South America, as well as across Europe. Case studies, identifying flood landforms, modelling floodwave evolution, and the descriptions of sedimentary sequences from the field, provide repositories of data and interpretation which will aid future investigations. Yet, studies focussed on key generic issues remain relatively few. This presentation will provide an appraisal of progress and highlight opportunities for future research which might provide an improved framework within which to interpret case studies.

Session 35: Dust dynamics through the Quaternary: terrestrial records of climatic and environmental impacts

Quaternary dust size variability in Antarctica: a proxy for air mass subsidence?

Prof. Barbara Delmonte [1], ***Prof. Valter Maggi*** [1], ***Prof. Marco Potenza*** [2]

***1.** University of Milano-Bicocca, **2.** University of Milan*

Mineral dust windblown from continental landmasses of the Southern Hemisphere to Antarctica and buried in snow and ice layers represents a key paleo-environmental and paleo-atmospheric proxy that can be studied within shallow and deep ice cores. Here we provide a comprehensive overview of the state of knowledge of Quaternary dust provenance and variability in Antarctica. In particular, we focus on the use of mineral dust grain size oscillations at different timescales as a paleo-atmospheric circulation proxy. Its relationship with the Southern Westerlies and with local subsidence of air masses is discussed in the light of new data from present-day measurements in the atmosphere above Concordia Station (East Antarctica), where a novel optical system (OPTAIR) capable of operating under extreme climate conditions was installed in 2018 in order to investigate year-round the atmospheric dust transport and its optical properties.

Atmospheric dust transport to high-elevation Dronning Maud Land, Antarctica, over the satellite era as observed in a seasonally-resolved ice core record of dust deposition

Mr. Kevin Henson [1]***, Dr. V Holly L Winton*** [1]***, Dr. Kyle Clem*** [2]***, Dr. Markus Frey*** [3]***, Dr. Robert Mulvaney*** [3]

1. *Antarctic Research Centre, Victoria University of Wellington,* ***2.*** *School of Geography, Environment and Earth Sciences, Victoria University of Wellington,* ***3.*** *British Antarctic Survey (BAS), Natural Environmental Research Council (NERC), High Cross, Madingley Road, Cambridge CB3 0ET, UK.*

Deposition of aeolian mineral dust recorded in Antarctic ice cores is associated with large-scale atmospheric circulation variability. This natural archive can therefore be used to extend knowledge about atmospheric circulation variability in the Southern Hemisphere prior to the satellite era (1979-2017). However, relationships between dust transport and circulation patterns vary regionally across Antarctica. Reliable atmospheric reanalysis datasets over the satellite era are thus crucial for identifying these regional relationships to interpret past dust records and infer past changes in the large-scale circulation.

This study investigates dust transport to high-elevation Dronning Maud Land (DML), Antarctica, through analysis of dust deposition recorded in a new 1300-year ice core recently drilled at Kohnen Station (75°00'S, 0°04'E; 2982 m.a.s.l.) as part of the Isotopic Constraints on Past Ozone Layer in Polar Ice (ISOL-ICE) program. The dust record is examined together with present-day dust transport simulations to the ISOL-ICE ice core site using the Flexpart model, and correlation analysis with atmospheric reanalysis data over the satellite era. An abrupt increase in dust deposition and particle size is observed in the ice core from 1915 to 1930 CE, translating to a 10-fold increase in dust flux and a 12 % increase in the proportion of coarse particles (2-5 μm / 0.9-5 μm) compared to the respective pre-1915 means. Interannual correlations from 1979-2017 between the proportion of coarse particles and atmospheric geopotential height show that cyclonic activity south of South America is an important mechanism by which dust is transported from southern South America (SSA) to high-elevation DML, explaining up to 36 % of variability in dust deposition at the ice core site. Dust transport modeling simulates dust trajectories consistent with cyclonic wind flow in the SSA region, suggesting that SSA as the dominant dust source region for high-elevation DML has not changed significantly since the Last Glacial Maximum based on comparison with previous ice core studies. Furthermore, horizontal dust trajectories are insensitive to particle size, seasonality, and transport height. These findings over the satellite era provide foundational work for interpreting the ISOL-ICE ice core dust record over the last century and beyond.

Late-Pleistocene Paleodust Records from the Guliya Ice Cap (Northwestern Tibet)

Dr. Emilie Beaudon [1], ***Prof. Elizabeth Griffith*** [1], ***Dr. Julia Sheets*** [1], ***Prof. Howie Scher*** [2], ***Prof. Michael Bizimis*** [2], ***Dr. Jim Sexton*** [2], ***Prof. Ellen Mosley-Thompson*** [1], ***Prof. Lonnie Thompson*** [3]

1. The Ohio State University, 2. University of South Carolina, 3. The Ohio State Universtiy

Pre-Holocene data are too sparse to constrain the composition of aerosols in climate models for the remote inner Asian continent despite that it is Earth's second largest source area for dust. To reduce climate model uncertainties pertaining to mineral aerosols' feedbacks on radiative forcing, this study provides the first datasets of the mineralogical and geochemical composition of aeolian dust preserved in two Guliya ice cores (Kunlun Mountains, Tibet, China). The dust composition is used to trace its geographical source and infer past environmental changes and changing atmospheric influences on the NW Tibetan Plateau. The sensitivity of the Westerlies and the Indian Monsoon system which are associated with abrupt changes in the chemical signatures of the dust is assessed.

The mineralogical, elemental, and Sr-Nd radiogenic signatures of the aeolian dust particles sampled along the two Guliya ice cores are characterized to identify the dust lithological and geographical sources, trace the long-term variability of paleo-hydro-climatic conditions prevailing in NW Tibet, and provide theoretical knowledge on how Holocene paleoenvironmental records are entrained into the ice at the Guliya summit site compared to that at the Guliya plateau site.

Late Pleistocene Sr-Nd isotopes time series extracted from the two Guliya drilling sites are presented. A particular focus is placed on the changing composition of dust through stadial/interstadial transitions recorded in the Guliya core, and on the different stratigraphic features visible in the ice (including the grey clay layers in the oldest part of the record). The results are interpreted in light of the composition of new Potential Source Area (PSA) samples and on previously published regional loess records.

High-resolution palaeodust archive from subantarctic Macquarie Island

Atmospheric mineral dust drives climate variability through its influence on radiative forcing, cloud properties, and precipitation. Additionally, dust deposition can drive primary productivity and subsequent drawdown of atmospheric carbon by providing nutrients to ecosystems. Inputs of Australian dust may be especially critical in the nutrient-limited ecosystems of the South Pacific Southern Ocean and subantarctic islands. This study seeks to understand dust flux to Macquarie Island and the potential response of plants to changing dust inputs. Our high-resolution palaeodust flux reconstruction is the first from Macquarie Island peat and provides insight into dust transport in the South Pacific Southern Ocean through the mid-Holocene.

We selected a 290 cm peat core collected from the North Head of Macquarie Island, as peat plants can effectively capture dust and preserve the dust signal in the peat column. Data from ^{210}Pb and radiocarbon dating techniques, with additional age-control provided by the anthropogenic ^{239,240}Pu peak, inform the Bayesian age-depth model created using rPlum. Peat accumulation rates vary through the core, with the deepest 70 cm of core, 5247 to 4295 calibrated years before Present (cal. yr BP), showing the highest accumulation rate, 0.07 cm yr^{-1}, indicating that Macquarie Island may have experienced a mid-Holocene warm period.

We reconstructed the flux of long-range mineral dust with elemental data from x-ray fluorescence (XRF) and inductively coupled plasma mass spectrometry (ICP-MS). Dust flux is indicated by excursions in the XRF ratio of aluminium to titanium, which rises significantly above the median seven times through the core, four times from 3000 to 4600 cal. yr BP, and three times in the most recent 800 years. Al/Ti remains high for 20-60 years before returning to baseline conditions, possibly indicating changes in regional synoptic conditions. Additionally, high Al/Ti occurs concurrently with a high percentage of organic content, found by igniting sub-samples at 500 °C overnight. The correlation between dust inputs and organic content may indicate an enhanced biological response to nutrients provided by dust or changes in peat decomposition. We use Fourier-transform infrared spectroscopy (FTIR) to characterise organic matter decomposition and elucidate the effects of dust input in the peat archive.

Atmospheric dust variability over the last 3000 years inferred from an ombrotrophic peatland in southwestern Patagonia

Peat bogs are remarkable paleoclimatic archives in the sense that they record past environmental and climatic change in terrestrial regions that are usually lacking in paleoclimatic reconstructions. They are, however, usually limited to the Holocene, as most wetlands began forming during or after the last deglaciation. In addition, the reconstruction of past climatic changes is complicated by the transition from ombrotrophic to minerotrophic sections, which limits the interpretation of the lower and older sections of retrieved peat cores. However, the abundance of organic material allows well constrained age models, and paleoclimatic proxy variability in the ombrotrophic section is usually thought to be representative of atmospheric changes. In peat cores, dust concentrations can be calculated using the measurement geochemical element concentrations, while dust sizes can be measured by analyzing grain sizes of the inorganic material. Such measurements allow inferences on the variability of past atmospheric dust concentrations, and indirectly on wind, precipitation, and general paleoenvironmental changes. Here, we present the paleodust deposition record from the upper 150 cm of a peat core from Rio Rubens, located in Patagonia in Southern Chile. The section comprises an ombrothrophic section of 100 cm. We present elemental and total mass dust deposition fluxes over the past 3000 years, and describe centennial and millennial variability in the record. We compare our results with centennial and millennial scale variability recorded in pollen data from other sites in the region, and highlight links with previously defined SAM-like multicentennial phases, and recent anthropogenic influence. We complement our multiproxy regional analysis with dust grain size analyses from the same core, obtained by calibrating a multilinear model using elemental concentrations as predictors.

Examining dust emissions from Australia’s largest lake, Kati Thanda-Lake Eyre (KT-LE) over the past glacial cycle: Do net-deflation events represent the largest dust pulses and has dust export reshaped the bathymetry of KT-LE over the last glacial cycle?

Dr. Sam Marx [1], *Dr. Tim Cohen* [2], *Dr. Jan-Hendrik May* [3], *Prof. Lee Arnold* [4]

1. GeoQuEST Research Centre, School of Earth, Atmosphere and Life Sciences, The University of Wollongong, Australia, 2. School of Geography, Earth and Atmospheric Sciences, The University of Melbourne, 4. School of Physical Sciences, Institute for Photonics and Advanced Sensing (IPAS), And Environment Institute, University of Adelaide

Globally dust ‘hot spots’, individual geomorphic settings, such ephemeral lakes, represent the largest dust sources. In Australia, the lower Kati Thanda-Lake Eyre (KT-LE) Basin, including KT-LE itself, is the major contemporary dust source. Distal records, downwind of Australia, show high variability in dust flux over the past 35 kyr, ascribed largely to hydro-climate variability (Marx et al., 2018, 2022). Palaeo-shorelines at KT-LE indicate pronounced variability over the past glacial cycle, particularly after 48 ka when the lake dramatically dried (Cohen et al., 2015). Dry periods, interpreted from lake-proximal deposits, have previously been linked to net-dust deflation events (major dust emission episodes), potentially altering the bathymetry of KT-LE (Magee et al., 1995). Recent detailed revaluation of the iconic Williams Point sequence allows net-dust deflation events to be re-examined (Cohen et al., 2022). Redating provides little clear support for net-dust deflation events before the last glacial cycle. However, exposure of lacustrine sediment in cliffs above the modern playa floor and deposition of a lake-proximal aeolian unit (the Williams Point Aeolian Unit) imply a major net-dust deflation event sometime after 50 ka. Critically, this event is not recorded in distal dust records. By contrast, a later dust episode, broadly coinciding with (although extending beyond) the Last Glacial Maximum (LGM), is recorded in both distal and proximal records. Overall, it remains unclear if either event resulted in widespread surface lowering at KT-LE and the jury is out as to whether KT-LE experienced transformative net-deflation events. Similarly, it remains uncertain whether KT-LE operated as a dust hotspot before the LGM/Holocene, with results implying a wider landscape contribution is required to produce Australia’s largest dust pulses (Marx et al., 2022).

The North African desert margin is under the influence of the dry Saharan and the wet Atlantic and Mediterranean air masses. It is one of the areas most sensitive to the ongoing climate change. Models predict a decrease of precipitation leading to hyper-aridity. However, uncertainties remain large with a predicted precipitation decrease ranging from -4.5 to -22.9% for the latest CMIP6 simulations. Better reconstructions and understanding of the mechanisms that drove past changes of air-mass trajectories under the Holocene warm conditions could help reduce these uncertainties.

We present new data from a sediment core recovered from Lake Sidi Ali (Middle Atlas, Morocco) aiming at reconstructing variations in dust provenance using radiogenic isotopes (Lead (Pb), Neodymium (Nd), and Strontium (Sr)) on the <10µm detrital fraction of the sediment. The Pb, Nd and Sr isotopic compositions variations are coherent over the Holocene. In particular, there is a marked variation centered around 8.2 ka. Between ca. 7.5 and 4.5 ka the Nd (Pb and Sr) isotope ratios decrease (increase), then values are more stable. Using the radiogenic isotopes, we show that local inputs from the recent and highly erodible Moroccan volcanism are negligible in the fine fraction of the sediment. We also show that, although considered a major North African dust source, the Bodélé depression does not contribute to the Sidi Ali lake area. We have identified three potential dust contributors: the distal Mauritania-Senegal and the Southern Algeria-Northern Mali areas, and the more proximal Moroccan Atlas surface sediments.

The 8.2 ka abrupt event has been identified in numerous climate archives. At Lake Sidi Ali oxygen isotopes of ostracod valves and *Cedrus* pollen records both show significant changes around this event and have been attributed to enhanced spring rains compared to that of winter and cooler summers. The new radiogenic isotopes records show that a change in either dust provenance and/or the relative contribution of dust sources occurred at the same time. Hence, these results show that an abrupt change in air-mass circulation over the North African desert margin occurred around 8.2 ka.

The AO driven climate change from 3 ka to 2 ka detected by an 8000-year record of dust deposition in Lake Motosu, Mt. Fuji

East Asia is a major source region for dust emissions. According to the average of 15 aerosol models, dust emissions from East Asia (330 Tg yr^{-1}) is equivalent to approximately 20% of the global total (1800 Tg yr^{-1}). Clarification of past dust transport can highlight variations in Westerly wind strength and pathway, as well as in source region aridity. However, reconstructing past dust transport in East Asia is complicated by several factors. The low sedimentation rate in the Northwest Pacific (<1 cm/1000 yr) is inappropriate for millennial- to centennial-scale studies, and distinguishing aeolian and riverine sources in coastal settings is challenging. While previous work used quartz physical properties to successfully separate the two signals, the obtained record is subject to relatively high chronological uncertainty.

Here, we use quantitative X-ray diffraction to determine quartz percentage, while leveraging the favorable conditions of Lake Motosu, to present the first chronologically well-constrained, high resolution dust transport record from the Pacific sector of Japan. Because the extremely small catchment provides no local source of quartz particles to Lake Motosu sediments, the record reflects East Asian dust transport, and with a ~0.5 mm/yr sedimentation rate, the high-quality age model is capable of resolving perhaps even decadal-scale deposition variability.

Despite the relatively stable Holocene climate, the Lake Motosu dust record reveals variable transport processes during the past 8000 years. Specifically, the amount of dust deposition is reduced from 3 to 2 ka. This low dust deposition event corresponds to elevated sea surface temperature in the Japan Sea and negative Arctic Oscillation (AO) phase. This suggests that these changes are associated with weakened Westerlies and with less frequent dust storms in the source region driven by negative AO phase. Moreover, a negative AO from 3 ka to 2 ka was coupled with the decreased North Atlantic Oscillation phase, which is strongly related to AO. Thus, detected climate change in East Asia is potentially linked to hemispheric scale climate change.

Holocene Dust Deposition in the western and central Pyrenees: The Arxuri peatbog and the Marboré and Arrablo lakes records

Dr. Blas Valero-Garcés [1]***, Dr. Juan Pablo Corella*** [2]***, Dr. Maria Pilar Mata Campo*** [3]***, Mr. Marcel Galofré*** [1]***, Dr. David Elustondo*** [4]***, Mr. Francisco Javier Martín Rodríguez*** [5]***, Dr. Jorge Pey*** [6]

__1.__ Consejo Superior de Investigaciones Científicas, Instituto Pirenaico de Ecologia, __2.__ CIEMAT, Departamento de Medio Ambiente, __3.__ IGME, __4.__ Instituto de Biodiversidad y Medio Ambiente (BIOMA), Universidad de Navarra, __5.__ Universidad de Granada, Instituto Andaluz de Ciencias de la Tierra (CSIC-UGR), 18071, Granada, __6.__ ARAID - Instituto Pirenaico de Ecología (CSIC)

Recent events have evidenced that most African dust input in the Iberian Peninsula occurs as wet deposition with the highest deposition rates in the Pyrenees. We investigate the input of Saharan dust in the western and central Pyrenees during the Holocene with multiproxy analyses of sediment cores from the Arxuri peatbog (497 m asl, western Pyrenees) and high altitude Marboré (2612 m a.s.l.) and Arrablo (2960 m a.s.l.) lakes in the central Pyrenees. We hypothesize that Holocene warmer periods were dustier and, consequently, we can expect more African dust in our atmosphere in the next future. The Arxuri sequence is composed of two older lacustrine units from early to mid-Holocene (< 9.5 ka BP) and an upper peat unit deposited during the last 3500 years. The Marboré sequence is composed of finely laminated silts and spans the last 14.6 ka. The Arrablo Lake is a newly formed lake and the sediment sequence spans a few decades. We use geochemical ratios (e.g, Fe/Ti) as indicators of Saharan dust input.

The Arxuri and Marboré sequences are coherent with regional dust records pointing to lower dust deposition during the early Holocene followed by enhanced dustiness during the mid and late Holocene after the end of the African Humid Period (ca. 7 - 4.5 ka BP). In Arxuri, decreased Fe/Ti ratios occurred during the Late Antiquity Little Ice Age (6^{th}-7^{th} centuries) and were relatively higher during the Roman Period and the last millennium, particularly during some phases of the Little Ice Age (15th-19^{th} centuries). In Marboré, during the last 2000 years, periods with relatively higher Fe/Ti are broadly synchronous with warmer phases: Iberian, Late Roman (4^{th}-5^{th} centuries), Medieval Climate Anomaly (10^{th}-13^{th} centuries) and early transition to the Little Ice Age and Recent Global Warming (mid-19^{th} century). In Arrablo, geochemical ratios suggest a recent increase in dust delivery, coherent with documented increasing dust transport towards the Western Mediterranean since mid 20^{th} century.

More geochemical, isotopic and biological proxies at higher resolution are in progress to better identify the sources and the relation to warmer periods in the past.

Lessons from recent dust storms for the paleoenvironmental interpretation of aeolian dust deposits: meridional Saharan dust transport towards higher latitudes

Lessons from recent dust storms for the paleoenvironmental interpretation of aeolian dust deposits: meridional Saharan dust transport towards higher latitudes
External dust addition to sedimentary sequences must be considered during paleoenvironmental reconstructions. However, delimiting areas of potential dust accumulation is quite problematic, but identifying the mineral dust particles and determining the extent of dust flux is even more difficult.
Here, we present some rather surprising results from recent long-range dust transport events, discussing the effects of current climate change and the issues of large dust particles.
In the context of paleoclimate reconstructions, it may be interesting to note that sometimes (1) much larger areas can be affected by dust deposition events; (2) not only the finest grain-size fractions are affected by dust addition (even >100 µm particles can travel several thousands of kilometres); and (3) the amount of dust deposited may be much larger than previously thought or indicated by numerical simulations.
Over the past decades, an increasing number of Saharan dust storm events have been identified across Europe, using satellite measurements and imagery, numerical simulation data, meteorological analyses, air mass back-trajectories and surface observations. Both the frequency and intensity of dust storm events have increased over the last decade.
Saharan dust reached the Carpathian Basin at least 250 times between 1979 and 2022. These episodes of intense dust deposition clearly showed the effect of the wavy jet stream patterns, leading to (1) extreme weather events and intense dust storms in the Atlas region and (2) increased atmospheric meridionality.
In order to identify such events, we started our research in Iceland, where we identified 15 Saharan dust storm events between 2008 and 2020, two of which were also surface sampled. Laboratory analyses of the sampled dust material revealed abundant quartz particles larger than 100 µm, indicating that large dust particles can sometimes travel thousands of kilometres. Similar research has been carried out in Finland, where we have also identified several (n>60) Saharan dust storm events from 1980 to 2022.
The research was funded by the NKFIH FK138692 project and National Multidisciplinary Laboratory for Climate Change, RRF-2.3.1-21-2021 project.

Enhanced understanding of large-scale Upper Pleistocene climatic and ecosystem changes through new Central European loess archives

Over the last glacial period North Atlantic climate forcing and variability is well documented in high resolution marine and ice core records. The propagation and impact of millennial to centennial-scale climate fluctuations (e.g., Dansgaard-Oeschger events) onto the European continent are still not fully understood as terrestrial archives may be discontinuous and lacked precise and independent age models for a long time. Thus, robust correlations with other archives and proxies of global climate and environmental changes often remain challenging.

In this context, Loess-Paleosol-Sequences (LPS) represent outstanding terrestrial archives. Given their polygenetic character, however, enhanced understanding of geomorphological and pedogenic processes involved in LPS formation, and of the interplay with changes in environmental conditions, is required to maximize correlation with other archives. When achieved, LPS allow high-resolution reconstruction of paleoclimate and palaeoenvironmental changes on different spatial and temporal scales.

This contribution focuses on the Schwalbenberg LPS located in the Rhineland in western Central Europe, which provides one of the most complete, high-resolution record spanning the Last Glacial Cycle. Along a transect from the interfluve position to the foot slope we combined geophysical exploration with Direct Push geophysical measurements, sediment coring and sampling along exposed profile sections. Sedimentological and geochemical parameters are used to detect palaeoenvironmental and palaeoclimatic signals, allowing for a synthetic stratigraphic formation model for all Schwalbenberg LPS. We show that the transect approach allows quantification of different formation phases, whether accumulative, erosive or pedogenic in character. For the time interval from c. 80-15 ka correlation of combined lithostratigraphic features and organic carbon contents from Schwalbenberg with the Sofular and NGRIP δ^{18}O-records can be established at millennial to centennial scale resolution. In addition, high-resolution radiocarbon dating of earthworm calcite granules is used to refine and consolidate the Schwalbenberg LPS age model over the period ~ 50-20 cal kBP, independent from time-scales of other archives that the Schwalbenberg LPS can be correlated with.

Our results prove the sensitivity of western European LPS to Atlantic-driven climate oscillations in much more detail than in any other terrestrial archive known in the region so far and indicate large-scale synchronicity of detected climate signals.

The grain size of Pampean loess as a proxy of southern South American atmospheric circulation during the Last Glacial Maximum

***Ms. Renata Coppo* [1], *Ms. Victoria Nogués* [2], *Mr. Diego Montecino Jara* [3], *Dr. Gabriela Torre* [4], *Dr. Nicolás Cosentino* [5], *Ms. Veronica Tur* [1], *Dr. André Sawakuchi* [6], *Dr. Edinei Koester* [7], *Dr. Diego Gaiero* [3]**

The Pampean loess is the most extensive terrestrial paleo-dust deposit in the Southern Hemisphere and a distinctive geological archive that records changes in past atmospheric circulation. Recent studies reported luminescence ages, mass accumulation rates (MAR), and Nd and Sr isotopic composition on three late Pleistocene-early Holocene Pampean loess sections (Lozada, Tortugas, and Gorina). These studies found a very mixed isotopic signal for the <44- and <5-µm fractions, dominated by a Puna-Altiplano Plateau (PAP) signal. Additionally, past investigations have reported a multi-modal grain size distribution on these loess sections.

To disentangle the origin of the Pampean loess multi-modal distribution, we report here a grain size unmixing analysis of bulk fraction, along with new Nd-Sr data for the >44-µm grain size fraction, on the late Pleistocene-early Holocene 2-m profiles of the Lozada and Tortugas sections. Unmixing methods allow differentiating three grain-size subpopulations/end members (EM) in the Pampean loess. EM1, only present in Tortugas, is composed of very fine silt and clay (mode = 5.7 µm) and has been associated with background dust transported from distant sources such as the PAP (~1300 km). EM2 is composed of fine silt (Lozada mode = 10.1 µm, Tortugas mode = 14.6 µm) and has also been previously associated with the PAP. EM3 is composed of a coarse-to-very-coarse silt fraction (Lozada mode = 48.8 µm, Tortugas mode = 49.5 µm) previously interpreted as a short-range-transported fraction associated with proximal sources (i.e., South-Central Western Argentina and/or Northern Patagonia).

In line with these interpretations, Nd-Sr isotopic data indicate Northern Patagonia and/or South-Central Western Argentina as the principal sources contributing to the >44-µm fraction (i.e., EM3) and the PAP as the dominant source contributing to the <44- and <5-µm fractions (i.e., EM2 and EM1, respectively). Our results indicate that the multi-modal grain-size distribution observed in Lozada and Tortugas loess sections originated at least partially from the contribution of multiple dust sources.

Further investigations should concentrate on understanding the temporal variability of the different source contributions and EM abundances, and their implications on the atmospheric circulation of southern South America.

Locally recycled late Pleistocene loess feeds modern dust storms at the desert margins of the eastern Mediterranean, Israel

***Mr. Ohad Shalom* [1], *Dr. Onn Crouvi* [2], *Prof. Yehouda Enzel* [1], *Prof. Daniel Rosenfeld* [1]**

__1.__ Institute of Earth Sciences, The Hebrew University of Jerusalem, __2.__ Geological Survey of Israel

Current dust storms, originating from afar, are common in Israel and the eastern Mediterranean, and thus most dust sources are considered to be distal. However, recent studies suggest that the latest Quaternary loess accreted in the Northern Negev can also serve as a proximal source of dust. These sources were mostly neglected in past discussions as contributors of dust. Here, we demonstrate that such proximal dust sources, mostly the Negev loess, currently contribute relatively large amounts of recycled dust to the regional dust cycle. We conducted a sampling campaign of deposited dust during individual dust storms and identified high content of coarse silt grains and quartzo-feldspathic minerals within and adjacent to the Negev loess that gradually decreases

toward the north. These grains, characteristics of the Negev loess, indicate a short transport distance. In addition, our data reveal that local wind speed is the limiting factor for emitting proximal dust, regardless of the synoptic system. We determined that proximal sources in Israel emit dust during either local events or as a part of regional dust storms originating from afar. We evaluate the minimal contribution of this proximal dust to the total mass of deposited dust as 58–74%, 54–70%, 52–64%, and 26–34% for the northern Negev, central Negev, central mountainous region, and northern Israel, respectively. These estimates indicate that at the desert fringe, both proximal and distal sources of dust should be considered when inferring dust sources from dust geochemistry that can sometimes be similar due to the long dust history.

A New Approach to Dust Deposition Fluxes over the Southern Ocean from Seafloor Surface Sediments and Dust Grain Size

***Dr. Michelle van der Does* [1], Dr. Frank Lamy [1], Dr. Stephan Krätschmer [1], Prof. Jan-Berend Stuut [2], Dr. Christoph Völker [1], Dr. Martin Werner [1], Dr. Gisela Winckler [3]**

Mineral dust is a major component of sediment input to the remote open ocean. About ten percent of all global dust emissions comes from Southern Hemisphere sources, and is important for (iron) fertilisation in the Southern Ocean. The main Southern Hemisphere sources include South America, southern Africa, Australia and New Zealand, but also inter-hemispheric transport from the Northern Hemisphere. In the South Atlantic, the majority of the total dust deposition originates from South American sources. However, in-situ measurements of dust deposition over the Southern Hemisphere oceans are scarce and there is a great need for an expanded geographical coverage of direct observations of dust deposition.

^{230}Th-normalised ^{232}Th deposition fluxes for lithogenic input are an important proxy for dust deposition. In areas with additional sources of lithogenic input, such as fluvial and hemipelagic sediments, ice-rafted debris (IRD), and (bottom)current-transported sediments, the lithogenic flux will be an overestimation of the dust flux. Here, we present grain size data and ^{230}Th-normalised ^{232}Th deposition fluxes of seafloor surface sediments covering the entire South Atlantic Ocean. By using end-member modelling we aim to disentangle the dust signal from these other sediment sources to reveal dust grain size. Combing the dust end members with the ^{230}Th-normalised ^{232}Th fluxes reveals the specific dust deposition fluxes to the South Atlantic. These more accurate dust fluxes show what dust sources are most important for different regions of the South Atlantic. We also apply this method to sediments from other regions of the Southern Ocean to investigate its general application of determining dust fluxes for open ocean sediments. As a result, the data produced will be valuable to calibrate and validate model simulations.

Provenancing terrigenous material in deep-sea sediment cores from offshore northwestern Western and South Australia, using on-land observations to understand XRF-scanned data

Prof. Jan-Berend Stuut [1], ***Prof. Patrick De Deckker*** [2]

1. *NIOZ - Royal Netherlands Institute for Sea Research,* ***2.*** *ANU - Australian National University*

It is common practice nowadays to assess the provenance of land-derived sediments (airborne dust, fluvial mud or ice-rafted debris) in sediment cores from marine, lacustrine and peat-bog environments using XRF scanning, but commonly very little is known about the transport modes or source(s) of these terrigenous sediments. In this presentation, we demonstrate an approach taken to geochemically fingerprint a large set of sediments collected from aeolian and fluvial sources in both southeastern Australia and northern West Australia to compare these data with records obtained from XRF scanning on long deep-sea sediment cores (MD03-2607, recovered south of Kangaroo Island and MD00-2361 recovered off northern Western Australia). In this approach, we successfully compare the chemical composition of source materials using XRF scanning of individual samples and records of XRF scanned sediment cores. In addition, we use trace elemental ratios obtained by ICP-MS and compare results for the same samples on which XRF analyses were conducted for the Kangaroo Island core. Finally, by sampling modern and palaeo-fluvial and aeolian sediments in the source areas of the sediment core off northern Western Australia, we can determine the sediment-transport mechanisms that brought the sediments out to sea in order to infer changes in palaeo-environmental and palaeoclimatic conditions in these source regions.

Session 36: Conservation paleobiology: late Neogene to Quaternary records as a baseline for conservation of modern ecosystems

Baseline Caribbean

Dr. Aaron O'Dea* [1], Ms. Brigida De Gracia [1], Dr. Julia Briand [2], Dr. Maybelline Ureña [1], Dr. Jonathan Cybulski [1], Ms. Kimberly García-Méndez [1], Dr. Jessica Lueders-Dumont [1], Dr. Erin Dillon [1]

1. The Smithsonian Tropical Research Institute, 2. University of Alberta

Caribbean coral reefs have changed dramatically in living memory, but it remains unclear if they have transitioned into functionally 'novel' states. We set out to address this question by using fossils to reconstruct reef states and functions before human impact. We mapped and sampled several hectares of mid-Holocene reefs in Caribbean Panama and the Dominican Republic and compared their composition and ecological function to nearby modern reefs. We quantified the remains of all major reef groups, but focus here on molluscs, corals and fishes. On modern reefs, filter feeding molluscs are twice as abundant relative to other feeding modes than on mid-Holocene reefs, commensurate with increased eutrophication from land use changes. At the same time, large herbivorous gastropods declined significantly in size due to millennia of human selective harvesting. The abundances of coral species in samples document the well-established loss of Acroporid corals, and functional analyses show a shift in dominance toward weedier, slower growing, and brooding species. Some modern coral communities appear to retain historical functional capacity, and isolated *Acropora* refugia do persist, but the corals in them are less robust than those in the mid-Holocene, questioning their functional resilience to future change. Numbers of otoliths in samples suggest an 80% decline in non-harvested fish and, of those remaining, planktotrophic fish species are now relatively more common—patterns best explained by the loss of coral structure and increased eutrophication. Otoliths also reveal that non-harvested fish assemblages on modern reefs are, on average, larger than they were in the past and experienced lower mortality rates, suggesting lower rates of predation due to a loss of predators. This conclusion is supported by the estimated 71% decline in shark abundances on the same reefs and a 400% increase in evidence of damselfish algal-gardening. These examples illustrate how both bottom-up and top-down processes have reshaped the structure, trophic interactions and ecosystem functions of Caribbean reefscapes. We discuss how these data can help answer if modern reefs exist in novel states and function in fundamentally different ways to those of the past, and what this means for the conservation of Caribbean coral reefs.

Ecological niche modeling of prominent Caribbean coral species

Ms. Claire Williams [1], ***Dr. Rowan Martindale*** [1], ***Dr. Corinne Myers*** [2]

1. The University of Texas at Austin, 2. University of New Mexico

Global warming and human impacts continue to be devastating for coral reef systems. In particular, Caribbean reefs have some of the poorest health ratings in the world. These reefs have been adversely affected by a variety of threats including elevated ocean temperatures, increased nutrient pollution, ocean acidification, and overfishing. To mitigate the effects of changing climates, it is vital to understand how ecologically important or prominent coral species in the Caribbean (i.e., *Acropora cervicornis, Acropora palmata, Agaricia agaricites, Colpophylia natans, Diploria labyrinthiformis, Pseudodiploria strigosa, Orbicella annularis, Siderastrea siderea*) are impacted by these threats. (Paleo)Ecological Niche Models were used to assess locations of suitable habitat for Caribbean coral species. Models from the Last Glacial Maximum, mid-Holocene, the modern ocean, and future projections were developed to determine which environmental variables are most important to these species, how niche occupancy changes, and how locations of suitable habitat shift over time. Utilizing the fossil record allowed this project to obtain a more complete picture of the coral's fundamental niche so better predictions could be made.

Mammal body mass as a community ecometric with utility for predicting future extinction risk

Mr. Oscar Wilson [1], ***Dr. Abigail Parker*** [2], ***Dr. Juha Saarinen*** [1]

1. Department of Geosciences and Geography, University of Helsinki, 2. Department of Computer Science, University of Helsinki

Body mass is a fundamental functional trait across vertebrate groups, which influences diet, locomotion and thermoregulation. Within mammals, it is well established that mass varies across space, both within and across species. For example, body mass increases in cooler climates. We used mammal body mass and geographic distribution data from the PHYLACINE database to assemble community body mass distributions for 51,873 global terrestrial mammal communities (~50km resolution) along with climate variables for each of these sampling points. We built linear models for mammal community species count and mass mean, standard deviation, maximum, minimum, range, skewness, and kurtosis vs. two climatic variables: Mean Annual Temperature (MAT) and Mean Annual Precipitation (MAP). We also compared these results to those obtained through generalised linear latent variable models (GLLVMs). These models include data on diet as well as body mass. In particular, we focused on South America, a continent where other approaches to paleoclimate reconstruction (e.g. dental ecometrics) are less well-understood.

We found that global models generally had a low predictive power, and whilst this was substantially improved by using continental models, the relative superior performance of GLLVMs suggests that this method better captures the functional differences between communities. We found that for both global models and in South America, the relationships were very sensitive to taxon choice. For example, we found a positive relationship between mean mass and temperature when bats are excluded, but a negative relationship between mean mass and temperature when bats are included. To demonstrate the ability of these models to predict paleoenvironments, we applied them to Quaternary localities across South America and tested their predictions against those made by other proxies. For spatially-explicit communities in South America, we tested how warming relative to modern temperatures is expected to shift mammal mass distributions, through extinction or range shifts on short time scales. Comparison of projected community statistics with modern communities (and projected future communities) highlights which functional groups within communities are vulnerable to extinction with changing climates.

Reconstructing millennial-scale variability in reef shark communities across the Isthmus of Panama

Dr. Erin Dillon [1], ***Dr. Douglas McCauley*** [2], ***Ms. Brigida De Gracia*** [1], ***Dr. Aaron O'Dea*** [1]

1. The Smithsonian Tropical Research Institute, 2. University of California, Santa Barbara

Shark populations worldwide have declined steeply over the last half century, but the patterns of change vary across space. Long-term records of shark abundance are limited, making it challenging to determine how local environmental conditions (e.g., ocean productivity) influence natural variability in shark populations and the magnitude of change from pre-exploitation baselines. Here, we use shark scales (dermal denticles) preserved in coral reef sediments to reconstruct shark communities during the mid-Holocene (~4-7ka) and today on both coasts of the Isthmus of Panama. We then pair these denticle assemblage data with comparable records of primary productivity and fish abundance to explore energy flow to higher trophic levels in each region. Panama's coasts are dramatically different. The Tropical Eastern Pacific is a highly productive, dynamic system driven by seasonal upwelling with a long history of shark exploitation that continues today. The Caribbean coast, on the other hand, is oligotrophic and environmentally stable, with much lower rates of harvesting. We find that denticle accumulation rates, a proxy for shark abundance, are an order of magnitude greater on reefs in Pacific Panama (Gulf of Panama) than those in Caribbean Panama (Bocas del Toro). Primary productivity and fish (prey) productivity are also substantially higher in Pacific Panama, helping to support this high predator abundance. Comparing patterns over time, denticle accumulation rates declined by 71% since the mid-Holocene on reefs in Caribbean Panama, including a selective loss of fast-swimming apex and mesopredatory pelagic sharks (e.g., families Carcharhinidae and Sphyrnidae). In sharp contrast, modern denticle accumulation rates in Pacific Panama are comparable to their range of variability during the mid-Holocene, and the functional composition of denticle assemblages remained similar through time—suggesting that the shark community in the Gulf of Panama has persisted despite intensive fishing activity. We postulate that the region's high productivity might underlie its high shark abundance and apparent resilience by increasing available resources for predators. Our preliminary findings provide insight into the role of energy in shaping natural variability in reef shark baselines and recovery potential in the face of ongoing overfishing. They also highlight the importance of incorporating oceanographic context into shark management.

Reconstructing Holocene changes in body size of Adriatic gobies using coupled radiocarbon dating and sclerochronological analyses of fossil and modern otoliths

Ms. Isabella Leonhard [1]***, Dr. Emilia Jarochowska*** [2]***, Dr. Rafal Nawrot*** [3]***, Dr. Konstantina Agiadi*** [3]***, Prof. Martin Zuschin*** [3]

1. *Institute of Evolutionary Biology, University of Warsaw,* ***2.*** *Department of Earth Sciences, University of Utrecht,* ***3.*** *Department of Palaeontology, University of Vienna*

Climate warming is expected to lead to a reduction in the body size of marine organisms, a trend already observed in commercial fishes, but the effects of temperature rise on size distribution in exploited populations are difficult to separate from the impact of overfishing and other anthropogenic stressors. We aim to test the hypothesis that fish body sizes, as well as growth rates changed during the late Holocene and Anthropocene in the northern Adriatic Sea due to environmental perturbations caused by climate warming. We perform sclerochronological analysis on modern otoliths from modern fish, as well as radiocarbon-dated fossil otoliths of non-commercial, demersal gobies (*Gobius niger* Linnaeus, 1758) sampled from a sediment core taken off Piran (Slovenia) to quantify changes in body size and growth parameters throughout the Holocene. Otoliths are the aragonitic structures of the fish' inner ear with species-specific morphology, and thanks to their incremental growth, they serve as unique environmental and life-history archive. Moreover, otolith size correlates with fish size. We use otoliths cut in half to perform both sclerochronology and radiocarbon dating, obtaining a high-resolution time series of changes in fish body size, growth dynamics and life history parameters. We employ backscatter electron (BSE) imaging and electron probe microanalysis (EPMA) to identify body sizes and growth dynamics, as well as to correlate their growth increments with climatic and other environmental parameters. The reconstructed changes in body size and growth rates of very common, non-commercial fish species over the last 7.000 years, can serve as an ecological baseline for evaluating the magnitude of ongoing temperature rise and future shifts in fish populations in response to global warming.

Changes in bivalve species richness in the Mediterranean area during the Plio-Pleistocene time-interval

Dr. Alessandro Mondanaro [1], ***Dr. Stefano Dominici*** [2], ***Dr. Silvia Danise*** [1]

1. Dipartimento di Scienze della Terra, Università degli Studi di Firenze, Via La Pira 4, I-50121 Firenze, Italy, 2. Museo di Storia Naturale, Università degli Studi di Firenze, Via La Pira 4, I-50121 Firenze, Italy

The Mediterranean Sea is a marine biodiversity hotspot. Such unordinary diversity is currently threatened by global warming that may impact marine communities and trophic relationships among organisms. To predict how and how much marine species are vulnerable to recent and future climate change it is necessary to investigate how past species reacted to environmental disturbance. In this study we used the fossil record of Mediterranean bivalves (more than 400 species) to analyse how species richness changed during the Plio-Pleistocene time frame, a period characterized by multiple waves of climatic-driven bivalve extinctions. Assembling a species level dataset, across the entire Mediterranean area, we measured changes in species richness across different palaeoenvironments (from the shoreface to the slope) and for different tiering and feeding categories, in order to verify if specific environmental conditions and mode of life played a role in terms of ecological resilience to climate disturbance. Ecosystem response was assessed in terms of species richness, species turnover, niche breadth, and geographical range size. We show a significant loss of biodiversity in the Mediterranean area after 3 million years, especially in shallow water environments, consistent with the onset of cooler and less constant climatic conditions. Our results suggest extinction waves mainly involved suspension feeders whereas environmental dynamics seem not to have affected deposit feeders. Eventually, although bivalve richness gradually decreased towards Pleistocene, this period has the higher proportion of species appearance. We hypothesize that this is due to the onset of Pleistocene climatic oscillations and the introduction of northern and southern guests.

The future of Mediterranean biodiversity in a warming planet

Dr. Paolo Albano [1]

1. *Stazione Zoologica Anton Dohrn*

The rate of warming of the Mediterranean Sea is among the highest globally. Warming is hitting particularly hard on the easternmost sectors where a massive climate-driven collapse of native biodiversity is ongoing. These new environmental conditions are more proper of a tropical sea and, indeed, hundreds of Indo-Pacific species introduced through the Suez Canal are here thriving. These two processes are changing considerably – and irreversibly – the taxonomic and functional composition of benthic assemblages. But what is now ahead of us? The Quaternary fossil record suggests that in some of the Pleistocene interglacials, also tropical species of West African origin entered the Mediterranean. Is thus a new wave of tropical species going to invade the basin? In this talk, I will i) summarize the biotic and abiotic properties of the Mediterranean Sea in the context of global warming, ii) show the extent of the current collapse of native biodiversity, iii) provide the results of our models on the suitability of the Mediterranean for tropical West African species and on connectivity along the northwestern African coastline, and iv) offer new perspectives on the conservation of Mediterranean biodiversity in a warming planet.

The past as a lens for biodiversity conservation on a dynamically changing planet

Dr. Jenny McGuire [1]

1. Georgia Institute of Technology

Given the magnitude of projected climate change, we anticipate that ecosystems will shift across the landscape as they struggle to adapt. The restoration of certain habitat connections and natural areas will be critical to maintain biodiversity and ecosystem service going forward. However, it can be challenging to identify the most effective strategies to allow ecosystems to bounce forward in the face of impending change. To create an effective landscape network, we must first understand how plants and animals are anticipated to respond to changing climates. How will species need to shift their ranges as climate changes? To what extent will habitat fragmentation hinder this movement? And what species will be most impeded by human-impacted landscapes? We use the late Quaternary fossil record from the Neotoma database to begin to address these questions and suggest ways forward for prioritizing landscape connectivity strategies.

We find that plants respond dynamically to changing climates, exhibiting rapid turnover once temperature changes exceed 1.5°C/500 years. This turnover translates to high climate fidelity, with plants tracking climate 86% of the time. If we examine today's landscapes, we see that the potential for range movement is quite limited. Only 41% of natural areas in the contiguous United States exhibit climate connectivity with human-impacted lands preventing climate tracking for 25% of natural land areas. However, we can also find that not all species are equally inhibited by human-impacted lands. We find that about one third of common mammal species in North America shift the climates where they live to avoid human-impacted regions, but that one third actually expand into agricultural- and urban-associated climates.

By identifying which plants and animals most respond to changing climates, what their range dynamics will be going forward, and which are hindered by the expanding human footprint, we can identify the most important regions for conservation and what restoration objectives will facilitate this dynamically changing landscape. Past, large-scale responses are critical to inform these objectives.

Lost ranges of plant species in the past anticipate modern endangered biodiversity

Prof. Donatella Magri [1]***, Dr. Igor Parra*** [2]***, Dr. Federico Di Rita*** [1]***, Prof. Jian Ni*** [3]***, Dr. Koji Shichi*** [4]***, Dr. James R.P. Worth*** [4]

1. *Dipartimento di Biologia Ambientale, Sapienza Università di Roma, Roma (Italy),* ***2.*** *Instituto Inicia Lebu,* ***3.*** *Zhejiang Normal University,* ***4.*** *Forestry and Forest Products Research Institute*

The palaeoecological community is frequently interested in studying past rates of spread of plant populations as a measure of their ability to survive predicted global warming but has much less experience in determining location, timing and extent of past-range losses of plant species, a topic that is equally important in terms of conservation of modern ecosystems. We compiled a worldwide database of published fossil records of pollen, stomata, plant macro-remains and ancient DNA (aDNA) over the last 30 ka documenting the last occurrences of plant taxa at regional, continental or worldwide scales. Records were restricted to those with a solid chronological control, located more than 25 km from the nearest modern population for macrofossils and stomata, or 100 km for those based solely on pollen. These records represent either species extinction or loss of populations of extant taxa.

Our study revealed widespread range losses of plant taxa across all latitudes, with the majority representing gymnosperms. Focusing on conifers, a group of plants with well understood distribution and conservation status, we found that past range losses often overlapped areas where species are endangered at present, suggesting that such areas have been prone to biodiversity loss through time. During phases of past rapid climate change, even areas that currently have low numbers of endangered species were affected by plant range losses, in some cases with disappearance of taxa from entire continents, islands or major geographic regions.

This global analysis of range loss of plant species raises several unexpected questions, including the apparent contrasting fate of gymnosperm versus angiosperm species, the high rate of range losses at middle-low latitudes, which are generally considered to be effective refuge areas for plant species, and the failure of several species to re-occupy their lost nearby ranges over time spans of thousands of years. It also shows that understanding the extent of past lost ranges at a regional/local scale, and the factors underlying them, may provide crucial information to assess the current vulnerability of threatened species.

Contributions of the study of continental Mediterranean Holocene fossil mollusc assemblages to the conservation of an endangered group

Mr. Quentin Wackenheim [1]***, Dr. Nicole Limondin-Lozouet*** [2]

1. *Physical Geography Laboratory, UMR 8591 CNRS, Paris 1-UPEC University, Meudon, France.,* ***2.*** *CNRS-Laboratoire de géographie physique: environnements quaternaires et actuels (UMR 8591 Université Paris 1 Panthéon-Sorbonne, UPEC)*

In Quaternary studies, fossil land shells are usually studied to investigate past environments and climates across various spatial and temporal scales. Over the last ten years, new molluscan successions from northeastern Morocco and southern Spain have revealed a high diversity of land snail assemblages during the Holocene. Nowadays, the highly anthropized Mediterranean Basin is considered one of the most sensitive areas to landscape and biodiversity modification due to climate changes driven by human activities. As one of the most threatened invertebrate groups, many Mediterranean land snail species require major conservation measures to ensure their survival.

On the basis of new Moroccan and Spanish sequences (Aït Said ou Idder; Blirh; Oued Charef, Galera) and a review of the existing paleomalacology literature, we discuss the significance of Holocene molluscan records from a perspective of paleobiology conservation. Most of the sequences provide records from the Middle Holocene (8200 – 4200 Before Present) consisting of a rich hygrophile fauna as common components. *V. moulinsiana* and *V. angustior*, both protected species under the European Directive, occur regularly. *V. enniensis* is common in several Holocene sites, but has a current distribution limited in Spain and is unknown living in Morocco. Likewise, the occurrence of the endemic *O. aragonica* at Galera and Baides shows that this species had much larger populations and a wider distribution during the Holocene which support its endangered species status

Middle Holocene molluscan successions provide an historical perspective of the occurrence of hygrophilous species before aridification and increased human impact led to the disturbance and fragmentation of wetland habitats. Molluscan fossil records are an ideal temporal tool to better understand the parameters that have shaped today's biodiversity and to identify the most vulnerable taxa.

Paleolimnology Meets Ornithology: Using Lake and Pond Sediments to Address Key Conservation Issues

Dr. John Smol [1], ***Dr. Matthew Duda*** [1], ***Dr. Neal Michelutti*** [1], ***Mr. Chris Grooms*** [1], ***Dr. Jules Blais*** [2]

1. Queen's University, 2. University of Ottawa

Long-term data are critical to contextualize population declines and to establish best management approaches. However, for most species, monitoring data are sparse or simply non-existent, and thus it is difficult to assess population baselines or rates of decline. Here we summarize several studies where we have used a broad spectrum of landscape-scale paleoenvironmental approaches on dated lake sediment cores to examine decadal, centennial, and millennial-scale dynamics of bird species. For example, we reconstructed long-term changes from two of the world's largest colonies of vulnerable Leach's Storm-petrel (*Hydrobates leucorhous*) on Baccalieu Island (Newfoundland, Canada) and Grand Colombier Island (St. Pierre and Miquelon, France) using multi-proxy approaches (e.g. diatoms, invertebrates, pollen, fungal hyphae, elemental and stable isotope analyses, fossil pigments, and sterols and stanols). Our reconstructed populations, based on paleolimnological changes from seabird-derived nutrient and metal inputs preserved in dated lake sediments, corroborate the limited survey data that suggest a recent decline. However, the much longer temporal perspective offered by paleolimnological analyses demonstrates that the most recent colony, from ca. 700 CE to present-day, is substantially larger than any of the prior colonies of the past millennia. Similar sedimentary approaches are also being used to track long-term changes in water birds (such as cormorants and eider ducks). Paleolimnological techniques have the potential to provide a long-term context for the size and persistence of seabird populations, as well as their effects on local terrestrial environments, which can lead to more realistic conservation strategies, within the context of multiple stressors.

De-extinction of mammoth traits to aid Asian elephants and arctic environments

Dr. Ana Queiroz [1], *Dr. Emil Karpinski* [1], *Dr. Ramiro Perrotta* [1], *Dr. Eriona Hysolli* [1], *Prof. George Church* [1]

1. *Harvard University*

The Pleistocene – Holocene transition resulted in immense ecological restructuring, primarily due to the combinatorial effects of glacial retreat and mass megafaunal extinctions. Previous work has shown that resulting Holocene environments are less biodiverse and less productive than their Pleistocene counterparts. Well considered rewilding efforts has successfully been employed to increase genetic and biological diversity, as well as allow a new long-term avenue for ecosystem remodeling and enrichment. Here we discuss how the paleontological record offers important genetic tools to adapt extant species to an increasingly anthropogenic world, through the example of engineering cold-adaptive traits in Asian elephants. We also discuss some of the potential challenges associated with modern de-extinction efforts and how they may be circumvented or addressed in the most ethical way possible. Our work highlights some of the potential positive roles tailored de-extinction and restorative biology approaches can have for ecological improvement, as well as offering an important refuge by adapting endangered species to new and less human-dense environments.

Ecomorphological and biogeochemical shifts in a late-Pleistocene to Anthropocene mesocarnivore community

Dr. Mairin Balisi [1]

1. Raymond M. Alf Museum of Paleontology

While North American fossil mammal history is dominated by large carnivores and prey, most mammalian carnivores today are small ("mesocarnivores"): a taxonomic transition that followed a combination of climatic change, megafaunal extinctions, and human disturbance at the end of the last Ice Age. Here, I evaluate response to these intersecting major impacts in a mesocarnivore assemblage spanning the last 55,000 years in southern California, USA. Excluding coyotes, the late-Pleistocene to Holocene Rancho La Brea (RLB) asphalt seeps in Los Angeles preserve five mesocarnivore species each represented by >=10 individuals: American badger (*Taxidea taxus*), bobcat (*Lynx rufus*), grey fox (*Urocyon cinereoargenteus*), striped skunk (*Mephitis mephitis*), and long-tailed weasel (*Mustela frenata*). While these five species continue to populate the area today, radiocarbon dates indicate that not all species inhabited RLB at the same time. Rather, almost all fossil specimens of bobcats, grey foxes, and striped skunks date from before the Last Glacial Maximum (LGM), with badgers largely a latest Pleistocene addition. No sampled mesocarnivore specimens date to the LGM itself, likely an effect of low sample size or taphonomy. In multiple ecologically relevant linear traits, RLB specimens differ significantly from historic (<100 years old) representatives of the same species from the same geographic area. Fossil mesocarnivores were generally larger—decreasing in body size toward the present by as much as 27%—and exhibited a greater degree of carnivory-adapted morphology, perhaps due to competition presented by now-extinct megafaunal predators. Species-specific differences in postcranial morphology highlight shifts in locomotor ability, potentially recording responses to environmental change. Further, stable isotope analyses of carbon and nitrogen show differences independent of taxonomic turnover, although to what extent these differences reflect changes in diet rather than environment is currently uncertain. All species except the weasel demonstrate higher-on-average and more variable δ13C toward the modern-day than pre-LGM; the striped skunk & grey fox also exhibit lower-on-average δ13N in the Holocene to Anthropocene than pre-LGM. Leveraging biogeochemical and ecomorphological techniques, this multi-proxy study provides complementary metrics for diet and resource use, illuminating the roots of today's mesocarnivore fauna in the last Ice Age and highlighting their potential responses to continuing anthropogenic change.

Using geohistorical records to inform urban greening in a biodiverse megacity

Dr. Emily Lindsey [1]***, Dr. M. Allison Stegner*** [2]***, Dr. Regan Dunn*** [1]***, Ms. Jessie George*** [3]***, Dr. Alexis Mychajliw*** [4]

1. *La Brea Tar Pits and Museum,* ***2.*** *Stanford University,* ***3.*** *UCLA,* ***4.*** *Departments of Biology & Environmental Studies, Middlebury College*

In a rapidly changing world, scientists and conservationists are increasingly leveraging fossils and other geohistorical records to inform restoration and management of global ecosystems, but these tools are rarely applied in human-modified landscapes. The ability of city planners and conservation biologists to respond to the challenges of the Anthropocene can be enhanced by incorporating local and regional geological, fossil, and historical collections, which can give insight into organisms' ecological flexibility, baselines for ecosystem structure and function, and correlates of extinction risk. While often thought of as connoting the erasure of natural baselines, cities can in fact possess rich records of pre-Anthropocene ecosystem states, including historic specimens and documents collected during the development of the city, and fossils and geological data unearthed during the construction of buildings, transportation corridors, and hydrologic conduits.

Los Angeles (California, USA) is home to 19 million people and located within the Californian Floristic Province, a biodiversity hotspot and one of the most floristically diverse regions in the world. A megacity with ambitious sustainability goals, Los Angeles embodies the tensions that city planners and conservation practitioners must navigate in balancing conservation priorities and human needs in populated landscapes. Access to green space is crucial to human well-being, and even minor botanical interventions in urban landscapes, like trees on city streets, have been demonstrated to help foster biodiversity. Understanding ecosystem structure, function, and resilience across periods of Quaternary environmental change in this region can be vital to creating sustainable green spaces in the context of ongoing global change.

Here we report on an ongoing collaboration between paleobiologists, urban ecologists, city planners, and conservation organizations to assemble and analyze data on the vegetational history of the Los Angeles Basin to support efforts focused on greening and enhancing biodiversity in urban spaces in Los Angeles. These efforts aim to address a range of urban conservation concerns including urban cooling, storm water filtration, biodiversity, equitable access to green space, and habitat connectivity. Our framework focused on community involvement also provides local stakeholders with new tools to advocate for natural spaces that are meaningful to them.

Drivers of changing parasite-host interactions in the Quaternary

***Dr. Karina Vanadzina* [1], Ms. Zahra Al lawati [2], Ms. Nussaibah Raja-Schoob [2], Ms. Eileen Straube [2], Dr. Kenneth De Baets [1]**

***1.** University of Warsaw, **2.** University of Erlangen–Nuremberg*

Parasitism is one of the most common modes of life on Earth, with up to 40% of species described as parasitic. While parasites are often viewed solely in the context of human disease, they play an important regulatory role in modern ecosystems and should therefore be considered as part of the effort to conserve their hosts. Despite the modern prevalence of parasites, past shifts in parasite distribution and diversity remain underexplored due to their poor preservation potential in the fossil record. A thorough search of archaeoparasitological literature could potentially address this knowledge gap – these studies document resistant remains (e.g., eggs and cysts) and genetic traces of parasitic organisms found predominantly in vertebrate coprolites and thus provide a rich source of information of parasite occurrences at archaeological timescales. Some groups of parasites such as hookworms, whipworms and roundworms are dependent on temperature to complete their life cycle and are particularly well-represented in the literature rendering them the ideal target for investigating how parasite distribution has been affected by past environmental change. Understanding such shifts is crucial for predicting the evolution of parasite-host interactions in response to the rapidly changing climate of the modern day. In contrast to recent modelling studies suggesting that warmer climates might lead to low-latitude parasites invading temperate ecosystems, our preliminary analysis of more than 600 parasite occurrences across different localities revealed an opposite trend of parasites shifting to higher latitudes during colder periods of Quaternary. As the next step, we aim to assess the impact of climatic fluctuations on parasite diversity and distribution using modelling approaches to increase the temporal and spatial resolution of our dataset. We additionally plan to estimate how biases in preservation and sampling – such as the overrepresentation of European and American localities in our dataset – might affect our findings.

A new ordination technique quantifying ecospace occupation of Pleistocene, modern, and projected future communities

Dr. Abigail Parker [1], ***Mr. Oscar Wilson*** [2], ***Dr. Liping Liu*** [2], ***Dr. Juha Saarinen*** [2], ***Dr. Indrė Žliobaitė*** [3]

Due to widespread human impacts on global ecosystems, terrestrial vertebrate communities today are depauperate in many functional groups. To answer the pressing questions of which of these communities will be resilient through rapid environmental change, we can turn to the fossil record for a larger sample of communities structured without excessive influence by humans. Here, we summarize the structure of terrestrial mammal communities in terms of how they are composed of diet and body mass categories. Focusing on Eurasia, we show how modern mammal communities differ from the communities present at Pleistocene fossil sites and examine how projected future extinctions will shift occupation in this ecospace. Our modern data consists of global communities sampled based on range maps and species' mass estimates and dietary categories in the PHYLACINE database. We used Generalized Linear Latent Variable Models to reduce the dimensionality of variation between communities in the abundances of mammals falling within 18 body mass/diet categories (i.e. herbivores, carnivores, omnivores, invertivores). These models reveal structural differences in community composition between modern biogeographic realms.

We then analyzed how past, present, and future Eurasian mammal communities differ, using distance in latent variable (LV) ordination space as a metric for community composition change. We drew Pleistocene mammal occurrence data for Eurasia from the NOW database of fossil mammals. To address low sampling at some sites, we used recommender system modelling to estimate community composition at these sites based on associations between genera across sites in the database. We compared the input and output communities of these models with modern communities from the same regions, evaluating how the recommender systems reconstruct community structures. Finally, we estimated future communities by excluding species categorized as at-risk by IUCN assessments. Plotting these communities in LV space reveals which future extinctions re-structure communities into non-analog compositions outside of the range of LV space occupied by modern or Pleistocene communities. Models for large herbivores exhibit the greatest shift in LV scores with future extinctions. This methodology can be used in future to evaluate how extinction and conservation scenarios maintain or alter the functional composition of communities.

Past, present and future of Baltic Sea phytoplankton

Dr. Sarah Bolius [1]***, Ms. Alexandra Schmidt*** [2]***, Prof. Laura Epp*** [2]***, Dr. Jerome Kaiser*** [1]***, Prof. Helge Arz*** [3]***, Dr. Olaf Dellwig*** [1]***, Dr. Anke Kremp*** [1]

1. *Leibniz Institute for Baltic Sea Research Warnemünde,* **2.** *University of Konstanz,* **3.** *Leibniz Insitute for Baltic Sea Research Warnemünde*

Climate Change and human impact have led to a profound decrease in marine biodiversity, particularly during the past decades. In the Baltic Sea, for instance, species composition of the phytoplankton primary producer communities has changed, affecting the food web and function of the marine ecosystem. Yet, the Baltic Sea underwent previous changes in its climate with alternating phases of increasing and decreasing temperature, salinity and nutrient conditions and additionally, an ongoing increasing anthropogenic influence.

Some phytoplankton species form resistant resting stages, which settle to the sea floor after annual blooms and can survive there for decades and centuries, particularly under anoxic conditions. Accumulating in distinct temporal sediment layers over years, they build up archives of temporal populations. Resurrected resting stages from respective sediment core samples can be used to study responses – specifically trait changes and adaptation of phytoplankton to environmental changes.

In this study we used Baltic Sea sediment cores and resurrection approaches to establish strains of ancient and recent populations of two common phytoplankton spring-bloom species, the diatom *Skeletonema marinoi* and dinoflagellate *Apocalathium malmogiense.*

We successfully resurrected strains, especially of *S. marinoi*, through different warm and cold periods of the Holocene, such as mid Holocene warm (~ 7000 years ago) and cold period (~ 3000 years ago), the warm medieval climate anomaly (~ 800 years ago), the end of the last little ice age (~ 170 years ago) and from the last recent decades, representing different anthropogenic affected periods.

To see how the historic and more recent strains respond to past and future climate scenarios and to establish and compare reaction norms, we conduct growth experiments under different temperatures and salinity levels and examine further traits like cell size, cellular nutrient ratios, stress and interaction. First results suggest a better growth of more ancient strains under higher temperature, assumingly in accordance with their habitual ambient temperature.

Together, this can help to understand the adaption of phytoplankton to increasing water temperatures and nutrients levels and to suggest their reaction to future climate scenarios. Further, this data can be used for management approaches.

Ecological niche modeling and distribution of planktic foraminifera from the Pliocene to the Anthropocene Epoch

Dr. Ekaterina Larina [1], Dr. Adam Woodhouse [1], Dr. Erin Saupe [2], Dr. Corinne Myers [3], Dr. Christopher Lowery [1], Dr. Rowan Martindale [1]

1. The University of Texas at Austin, 2. University of Oxford, 3. University of New Mexico

Although current anthropogenic climate change and biodiversity crises are unprecedented throughout geological time, lessons from past climate shifts can provide important information. Specifically, deciphering patterns, drivers, and biological responses across episodes of climate change in the past may constrain our understanding of extinction and survival risks associated with projected future ecosystem restructuring. During the last ~4 Ma years, the Earth System has experienced numerous glacial-interglacial cycles, providing an opportunity to deepen our understanding of how marine organisms responded to these different climate states.

Planktic foraminifera exhibit biodiversity patterns comparable with many marine trophic resources fundamental to humankind and have the most complete species-level fossil record of any known phylogenetic group. Here we investigate the exceptional record of extant and extinct species of planktic foraminifera using the Triton database from the Pliocene to the Anthropocene, applying ecological niche modeling and other quantitative methods to determine ecological responses, extinction, and survival risks for foraminifera during glacial-interglacial cycles.

Our preliminary results show that the biogeographic ranges of extant foraminifera shifted towards higher latitudes during warm climate states and contracted during glacial intervals. In contrast, extinct species of planktic foraminifera did not show significant range shifts during both warming and cooling events. The biogeographic range shifts of extant species were closely correlated with a benthic foraminiferal $\delta^{18}O$ record, a proxy for temperature and ice volume, based on the Generalized Least Squares regression modelling. These results indicate that the global extant of ice sheets and ocean temperatures are primary environmental drivers of range shifts in extant species; however, amongst extinct species, atmospheric CO_2 was the most important driver, with higher CO_2 levels corresponding to greater biogeographic ranges. The last ~4 Ma years was characterized by significant changes in global ice volume. Thus, we hypothesize that extinct species lost their suitable habitat as ice sheet changes became more significant. Many modern extant species appear to have responded to changes in the $\delta^{18}O$ signal associated with ice sheet and temperature fluctuations, which may suggest they can react to future changes in ice sheet associated with anthropogenic warming.

Late Pleistocene trophic networks from central Chile: using the record from Tagua Tagua (34.4°S, 71.1°W) to understand the role of humans as an agent of environmental change.

Dr. Natalia Villavicencio [1], ***Dr. María Isidora Ávila-Thieme*** [2], ***Dr. Derek Corcoran*** [3], ***Dr. Cristóbal Quiñiñao*** [1]

1. Instituto de Ciencias de la Ingeniería, Universidad de O'Higgins, Rancagua, Chile, 2. Pontificia Universidad Católica de Chile, 3. Department of Biology, Aarhus University

One of the methods for reconstructing past ecosystems is to use fossil and archaeological records in combination with elements of theoretical ecology to generate models that bring us closer to the understanding of past ecological processes and states. In this context, the archaeological and paleontological record from the Antiguo Lago de Tagua Tagua (ALTT, 34.4°S, 71.1°W) in central Chile represents a unique opportunity for reconstructing of past ecosystems. Here, excavations at three different sites (TT1, TT2, TT3) have revealed a rich faunal record going from ~13 to 6 kyr BP along with events of human occupation and exploitation of animal resources. The record covers moments of important environmental changes such as the glacial-interglacial transition, megafaunal extinctions, and human arrival. All these together present the opportunity to reconstruct complex ecological features during the Pleistocene-Holocene transition in central Chile, such as species interactions, human-fauna interactions, and ecosystem stability. The present work shows the reconstruction of trophic networks using the records from the ALTT. The aim is to reconstruct two moments: 1) prior to human arrival, where other species interact in a late-Pleistocene ecosystem, and 2) after humans arrived (~12.6 kyr BP) and establish trophic links with several species. Using published data for TT1, we established a vertebrate species richness of 28 taxa during the Pleistocene-Holocene transition, including extinct and extant taxa. Feeding relationships among different taxa were estimated from the literature. Trophic interactions between humans and other vertebrates were inferred from published taphonomy studies. Network models were developed and analyzed using the NetworkExtinction package in R. Prior to human arrival the network presents 31 nodes and 107 trophic interactions, which increases to 32 and 126 respectively once humans arrive. In the scenario with humans, network properties increase indicating an enhancement in network stability. Extinction analyses did not reveal any secondary extinction due to the arrival of humans. Nor do secondary extinctions occur when megafaunal extinctions are incorporated into the model. Given the simplicity of our results, we are working in incorporating interaction strength and changes in primary productivity into the models, to better assess the resilience of a more realistic ecological system.

Going back for the future: incorporating prehistoric fossil records of saiga antelope (Saiga tatarica, Linnaeus 1776) into habitat suitability models to inform future conservation actions

Ms. Mollie Mills [1], ***Prof. Danielle Schreve*** [1], ***Dr. Christopher Sandom*** [2]

1. Royal Holloway, University of London, 2. University of Sussex

Globally, biodiversity needs immediate and effective conservation action. Prioritising suitable areas for conservation requires detailed knowledge of species-environment relationships. However, many species have suffered human-induced range contraction and may no longer occupy the full breadth of environmental conditions they could inhabit. This is particularly problematic for habitat suitability models (HSMs), which relate georeferenced occurrence records with environment variables to predict probability of presence or habitat suitability. The outputs are used to inform conservation management decisions, such as identifying reintroduction sites and designing protected area networks. HSMs assume that a species' contemporary range reflects its full species-environment relationship and may consequently underestimate suitable habitat predictions, thereby misinforming and biasing conservation decisions. Incorporating historic (centuries-old) occurrence records partly reduces this bias, yet even these records are still subject to anthropogenic range modification. The inclusion of deeper-time Pleistocene fossil records into HSMs is an effective way to broaden understanding of species' ecological tolerances and environment relationships prior to extensive anthropogenic actions. Here, we used prehistoric fossil records of the critically endangered and evolutionary distinct saiga antelope (*Saiga tatarica*, L., 1776) from the Late Pleistocene, alongside historic and modern occurrence records, to model suitable habitat under current and future (2070) climate projections. The results found an underestimation of predicted suitable saiga habitat using modern and historic records alone. The addition of prehistoric fossil records increased suitable saiga habitat by 700% and 608%, under current and future climate projections respectively. Our results suggest the saiga is not a refugee species but is occupying only a portion of its environmental range, having suffered species-environment truncation. Overall, this study highlights the importance of incorporating prehistoric fossil records into HSMs, to reduce the effects of species-environment truncation and to better inform conservation management decisions.

Multiple extinction and distributional changes of dung beetles reveals a collateral ecosystem collapse in Pleistocene-Holocene boundary

Dr. Francisco Tello [1]***, Dr. Fernando Vaz-de-Mello*** [2]***, Dr. Fernando Silva*** [3]***, Dr. Michele Rossini*** [4]***, Dr. José Ramón Verdú*** [5]***, Mr. Gerardo Arriagada*** [6]***, Dr. Mario Pino*** [7]

During the Pleistocene-Holocene boundary (P-H; ~16 to 11 k cal BP) the South American megafauna result drastically reduced in diversity. At least 83% of the large mammals result extinct, including all megaherbivores over 1000 kg. This extinction most likely triggers a series of co-extinction events on dependent-species or with which megafaunal interacted.

Dung beetles have formed close associations with multiple groups of vertebrates, including dinosaurs and mammals. However, the lack of fossils records or analogue interactions has made it difficult to link the extinction of megafauna with the extinction of these beetles during P-H boundary.

Here we analyzed Upper Pleistocene – Middle Holocene layers in southern Chilean (Pilauco site) to explore the changes in diversity and distribution of dung beetles. Additionally, we evaluate the relation between dung beetle fossils and megafaunal bone records. We found that several taxa of beetles result extinct at the end of Pleistocene, distributed on multiple taxonomic groups. This pattern was also recorded in predator beetles and facultative dung beetles. Additionally, we recorded that some extant taxa have a discrepancy between the fossil and the modern distributional records.

We found that both extinction and changes in distribution are related to extinct megaherbivores. Thus, the presence of mammal records changes the assemblage composition and increases the diversity of dung-related species. Moreover, when megafauna records are absent, the dung-related species decreases notoriously.

We suggest that the extinction of megafauna causes a collateral and multiple extinction of dung-dependent beetles. Thus, the collateral extinction affected in *cascade* to multiple trophic groups of beetles, resulting in a collapse of the dung-related organisms.

These findings could partly explain the notorious low diversity of modern dung beetle Chilean fauna. Finally, future management decisions based on dung beetles (e.g., agroecology) should consider the fossil diversity recorded in Pleistocene deposits.

Drivers of shallow molluscan biodiversity change in the Piacenzian-Gelasian of the southern North Sea Basin shows baseline resilience and thresholds of shallow marine biodiversity.

Dr. Frank Wesselingh [1], *Mr. Dirk Munsterman* [2], *Prof. Lucas Lourens* [3], *Mr. Bram Langeveld* [4], *Mr. Damian Smits* [5], *Mr. Tom Meijer* [6], *Mr. Ronald Pouwer* [6], *Dr. Freek Busschers* [2]

Natural History Museum Rotterdam, Westzeedijk 345, 3015 AA Rotterdam, 5. Faculty Earth Sciences, Utrecht University, Utrecht, 6. Naturalis Biodiversity Center

Shallow marine ecosystems and biota world-wide are undergoing rapid and profound turnover as a result of direct and indirect human-mediated activity. Yet we have little understanding how these will permanently alter/damage the functioning of these ecosystems. Understanding drivers and recovery of marine communities during adverse conditions from the fossil record can provide insights into recovery potential (resilience) and thresholds for ecosystem collapse required to assess the severity and outlook of today's biodiversity crisis. Even though depositional/fossil time series can be hugely informative, within shallow marine settings they suffer from widespread reworking and mixing, as well as post-depositional degradation. Also the poor resolution of stratigraphic age constraints the use of time series. We need time series that are adequate to understand todays challenges. In this study we use unprecedented borehole records of Late Pliocene-Pleistocene marine mollusk communities from the southern North Sea Basin (SNSB) in order to document faunal turnover, decipher drivers of turnover and understand recovery of taxa, communities and ecosystem functions. Using stable isotope analyses we constrain time intervals to the glacial cycle. The Pliocene-Pleistocene transition coincides with increasingly severe glacials, the arrival of Pacific immigrant species as well as strong changes in sediment load in the SNSB. The high diverse and specialized Late Pliocene communities became replaced by low diverse more generalist communities with a large percentage of (descendants of) immigrant species. We show that the latter were already established in low numbers prior to disruption episodes and profited from, rather then drove turnover. Within the overall biodiversity decline repeated short episodes of turnover occurred related to the disappearance of clear water environments and severe cold glacials. Turnover rates were very high (over 80% of species could be replaced within single episodes). Biotic decline and response in successive crises periods provide important insights into vulnerability and capacity of individual taxa, ecological groups and communities to withstand and respond to adverse conditions. Hence our study provides important insights into natural baseline dynamics and resilience of shallow marine communities in crisis periods relevant for the current Anthropocene Biodiversity crisis.

Session 37: Reconstructing Quaternary ice sheets

East Antarctic Ice sheet reconstruction inferred from geological evidence and glacial isostatic adjustment model

Dr. Takeshige Ishiwa [1]

1. National Institute of Polar Research

Further understanding of the mechanism of Antarctic Ice Sheet (AIS) change requires the reconstruction of AIS variability over a wide range of timescales. Reconstructing ice sheets and sea level changes from geological data is useful for reconstructing changes on timescales over a few decades. East AIS is more stable and about ten times larger than West AIS. Recent studies indicate that part of East AIS melted during past warm periods (Crotti et al., 2022; Wilson et al., 2018). As in West Antarctica, where the ice loss is accelerating, a more detailed understanding of East AIS change is needed. However, the number and quality of geological data that cover the entire East Antarctic region are still sparse, and it is essential to utilize existing data and acquire new data.

As an example of research using existing data, this presentation will present constraints on AIS variability during the glacial period. The AIS has generally reached its maximum during the Last Glacial Maximum (LGM). However, there is insufficient data prior to the LGM to determine when the Antarctic ice sheet reached its maximum, which is largely uncertain. In East Antarctica, relative sea-level observations of about 30,000-50,000 years ago, corresponding to Marine Oxygen Isotope Stage 3, are available from lake and terrestrial sediments. However, there are deviations from the GIA model calculations, and the Antarctic ice sheet change history prior to LGM has not been fully constructed. Re-evaluation of the observations and reconsideration of the ice sheet history indicates that the Indian Ocean sector of East AIS has reached its maximum volume prior to the LGM.

Furthermore, we present the proceedings of the JARE geomorphological field surveys, aiming to reconstruct the East AIS changes from the Last Interglacial period. This field survey has sampled seamlessly shallow water, lake, and land-based sediments in Lützow-Holm Bay, East Antarctica. This talk will also present preliminary results on these sediments and the topographic survey, which is essential for deciding on coring sites.

Mud, boulders and bird vomit: constraining Antarctic ice sheet models

Prof. Mike Bentley [1], ***Prof. Dominic Hodgson*** [2], ***Dr. Andy Hein*** [3], ***Dr. Steven Binnie*** [4], ***Dr. Mark Pittard*** [5], ***Prof. Pippa Whitehouse*** [5], ***Dr. David Small*** [6]

Determining the past size of ice sheets matters for a range of reasons including understanding sea level contributions, the forcing mechanisms responsible for ice sheet change, and for correction of the satellite gravimetric data recording contemporary ice sheet mass balance that are affected by glacial isostatic adjustment (GIA). Work is ongoing to reduce the uncertainty in understanding of Antarctic Ice Sheet history and one key area for this work is the Coats Land-DML region of East Antarctica.
Here we report a multi-disciplinary study to improve our understanding of ice load history in this region. We report here on a programme of glacial geology, GPS and seismometer deployment, and modelling; all aimed at improving GIA corrections and thus reducing the uncertainties in ice sheet mass balance in a key region. We have mapped and sampled the glacial geological record of ice sheet fluctuations on a transect of nunatak sites stretching ~900 km from the Heimefrontfjella (74° 30'S) to the Whichaway nunataks (81° 30'). The glacial geomorphology is a consistent pattern of landforms and glacial deposits, which record a glacial (ice loading) history of the region that we have dated using two independent approaches of cosmogenic Be-10 surface exposure dating and by radiocarbon dating of stomach oil deposits (preserved stratigraphic deposits of proventricular stomach oil from snow petrels, *Pagodroma nivea*). The independent approaches provide remarkably consistent and complementary approaches to ice history and provides constraints for our ice sheet modelling.
We report an ensemble of continent-wide ice sheet models that are scored against geological data. Exploring the characteristics of the highest-scoring ensemble members highlights some key features of deglacial behaviour including a relatively narrow range of past excess ice volumes at the LGM, Holocene retreat behind present-day grounding lines with commensurate volume minima, and readvance behaviours. The comparison also allows us to identify areas where more geological data would have high constraining power for ice sheet models.

Southern limit of the Patagonian Ice Sheet

1. *British Antarctic Survey,* ***2.*** *British Antarctic Survey (BAS), Natural Environmental Research Council (NERC), High Cross, Madingley Road, Cambridge CB3 0ET, UK.,* ***3.*** *(1) Departamento de Geografía, Prehistoria y Arqueología, Universidad del País Vasco/Euskal Herriko Unibertsitatea (UPV/EHU), Francisco Tomás y Valiente s/n., 01006 Vitoria-Gasteiz, Spain.,* ***4.*** *CNRS/CONICET/IRD/UBA,* ***5.*** *Geography and Earth Sciences, Llandinam Building, Penglais Campus, Aberystwyth University, SY23 3DB, UK.,* ***6.*** *Department of Geography, Arthur Lewis Building, Oxford Road, Manchester M13 9PL, UK,* ***7.*** *Centro de Investigación en Ecosistemas de la Patagonia (CIEP), Coyhaique, Chile.,* ***8.*** *Universidad de Magallanes*

The southern latitudinal limit of the Patagonian Ice Sheet at the Last Glacial Maximum is poorly constrained due to a paucity of field data. This particularly applies to southern outlet glaciers of the Cordillera Darwin Ice Field whose full extents have been debated by glacial geologists since 1899, affecting estimates of total ice volume. Here we report on the stratigraphy of exposed sections on the west coast of Isla Hermite which include glacial tills overlain by successions of peats and sandy silt. The location and orientation of the tills suggest that an ice lobe extended south from Cordillera Darwin across an extended Magellan outwash plain through Paso Mantellero and past Islas Hermite and Cabo de Hornos (Cape Horn). This was similar in extent to the Canal Beagle and Lago Fagnano Ice Lobes which extended to the east. Maximum extent occurred sometime before from 12880 cal. yr BP, and we discuss whether this is a close minimum age, or a product of delayed onset of peat accumulation at the sampling site. We provide a brief interpretation of the late Glacial and Holocene deposits overlying the till and from peat cores inland. These suggest peatland initiation before 15,400 cal. yr BP and the establishment of woody Magellanic moorland peat from 12880 cal. yr BP indicating a southward shift of the SHW during the early Holocene climate optimum.

Constraining the evolution of the Laurentide Ice Sheet through multiple glacial-interglacial cycles in central Canada

Mr. Tyler Hodder [1]***, Dr. Michelle S. Gauthier*** [1]***, Dr. Martin Ross*** [2]***, Dr. olav lian*** [3]***, Dr. Maria Schaarschmidt*** [3]***, Dr. April S. Dalton*** [4]

***1.** Manitoba Geological Survey, **2.** University of Waterloo, **3.** University of the Fraser Valley, **4.** Memorial University*

The Hudson Bay Lowland (HBL) contains some of the most extensive depositional records of glacial and nonglacial events from inside the limits of the Laurentide Ice Sheet, including at least the last 3 glacial-interglacial cycles (MIS 2 to MIS 7+). The Quaternary stratigraphy in the western HBL has nonglacial units which have been correlated to contradictory marine isotope stages. There is a lack of reliable chronological constraints on both the glacial (typically till) and nonglacial units, leading to correlations based on elevation and superposition. Here, we present new optical ages and paleobotanical data constraining numerous intertill nonglacial sediments to the last interglaciation (MIS 5), including beds previously assigned to MIS 3. Furthermore, we document the fragmented nature of the stratigraphic record and show that MIS 7-aged nonglacial sediments are situated near the surface underlying one or two till(s) in some localities. The nonglacial beds, with age constraints and paleobotanical data, are then combined with detailed till stratigraphy studies to improve the regional stratigraphic framework. This provides insights into how the Laurentide Ice Sheet evolved across multiple glacial cycles. Our evidence shows that ice first advanced into the western HBL from the Quebec-Labrador dome during the onset of at least the last two glaciations. This suggests that growth of the Quebec-Labrador dome was more rapid, relative to the Keewatin dome, during the build-up phase of continental glaciations of North America.

Reconstructing the central sector of the Cordilleran Ice Sheet and readvance mountain glaciers in northern British Columbia during the Late Glacial

Ms. Helen Dulfer [1]***, Dr. Martin Margold*** [1]***, Dr. Christopher Darvill*** [2]***, Prof. Arjen P Stroeven*** [3]

1. Charles University, 2. The University of Manchester, 3. Stockholm University

The Cordilleran Ice Sheet (CIS) repeatedly covered western Canada during the Pleistocene and attained a volume and area similar to that of the present-day Greenland Ice Sheet at the Last Glacial Maximum (LGM). Glacial isostatic adjustment models indicate the rapid climate oscillations of the Late Glacial had a dramatic effect on CIS thickness, with abrupt Bølling-Allerød warming causing significant ice sheet thinning and ~50% mass loss. The subsequent cooling caused the expansion of alpine glaciers across the former central sector of the CIS, which is documented by the presence of readvance moraines. However, the mountainous terrain and remote location have thus far impeded our ability to collect the empirical evidence required to validate numerical ice sheet models and the configuration of the CIS during this period of rapid climate change remains enigmatic.

Here we use the glacial landform record to determine ice dynamics for the central sector of the CIS in northern British Columbia, Canada, beneath the LGM ice divide. Numerous high elevation meltwater channels indicate early emergence of mountain peaks and the orientation and distribution of other ice-contact glacial landforms, such as eskers, lateral and submarginal meltwater channels, kame terraces, and perched deltas, indicate active post-LGM ice retreat westward towards the Coast and Skeena mountains. We map the regional distribution of independent mountain glaciers, ice caps, and ice fields that regrew during a cooling event in the Late Glacial and show that some of these readvance glaciers were subsequently overrun by advancing outlet glaciers of the CIS. We use the cross-cutting relationship between readvance glaciers and CIS outlet glaciers, together with available chronological data, to reconstruct the eastern CIS margin during the Late Glacial for the first time. This provides new details on the deglacial dynamics that numerical ice sheet models might aim to replicate.

Paired cosmogenic isotopes reveal Early Pleistocene glacial history in northwest Greenland

Dr. Shaun Marcott [1], ***Dr. Elizabeth Ceperley*** [1], ***Dr. Jeremy Shakun*** [2], ***Mr. Andrew Jones*** [1], ***Mr. Jeremy Brooks*** [1]

1. Department of Geoscience, University of Wisconsin-Madison, Madison, WI 53706, USA, 2. Department of Earth and Environmental Sciences, Boston College

Long-lived cosmogenic nuclides in erratic boulders offer the opportunity to investigate pre-Last Glacial Maximum glacial history. In northwest Greenland, an expansive ice-free area between the Petermann and Humboldt Glaciers (Washington Land) preserves a record of Early Pleistocene glaciation in the form of cosmogenic isotopes that have accumulated in quartz-bearing erratic boulders. These erratic boulders were sourced from deep within Greenland's interior based on their lithologies, which do not outcrop in these locations today, and now litter the carbonate bedrock landscape. Here, we report paired measurements of ^{10}Be and ^{26}Al collected from the surface of 11 of these erratic boulders. These boulders have simple ^{10}Be and ^{26}Al exposure ages that are tens of thousands of years greater than the expected deglacial history based on existing radiocarbon and cosmogenic chronologies, and therefore contain inherited cosmogenic nuclides from prior exposures. The ^{26}Al/^{10}Be ratios from these boulders are 1.5-2x lower than a constant exposure history, revealing long periods of burial following past exposure. These low ^{26}Al/^{10}Be ratios require at least a 1.8 Myr history of burial during glacial periods and exposure during interglacials with ice smaller than present for 10s of kyr and larger for the majority of this period. The preservation of the boulders on the landscape also indicates that cold-based ice conditions have persisted in this sector of northern Greenland since the Early Pleistocene, which has implications for understanding the evolution of the Greenland Ice Sheet during the Pleistocene.

Saltmarsh records of recent mass balance changes in Greenland

Dr. Sarah Woodroffe [1], *Dr. Leanne Wake* [2], *Prof. Glenn Milne* [3], *Prof. Antony Long* [1]

1. Durham University, 2. Northumbria university, 3. University of Ottawa

Saltmarshes provide excellent archives of relative sea-level (RSL) changes over a range of different timescales. In Greenland they yield precise RSL data over the past few decades to hundreds of years that can help constrain Greenland Ice Sheet mass changes during and after the Little Ice Age (LIA). They are particularly valuable as they provide a longer-term context upon which to evaluate recent tide gauge and GPS records which span only the past couple of decades.

This paper summarises more than a decade of work into fossil saltmarshes around the southwest and southeast margins of the Greenland Ice Sheet that record patterns of RSL change which indicate regional changes in the mass balance over the past few centuries. The data allows investigation into ongoing mass changes during and since the LIA and the timing of the end of the LIA in the climatically sensitive southwest and southeast portion of the ice sheet.

Microfossil (diatom) evidence from saltmarsh sediments at all studied locations record a recent change from RSL rise to stable RSL during the past 200 years. We interpret this change as evidence for the initial onset of mass loss locally from the Greenland Ice Sheet at the end of the Little Ice Age. We see no evidence for the recent accelerated GPS-recorded bedrock uplift around the coast of Greenland which we interpret as an extremely recent phenomenon. Geophysical modelling of the RSL data suggests that there are still things we do not understand about the response of the solid earth to changes in loading over decadal to centennial timescales.

This paper provides direct evidence that Greenland saltmarsh sediments can be used to reconstruct the timing of recent mass changes from marginal areas of the Greenland Ice Sheet, extending direct GPS observations back to the end of the Little Ice Age and beyond using geological data.

Network of lake records constrain deglaciation and Late Glacial expansion of the Iceland Ice Sheet

Dr. Wesley R. Farnsworth [1]***, Ms. Nína Aradóttir*** [2]***, Dr. Ívar Örn Benediktsson*** [2]***, Dr. Skafti Brynjólfsson*** [3]***, Prof. Egill Erlendsson*** [4]***, Prof. Esther Ruth Guðmundsdóttir*** [5]***, Prof. Ólafur Ingólfsson*** [2]***, Prof. Kurt H. Kjær*** [1]***, Prof. Nicolaj Krog Larsen*** [1]

During the Last Glacial Maximum, the Iceland Ice Sheet (IIS) extended out to the continental shelf edge, over 100 km offshore from the modern coastline. Following the collapse of the marine based sector (*c.* 14.5 ka BP), the 2 km thick ice sheet thinned and retreated to *c.* 40% of its volume, exposing widespread low elevation and coastal terrain. The subsequent regrowth of the IIS during the Late Glacial is constrained in several locations around Iceland, however, large uncertainties exist as to the timing, extent and thickness of the IIS during the Younger Dryas period as well as the rate and style of retreat during the Early Holocene. Here we introduce a network of well dated (radiocarbon) and tephrochronologically constrained lake records from around Iceland. Lake core basal ages limit Iceland´s glacial history during this dynamic transition into the Early Holocene and complement our current understanding of the deglaciation. Ultimately, new findings provide a more detailed history of the IIS as well as the response of marine-based ice sheets to changing climate and environment. Results will guide future glacier and glacio-isostatic adjustment models.

Submerged landscapes: uncovering the footprint of ice streaming in the Baltic Sea

Dr. Sarah L. Greenwood [1], ***Dr. Rachael Avery*** [1], ***Dr. Richard Gyllencreutz*** [1], ***Dr. Carl Regnéll*** [1], ***Dr. Karol Tylmann*** [2]

1. Department of Geological Sciences, Stockholm University, Sweden, 2. Faculty of Oceanography and Geography, University of Gdansk, Gdynia, Poland

The southern sector of the Fennoscandian Ice Sheet occupied terrain that today is submerged by an epicontinental sea that penetrates into the heart of the ice sheet domain. The Baltic Sea catchment supported an ice sheet grounded well below sea level yet distant from the open ocean, and which, during deglaciation, terminated in a setting that was episodically (and spatially variably) a huge proglacial freshwater lake, a brackish sea, and/or near-shore subaerial terrain.

Compared to the present-day terrestrial areas surrounding the Baltic, extremely little is known of ice sheet flow and retreat through the submerged Baltic corridor. Rather, the palaeo-glaciology of the Baltic sector has been inferred based on the physiographic setting and implied from evidence in peripheral coastal zones. Yet, ideas of how the ice sheet behaved in the Baltic abound, from early ideas of rapid grounding line collapse to concepts of widespread ice streaming connecting to terrestrial lobate ice flow corridors along the whole southern margin of the ice sheet.

Recent and growing acquisition of seafloor bathymetric data from the Baltic opens up this ice sheet sector to interrogation for the first time. High-resolution terrain models reveal: i) the landform imprint of ice streaming and the dynamic evolution of stream pathways; ii) grounding line retreat that, in different sectors and at different times, has behaviour akin to the surrounding terrestrial sectors and to marine-based collapse; iii) a widespread and complex landform record of subglacial meltwater drainage; and iv) a strong influence of the underlying bedrock substrate on inscription of a glacial landform record. Here we present the footprint of ice streaming in, and deglaciation of, the Baltic catchment. We discuss its wider role in the deglaciation of the southern sector of the Fennoscandian Ice Sheet, and the styles, rates and potential drivers of behaviour in this shallow epicontinental setting.

Comparing the impact of input parameter sampling methods for sensitivity analysis when numerically modelling the last Eurasian Ice Sheet

Ms. Rosie Archer [1]***, Dr. Jeremy Ely*** [1]***, Dr. Tim Heaton*** [2]***, Prof. Jeremy Oakley*** [3]***, Prof. chris clark*** [1]

1. *Department of Geography, University of Sheffield,* ***2.*** *University of Leeds,* ***3.*** *University of Sheffield*

Numerical modelling of continental-scale palaeo-ice sheets can be computationally expensive given the large spatial and temporal scales involved. An ice sheet model requires parameter values to be chosen. Typically, many of these values are not precisely known. Unknown parameter values contribute to uncertainty in the model output, so understanding the effects of changing each of the model parameters is important. To incorporate the uncertainty in all of the model parameters, many model simulations would be needed to create a large ensemble. Instead, by conducting an initial sensitivity analysis, we can assess which parameters have the greatest impact on the ice sheet model output. Unimportant parameters may then be discounted from the ensemble, thus reducing the number of simulations required.

Here we compare multiple sensitivity analysis methods to decide which approach is most informative when conducting a small number of model simulations. Our model experiment of the Eurasian Ice Sheet accounts for 21 unknown parameters, which we sample in different ways. We start with a simple method of varying one parameter at a time to the extremities in each parameter's predetermined range. We then move to more complex statistical methods to investigate parameter interaction effects, by varying all parameters together and considering their dependencies. This work demonstrates the importance of parameter interactions when designing an ice sheet model ensemble.

Reconstructing deglaciation dynamics for the terrestrial margin of the last Irish Ice Sheet

Dr. Cathy Delaney [1], Dr. Kathryn Adamson [1], Dr. Timothy Lane [2], Dr. Derek Fabel [3], Prof. PHILIP HUGHES [4]

1. Manchester Metropolitan University, 2. School of Biological and Environmental Sciences, Liverpool John Moores University, 3. Scottish Universities Environmental Research Centre, 4. The University of Manchester

Reconstructions of the retreat of the last Irish Ice Sheet (c.21-14ka BP) provide important models for deglacial ice sheet behaviour, as the relatively small size of the ice sheet meant that it responded rapidly to shifts in atmospheric and ocean circulation. Recent mapping and dating of offshore retreat have shown the importance of marine-terminating margins and local topography in controlling the overall retreat rate. However, the pattern and dynamics of retreat of land-terminating margins of the ice sheet during the later stages of deglaciation are less well understood, for two reasons. Firstly, evidence for successive ice marginal positions is fragmented and the ice sheet configuration is not always clear. Secondly, while multiple dates exist to constrain the timing of ice recession offshore and along the Irish coastline, no absolute dates are available for the retreat across the central and northern lowlands. Consequently, attempts at modelling ice sheet configuration during later stages of the last deglaciation are poorly constrained by the physical record, leading to wide variation in proposed models.

We present new geomorphological mapping from high-resolution digital elevation models (1 m resolution), together with new ^{36}Cl terrestrial cosmogenic nuclide results from 18 limestone boulders from the central Irish Midlands, to reconstruct the regional pattern and timing of deglaciation. Larger glacial landforms in the area include drumlins and a large esker system, and the area was partly covered by a large ice-contact lake during deglaciation, Palaeolake Riada. A suite of previously undetected, low-amplitude landforms (mega-scale glacial lineations, crevasse-squeeze ridges and controlled moraine) indicates that the ice sheet was polythermal for at least part of deglaciation and also that surging occurred along the ice margin during deglaciation. The new results provide important new insights constraining for the first time the timing of ice margin retreat and proglacial lake drainage.

Investigating the controls on ice sheet dynamics: Insights from a new reconstruction of the land terminating sector of the last Scandinavian Ice Sheet

Mr. Christiaan Diemont [1], ***Prof. chris clark*** [1], ***Dr. Stephen J. Livingstone*** [2], ***Dr. Anna L.C. Hughes*** [3], ***Dr. Sarah L Bradley*** [1], ***Dr. Frances E. G. Butcher*** [4]

The last Scandinavian Ice Sheet (SIS) offers a data-rich palaeo environment to study the processes controlling ice sheet dynamics. Theoretical and numerical modeling efforts investigating controls are greatly assisted by, and often require, ice sheet scale empirical reconstructions. The soft bedded, land-terminating maximum extent of the SIS (from Denmark to the Kola Peninsula) has seen spatially-varying levels of investigation using chronological, geomorphological and stratigraphic methods. It is difficult to synthesize and reconcile the range of differing methods and observations into a coherent sector-wide reconstruction. Here we present a spatially-consistent landform-based reconstruction of the entire land-terminating sector of the last SIS. Digital elevation models, a rapid symbolization mapping approach, and iterative testing of flow pattern scenario form the basis of our new reconstruction method. We briefly outline this empirical reconstruction method and the guiding 'rules' it uses. Our criteria for integrating the vast number of available dates with our retreat pattern reconstruction is outlined. This sector-wide reconstruction allows for the evaluation of hypothesized controls on dynamics. The reconstruction suggests a re-evaluation of ice divide organization is require to explain the observed flow geometries. We also discuss the importance of the growth and collapse of the marine sectors on land terminating ice margin dynamics and the SIS's interaction with neighboring Barents Sea and British Irish Ice Sheets.

Flow patterns of the Fennoscandian Ice Sheet derived from subglacial bedforms using high-resolution digital elevation models.

Dr. Frances E. G. Butcher [1], ***Dr. Anna L.C. Hughes*** [2], ***Dr. Jeremy Ely*** [1], ***Prof. chris clark*** [1], ***Dr. Emma L. M. Lewington*** [1], ***Mr. Christiaan Diemont*** [1], ***Dr. Benjamin Boyes*** [1], ***Ms. Alex C. Scoffield*** [3], ***Mr. Stephen Howcutt*** [4]

Empirical reconstructions of palaeo-ice sheets, based on observations their landform records, are required to better understand ice sheet dynamics, and to improve numerical ice sheet models. We present a new reconstruction of the flow pattern evolution of the Fennoscandian Ice Sheet (FIS) from subglacial bedforms, exploiting the recent expansion in availability and coverage of very-high-resolution (1–2 m/pixel) digital elevation models (DEMs) over Finland, Sweden, and Norway.

Previous data-driven, ice-sheet-scale ice flow reconstructions of the FIS relied upon landform mapping from relatively coarse-resolution (decametre-scale) data, predominantly from satellite images and aerial photographs. Recently, however, 1–2 m/pixel LiDAR DEMs became available over Finland, Sweden, and Norway. They provide near-complete coverage of the ice sheet interior above contemporary sea level, and reveal additional complexity in the flow evolution of the FIS. However, this data richness and the size of the ice sheet domain amplify labour-intensity challenges of performing an ice-sheet-scale empirical reconstruction. We therefore applied a new, systematic multi-scale sampling approach for ice-sheet-scale mapping and flow pattern reconstruction, which overcomes the data-richness challenge while still providing informative data products for model-data comparisons.

We present new 'flowsets' for the FIS, which describe discrete ice sheet flow patterns and their relative timing. We also present the multi-scale mapping products we used to generate flowsets. This includes a map of >250 000 subglacial bedforms and bedform fields over Finland, Sweden, and Norway, and a map of 'landform linkages'. Landform linkages summarise the detailed landform mapping but do not extrapolate over large distances between observed landforms. They provide a reduced data product that is useful for regional-scale flow reconstruction and model-data comparisons, and remains closely tied to landform observations. Where relevant, we ascribe a relative chronology to overlapping flowsets based on landform cross-cutting relationships. Our flow pattern reconstruction over Finland, Norway, and Sweden is one ingredient of a reconstruction of the entire FIS within the ERC-funded 'PALGLAC' project (PI Prof Chris Clark).

Glaciodynamics of the Younger Dryas ice marginal zone in northwest Russia

Dr. Benjamin Boyes [1]***, Dr. Danni Pearce*** [2]***, Dr. Lorna Linch*** [3]***, Prof. David Nash*** [3]

1. *Department of Geography, University of Sheffield,* ***2.*** *Norwegian University of Life Sciences,* ***3.*** *University of Brighton*

Previous reconstructions of Fennoscandian Ice sheet (FIS) glaciodynamics in northwest Russia during the Younger Dryas (YD) stadial are limited in scope owing to a lack of detailed empirical geomorphological and chronological data. As a result, previous reconstructions suggest the Kola Peninsula was glaciated by either the FIS, the Ponoy Ice Cap, or the Kara Sea Ice Sheet. In the neighbouring Republic of Karelia, the contrasting moraine assemblages are often grouped into alternative YD ice marginal zone (IMZ) scenarios. Utilising new databases of mapped glacial landforms and numerical ages, we present a new YD IMZ and early-Holocene (*c.* 12.9-11 ka) deglaciation reconstruction and investigate ice sheet dynamics of the FIS in northwest Russia.

Moraines and meltwater landforms are used to reconstruct IMZs and ice sheet retreat patterns in northwest Russia. The Tuloma IMZ extends the Norwegian 'Main sub-stage' moraines along the Murmansk Coast, with landform assemblages and topography suggesting that this ice margin was marine terminating. On the Kola Peninsula, extensive 'ring and ridge' hummocky moraine deposits were likely deposited by a cold-based ice margin readvance. Large cross-valley end moraines at the perimeter of the Khibiny Mountains also indicates that the FIS did not glaciate this massif during the YD. It is likely that the Kuusamo Ice Stream was active during the YD stadial; however, it is uncertain whether this extended as an ice lobe into the White Sea, or whether the ice stream was retreating. In the Republic of Karelia, six prominent and arcuate moraine and glaciofluvial outwash assemblages are interpreted as separate ice marginal zones attributed to independent ice margin readvance events. Abundant eskers and subglacial meltwater channels suggest that ice margin readvances in this region were associated with basal sliding. Available numerical ages indicate that the YD IMZ on the Kola Peninsula was established *c.* 12 ka, while the IMZs in the Republic of Karelia were deposited between *c.* 12.3 and 11 ka.

This new reconstruction provides a framework into which sedimentary and chronological reconstructions can be contrasted and compared, and crucial empirical data for validating numerical model simulations of the FIS.

Cosmogenic burial dating constrains the first major glaciations in the Western Alps

Pleistocene glaciers descending from the Western Alps have repeatedly invaded the southern Alpine Foreland. At the Aosta Valley outlet, a spectacular set of arcuate ridges known as the Ivrea Morainic Amphitheatre contains one of the most complete sedimentary records of Pleistocene Alpine glaciation. Magnetostratigraphic analyses have attributed the timing of the earliest glacial advances to around the Brunhes-Matuyama geomagnetic reversal (~ 0.78 Ma), but this estimate is yet to be confirmed with absolute dating methods. Here, we target the earliest glaciations recorded at Ivrea by applying cosmogenic ^{26}Al/^{10}Be burial dating to the basal glacial unit, Mongrando, and an underlying preglacial fluvial unit, Muzzano. To the measured abundances of cosmogenic ^{26}Al and ^{10}Be, we apply the Monte Carlo-based inversion model, P-PINI, a burial dating method that specifically accommodates the low nuclide concentrations and non-steady erosion rates that are typical of glaciated landscapes. Our results resolve the timing of the first large-scale glaciations of the Western Alps at one of the classic sites of Quaternary geology.

What have we learnt about glaciology from palaeoglaciology?

From valley glaciers to ice sheets, till deposition to Heinrich events, the practise of studying past ice masses (palaeoglaciology) has produced interesting avenues of research spanning scales from micro to global. Beyond being a fascinating intellectual curiosity to many, the potential that palaeo records have for informing about contemporary glacial processes and prospective future states of contemporary ice masses, is often touted as a justification for studying the past. Here we review the literature on palaeoglaciology to examine the extent to which this justification is true, asking what have we learned from palaeoglaciology? We review how palaeoglaciology was at the centre of the inception of glaciology in Europe, emphasising that knowledge passed down through generations about palaeoglacial events and locations meant that the indigenous peoples of glaciated regions have recorded palaeoglaciology for millennia. Since then, palaeoglaciology has continued to provide numerous insights for glaciologists, a few of which are mentioned here. One of the largest insights from palaeoglaciology was the realisation that ice sheets could rapidly change, as was revealed by Heinrich events. The accessible landscapes of deglaciated areas have provided insights into subglacial processes, for example revealing the architecture and evolution of subglacial hydrology over timescales beyond that of the current observational record. Hypothesising about one of the most abundant landforms found in deglaciated regions, drumlins, led to the idea of till deformation prior to it being considered in a contemporary setting. Recently, a greater integration of numerical models and palaeo-data has revealed a lag between the response of a glacier to climatic changes, and enabled the study of the marine ice sheet and ice cliff instabilities. Our review finishes by touching on how the palaeo-record may contribute to solving many of the puzzles facing glaciology today. Perhaps most importantly, projections of ice sheets and glaciers in our warming world, must account for historical conditions and hysteresis. Thus, perhaps unsurprisingly, we conclude that palaeoglaciology is more relevant than ever.

Session 38: Reconciling deformation through Geomorphology, Active tectonics and Paleoseismology investigations along the India plate

Active Transfer faulting in the Western Sub-Himalaya of India: Implications to seismic hazard assessment

Dr. Tejpal Singh [1], ***Prof. Riccardo Caputo*** [2], ***Mr. Hitander Singh Gill*** [3], ***Dr. Seema Singh*** [3]

1. *Academy of Scientific and Innovative Research (AcSIR), Ghaziabad 201002, India,* ***2.*** *University of Ferrara,* ***3.*** *Geology, Panjab University Chandigarh*

The Himalaya presents a complex tectonic deformation scenario with variable fault geometries in the sub-surface and wavering fault traces on the surface. In three dimensions this complexity tends to modulate the stress trajectories and therefore the style of faulting. Accordingly, non-Andersonian tectonic regimes could affect large crustal volumes and generate faults with oblique-slip kinematics, where both dip- and strike-slip components occur. Field observations from Western Sub-Himalaya of India allowed to recognise and record such complex faulting.

In particular, Remote Sensing of such complex deformation allows a bird's eye view of the landforms and is best suited to observe lateral motion which may otherwise not be observable in the field. We present a suite of geomorphic features such as offset drainage, abrupt truncation of streams, faulted basin geometries etc. to spatially locate the fault line. Subsequent detailed landform evaluation is employed to establish the sense and dimension of lateral motion.

Our examination suggests that the investigated landforms are consistent with left-lateral motion along an oblique fault across the Western Sub-Himalaya. It is inferred that in the context of fault geometry, such lateral motion is possible due to the obliquity of the identified fault. However, the fault line does not demonstrate any significant seismicity throughout the instrumental recordings. Of course such behavior of the fault may be a matter of different temporal scales of observations.

Therefore, in view of the active tectonic landforms the mechanism of fault slip is open for debate: whether it slips aseismically or seismically with a long-return period. In either case it may play a significant role in redistributing tectonic stresses which may have important implications to earthquake hazard in Sub-Himalaya.

Paleoseismic evidence of an 1100 CE earthquake along a blind frontal thrust segment in the Central Himalaya

Dr. Ananya Divyadarshini [1], ***Prof. C P Rajendran*** [2], ***Dr. Biju John*** [3], ***Dr. VIMAL SINGH*** [4], ***Dr. M G Yadava*** [5], ***Mr. Arkaprabha Sarkar*** [4], ***Dr. Sukumar Parida*** [5]

1. *Utkal University, Odisha,* ***2.*** *National Institute of Advanced Studies, Bengaluru,* ***3.*** *National Institute of Rock Mechanics, Bengaluru,* ***4.*** *University of Delhi, Delhi,* ***5.*** *Physical Research Laboratory, Ahmedabad*

Paleoseismic studies along the 2500 km Himalayan arc have been able to locate several stretches where fault strands arising from the Main Frontal Thrust (MFT) during discrete seismic events have propagated into the recent alluvium cover of the Indo-Gangetic plains and caused folding and thrusting of the young sediment layers. Successive great earthquakes have been reported along the Himalayan front at 1344 CE, 1255 CE and 1100 CE that produced surface ruptures for lengths of >700 km on overlapping MFT segments. This study is aimed at carrying out paleoseismic investigations along a stretch of the Central Himalayan front, in order to determine the timing, and extent of past major earthquakes in the area. The study involves detailed mapping of the terraces followed by trenching along a frontal fold scrap near the Sofa temple site in Manguraha village of northern Bihar. Radiocarbon and OSL dating of the trench sediments was carried out to establish the trench stratigraphy. Trenching was carried out at the topographic break of a laterally extending elongated ridge that arises from the base of the Siwalik hills and resembles a fold topography. The trench section shows distinct folding of the sediment layers, but noticeable fault offsets are absent which led us to infer folding on a blind thrust. We explore various scenarios that produced the deformation at the Sofa temple site. The latest event in the Sofa temple trench is most likely related to the ~1100 CE earthquake that has been previously reported from trench sections in eastern Nepal, Bhutan and eastern India. Uncertainties in rupture length, width and slip are tested, based on which, the size of the ~1100 CE earthquake is inferred as Mw ~9 that produced surface deformation over a length of ~850 km between the central, east-central and eastern Himalaya. While co-seismic offsets associated with the event have been recorded at previous trench locations, the ~1100 CE earthquake failed to reach the surface in the present study area. Our study highlights on the need to investigate lateral heterogeneities in the Himalayan décollement that could lead to inconsistencies along the rupture plane.

New Paleoseismic Excavations Across the Main Frontal Thrust of the Himalaya at the Chor Ghalia Site in Northern India

Dr. Tina Niemi [1], ***Dr. Robyn Daniels*** [2], ***Ms. Kaylee Thomas*** [1], ***Mr. Piyoosh Ratuela*** [3], ***Dr. R. Jayangondaperumal*** [4]

1. University of Missouri-Kansas City, 2. Missouri Geological Survey, 3. Diaster Mitigation & Management Centre, Uttarakhand, 4. Wadia Institute of Himalayan Geology

The Main Frontal Thrust (MFT) of the Himalaya orogenic convergence at the site of Chor Ghalia, located between Haldwani and Tanakpur in eastern Uttarakhand, India, forms a scarp along fluvial terraces of the Nankhaur River that are at heights of approximately 50 m, 25 m, and 7 m above the stream bed. The Nandhaur River crosses the MFT where a knickpoint marks the adjustment of the stream from the last scarp-forming event. Colonial-era waterworks which likely followed the Medieval aqueducts require a mechanism to drop the water over the fault scarp into the irrigation system of the terraced agricultural fields. In this study, we excavated 5 m-deep trenches across the MFT at the base of the high scarp where clear topographic inflections suggest scarp-forming events at the toe of the slope. In the footwall, the stratigraphic section contains basal boulder-cobble gravel and an upper muddy cobble-pebble gravel that is overlain by brown silty sand. This upper portion of the sand is darkened with organic material, contains potsherds, and is evidence of an anthropogenic surface. The hanging wall contains two stacked recumbent folds. The nose of the lower anticline runs far out over the anthropogenic surface in the footwall and is accommodated by the rotation of pebbles and cobbles. The upper fold is cut by an additional thrust. Two sequences of colluvium were mapped. The expression of deformation is similar to other sites along the MFT including LalDhang located about 150 km to the west. Samples were collected for dating from *in situ* burns on the footwall below the colluvium that post-dates the fold deformation and from the colluvium above the nose of the fold. Whereas the timing of these events awaits results of radiocarbon dating, the data from this study show that two major events likely ruptured this section of the MFT. Previous investigation of the site by Rajendran et al. (2018) suggests that the 1344 earthquake ruptured the site. As erosion has modified the scarp and colluvium contains remobilized organic material, it may be difficult to clearly define the timing of closely spaced historical earthquakes in the Medieval period.

Evidence for Active tectonism in tropical climatic zone: clues from Peninsular India

Dr. Biju John [1], *Dr. Yogendra Singh* [1]

1. National Institute of Rock Mechanics, Bengaluru

Present tectonic regime of Peninsular India is compressional and damaging earthquakes usually occur at favorably oriented pre-existing weaker planes/faults. However, identifying neotectonic signatures from such a cratonic region especially Tropical (humid) climatic regions are very challenging due to its characteristic slow movement. Based on the paleo-continental position, Indian landmass was in favorable position for laterization since pre-Oligocene, thus the laterite could preserve deformation since Oligocene. The quest for identifying evidence from such a terrain has led us to identify features indicating deformation in the present compressional tectonic regime.

Our studies shows that any deformation occurred in vermicular laterite is brittle in nature. Continued leaching processes leads to sealing of these cracks by iron rich minerals like Goethite or Hematite up to the depth zone of oxidation in the form of veins. The cracks which appear fresh or does not hold any mineral precipitation indicate lack of time for leaching. Our studies in areas of reverse faulting indicate that the saprolite, acting as a décollement, deforms like semi-ductile or ductile and can produce folding, shear band boudins Reidel fractures and/or injunction of material upward into cracks in laterite like dykes. The emerging segments of reverse fault at lateritic top often show bulging and as well as antithetic movement in the hanging wall block. Our studies close to southern tip of peninsular India discovered several trapped aeolian deposits due to reverse faulting in vermicular laterite. These deformations are dated around 1.7 and 4.3 ka. In the areas of strike-slip fault zone, the movement appears reach the surface. Here presence or absence of saprolite does not makes much difference for deformation at the surface as the movement is confined to narrow zone. Intense crushing of laterite results in growth of vegetation along the trace of the fault. Geomorphology of the fault zones indicate controlled/deflected drainages and linear valleys along the fault zones.

The present hindrance for active fault evaluation is the scarcity of datable material for event bracketing. However, these clues will be touchstones for future studies in the field of active fault evaluation in such terrains.

Surface Deformation, Fault Model and Tectonics of the 22 June 2022 Afghanistan (SW of Khost) earthquake

***Dr. Claudio De Luca* [1], *Dr. Fernando Monterroso* [1], *Dr. Riccardo Lanari* [1], *Dr. Mariarosaria Manzo* [1], *Prof. Riccardo Caputo* [2], *Dr. Tejpal Singh* [3]**

***1.** CNR IREA, **2.** University of Ferrara, **3.** Academy of Scientific and Innovative Research (AcSIR), Ghaziabad 201002, India*

The Afghanistan earthquake of 22 June, 2022 was located about 150 km south of capital city of Kabul. It struck post-midnight in the SW of Khost town of Eastern Afghanistan. Almost 5000 lives were directly impacted where more than 1000 were reported dead and another 2000+ were injured. It also caused damage to houses either complete or partial. However, the actual ground deformation and source mechanisms could be only poorly constrained due to scanty field and instrument data. This is perhaps limited by the remote location and poor access to the affected areas. The Preliminary reports suggest that *the* earthquake event was predominantly strike-slip faulting, either left-lateral slip on a northeast-striking fault or right-lateral slip on a northwest-striking fault (USGS). Although this information is consistent with the larger tectonics of the western boundary of the India plate that corresponds with the Chaman Transform the details of actual surface deformation are lacking. The present scenario allows taking advantage of the remote sensing measurements, particularly Differential Interferometric Synthetic Aperture Radar (DInSAR) technique to pin-down the extent and nature of surface deformation. To this aim we investigate the surface deformations induced by the occurred seismic event by using DInSAR products generated from Sentinel-1 (S1) constellation SAR data, via the Parallel Small BAseline Subsets (P-SBAS) algorithm. In particular, we exploited the co-seismic interferograms and relevant displacement maps generated over ascending and descending orbits and available from the European Plate Observation System (EPOS) catalog. The processed S1 interferograms are characterized by 12-days temporal baseline, 18062022 – 30062022 S1 acquisitions for ascending orbits and 19062022 – 01072022 acquisitions for the descending ones. The DInSAR deformation results are inverted to determine a reliable fault model that could justify the co-seismic surface deformation, geology of the area and larger tectonic context of the earthquake. The importance of our study lies in, besides the humanitarian and economic concerns, its scientific value to understand the active tectonics, source mechanism and earthquake hazard of the western transform boundary.

How earthquake influence shallow aquifer system? Lessons learned from the coseismic liquefaction-induced deformation following the 2019 Mirpur earthquake, Pakistan

Dr. Muhammad Younis Khan [1]

1. *University of Peshawar*

The Mirpur city and surrounding villages were severely damaged by extensive coseismic liquefaction within 6 km of the epicentre of the Mw 5.8 Mirpur earthquake on 24 September 2019. The earthquake-induced coseismic deformation on the ground surface included sand blows, ground failure and lateral spreading, whereas subsurface coseismic signatures were observed in the form of elevated groundwater table, fractures, water-filled zones, sand dikes, and lenses of high conductivity. The geology of the study areas is dominated by the Quaternary alluvial deposits overlying a liquefied sandy soil. The inverted electrical resistivity models reveal three regional geoelectric layers having thickness ranging from 2 to 8 m characterized by resistivity values from about 25 Ωm to >100 Ωm. The fractures and elevated groundwater table were mapped on the resistivity and ground penetrating radar measurement (GPR) sections. The subsurface detection of sand dikes produced by transported liquified sand into the shallow subsurface layers and other liquefaction features (conductive clay pockets, and water enriched zones) provide unequivocal evidence of coseismic deformation/unstable ground conditions. Coseismic deformational patterns were found within the area of ground shaking intensity of VI where residential buildings and critical infrastructure (e.g., the Upper Jhelum Canal, bridges, and the main Jhelum–Jatlan road) were severely damaged. ERT and GPR surveys assisted in the reconstruction of these structural and hydrogeological features in the near-surface. Geophysical results were found in agreement with the field observations (sand blow, fissures etc.). Based on geophysical and geological measurements, we infer that the Mirpur earthquake-induced changes in the shallow aquifer system and associated deformation were primarily controlled by the local geological setting and groundwater table amongst other factors.

Crust and upper mantle velocity structure of India, Tibet and surrounding regions analysed using Rayleigh wave dispersion data of earthquakes.

Dr. Siddharth Dey [1]***, Mr. Monumoy Ghosh*** [1]***, Prof. Supriyo Mitra*** [1]

1. *Department of Earth Sciences, IISER Kolkata*

We model the 3D shear-wave velocity structure of crust and upper mantle of India, Himalaya, Tibet and surrounding regions. This highly resolved lithospheric velocity structure upto a depth of 200 km provides detailed understanding and improved clarity on key evolution and deformation aspects. The work provides holistic perspective on the Indo-Eurasian region highlighting three subduction zones, world's largest mountain range, several sedimentary basins, world's largest plateau system, and one major island group in context of their structure and the natural risk they possess with respect to earthquakes.

2D group velocity tomography maps, resolvable laterally at 3°, are produced from 1D event-raypath dispersion curve between 10-120 s. They provide first order insights about the high velocity persistent in cratons of the Peninsular Indian shield, Eastern Himalayan syntaxis, Pamir, Hindukush and other regions representing high grade metamorphic rocks. Similarly, the Mahanadi and Godavari rift, Bay of Bengal basin, Himalayan foreland basin, Afghan Tadjik basin, Makran subduction zone, and Andaman islands represent the sediment-laden low group velocity structures.

The shear-wave velocity (Vs) structure obtained by isotropic inversion is presented as depth sections and profiles to study its lateral variations across the entire region. Focal mechanisms of moderate-to-large earthquakes, Moho depth computed from Airy's isostatic compensation, free-air gravity anomaly data, petrological studies from previous works are investigated in-tandem and discussed with the Vs structure to unravel the tectonic evolution.

Salient insights include flexural bending, underthrusting of Indian plate till Altyn-Tagh fault in western Tibet and till Jiasha suture in central and eastern Tibet, crustal thickness of each tectonic unit, and sediment thickness of major sedimentary basins. Very high velocity in upper mantle region of Indian cratons, Tibet and Hindukush-Pamir is speculated to be due to eclogite facies rocks unlike the Deccan Volcanic Province and eastern Dharwar craton where this high velocity layer is absent, possibly due to plume volcanism related thermal anomaly or metasomatism.

The coherence between the convergence rate, deformation of topography, and the earthquake records discloses this regional scale velocity model as a baseline model that can be considered for disaster mitigation and research studies of local extent within the Indo-Eurasia region.

Archaeoseismology reveals intraplate seismicity – the Indian Peninsula

Prof. Miklos Kazmer [1], ***Dr. Siddharth Prizomwala*** [2], ***Dr. Hamid Sana*** [3], ***Dr. Krzysztof Gaidzik*** [4]

1. Eötvös Loránd University, 2. Institute of Seismological Research, Gandhinagar, gUJARAT, 3. Institute of Rock Structure and Mechanics, Prague, 4. University of Silesia, Institute of Earth Sciences, Faculty of Natural Sciences, Sosnowiec, Poland

Mountainous perimeter of the Indian subcontinent is seismically highly active, while the Peninsula is considered a stable region. Short instrumental record of earthquakes in India make it imperative to use historical and archaeological means to understand past seismic activity. While seismicity of the Himalayas is in the centre of attention of researchers, with a new dedicated monographic volume carrying valuable information, the Peninsula itself is much less studied. We review recently published data on various Hindu, Muslim and Portuguese monuments in Delhi, Konark (Odisha), Mahabalipuram (Tamil Nadu), and Diu, to illustrate the rich possibility of archaeoseismological research. Unknown earthquakes and tectonically raised coasts are identified. Destructive seismic activity is proven in sites considered to be of low seismicity. Deformed man-made structures can be evidence for earthquakes in deep time.

Session 40: The Anthropocene as a tool for characterizing recent planetary change and predicting future environmental challenges

A consideration of global stratigraphic markers for identifying the base of the proposed Anthropocene epoch in the mid-20th century

***Prof. Neil Rose* [1], *Prof. Andrew Cundy* [2], *Dr. Simon Turner* [3], *Dr. Sarah Roberts* [4], *Dr. Jun Inoue* [5], *Dr. Stephen Himson* [6], *Prof. Yongming Han* [7], *Dr. Pawel Gaca* [8], *Dr. Colin Waters* [9]**

Human activities on Earth have become so far-reaching, and the scale and extent of our impacts on biodiversity, biogeochemical cycles, Earth surface processes and climate so profound, that they have led to the proposal that a new geological time period (known as the Anthropocene Epoch) can be defined by this global human influence, starting in the mid-20th century. The process of defining a new epoch requires the identification of a globally synchronous stratigraphic marker for its start point, known as a Global boundary Stratotype Section and Point (GSSP) or 'golden spike'.

While a large number of potential markers have been considered across 12 candidate GSSP sections including radio- and stable isotopes, black carbon, fly-ash particles, organic pollutants, trace metals and microplastics, just a few have been shown to provide the synchroneity required across multiple natural archives. Here, we use data primarily from the Anthropocene GSSP investigations but also from other studies to consider just two of these: plutonium isotopes and spheroidal carbonaceous fly-ash particles (SCPs). We discuss why these markers are especially useful for the Anthropocene and show how records of globally distributed indicators (e.g., Pu) and records of indicators which are regionally distributed but still globally synchronous (e.g., SCPs) can both provide high resolution and reliable stratigraphic records for the new epoch. However, while the global increase in plutonium following the onset of high-yield thermonuclear weapons testing in 1952 is being considered as the main candidate for the primary marker of the Anthropocene, many other indicators also show considerable stratigraphic changes in the mid-20th century. Although the definition of a primary marker is required, ultimately it will be multiple indicators of the extraordinary human impact since the mid-20th century that will identify the new epoch in environmental archives across the world.

The Anthropocene record preserved in the annually laminated sediment succession of Crawford Lake, Ontario, Canada

The varved sedimentary succession preserved in Crawford Lake, Ontario, Canada is one of 12 potential candidate sections to be selected as the Global boundary Stratotype Section and Point (GSSP) for the Anthropocene series/ epoch, with a proposed base in the mid 20th century. The sedimentary succession is comprised of seasonally deposited laminations of organic matter capped by calcite that is precipitated each summer in alkaline surface waters when pH and temperature exceed 7.76 and ~15°C respectively. The sedimentary record preserves diverse proxies that reflect environmental change at local to global scales that have been documented to characterize the beginning of the Anthropocene. The spheroidal carbonaceous particles and bulk sediment nitrogen isotope sequence records a significant increase in fossil fuel combustion in the early 1950s. Ratios of 239Pu:240Pu and 14C:12C both peak in the 1960s, coincident with an increase in radioactive fallout from thermonuclear testing; the latter more than compensating for the effects of old carbon in the dolomitic basin of Crawford Lake. The rapid industrial expansion in the North American Great Lakes region that occurred during, and particularly after, WWII, associated with what has come to be known as the Great Acceleration, led to enhanced leaching of terrigenous elements by acid precipitation. A reduction in calcite precipitation and low primary productivity produced thin calcite laminations coeval with the proposed GSSP. The relative thickness of laminations can be linked to the influence of trends and cycles in climate and lake productivity. Time series analysis identified cycles that are attributed to the Quasi-biennial Oscillation (2.3 years), El Nino-Southern Oscillation (2-7 years), the 11-year Schwabe sunspot cycle and Pacific Decadal Oscillation (50-70 years). The absence of fossil pigments from obligately anaerobic purple sulfur bacteria indicates the presence of an oxygenated monimolimnion with elevated bottom-water salinities being responsible for the preservation of varves. This inference is confirmed by water property data collected through the modern lake water column in all seasons. Such an aerobic depositional environment is unusual for a meromictic lake and serendipitously hindered the mobilization of 239Pu in the lake sediments, the proposed primary stratigraphic marker for the Anthropocene.

Dynamics of biotic and abiotic markers of the Anthropocene at Jasper Ridge Biological Preserve, California, USA

Humans have been altering our planet throughout the Holocene, but the scale of impacts increased dramatically in the mid-20th century, representing the start of the proposed Anthropocene Epoch. These pervasive anthropogenic impacts are comparable in magnitude, uniqueness, and geologic perseverance to the global changes that mark previous major geologic time intervals. To identify the geologic signals that characterize the Anthropocene, we studied two sediment cores from Searsville Reservoir, located at Jasper Ridge Biological Preserve in the eastern foothills of the San Francisco Peninsula, California. These cores have distinct seasonal layers and exceptionally high sedimentation rates—they are 944.5 and 852.5 cm long, and span from 1900 to 2018 CE—which has allowed detailed investigation of the Holocene-Anthropocene transition. One of these cores is being considered as a Global Boundary Stratotype Section and Point for the Anthropocene.

We analyzed concentrations of mercury, lead, and other heavy metals in the cores and found a temporal sequence of increases and declines which likely reflect atmospheric concentrations and historic records of global mining intensity and peak commercial uses. Stable isotope analyses show depletion of ^{13}C caused by burning of fossil fuels, and depletion in ^{15}N caused by global increases in reactive nitrogen—signals which track known atmospheric patterns over the last century. We also analyzed the radionuclides Plutonium-239,240 and Cesium-137, generated by nuclear bomb testing which began in 1945, peaked in 1962, then declined sharply beginning in 1963. In Searsville, the first appearance of ^{239,240}Pu was in late 1946, and both ^{239,240}Pu and ^{137}Cs peaked in 1963, consistent with a lag of 1-2 yrs between ejection of into the atmosphere and deposition. Local indications of human impacts are evident in the pollen and plankton microfossil assemblages and are linked to well-documented historic events in the watershed. Our analyses document the local expression of both local and global human impacts at Searsville and are providing context and critical data for a proposed watershed restoration project. Searsville is particularly emblematic as a geological record of the Anthropocene because the section is itself a direct consequence of human activity—the emplacement of a dam.

Cumulative numbers of anthropogenic fingerprints as a potential marker of the onset of the Anthropocene—an example of the Beppu Bay stratigraphy

For assessment of the potential of the Beppu Bay sediments as a Global Boundaries Stratotype Section and Point (GSSP) candidate for the Anthropocene, we have integrated datasets of 99 proxies. The datasets for the sequences date back 100 years for most proxy records and more than 1300 years for several records. The cumulative number of occurrences of the anthropogenic fingerprints reveals unprecedented increases above the base of the 1953 CE flood layer, which coincides with an initial increase in global fallout of $^{239+240}$Pu. The onset of the proliferation of anthropogenic fingerprints was followed by diverse human-associated events, including a rapid increase in percent modern ^{14}C in anchovy scales, changes in nitrogen and carbon cycling as recorded by anchovy δ^{15}N and δ^{13}C, elevated pollution of heavy metals, increased depositions of novel materials, the occurrence of hypoxia and eutrophication, unprecedented microplankton community changes, abnormally high spring air temperatures, and lithological changes. These lines of evidence indicate that the base of the 1953 CE flood layer is the best GSSP-level candidate in stratigraphy at this site. The cumulative number of anthropogenic fingerprints continues to be high level (no longer decrease) or to increase as long as human impacts on the geological environments persist. The large cumulative number of anthropogenic fingerprints characterizes the Anthropocene Series and is a potential measurable marker for detecting the onset of the Anthropocene.

The Śnieżka peatland as a candidate for the Global Boundary Stratotype Section and Point for the Anthropocene series

The subalpine, atmospherically fed Śnieżka peatland, located in the Polish part of the Sudetes, is one of the nominated candidates for the GSSP of the Anthropocene. Data from two profiles, Sn1 (2012) and Sn0 (2020), from this site are critical for distinguishing the proposed epoch, while an additional core Sn2 is presented to support main evidence. The Sn0 archive contains a wide array of critical markers such as plutonium (Pu), radiocarbon ($F^{14}C$), fly ash particles, Hg and stable C and N isotopes which are consistent with the previously well documented $^{210}Pb/^{14}C$ dated Sn1 profile, which provides a high-resolution and comprehensive database of trace elements and rare earth elements (REE), Pb isotopes, Pu, Cs, pollen, and testate amoebae.
The 1952 worldwide appearance of Pu, owing to its global synchronicity and repeatability between the cores, is proposed here as a primary marker of the Anthropocene, supported by the prominent upturn of selected chemostratigraphic and biostratigraphic indicators as well as the appearance of technofossils and artificial radionuclides.

Distribution and accumulation of SCPs and charcoal particles in the Coosa River, AL, USA

Ms. Emma Henderson [1], ***Dr. Richard Vachula*** [1], ***Dr. Ann Ojeda*** [1]

1. *Department of Geosciences, Auburn University*

Charcoal particles and spheroidal carbonaceous particles (SCPs) in sediments can provide information for paleofire reconstruction, identifying anthropogenic carbon pollution, and dating sediment cores. Recently, SCPs in lakes and peatbogs have been proposed as a potential Global Boundary Stratotype Section and Point (GSSP) for the Anthropocene. Numerous studies of SCPs and charcoal in peatbog, lake, and reservoir sediments have been published. However, few studies have examined their accumulation in riverine sediments, even though fluvial accumulation and transport are plausible mechanisms for their eventual sedimentation in these systems. We address this knowledge gap by analyzing sediments (n=14) along the Coosa River in eastern Alabama (AL), USA near two electric generating plants that have burned coal since the mid-1950s. One plant was completely converted from coal to natural gas in 2015, whereas the other still utilizes some coal combustion but was partially converted to natural gas in 2016. For this study, sediments were collected upstream, adjacent to, and downstream each of the power plants. SCPs and charcoal were measured in replicates (n=30 or 50) for each site. For SCPs, the particle size distribution was also measured using CharTool. We found that for smaller subsample sizes (n<15), the SCP and charcoal counts were highly variable. For SCPs, larger subsample sizes (n>30) followed normal distributions that could adequately be described by a mean and standard deviation ($\bar{x}$=133-261 and σ=46-136). For charcoal, often, the particle count frequency did not follow a normal distribution even at high subsample sizes ($\bar{x}$=278-611 and σ=194-376). These results suggest that quantifying SCPs and charcoal based on a single subsample is insufficient to describe the particle concentrations, particularly in fluvial systems. The mean particle count and size distribution for each site were also mapped spatially to understand accumulation and transport in the context of the two power plants. This study helps to quantify the flux and spatial distribution of SCPs and charcoal in a fluvial system, which has important implications for understanding particle sources and accumulation in lake sediments. Further, our replicate counts have important implications for the use of SCPs as a GSSP for the Anthropocene.

Relationship between Anthropocene, environmental inequality and Sacrifice zones: a study case informed by contemporary paleopollution archives

Dr. Eugenia Gayo [1]***, Dr. Ariel Muñoz*** [2]***, Dr. Antonio Maldonado*** [3]***, Dr. Laura Gallardo*** [4]***, Dr. Paul R. Sheppard*** [5]

1. *Center for Climate and Resilience Research (CR)2,* ***2.*** *Instituto de Geografía & Center for Climate Action, Pontificia Universidad Católica de Valparaíso,* ***3.*** *Centro de Estudios Avanzados en Zonas Áridas (CEAZZA),* ***4.*** *Departamento de Geofísica, Universidad de Chile,* ***5.*** *Laboratory of Tree-Ring Research, University of Arizona, Tucson*

Despite the progress and economic contribution of industrialization over the last 250 years, such productive activities have altered the functioning of the Earth System but with socio-environmental costs bearing disproportionally on low-income communities. Such is the case of sacrifice zones -i.e., territories severely degraded by polluting activities- which have proliferated worldwide since the mid-20th century. By this means, sacrifice zones are deemed as Anthropocene spaces since environmental inequality persists by decisions aimed at increasing consumption/production demands. How global, national, and local socio-economic and policy cycles interact in perpetuating environmental injustice in these territories, however, have been rarely explored. Here, we evaluate the relationship between environmental injustice and Anthropocene by integrating macroeconomic trends, data for social inequality and environmental policies as well as a centennial-scale reconstruction for the pollution burden by unregulated Potentially Toxic Elements (PTEs, i.e., metal(loid)s). Specifically, we outline a case study for the Puchuncaví sacrifice zone (Chile). The trajectory for local pollution loads is informed by geochemical characterizations of dendrochronological and sediment records that span the period between 1872 and 2008 CE. Our results point to an ever-growing load of PETs paced by the staggering growth of local industrial activities, which has ultimately been spurred by national and transnational market forces. Local poverty levels declined concomitantly, but the reduction in environmental inequality is marginal as pollution burden worsened through time. Although national and international regulations succeeded in controlling short-lived pollutants through technological solutions, these instruments appear insufficient in mitigating PETs. This implies that environmental policies to address risks in sacrifice zones should not only focus on mitigation, but also on reducing exposure to hazards accumulated over decades. That is, considering rehabilitation actions based on the preventive principle. For instance, in our study case the just transition process is not guaranteed -even under a carbon neutrality scenario- as this territory will continue to be affected by long-lived PETs. Thus, integrative historical reconstructions for socio-environmental processes have the potential to inform the discussion on governance in the Anthropocene. Particularly, regarding how environmental justice could be assessed when economic models prioritize growth to the detriment of the human and environmental well-being.

Session 41: Late Quaternary desertification, landscape changes, paleoclimate, and human adaptation

Late Quaternary palaeoenvironment history of the Kashmir Valley, Western Himalayas

Dr. Rayees Shah [1] ***, Prof. Shakil Romshoo*** [2]

1. Islamic University of Science and Technology, University Avenue, Awantipora -192122, India, 2. Islamic University of Science and Technology University Avenue Awantipora, Pulwama, Pin-192122 Jammu and Kashmir,

The climate during the Late Quaternary Period was characterized by the repetition of cold glacial and warm interglacial periods, with glacial periods being much longer than interglacial periods. The Karewa group of sediments in the Kashmir Valley is an excellent archive to study the climate fluctuation of the Late Quaternary Period. We studied loess-palaeosol sections and lake sediment sequences of the Kashmir Valley to understand the evolution of the Late Quaternary palaeoclimate. Statistical deviation in the multi-proxy data of the loess-palaeosol sections reflected variable depositional and post-depositional processes that operated in the study area. The palaeosols of the studied profile indicated polycyclic nature probably developed during the cycles of climate amelioration. The presence of well-developed AhBtk palaeosol during the MIS-3 indicated a wetter climate during this phase. A steady increase in the $CaCO_3$ content and the C/N ratio in the loess indicated arid and drier climatic conditions during the MIS-2. Multi-proxy studies (δ13C, δ15N, major oxides and trace geochemistry, etc.) carried out on various lacustrine trenches and cores revealed the occurrence of a cold climate from 29 to 20 ka, with peak intensity at around 26 to 24 ka. The Kashmir Valley observed substantial glacial advance during the Last Glacial Maximum. The proxy records revealed continuous climate warming from 20 to 12 ka. The lacustrine records of the Holocene Epoch revealed signatures of cold climate phases that corresponded to the Bond events 0, 3, 4, 5, and 7. This indicates the substantial influence of the westerly-dominated climate during the Holocene Epoch. The sedimentary process revealed strong anthropogenic influence due to forest land clearing and agriculture extension during the last 2 ka.

Tropical Rainforest Paleoenvironmental Shifts Since The Late Pleistocene Based On Lake Sediments, Kodaikanal-Nilgiris, India

Prof. Hema Achyuthan [1]***, Dr. Priyanka Raja*** [2]***, Dr. Vijayaraj Rajamanickam*** [3]

1. *Institute for Ocean Management, Anna University, Chennai 600025,* ***2.*** *Department of Geology, Anna university, Chennai 600025,* ***3.*** *Department of Geology, Anna University, Chennai 600025*

Limnological studies in Kodaikanal (Kukkal ~1890 masl, Berijam Lakes ~ 2165 masl, and Parsons lake~2285 masl) were carried out to determine paleoenvironmental shifts and their possible impact on vegetation since the late Pleistocene period. This region dominantly receives the southwest monsoon rains from June to September. Lake trenches and sediment cores retrieved from these lakes were radiocarbon dated and the ages reveal non-linear phases of deposition. Berijam lake core is dated from 2400 yrs BP to the present and older ages for Kukkal (9000 yrs BP to Present) and Parsons Lake (~29,800 yrs BP to present). Integration of all the proxy data signifies six distinct paleoenvironmental phases: 1) Warm and humid conditions with a high lake stand before the last glacial maximum (LGM- ~29,800 cal yr BP), subsequently altering to a relatively cool and dry phase during the LGM. 2) Drier conditions and lower precipitation occurred between ~16,300 and 9500 cal yr BP causing vegetation to shrink and possibly being confined to moister pockets or riparian forest cover. 3) An outbreak in the shift of monsoonal precipitation was witnessed at the beginning of the mid-Holocene in the Parson's lake, around 8400 cal yr BP, implying alteration in the shift toward warm and humid conditions, resulting in relatively high pollen abundance for evergreen taxa. However, wet, Holocene climatic optimum (9000 yrs to 5000 yrs BP) was noted in the Kukkal sediment core. 4). From 5000 yrs BP to the present, drier conditions prevailed due to the decline in southwest monsoon intensity and its amount. During this long dry period, several wetter events of shorter duration occurred. 5). Medieval warm period and Little Ice Age events were noted in the Berijam lake core. 6) Around ~1850 cal yr BP, a shift to heavier $\delta^{13}C$ values with the emergence of moist deciduous plants points to drier conditions. Anthropogenic activity contributed to the high percentage of *Acacia* and *Pinus* pollen during the Little Ice Age. Variations in the grain size distribution indicate paleoflood events influenced by regional climatic conditions and identified by the silty sediment matrix around □29,838 and □8405 cal yr BP.

Late Quaternary sediment characterization, neotectonics and climatic record of Ladakh, Northwest Trans-Himalaya, India

Dr. Biniita Phartiyal [1], *Dr. Debarati Nag* [1], *Ms. Priyanka Joshi* [1]

1. Birbal Sahni Institute of Palaeosciences

Ladakh is a cold arid high altitude desert lying in the Trans-Himalaya is surely a treat for geographers and geologists eyes because of its lunar/martian landscapes; exposures of sedimentary, metamorphic, and igneous rock types; glacial, fluvial-lacustrine sediments and active tectonic and climatic processes. This work sums up the sedimentary characteristics, tectonic and climatic history with examples from the variety of sediment exposures along the Indus River and Ladakh Range. The overall geomorphological evolution of Ladakh is basically governed by two sets of geological processes- the continental scale geological processes that have primarily provided the basic framework for the landscape and second the regional/local scale geological processes in which the role of tectonics and climate which has been significant in determining the glacial, fluvial, lacustrine and aeolian processes. The transient topography of the region is attributed to -movement along active Stok thrust along the Indus Sut ure Zone; long-term steady-state perturbed by climate change; situated in the orographic rain shadow zone, and landscape not in the cosmogenic steady state due to topographic effect and methodological uncertainties of data. A number of lake sediments (paleo and proglacial) were studied with a multi-proxy approach for recording the climate. A composite and complete picture of the Holocene climatic variation shows five prominent arid phases mark the Holocene period in Ladakh (~10800-10000; ~8800-8600; a longer arid phase at ~5200-2600 with increasing aridity towards the top part; ~1700-1500 and ~500 cal yr BP) intervened by comparatively warmer conditions in between. Two sources of precipitation (Westerlies and ISM) are responsible for governing the hydro-climate of the region. The westerly dominates at the beginning of the Holocene while the mid-Holocene sees the advent of ISM to the region. The lake records and other published records from the region show that this change in the moisture source has occurred several times in the Holocene- 7200, 5200, and 2600 cal yr BP although the westerly has been a dominant precipitation source in the Ladakh region through most of Holocene. Both exogenic and endogenic forcings are responsible to shape the topography of the region.

Holocene climatic variations inferred from the multi-proxy record from Chilika Lagoon, East coast India

<u>*Dr. Imran Khan*</u> [1], ***Dr. Rayees Shah*** [2]

1. *Aligarh Muslim University,* ***2.*** *Islamic University of Science and Technology, University Avenue, Awantipora -192122, India*

Holocene climatic variability and associated societal growth and demise have received considerable attention and key research domain because of the concerns about their reoccurrences in the future. Therefore, several important studies have been conducted focused on understanding the Holocene aridification at ~8.2 and ~4.2 ka BP around the globe. The present study focused on the Holocene palaeoclimatic records reconstructed based on new multi-proxy high-resolution geochemical and ^{14}C chronological data from the Chilika Lagoon (Odisha), east coast of India. Around 1.3 m long sediment core, obtained from the lagoon's southern shore, showed a consistent sedimentation history between 8.49 and 0.99 ka BP. The variations in total organic carbon (TOC) content, major and trace element abundances, and the isotopic signatures of organic carbon composition ($\delta^{13}C$) pointed out a significant climatic effect from the dry events that occurred at 8.2 and 4.2 ka BP. Additionally, a significant warm climate anomaly was also noted at 1.2 ka BP. It's interesting that increased sedimentation rates were observed after 4.2 ka, which is linked to a substantial shift in the settlement pattern and human activity. As a result, we postulated that the eastern part of Odisha witnessed human migration and change in agricultural practices in line with societal changes documented in north-western India after the 4.2 ka aridification event. We speculated that people moved to new locations, which eventually led to increased pastoral activity in the newly occupied regions. Consequently, the region experiences increased land use and land cover changes, as well as increased soil erosion, which corresponds to high sedimentation rates. The fact that several periods coincide with significant societal upheavals shows the importance of Holocene climate variability for humans.

Palaeohydrological reconstruction of Laguna de Villena (SE Iberian Peninsula) since 9100 yr cal BP to 5400 yr cal BP inferred from high-resolution geochemical analyses

Endorheic saline lakes are usually highly sensitive to hydrological processes. Therefore, the sensitivity of this environments means that, with multi-proxy analysis, they are good sedimentary systems to investigate the impacts of past climate changes. This work presents the results of the geochemical analysis of a core from Laguna de Villena, ephemeral salt-lake located in southeastern Spain. Powder X-ray diffraction (PXRD) measurements have been performed on 84 samples, from 120 cm to 284 cm depth. The selection of the samples corresponds to the geochronology we focus on in this study, from cal. 9100 yr. BP to 5500 yr. BP, during the Early-Middle Holocene transition.

Numerous mineral phases were identified from the PXRD and include calcite, magnesium calcite, muscovite, aragonite, quartz, dolomite (including Fe-rich dolomite), gypsum and halite. These phases are classified into four groups: 1) calcite, Mg-calcite and muscovite, linked with increased freshwater either via torrential rainfall or discharge from runoff water; 2) quartz, associated to increased terrigenous input; 3) halite and aragonite, which indicate more arid conditions and a decrease in the water level; and 4) gypsum and dolomite, which indicate increased in salinity and is linked to arid conditions. However, because ambiguous gypsum's origin, water table reconstruction have been performed with aragonite, calcite and dolomite.

The results show a significance water table variability during the Early-Mid Holocene. Humid conditions and an increase in the water table will be from cal. 7100 yr. BP to 6800 yr. BP, and from cal. 5900 yr. BP to 5500 yr. BP. During these two periods, weight contents of calcite, magnesium calcite and muscovite are higher and, on the opposite, aragonite and dolomite show low values. On the other hand, arid conditions and a decrease in the water level will be from cal. 9100 yr. BP to 8900 yr. BP, and peaks in cal. 8300 yr. BP, 7800 yr. BP, 6600 yr. BP and 6000 yr. BP, when there are positive trends of aragonite and dolomite, and negative trends of calcite, muscovite. As a conclusion, climate variability is reflected in geochemical properties as well as water level fluctuations are linked to climate fluctuations.

Luminescence chronology of Diêm and Mang Chieng Caves in northern Vietnam, and the archaeological and palaeoenvironmental implications

***Dr. Xiao Fu* [1], Dr. Alexander Kandyba [2], Dr. Conor McAdams [3], Prof. Anatoly P. Derevianko [2], Dr. Doi Gia Nguyen [4], Dr. Dong Truong Nguyen [4], Prof. Richard G. Roberts [5]**

Northern Vietnam is a critical migration corridor for late Pleistocene hominins in East Asia. The abundant cave sites discovered in this humid tropical region are important for understanding the complex human history of Southeast Asia, as well as their linkages to prehistoric cultures in southern China. Reliable chronologies are essential for unravelling the archaeological significance of these sites. In this paper, we present chronological results of single-grain (SG) optically stimulated luminescence (OSL) dating of two karst caves located in Cúc Phương National Park in northern Vietnam—Diêm and Mang Chieng Caves. Both sites contain multiple shell-rich layers associated with prehistoric human occupation, as well as stone artefacts exhibiting features typical of the 'Hoabinhian' culture. SG equivalent dose (De) distributions of quartz grains and micromorphological features indicate that most of the shell-rich layers have been subjected to post-depositional mixing. The De populations representing the original depositional ages of the layers were identified according to the SG De distribution pattern and the consistency between the ages and depths of the samples, and the impact of shell fragments on the estimation of the environmental dose rates—and, hence, the OSL ages—is modelled and discussed. A chronological framework of the cave sediments is established based on Bayesian age-depth modelling. The chronologies for the two cave sites reveal the emergence of the Hoabinhian in northern Vietnam earlier than 20,000 years ago, suggesting this region has one of the earliest records of this culture in Southeast Asia. The environmental context of hominin occupation of the two caves is discussed by combining these chronologies with microstratigraphic study of the cave deposits and with other evidence of palaeoclimatic changes in mainland Southeast Asia.

Early- to mid-Holocene lake formation in NW Arabia was driven by the West African Monsoon

The early- to mid-Holocene humid period (HHP) is well established for North Africa and the southern Arabian Peninsula. Evidence from northern Arabia has been ambiguous so far. The impact of a more humid climate on hydrography and the vegetation has been controversially discussed, with some researchers challenging the existence of perennial lakes in northern Arabia at that time. Here, we present a new Holocene shoreline record mainly consisting of bioclastic deposits (gastropods, barnacles, foraminifers, ostracods) up to several metres thick. These deposits are partly eroded and frame an endorheic basin in the oasis of Tayma (NW Arabia) indicating the presence of a >17 m deep and >22 km² palaeo-lake. Taphonomic macrofossil analysis based on a newly developed key of preservation reflects the rising lake (base of the profile) and the highest lake stand (mid- to upper part of the deposit) with many entirely preserved autochthonous barnacle carapaces. Sub-decadally resolved proxy data from the varved lake sediments at the centre of the basin (micro-facies analyses, pollen record of shoreline and submerged vegetation, TOC, stable isotopes) and varve and radiocarbon dating point to five phases of lake development between 8,800 and 7,900 cal yr BP. The most humid phase with highest lake levels corresponding to the mapped shoreline deposits is dated to 8,550–7,950 cal yr BP. A transient simulation conducted in the Earth System Model MPI-ESM for the last 8000 years indicates much stronger late-summer rainfall than today during early to mid-Holocene embedded in the intensified West African monsoon (WAM) circulation. Based on the model, the monsoon rainbelt reached substantially further east and north onto the Arabian Peninsula 8000 years ago and retreated back to its modern position during the mid- to late Holocene. Tayma is located at the distal fringe of this increased monsoonal influence. This may explain the very short existence of the perennial lake of a few centuries only, compared to the HHP's millennial-scale impact on landscapes in areas closer to the core domains of the WAM and also the South Asian Monsoon.

Session 42: Ecosystem change and hunter-gatherer behavioral decisions in the terminal Pleistocene Pacific Rim

The American Upper Paleolithic and the Coastal Migration Theory

Dr. David Madsen [1], ***Dr. Loren Davis*** [2]

1. *University of Nevada-Reno,* ***2.*** *Oregon State University*

In North America there are now enough sites with relatively large stone tool assemblages predating ~14.5 ka, well before an ice-free corridor became available, to allow some assessment of the underlying characteristics of the lithic tradition they share and to hypothesize where and when in the world this lithic tradition may have originated. These sites share a broad technological similarity involving the use of dual core-and-blade and biface technologies similar to that found in the late Upper Paleolithic of northeast Asia. In the core and blade system, flat-faced, wedge-shaped, and occasionally conical cores are used to produce elongate blades and/or blade flakes which constitute one of the primary tool forms used by the initial occupants of North America. These elongate, prismatic blade flakes were often used unmodified as cutting tools but were also retouched into a variety of other tools such as scrapers, drills, and projectile points. In the parallel biface technology comedial flaking was used to produce proportionally flaked bifaces, with many of the removal flakes used expediently as modified flakes. These dual technological approaches were often merged to produce small projectile points, usually less than 5 cm in length, which vary in morphological form from site to site but often include stemmed point forms. Similar dual core-and-blade and biface technologies are found in Late Upper Paleolithic assemblages in northern Japan dating to ~20 ka. We suggest a group with a similar lithic technology became isolated somewhere in the vicinity of the Japan/Paleo-Hokkaido, Sahkalin, Kuril (PSHK) region of northeast Asia, developing genetically into ancestral ancient Native American population. Between ~22-18 ka a subset of this population began migrating by foot and boat along the southern Beringian coast and down the Alaskan and Canadian coastline into the Americas. By ~15-16 ka they had become widely dispersed across North America south of the continental ice sheets.

Geochronology and techno-typology of the stemmed point on blade in the Japanese archipelago

Dr. Kazuki Morisaki [1]

1. The Univeristy of Tokyo

The stemmed point across the northern Pacific Rim, which includes the Japanese archipelago, has recently been the focus of discussion with respect to the peopling of Northeast Asia and the Americas. This presentation discusses the geochronology and techno-typology of the stemmed point in the Japanese archipelago. During the late Pleistocene, several mid-latitudinal islands of this archipelago formed a large landmass named Palaeo–Honshu (P–Honshu). The stemmed point abruptly appeared in the Kyushu region, the western edge of P–Honshu, for a short period between 29,300 and 27,500 cal BP and was utilized as a primary hunting weapon. It was first named the *hakuhen-sentoki* stemmed point (HSP), which is produced by notching both laterals of the proximal end of a pointed blade. The techno-typology of HSP has a distinct similarity with the stemmed or tanged point of the adjacent Korean Peninsula, which long prospered from between about 40,000 to 20,000 cal BP, strongly suggesting that the HSP was derived from the tanged point in the peninsula and was adopted by foragers in the Kyushu region at the beginning of MIS2. After 27,500 cal BP, HSP rapidly changed their form into flake-based ones and subsequently disappeared. This observation indicates a short-term/small-scale human migration/interaction between the Korean Peninsula and Kyushu led to the emergence of the HSP in Kyushu. Outside Kyushu, several archaeological sites bearing the HSP were scattered throughout P–Honshu. However, among the whole hunting weapons at each site, its percentage is quite low, indicating that the HSP outside Kyushu appeared occasionally or was simply an alternative to different hunting weapons. Geochronologically, the traditional connection between the HSP and the bifacial stemmed point of the Incipient Jomon, after 16,000 cal BP, has not been clarified on P–Honshu.

Using geophysical and geological data to reconstruct submerged coastal landscapes along the eastern Pacific margin of North America

Prof. Jillian Maloney [1], ***Dr. Amy Gusick*** [2], ***Prof. Shannon Klotsko*** [3], ***Dr. Todd Braje*** [1], ***Dr. Loren Davis*** [4], ***Dr. Jon Erlandson*** [5], ***Mr. David Ball*** [6]

1. *San Diego State University,* ***2.*** *Natural History Museum Los Angeles County,* ***3.*** *University of North Carolina Wilmington,* ***4.*** *Oregon State University,* ***5.*** *Museum of Natural and Cultural History, University of Oregon,* ***6.*** *Bureau of Ocean Energy Management*

During the last glacial maximum, eustatic sea level was ~120 m below present, exposing most of the world's continental shelves, and providing a vast landscape for human migration and occupation that is now submerged due to post glacial sea-level rise. Reconstructing the late Pleistocene landscape of the continental shelf is critical for locating submerged archaeological sites and improving our understanding of human migration pathways and human adaptation to a changing climate. We present high-resolution subbottom and sediment core data from two locations along the eastern Pacific margin of North America: the Northern Channel Islands, California, and central Oregon. These data were used to identify paleoshorelines, paleochannels, and intact terrestrial and estuarine deposits preserved beneath Holocene marine sediment. The identification and mapping of these paleolandforms is used to characterize how continental shelf landscapes have evolved since the last glacial maximum and assess the relevant forcing mechanisms of coastal and nearshore landscape change. These data are critical for landscape reconstruction models and refining the search for submerged archaeological sites.

Submerged Pleistocene-aged Landscapes and a Coastal Route of Entry into the Americas

Dr. Amy Gusick [1]***, Prof. Jillian Maloney*** [2]***, Dr. Todd Braje*** [2]***, Prof. Shannon Klotsko*** [3]***, Dr. Jon Erlandson*** [4]***, Mr. David Ball*** [5]

1. *Natural History Museum Los Angeles County,* ***2.*** *San Diego State University,* ***3.*** *University of North Carolina Wilmington,* ***4.*** *Museum of Natural and Cultural History, University of Oregon,* ***5.*** *Bureau of Ocean Energy Management*

Sea-level rise following the Last Glacial Maximum submerged millions of square kilometers of coastal landscapes around the world, complicating efforts to understand the paleolandscapes, paleoecology, human dispersals, and the cultural history of these now drowned regions. This situation is particularly troublesome in the Southern California Bight on the eastern Pacific Coast where sea-level rise inundated thousands of square kilometers of coastal terrain, including entire islands. Still, this region boasts one of the highest densities of terminal Pleistocene and early Holocene archaeological sites in the Americas, making it an ideal location to consider early maritime human populations and a hypothesized Pleistocene coastal route of entry into the Americas. Over the past few decades, researchers have identified hundreds of subaerial Paleocoastal archaeological sites in this region, but these likely represent a fraction of the resources and maritime spaces used by peoples present across the terminal Pleistocene and earliest Holocene landscape. Recognizing that these resources and spaces are critical to understanding our human past, recent interdisciplinary research is focusing on the area's submerged paleolandscapes to identify how rapidly shifting habitats and evolving landscapes affected human migration, settlement, and resource strategies during periods of drastic climatic change. This marine social science research is informed and supported by geological, biological, and geophysical marine science disciplines and considers both the landscape and seascape as a continuous ancient maritime cultural space. This presentation will focus on this interdisciplinary research that investigates the timing and nature of environmental and ecosystem change to inform the search for sensitive cultural maritime landscapes. Data gleaned from these landscapes provide critical data to understand the history of maritime adaptations and a Pleistocene coastal route of entry into the Americas.

Western Pacific landscape changes during the Late Pleistocene and the early Holocene related to global ice volume changes

Prof. Yusuke Yokoyama [1]

1. *Atmosphere and Ocean Research Institute, University of Tokyod*

Variations in global mean sea level (GMSL) are controlled mainly by growth and decay of continental glaciers and temperatures that are closely correlated with the mean global climate state such as glacial and interglacial cycles. Fluctuations on millennial time-scales produce locally complex changes coastlines, associated with short-term influence on species development including modern human. Recent developments in sampling and analytical methods enable us to more precisely reconstruct past sea-level changes using geological indicators dated by radiometric methods. These revealed rapid changes in sea levels during the late Pleistocene and Holocene from the time into and out of the last glacial maximum (LGM: 20ka). The GMSL was around -125 to -130m during the LGM, approximately 10 kyrs long, was the coldest period in Earth's recent climate history and tropical sea surface temperatures were about 3 to 5 degrees Celsius lower. The LGM began when GMSL abruptly dropped by about 40 m around 31 ka and was followed by about 10 kyrs of rapid deglaciation into the Holocene. Ups and downs of GMSL reached as fast as more than 3 milli metres per year. This leads the coastline changes and the opening or closure of ocean passages, as narrow bridges allowing limited species crossing or as fully colonized corridors, had severe impact on eco-fragmentation and the expansion or contraction of species. This presentation will review the sea-level and climate during the last late Pleistocene to the early Holocene in Western and North Western Pacific region.

Microblade and bifacial point technology for Late and Terminal Upper Paleolithic in Hokkaido, northern Japan

Dr. Daigo Natsuki [1]

1. The University of Tokyo

Recent studies on peopling of the America have focused on stemmed points in the late Pleistocene as evidence for coastal migration through the Pacific Rim. This study examines the diversity, age and distribution of Late Upper Paleolithic (LUP) and Terminal Upper Paleolithic (TUP) lithic assemblages in Hokkaido, with a particular focus on microblade and bifacial point technology. During the late Pleistocene, Hokkaido was a southern margin of the "Paleo-Sakhalin/Hokkaido/Kurile Peninsula", connected to mainland of northeastern Asia. LUP and TUP lithic assemblages have been found from strata above En-a tephra (21,000-19,000 cal BP) in Hokkaido. The LUP and TUP assemblages are characterized by a variety of microblade technology, blade tools, and bifacial tools, and can be divided into at least eight technocomplexes. Although a large number of excavations and studies of archaeological sites in Hokkaido have reported many results radiocarbon dating associated with the UP, there were few dates acceptable for the chronological order of LUP and TUP due to the thin sediment deposition on the gentle slopes and post-depositional processes. Acceptable dates associated with the assemblages are 18,000-17,000 cal BP for the technocomplex of the late LUP, which includes the Togeshita type and the Sakkotsu-type microblade cores. Many previous studies have emphasized bifacial stemmed points, stone axes, and large blades as archaeological components of the TUP in order to compare the TUP (or the Late microblade assemblages) in Hokkaido with the Incipient Jomon period after 16,000 BP in the Paleo-Honshu. Analysis of the lithic assemblages and their associated ages in this study reveals that several technocomplexes previously included in the TUP are incorporated into the early LUP (21,000-18,000 cal BP). The result makes it possible to better understand temporal changes in lithic technology that are consistent between the Paleo-SHK and the Paleo-Honshu during the terminal Pleistocene. This implies that the migration of people and the diffusion of lithic tool technology, including microblade and bifacial point technology, between the Paleo-SHK and the Paleo-Honshu rapidly triggered widespread changes in adaptive strategies in response to environmental changes.

Palaeoenvironment of southeast Alaska during the terminal Pleistocene

Dr. Kelly Monteleone [1], ***Dr. Rosita Worl*** [2], ***Dr. Andrew Wickert*** [3], ***Dr. Richard Barnes*** [4], ***Dr. Kerry Lee Callaghan*** [5]

1. *Department of Anthropology and Archaeology University of Calgary,* ***2.*** *Sealaska Heritage Institute,* ***3.*** *Department of Earth and Environmental Sciences, University of Minnesota,* ***4.*** *Lawrence Berkeley National Lab,* ***5.*** *Department of Earth and Environmental Sciences, University of Illinois Chicago*

At approximately 17,000 cal BP, sea levels in southeast Alaska dropped by as much as 165 m below modern. The continental shelf would have been along the coastal migration route of early people to the Americas. The biological evidence indicates glacial refugia and the terrestrial archaeological record indicates that people were present by at least 12,000 cal BP. The main focus is on Shakan Bay, a sheltered inlet in northwest Prince of Wales Island, southeast Alaska. Shuká Káa Cave just north of Shakan Bay dates to 12,129 cal BP and includes lithics from south of Shakan Bay, indicating that people knew this area before 12,000 cal BP. Additionally, a submerged fishing structure or weir has been identified at approximately 50 m or 11,100 years ago based on the current sea level reconstruction. This project combines environmental reconstruction, an archaeological resource-based predictive model, and marine geophysical surveys to better the changing environment at the end of the Pleistocene and early Holocene and human responses to these changes.

The peopling of Eurasia and the Americas inferred from human genome analysis

Dr. Kae Koganebuchi [1] ***, Prof. Hiroki Oota*** [1]

1. *Department of Biological Sciences, Graduate School of Science, The University of Tokyo*

Eastern Eurasia at the end of the Late Pleistocene was the gateway to the northern part of the Americas. Modern and ancient human genome analyses can provide insight into the migration process and reveal the paths taken by populations that arrived in the Americas. The people had to reach first the Northeastern part of Asia, but the route they followed to cross the vast distances in the Asian continent is still a matter of debate. Two major routes have been proposed: The first one is a route that circumvents the Himalayas going through the North, and the second one is a route that occurred through the Indian subcontinent that is the South of the Himalayas. Due to the cooler climate on the northern route, preservation of biological remains is better than on the southern route. Moreover, the southern route has a warmer and more humid environment. This makes it an unsuitable place for the preservation of old bones. For these reasons, ancient DNA research in the southern region was more difficult and fell behind that in the northern region. However, research on there has been accumulating in recent years due to improved sequencing techniques and the discovery of human remains containing adequate amounts of endogenous DNAs. The findings reinforce our understanding of when and how Upper Paleolithic Northeast Asian peoples inhabited the northern part of the Pacific rim. Therefore, we summarize the findings of migration and admixture inferred from genome analyses, and consider the first migrants to the Americas. In addition, the possibility of detecting traces of occupation based on paleoenvironmental analysis using sedimental ancient DNA analysis is also presented.

Using Archaeological and Human Genetic Evidence to Evaluate the Migration Routes taken by the Earliest Americans into Unglaciated North America at the end of the Pleistocene

Dr. Michael Waters [1]

1. *Center for the Study of the First Americans, Texas A&M University*

The Laurentide and Cordilleran ice sheets of North America reached their maximum extent during the Last Glacial Maximum (~26,000-19,000 yr B.P.) and blocked the movement of people into unglaciated areas to the south. Eventually, as temperatures increased, the western edge of the Cordilleran ice sheet receded opening a Pacific coastal corridor and the western edge of the Laurentide ice sheet retreated opening an inland corridor. Geological and geochronological evidence indicates that the inland corridor opened by ~13,800 ± 500 yr B.P. and the coastal corridor was passable by ~16,000 yr B.P. Because the oldest archaeological evidence from either corridor only dates to the Younger Dryas, the route taken by the first people to enter the Americas remains unclear. However, genetic studies indicate that people were south of the continental ice sheets by ~15,700 yr B.P. Additionally, archaeological evidence from the Debra L. Friedkin and Gault sites, Texas; Hebior and Schaefer sites, Wisconsin; Page-Ladson site, Florida; Paisley Caves, Oregon; Cooper's Ferry site, Idaho; and the Manis site, Washington, indicate that people entered the Americas by ~16,000 yr B.P. and were widespread in North America by ~15,000-14,500 yr B.P. Based on the current geological and geochronological evidence from the coastal and inland corridors, the genetic and archaeological evidence from what was unglaciated North America is most consistent with the first Indigenous people entering the Americas via a coastal route.

Subsistence strategies of prehistoric hunter-gatherers on a small island of Tokunoshima, Japan

Prof. Katsuhiro Sano [1], ***Prof. Yoshihisa Suyama*** [1], ***Prof. Yasufumi Iryu*** [1]

1. *Tohoku University*

Tokunoshima is a small island located in the middle of the Ryukyu Islands, around 400 km to the south-southwest from Kyushu (the third-largest island of Japan), and around 800 km to the east-northeast from Taiwan. Recent archaeological investigations indicate that hunter-gatherers have continuously occupied on the Tokunoshima island since the Terminal Pleistocene at ~14 ka. However, cxcept for the Ryukyu Islands, few small islands in the world have been successfully colonized by prehistoric hunter-gatherers, as their subsistence required large landmass. It is little known how Ryukyu hunter-gatherers successfully adapted to the environment on small islands where natural resources were limited. In this talk, we present preliminary results of the FRiD (Frontier Research in Duo) grant project that tries to better understand subsistence strategies of the island hunter-gatherers that enabled them to settle on a small island over 10,000 years. Besides studies on archaeological materials, including stone artifacts, pottery, and ornaments, we analyzed carbon and oxygen isotope records in *Tridacna*shells recovered from prehistoric sites on the Tokunoshima island to precisely reconstruct the paleoclimate. We also undertook ancient and present DNA analyses of plant and animal samples to detect the roots of the domestication. The multidisciplinary approaches provide us with an opportunity for elucidating adaption strategies of the hunter-gatherers to the drastic climate changes from the Terminal Pleistocene to the Holocene on the small island of Tokunoshima.

Pottery, lithics, and geochronology: late Pleistocene ceramic users of the northwestern Pacific rim and human migration event to the Americas, an updated view

Dr. Fumie Iizuka [1], ***Prof. Masami Izuho*** [2], ***Dr. Loren Davis*** [3], ***Dr. David Madsen*** [4]

1. University of Missouri, 2. Tokyo Metropolitan University, 3. Oregon State University, 4. University of Nevada-Reno

Current evidence from archaeological sites in North America suggest that humans were present south of the continental ice sheets by ca. 16,000 cal BP. Archaeological data, paleoenvironmental conditions, and genomic data combined indicate that Native American ancestors likely migrated from Northeast Asia along the coast of Pacific rim. On the western Pacific rim, the Japanese archipelago has ceramic-bearing sites confidently dated to the late Pleistocene. These occupations are loosely categorized as the Incipient Jomon. Due to general geochronological overlaps, scholars have compared Jomon-related lithic technology, and genetic signatures with Pleistocene North American context. Results have been somewhat controversial. While there is no genomic data that suggest a direct connection of Jomon and Native American ancestors, bifacial stemmed points in the Incipient Jomon have been inferred as having similarities to assemblages found along the eastern Pacific rim. Unlike the Incipient Jomon sites, however, pottery is absent at first American sites. In this presentation, we critically review data on Incipient Jomon ceramics and associated lithics and geochronology. This study updates the work by Iizuka (2018) by paying more attention to the timing of the emergence of lithic types that overlap with early American assemblages. Our research suggests that in the Paleo-Sakhalin-Hokkaido-Kuril Peninsula, pottery and lithic technology of the Incipient Jomon did not emerge before ca. 14,700 cal BP. Aceramic sites bearing bifacial stemmed points suggested as Incipient Jomon (Natsuki 2022) await confirmation of absolute dates; absence of pottery in this context can be due to diagenesis. In central paleo-Honshu Island, pottery appears with bifacial stemmed points, but only by ca. 15,500 cal BP. Based on currently available data, we suggest that low visibility is not the reason pottery is absent in the terminal Pleistocene Americas; pottery using behaviors associated with bifacial stemmed points with subsequent patterns in morphological changes in the western Pacific rim, emerged after humans had migrated to North America.

Hooks of the Ancient Mariners: The Oldest Specialized Maritime Technology in the Americas

Dr. Matthew Des Lauriers [1], ***Dr. Loren Davis*** [2], ***Mr. Antonio Porcayo-Michelni*** [3], ***Dr. Claudia García-Des Lauriers*** [4]

1. *California State University, San Bernardino,* ***2.*** *Oregon State University,* ***3.*** *Instituto Nacional de Antropologia e Historia,* ***4.*** *California State Polytechnic University, Pomona*

Isla Cedros, Baja California, México is a remarkable place; it is a high, mountainous and tectonically active island located on the extreme west coast of the North American continent. It is home to some of the oldest evidence for human occupation of the coast along the Pacific margin of the American continents, represented by assemblages from multiple sites demonstrating a robust maritime focus of resource harvesting with sustained occupation at prime locales. Significantly, archaeological excavation at several of these sites has also produced unequivocal evidence of specialized maritime *technology* dating to the Terminal Pleistocene in the form of the oldest fishhooks between the Bering Strait and the Atlantic. These assemblages of fishhooks were recovered from contexts securely dated by extensive radiocarbon assays to between 10,000 and 13,000 CalBP. One of the most essential evaluations of human engagement with the environment is the degree to which the natural and ecological conditions have shaped the nature and form of the human technological system. The size of this assemblage (n=42) allows some degree of investigation of concepts of design and engineering even from such a remote timeframe. These hooks are manufactured from abalone (*Haliotis* sp.) and mussel (*Mytilus californianus*) shell and range in size between less than 3cm in length to over 8cm in length. Comparing the assemblages of maritime technology from Isla Cedros, México to other early maritime systems of the Pacific Rim and elsewhere should provide a baseline for understanding the early adaptive contexts of Pleistocene migrants along the Pacific Coast of the Americas. Notably, the investigations at Isla Cedros have produced one of the largest assemblages of Pleistocene-aged fishhooks anywhere in the world.

The Search for Late Pleistocene-Aged Submerged Sites on Oregon's Continental Shelf: Methods and Recent Discoveries

Dr. Loren Davis [1], ***Prof. Jillian Maloney*** [2], ***Prof. Shannon Klotsko*** [3], ***Mr. Alexander Nyers*** [4], ***Mr. Dave Ball*** [5]

1. Oregon State University, 2. San Diego State University, 3. University of North Carolina Wilmington, 4. Northwest Archaeometrics, 5. Bureau of Ocean Energy Management

Geographic information systems-based modeling of submerged paleolandscapes along the central coast of Oregon, USA combined with offshore geophysical and marine coring studies led to the discovery of multiple submerged and buried alluvial drainage systems dating to the late Pleistocene period. Here, we briefly review the modeling, offshore surveys and coring, and subsequent analyses that led to such discoveries. These discoveries highlight the preservation of landscape-scale stratigraphic units that may hold archaeological evidence of early coastal peoples or signal the nearby presence of geoarchaeologically relevant landform targets. The archaeological implications of this research are important and far-reaching: late Pleistocene-aged landforms that were undoubtedly attractive to early coastal people are preserved on Oregon's continental shelf. Further exploration that focuses on these localities provides a viable path forward for finding archaeological evidence of early human presence on the Pacific coast of North America.

Paleoceanographic insights on viable time periods for human migration along the Pacific coastal route during the late Pleistocene

Genomic evidence suggests that the primary founding human populations of the Americas arose from Beringia during the Last Glacial Maximum (LGM), but the timing, pathways, and modes of their subsequent southward transit remain unknown. We utilize model simulations and multi-proxy paleoceanographic data to shed light on the ocean and climate conditions in the Northeast Pacific from the late Pleistocene to early Holocene to assess viable time periods in which humans could have traversed the Cordilleran coastal corridor. Our synthesis provides new insights and constraints on the debates about the first human migrations along the Pacific Northwest coastal route. We find that the cyclonic currents along the Alaskan margin would have been strengthened during the LGM and times of enhanced meltwater input, making a southward transit by boat more difficult. We infer that the Cordilleran ice-surge episodes (“Siku events”) would have been particularly challenging for a coastal transit due to regional cooling, abundant icebergs, and strong coastal currents, possibly creating episodic (1-2 kyr) barriers to southward transit. Given the prevalence of seasonal sea ice throughout the LGM and early deglacial period, we suggest that stable winter sea ice may have acted as a platform that facilitated early coastal migrations into the Americas. Viable time periods for this scenario would likely have occurred intermittently between the Siku events when intermediate sea-ice conditions prevailed and ice-free coastal refugia were available along the Alaskan margin. We identify 24.5-22 ka and 16.4-14.8 ka as the most likely time periods to accommodate early coastal migration along the Alaskan coast.

Peri-Beringia as a cradle of the first Americans

Prof. Masami Izuho [1]

1. Tokyo Metropolitan University

Recent genetic studies clearly show that eastern Eurasia was the homeland of the first Americans. The debate on the place of population standstill just before entering the Americas during or after the Last Glacial Maximum are still open. The cultural evidence, however, linking Siberian Upper Paleolithic (UP) assemblages to the Late Pleistocene assemblages south of the ice sheets in North America is yet unclear. Rather, stronger similarities of lithic technology and the assemblage pattern in the earliest assemblages of North America dated to ~16-14ka Cal BP are found in the coastal area of Asia. Those are, for example, late Upper Paleolithic assemblages found in the Paleo-Sakhalin-Hokkaido-Kurile (PSHK) Peninsula in Peri-Beringia. Here I deal with several archaeological evidence as the proxy, such as the number of sites, technological adaptation patterns, and the intensity of cultural occupations, from the late Upper Paleolithic to Incipient Jomon, between PSHK and Paleo-Honshu (P-Honshu) in order better elucidate when and how the population dispersal, continuity, admixture, and replacement occurred. Two main conclusions are obtained; (1) the biggest local climatic deterioration of Kenbuchi stadial pushed the foragers to somewhere north around 18-15ka Cal BP from PSHK, (2) complete replacement from the late UP to Incipient Jomon likely happened on PSHK, possibly after 14 ka Cal BP. The suite of blade-based, bifacial-based, flake-based lithic reduction, found in the late UP of PSHK in Peri-Beringia, which was well-adapted in coastal and forest-steppe environments, was likely advantageous for the dispersal to the south of the continental ice-sheets of north America.

Session 43: Millennial paleo-landscape reconstructions of coastal areas. From field data to modelling approaches

Geomorphology vs archaeology; the Colombaio stack and the reconstruction of Late Holocene coastal evolution at Ustica Island (Palermo, Italy)

Prof. Stefano Furlani [1], ***Dr. Franco Foresta Martin*** [2]

1. *Department of Mathematics and Geosciences - University of Trieste, Trieste,* ***2.*** *Istituto Nazionale di Geofisica e Vulcanologia, Sezione di Palermo,*

Both geomorphology and archaeology contribute to studies about the evolution of the coastal landscape. Landforms and archaeological remains provide valuable data for interpreting past geographies. The Colombaio stack lays at about ~60 m off the northern coast of the volcanic island of Ustica (Palermo, Italy). It is roughly parallelepiped in shape, with a basement area of ~180 m^2, a height of 17 m asl and a maximum depth of 8 m toward the sea. The total volume of the stack is about 2000 m^3. The northern coasts of the island are dominated by 20 m high volcanic sea cliffs which are affected by storm wave processes and consequent coastal retreat which can leave morphological relics, such as the stacks. Moreover, the Colombaio stack is located in front of a Middle Bronze Age coastal settlements. Finding of coeval huts and pottery at the flattened top of the stack seems to confirm its use also during historical age.

Multidisciplinary surveys, such as UAV-DP, ISR-DP and iPhone Lidar acquisition allowed us to study morphometric parameters and discuss its origin and evolution.

The stack is composed by two lava units interlaced in the form of columnar lavas and breccias. The enlargement of a joint between these units favored the formation of a sea cave inside the stack of roughly 750 m^3. Cliff retreat is also highlighted by a nearby rock, separated from inland by a dike. It can be considered as a stack-in-formation similar to the Colombaio one. The maximum depth between the coast and the stack is max 2.5 m. Consequently, during the Middle Bronze Age, people could walk to the stack, because the sea level was 2.5 m lower than nowadays. Probably it was not yet a stack, as it was not yet detached from mainland, but it was neither part of the terrace on which the archaeological settlement lays.

Multidisciplinary approach to characterize the environmental and coastal evolution at Ksar Seghir, Morocco: natural processes, extreme events and historical occupation

Dr. Ana Maria Costa [1]***, Prof. Maria da Conceição Freitas*** [1]***, Prof. André Teixeira*** [2]***, Prof. Pedro JM Costa*** [1]***, Dr. Ricardo Santos*** [3]***, Prof. Mário Cachão*** [1]***, Prof. Francisco Fatela*** [1]***, Dr. Ricardo Pereira*** [4]***, Dr. Vera Lopes*** [1]***, Mr. Abdelatif El-Boudjay*** [5]

1. *IDL – Instituto Dom Luíz, Faculdade de Ciências da Universidade de Lisboa,* ***2.*** *CHAM,* ***3.*** *Department of Environmental Sciences, University of Basel,* ***4.*** *GeoBioTec, Faculdade de Ciências e Tecnologia, Univ Nova Lisboa,* ***5.*** *Direction Régionale de Culture Tanger*

In this work we present the results of the multidisciplinary study performed in river Laksar, north Morocco, aimed at characterizing the environmental evolution of the coastal area, considering natural processes, the anthropic occupation and extreme events (floods/tsunamis).
Our findings are based on a 5.4 m long sediment core - KS1 - and in high-resolution multiproxy analyses (X-Ray, magnetic susceptibility, sedimentology, organic chemistry and micropaleontology) together with ^{14}C dating to establish a chronological model.
The sedimentary succession corresponds to fine sand and mud intercalations. Results point to deposition in subtidal conditions between the core base (ca. 2500 cal BP) and the 15th century (388 cm below surface). The dominance of marine foraminifera assemblages with high number of juveniles and high diversity index suggests an environment frequently under open marine conditions during this period. By opposition, the low δ^{13}C values, together with the occurrence of charophytes and reworked nannofossils (Cretaceous, Paleogene and Neogene) and foraminifera (Cretaceous), reflect the contribution of fluvial processes. This sedimentary record points to environmental conditions marked by changes in fluvial discharge and marine influence due to changes in beach morphology, i.e. alternate growth and erosion of a sandy barrier.
The accumulation of magnetic (heavy) minerals at the core base is the likely result of at least one high-energy event, occurred ca. the 1st century BC.
After the beginning of the Portuguese Ksar Seghir occupation (15th century AD), the sedimentation rate increases, silting-up the channel margins. Deposition occurs under low subtidal to intertidal conditions. Foraminifera assemblages point to low salinity, with coarse materials mostly constituted by minerogenic particles transported by the fluvial network. Changes in the sedimentary succession were detected between 219 and 140 cm below surface that, according to the age-model point to the 18th century AD and are possibly related to the 1755 tsunami.
Work funded by the Portuguese Fundação para a Ciência e a Tecnologia (FCT) I.P./MCTES through national funds (PIDDAC) – UIDB/50019/2020.

Application of acoustical and optical techniques in Underwater Cultural Heritage sites. Case study: Ancient Aegina Harbour

Mr. Fabrizio Fuoco [1]***, Dr. Nikos Georgiou*** [2]***, Dr. Xenophon Dimas*** [2]***, Dr. Elias Fakiris*** [2]***, Dr. Dimitris Christodoulou*** [2]***, Prof. Kalliopi Baika*** [3]***, Dr. Despina Koutsoumpa*** [4]***, Dr. Pari Kalamara*** [4]***, Prof. Fabio Bruno*** [5]***, Dr. Antonio Lagudi*** [5]***, Prof. George Ferentinos*** [2]***, Prof. Maria Geraga*** [2]***, Prof. George Papatheodorou*** [2]

__1.__ 3D Research S.r.l., Rende (CS) 87036, Italy, __2.__ Laboratory of Marine Geology and Physical Oceanography, Department of Geology, University of Patras, 265 00 Rio Patras, Greece, __3.__ Centre Camille Jullian, Aix Marseille Univ, CNRS, 13090 Aix-en-Provence, France, __4.__ Ephorate of Underwater Antiquities, Hellenic Ministry of Culture and Sports, 117 42 Athens, Greece, __5.__ Department of Mechanical, Energy and Management Engineering (DIMEG), University of Calabria, Rende CS 87036, Italy

In this study, we present a multidisciplinary, non-intrusive downscale approach for the documentation of Underwater Cultural Heritage (UCH) and paleo-landscape 3d reconstruction, implemented on the coastal area of Aegina Island, Greece, where one of the most extended submerged harbour complexes is preserved at least over the last 2.5 ka.

This approach succeeded in obtaining information that serves both geomorphological and archaeological purposes in a time- and cost-effective way, while obtaining information on centimetres to millimetres scale. Through marine acoustic devices, geomorphology and ancient submerged conical/linear rubble structures' morphometric parameters (geometry and terrain statistical parameters) were documented. Automatic seafloor segmentation techniques documented and verified known and unknown sites of archaeological interest. The spatial distribution of the structures revealed the construction of a well-planned harbour complex with multiple passages and different possible functionalities. The structures' morphometric analysis showed their preservation status, demonstrating the anthropogenic impact on the submerged ancient structures due to the modern harbour activity.

During the investigation, a Remotely Operated Vehicle (ROV) was utilized for the visual verification of the findings and the establishment of a 3D ortho-mosaic model of the site. Methods of image enhancement were applied to the ROV data aiming to reduce poor visibility conditions and mitigate the effects of light absorption in the water medium. The post-processing produced a more photo-realistic 3D photogrammetry model exposing the microstructure of the conical structures. Finally, the Multibeam Echo Sounding (MBES) data combined with the processed optical data produced a 3D explorable virtual environment of the submerged archaeological area. The 3d digital environments promote the UCH sites and allow their further exploration by experts and not experts in the field.

At present, Aegina is studying within the framework of Aegina Harbour city Project which is an interdisciplinary project focusing on the systematic study of the submerged and coastal archaeological infrastructure of the city harbour of Aegina. In addition, Aegina is one of the main pilot sites of the TECTONIC project which promotes the collaboration between professionals in the field of Underwater Heritage aiming to provide detailed and multi-disciplinary documentation to assess and improve techniques and methodologies for the UCH.

Reconstructing Holocene RSL changes in the Bay of Cádiz from stratigraphic records

Dr. Claudia Caporizzo [1], _Prof. Francisco-Javier Gracia_ [2], _Dr. Gaia Mattei_ [3], _Dr. Celia Martin-Puertas_ [4], _Prof. Paolo Stocchi_ [5], _Prof. Pietro P.C. Aucelli_ [1]

__1.__ Dipartimento di Scienze e Tecnologie, Università degli studi di Napoli Parthenope, __2.__ Department of Earth Sciences, Facultad de Ciencias del Mar y Ambientales, Universidad de Cádiz, Puerto Real, Spain, __3.__ Dipartimento di Scienze e Tecnologie, Università degli Studi Parthenope di Napoli, __4.__ Royal Holloway, University of London, __5.__ Utrecht University

The Bay of Cádiz, located in South-western Spain (Andalusia Region), constitutes an example of a typical estuarine saltmarsh environment with a long human occupation affected by notable historical changes that have conditioned the sedimentary evolution of emerged and submerged zones. The Bay is constituted by two semicircular embayments and the sediment supply of the area is mainly related to the presence of the Guadalete River estuary in the northern one.

The aim of this study is to reconstruct the Holocene morpho-evolution and the relative sea-level change history of the study area by assembling a geodatabase standardized to the most recent international guidelines for RSL studies of geological sea-level markers (SLMs) derived from new boreholes and bibliographic data.

The SLMs interpreted as high-precision sea-level index points (SLIPs), based on the characteristics of the related depositional environments, were compared to a number of new glacio-hydro-isostatic adjustments (GIA) models to identify the main components which influenced the sea-level evolution and obtain the vertical displacement (VD) trends by using a Bayesian statistical approach implying Montecarlo simulations.

Comparing the resulting VD values, it is possible to assume that the whole area was affected by general subsidence related to the local sediment compaction which influenced the morpho-evolution of the different zones with a variable entity and completely outclassed the GIA-driven component.

In particular, the oldest data from the northern sector showed that the area was characterized by subsidence rates of about - 0.65 mm/yr between 6.7 and 3.0 ka BP. On the other hand, during the last 3.0 ka, the general trend appears to be homogeneous for both the main sectors of the Bay with an average subsidence rate of - 1.6 mm/yr.

Moreover, the interplay between new data from the boreholes and bibliographic sources allowed the realization of three sketches representing the morpho-evolution of the Bay of Cádiz during the last 6.0 ka BP, respectively related to 6.0-5.0 ka BP, 3.0-2.0 ka BP, and the present-day coastal configuration.

Quaternary sea level changes vs vertical movements in old Cape Verde volcanic islands

Dr. Teresa Bardají [1]***, Prof. José L. Goy*** [2]***, Prof. Caridad Zazo*** [3]***, Prof. Cristino J. Dabrio*** [4]***, Prof. Ángel González*** [2]***, Prof. Claude Hillaire-Marcel*** [5]***, Dr. Bassam Ghaleb*** [5]***, Dr. Vicente Soler*** [6]***, Prof. Javier Lario*** [7]

1. *Universidad de Alcalá,* ***2.*** *Universidad de Salamanca,* ***3.*** *Museo Nal. CC. Naturales, CSIC,* ***4.*** *Universidad Complutense de Madrid,* ***5.*** *Geotop-Université du Québec à Montréal, Montréal, Canada,* ***6.*** *IPNA, CSIC,* ***7.*** *Universidad Nacional de Educación a Distancia (UNED)*

The geomorphic evolution of volcanic islands, such as those of Cape Verde, is linked to vertical movements driven by the growth and decay of volcanoes as they move away from their genetic hot spot. The Older Cape Verde islands (Sal, Boa Vista, Maio) present a wide record of Quaternary marine terraces, the different arrangement of which can help to unravel the complex history of sea level and vertical movements in these particular settings. Information on the timing of this evolution may be obtained from radiometric (U-series, ^{14}C) and paleomagnetic measurements. Such volcanic islands evolve from an initial submarine growth stage, to final erosion and decay, through different stages: 1) Submarine growth – shoaling; 2) Emergence and shield building; 3) Erosion; 4) Rejuvenation; 5) Sinking and/or erosion. This last stage occurs in different site-dependent ways. In some volcanic archipelagos, the late subsidence leads to submersion and development of an atoll – guyot. Other archipelagos may show erosion under gentle uplift.

The general morphology and distribution of marine terraces in Sal, Boa Vista and Maio indicate that the islands underwent a general uplift, although with distinct rates, during the Quaternary. Sal Island presents an almost flat morphology suggesting an advanced erosional stage, whereas a few high elevation eruptive bodies (up to of 406m in its NE area) respond to a rejuvenation stage (1.06 to 0.6My; Holm et al., JGR 2008). The general morphology of Boa Vista indicates a younger erosion stage than that of Sal, as it has not attained the flatten stage. Its sedimentary environment is marked by islets and shallows, where Quaternary marine units developed. No younger volcanism marker of a rejuvenation stage has occurred so far. The general relief of Maio points to an even younger erosional stage, with a maximum elevation of 463m without any trace of rejuvenating volcanism either.

The general layout of the Quaternary marine terraces in these islands points to a general uplift during the Quaternary, slowing down towards the late Pleistocene, with the Last Interglacial marine units being generally close or even below present sea level, suggesting a recent inception of the subsidence stage.

Submarine terraced landforms and paleoshorelines of the Dalmatian islands in the Eastern Adriatic Coast, Croatia

***Dr. Ozren Hasan* [1], Mrs. Natalia Smrkulj [1], Dr. Dea Brunović [1], Prof. Maria Geraga [2], Dr. Dimitris Christodoulou [2], Dr. Nikolina Ilijanic [1], Dr. Slobodan Miko [1]**

1. Croatian Geological Survey, Department of Mineral Resources, 2. Laboratory of Marine Geology and Physical Oceanography, Department of Geology, University of Patras, 265 00 Rio Patras, Greece

Sea level has changed significantly since the lower Pleistocene, with up to 135 m lower levels than at present. Periods of long-term standstills of sea-level could enable the formation of marine terraces. Bottom-current activity such as Complex Adriatic Sea water circulation can also induce a formation of terraced erosional features.
The investigated area is in the central part of the Eastern Adriatic Coast (EAC), in the SW part of the Žirje Island archipelago, at the eastern rim of the Mid Adriatic Deep. The archipelago is characterized by steep escarpments and submerged islands. The island geomorphology, with almost vertical SW island shores, is typical for the outer rim of the Dalmatian islands and extends to Telašćica and Kornati archipelago.
To detect the distribution and characteristics of submarine terraces, we used high-resolution acoustic methods – Multibeam Echosounder (MBES), Multibeam Backscatter (BSE) and Sub-bottom profiler CHIRP (SBP). The results of the extensive survey display abundant evidence of terraced landforms. The process of analysis involved the interpretation of SBP profiles and BSE data to differentiate terraces formed in sediment and those formed in carbonate rocks. Morphometric analyses of the MBES digital elevation model for terraces formed in carbonate rocks were made in the “TerraceM” software.
The resulting landforms recognized with TeraceM tools were detected at 96.8, 90.1, 81.5, 67.1, 63.1, 51.4, 36.2 and 26.1 m b.s.l. In addition, submarine terraces identified in SBP profiles were detected at 210, 195, 182, 176, 152, 128, 115 m b.s.l. Furthermore, progradational shoreline clinoforms were detected in multiple SBP’s at depths 128-130 m b.s.l., elevation indicative of Last Glacial Maximum (LGM) shoreline. These morphological features are erosional unconformities typical for shoreline progradation, whose rollover points (upper part of the clinoforms) mark the sea level position. They were detected at the slope towards the Mid Adriatic Deep in the submerged Krka River delta south of Žirje Island.
It can be concluded that detected submarine terraces were formed during MIS8, MIS6, MIS4/3 or MIS 2 (LGM) standstills, while LGM paleoshoreline was not previously detected along the EAC.
This work was supported by the Croatian Science Foundation project “QMAD” (HRZZ IP-04-2019-8505).

A 2400 year's record of volcanogenic ground deformations, coastal changes, and consequences for humans from Campi Felgrei area (S. Italy)

Dr. Gaia Mattei [1], *Prof. Aldo Cinque* [2], *Dr. Claudia Caporizzo* [3], *Dr. Lucio Amato* [4], *Prof. Gerardo Pappone* [3], *Prof. Paolo Stocchi* [5], *Prof. Pietro P.C. Aucelli* [3]

1. *Dipartimento di Scienze e Tecnologie, Università degli Studi Parthenope di Napoli,* **2.** *Dipartimento di Scienze della Terra, dell'Ambiente e delle Risorse, Università degli Studi di Napoli Federico II,* **3.** *Dipartimento di Scienze e Tecnologie, Università degli studi di Napoli Parthenope,* **4.** *TecnoIn spa,* **5.** *Utrecht University*

This study aimed to assess the joint effects of ground deformation trends and anthropic forcing along the coasts of Campi Felgrei caldera, which is one of the most dangerous volcanos of the Mediterranean area, since the first Roman occupation.

A huge dataset of hundreds of archeo-stratigraphic boreholes was coupled with direct and indirect surveys of the main underwater archaeological sites scattered along the whole coastal area and the reinterpretation of bibliographic sources.

Clear evidence of a differential volcano-tectonic behaviour led us to divide the study area into three coastal stretches with homogeneous ground deformation trends. In each sector, a new relative sea level (RSL) curve was reconstructed, by interpreting our stratigraphic and archaeological data in terms of SL markers covering a wider timespan compared to the previous studies, from the first Roman urbanization to the present day. The comparison between RSL curves and GIA models allowed calculating vertical ground movements occurred along the coast with decimetric precision.

For each recognized phase of uplift or subsidence, we also studied the effects they had in terms of coastal geomorphological change, and advantages or negative impacts on ancient human activities. We measured an overall subsiding trend that brought the RSL from -12 m (4th century BC) to 7 m during three different episodes between 5th and 15th centuries, which was interrupted by short-lived falls of RSL. During the phases of RSL fall and/or volcano-tectonic stability, a basinward shift of the coastline created new emerged land even at the base of the local sea cliffs, where wide shore platforms emerged, favouring intense phases of urbanization on them. This trend also favoured the closure of the Lucrino lagoon with an extended spit bar during the 2nd century BC, allowing the establishment of a large oyster farming system by Sergio Orata. On the contrary, the subsiding phases resulted in the flooding of coastal areas and anthropic structures such as villas, nymphaea and ports inducing the construction of coastal protection works. In the extreme case of Portus Julius, subsidence led to the abandonment of the military port and its move to nearby Miseno.

Late Quaternary facies architecture of the Chienti River incised valley fill (Marche Region, Italy)

Ms. Michela Pierini [1]***, Mr. Andrea Di Martino*** [2]***, Dr. Federico Di Rita*** [3]***, Mr. Mauro Caffau*** [4]***, Prof. Alessandro Amorosi*** [5]***, Mr. Claudio DiCelma*** [1]***, Mr. Pietro Paolo Pierantoni*** [1]***, Prof. Donatella Magri*** [3]***, Prof. Alessandra Negri*** [6]***, Mr. Michele Leoni*** [7]

Dipartimento di Scienze della Vita e dell'Ambiente, Università Politecnica delle Marche, 7. Arpa Marche

An incised-valley system is composed of the valleys formed as a result of base-level drop and of its depositional fill accumulated during the following base-level rise. Reconstructing the stratigraphic record of incised-valley systems is an important tool for water resources investigation, reconstruction of pollutant distribution and for predicting the environmental effects of future sea-level rise.
In order to understand the impact of late Quaternary sea-level changes along the southern coast of the Marche Region (eastern central Italy), we reconstructed the stratigraphic architecture of the Chienti River valley fill.
High-density subsurface stratigraphic information was provided by a database of almost 500 boreholes, and by the recovery of two continuous cores, 23 and 46 m long, respectively. A detailed facies characterization was carried out through detailed sedimentological analysis, including grain size, colour, sedimentary structures, presence of plant remains or fossils, and carbonate nodules. The paleoenvironmental reconstruction was also supported by pollen and meiofauna analysis carried out on the core samples. Pocket penetration values were also collected on clayey and silty deposits to support facies interpretation.
A series of detailed stratigraphic panels oriented both parallel and transversal to the coastline highlights the 3D facies architecture of the valley fill: amalgamated fluvial-channel and floodplain facies associations dominate at proximal locations, whereas alternating fluvial-channel, floodplain, swamp, and beach deposits occur distally.
Reconstructing the stratigraphic architecture of the fluvial incised valley fill is a crucial requirement toward an effective three-dimensional representation of the aquifer systems and for delineating past climate changes. It is also an essential tool for successful environmental remediation, given that the study area being classified as a polluted site of regional interest since 2001.

The 4th millennium BC in light of the submerged sites at Ropotamo and Sozopol: Are there evidences for climate change?

Mr. Pavel Georgiev [1]

1. Centre for Maritime Archaeology, University of Southampton

The 4th millennium B.C. on the Balkan peninsula is a period of great change, a transition from the Late Chacholitich to the Early Bronze Age cultures with a gap in the C14 dates of several hundreds of years. The archaeological records of those two cultures are very distinct. By the end of the LCA, there is evidence of a very complex social structure (Varna necropolis and tell settlements) the population of which relied mostly on agriculture with a vast network of connections and trade that spread from the Aegean all the way to Central Europe (the spondylus shells) as well as advanced metalworking and craftsmanship (again, the Varna necropolis). In comparison, the EBA can not be more different, flat isolated settlements with predominant stock-breeding traditions and a more mobile way of living.

Ever since the gap was identified there have been debates among scholars on the reasons for this drastic change in the way of prehistoric life. The most predominant being attributed to climate change and fluctuations of the sea level that were followed by a northern invasion that destroyed the LCA population.

With this archaeological background comes the rationale behind this research. That is to enrich our understanding of the 4th millennium BC on the Balkan peninsula by answering a very specific research question: Are there evidences of climate change in the submerged prehistoric sites at Ropotamo and Sozopol, if so what is their nature and how were the inhabitants of those settlements affected by it during the 4th millennium BC? The aim is to gather qualitative and quantitative data from submerged prehistoric sites that will give an irrefutable answer to that question. It will be done through underwater excavations with very a high-resolution documentation and interdisciplinary research. The results of which will be combined into a complete image of the past.

Interdisciplinary analysis of partially submerged pre-Columbian sites of Martinique, French West-Indies. Research issues, methodology and further perspectives

***Ms. Morgane Blanot* [1], Prof. Benoit Bérard [2], Mr. Frédéric Leroy [3], Dr. Doriane Delanghe [4], Prof. Christophe Morhange [5]**

In the actual alarming context of global warming and environmental change, all eyes are focused on the relative sea level rise and its catastrophic consequences. The impacts of this phenomenon on contemporary societies are extremely diversified. Among them the programmed disappearance in the coming decades of a large part of the coastal cultural heritage requires a specific reflection. The French West Indies are, because of their geographical position and their insularity, dramatically exposed to the coastal regression. This phenomenon of exposure to marine risks is not new. Since the last Pleniglacial period (18,000 BP), marine transgression is estimated to about +120 meters around the Caribbean basin. By developing a diachronic geoarchaeological approach to the material evidence of the submerged history of Martinique, we aim to determine the erosive and relative sea level processes behind the mobility of the shoreline as well as the relationship to the ocean of a corpus of three pre-Columbian deposits distributed on this territory. We will develop an original geoarchaeological methodological approach to the paleoenvironmental, taphonomic and predictive characterization of these sites, witnesses of the holocene land-sea interface in perpetual mutation. Thus, this holistic and unreleased approach in the pre-Columbian context of Martinique raises a plurality of research issues related to the prehistoric occupation modalities of this space. It must therefore fall within a solid methodological framework that must be reproducible on the scale of the entirety of the pre-Columbian submerged Antillean deposits. From sedimentary studies to three-dimensional paleoenvironmental simulations and from archaeologists to the actors of cultural mediation, a plurality of perspectives should emerge from our study which strive to contribute to an interdisciplinary archaeology of West Indies paleolandscapes.

Late Holocene submerged beachrocks in the Sea of Marmara (Tekirdag-Altinova, NW Turkey): Revealing tectonic uplift rate through LA-AMS dating technique

Dr. Ufuk Tari [1], ***Prof. Gursel Sunal*** [1], ***Dr. Caroline Welte*** [2], ***Prof. Cenk Yaltirak*** [1], ***Prof. Orkan Özcan*** [3], ***Dr. Melina Wertnik*** [4]

Tectonically active coasts are dynamic environments characterized by the presence of beachrocks formed by the combined effects of wave erosion, tectonic uplift, and sea-level fluctuations at glacial-cycle timescales. The beachrock formations represent a significant paleo-environmental proxy because they are ideal marker horizons used for reconstructing past sea-level positions and revealing vertical uplift rates. Here in this study, it was used to assess the late Holocene coastline evolution of the northern Sea of Marmara.

The Tekirdag-Altinova coastal area is located in the tectonically active western Marmara Region. This tectonic activity is controlled by the North Anatolian Fault Zone (NAFZ) which played a crucial role in the coastline evolution at different periods of the region. This study aims to investigate the role of tectonic processes in the late Holocene evolution of the coastal landscape of the Tekirdag-Altinova area by assessing long-term vertical deformation rates. To document and estimate coastal uplift, beachrocks were used in conjunction with a novel laser ablation (LA)–accelerator mass spectrometry (AMS) technique and correlation to late Holocene sea level variations. In this study, we report the existence of the less known submerged beachrocks in the nearshore coastal area of Tekirdag city (Altinova), the northern Sea of Marmara. The beachrocks are distributed parallel to the modern shoreline with an extension of about 5 km and at depths ranging from -2 to 0 m below the present sea level. The well-preserved beachrocks have been identified and mapped using Unmanned Aerial Vehicle-UAV (a 5 cm resolution), sampled by the coring method.

Here, we present the novel LA-AMS system and apply it for the analysis of marine shells and calcite-cement of the selected samples from submerged beachrocks. The radiocarbon age results allowed us to correlate them with late Holocene sea-level high-stand and to estimate the long-term uplift rate. Based on the findings, an uplift rate of about 0.44 mm/year over the last 3000 yrs has been suggested for the study area.

Refined Geologic Mapping Reveals A More Complicated Depositional History of the US Mid-Atlantic Coast Since the Last Interglacial Period

Ms. Kayla Cahoon [1], ***Dr. Chris Hein*** [1], ***Dr. Michael Fenster*** [2], ***Ms. Cameron Clarke*** [3], ***Mr. Joseph Vaughn*** [2], ***Dr. Kelvin Ramsey*** [4], ***Dr. Sebastien Huot*** [5], ***Dr. John Wehmiller*** [6]

1. *Virginia Institute of Marine Science, William & Mary,* ***2.*** *Environmental Studies Program/Geology, Randolph Macon College,* ***3.*** *Department of Geology, William & Mary,* ***4.*** *Delaware Geological Survey,* ***5.*** *Illinois State Geological Survey,* ***6.*** *Department of Earth Sciences, University of Delaware*

Located along the former glacial forebulge of the Laurentide Ice Sheet, the Delmarva (Delaware, Maryland, and Virginia) Peninsula (central United States Mid-Atlantic Coast) is composed of ancient coastal deposits (beaches, barrier islands, spits, etc.) formed during sequential periods of sea-level highstand throughout the middle to late Pleistocene. Subaerially exposed remnants of these coastal systems are prime targets for sea-level reconstructions and studies of glacial-isostatic adjustment (GIA) processes. Nevertheless, the sea-level history of this area remains unrefined. This reflects wide variability in the ages of dated coastal deposits and conflicting interpretations of their depositional environments. Here, we combine field sedimentology and stratigraphy (sediment cores ≤ 27 meters deep), subsurface geophysics (ground-penetrating radar and seismic profiling), and high-resolution topographic-bathymetric digital elevation models (largely derived from lidar) to produce a 1:62,500 map of ~300 km^2 of the central Virginia portion of the southern Delmarva Peninsula. Mapping is supplemented with geochronology based on infrared-stimulated luminescence dating and amino acid racemization. Our findings indicate that there are five distinct sedimentary sequences preserved in this region, each recording intervals when relative sea level was at or higher than modern mean sea level over the past 200 kyr; four of these post-date the last interglacial (120 ka). The internal geometry of each of these units reveals state changes between transgression (e.g., landward-migrating coastal systems) and regression (e.g., progradational beach and foredune ridges). Importantly, the youngest transgressive-regressive set—the newly mapped “Upshur Neck Member”—dates to ~55 ka, and was previously included in the “Wachapreague West” highstand depositional system (~70 ka) rather than as associated with a distinct period of highstand. This new interpretation improves our understanding of both the depositional history of this region and, by extension, its relative sea-level history. Further, our refined geochronology reveals a time lag during the last glacial period of 5,000–10,000 years between the onset of global sea-level highstands and the period of maximum local sea level along this ‘mid-field’ coast. This observation emphasizes the complex role of glacial geometry and associated forebulge uplift and subsidence in driving relative sea-level change along the U.S. Mid-Atlantic.

A review of the coastal and marine Pleistocene deposits of the southern Cape of South Africa

Dr. Hayley Cawthra [1]***, Dr. Zenobia Jacobs*** [2]***, Prof. Curtis Marean*** [3]

__1.__ Geophysical and Remote Sensing Unit, Council for Geoscience, Western Cape Regional Office & African Centre for Coastal Palaeoscience, Nelson Mandela University, Gqeberha, __2.__ OSL Dating Laboratory, University of Wollongong, Australia, __3.__ School of Human Evolution and Social Change, Arizona State University & African Centre for Coastal Palaeoscience, Gqeberha, South Africa,

South Africa is a far-field site with respect to global ice sheets, and as such, has remained unglaciated through the Quaternary glacial-interglacial cycles. This spatial setting means that geological deposits within the range of these sea-level fluctuations may be better preserved than other regions globally that were scoured by shifting ice sheets. The vertical range of sea-level change experienced in the late Quaternary of South Africa has generally been between ~10 m above present sea level in periods of warming, and ~130 m below present sea level during times of cooling. As sea level receded in response to glacial cycles, the continental shelf was exposed as a terrestrial landscape. In the southern Cape, within the Cape Floristic Region, this corresponds to an area the size of the country of Ireland. Across the present-day coast and continental shelf, despite the contrasts in the extent of exposure at different times, aeolianite and cemented beach deposits have been preserved that illuminate the nature of past coastlines and environments. Offshore of Mossel Bay, these have been mapped with high-resolution hydroacoustic methods (multibeam bathymetry, side-scan sonar and shallow sub-bottom profiling) and some have been sampled by scuba diving and sediment coring. Dating was carried out using Optically Stimulated Luminescence (OSL). Onshore-offshore correlation and comparison has been conducted between the now-onshore and now-offshore Pleistocene rock outcrops. There are distinct age clusters of aeolian and palaeosol deposits in large embayments, remnants on neo-coastal cliffs, and on the now-submerged shelf that broadly date to 90, 70 and 50 ka. Here we discuss land-sea connectivity, sediment supply, and preferential preservation of these deposits at specific times. We investigate the impact of ancient human use of these coasts, and how this analysis assists reconstruction of now submerged landscapes.

Present-day tidal notch elevation: the water level bias

Dr. Valeria Vaccher [1], ***Dr. Fabrizio Antonioli*** [2], ***Prof. Stefano Furlani*** [1], ***Ms. Eleonora de Sabata*** [3], ***Prof. Mauro Agate*** [4], ***Ms. Giulia Visconti*** [5]

1. Department of Mathematics and Geosciences - University of Trieste, Trieste, 2. CNR IGAG, 3. MedSharks, Rome, 4. Dipartimento di Scienze della Terra e del Mare, Università degli Studi di Palermo, 5. Marine Protected Area of Pelagie Islands, Municipality of Lampedusa and Linosa - AG, Sicily

Tidal notches are believed to form roughly at mean sea level tide. with well-defined morphometric parameters compared to the reference sea level, and have been used as sea level markers for more than 150 years.

Through different field surveys, were observed on tidal notches cut along carbonate coasts from 73 sites in the central Mediterranean Sea, observing fauna and flora living in the tidal zone. Tidal notches genesis was correlated with wave energy, tidal range, lithology, and depth of the cliff foot.

In the campaign carried out in 2020, included in the Geoswim project, we investigated Lampedusa, the southernmost island in Italy (Pelagie Islands), 'anomalous' notches were observed compared to "regular" tidal notches usually observed in other areas. We discovered in two bays in the southern part of the island tidal notches constantly deepen in the inner part of the bays. Outside the bay, notches are at the usual elevation, while in the inner part of the inlets they deepen up to a maximum depth of about 30 cm below sea level and tend to narrow inwards. The same was recently surveyed on the southern coast of Gozo Island (Malta), within a narrow bay.

During the survey, time-lapse images were collected both above and below the water level, and the morphometric parameters of tidal notches were measured together with physical/chemical parameters, in particular temperature and electrical conductivity. A similar phenomenon was recognized and studied near Marseille (France) and published in 2017. Consequently, a comparison can be made for Lampedusa.

Literature and data collected confirm in all the studied cases the tectonic stability of the area up to MIS5.5. This, together with the rapid change of morphometric parameters within the bay allows us to exclude vertical tectonic movements of the coastline.

Tentatively, we hypothesize that a mix of hydrodynamic and environmental factors allows the formation of these anomalous notches. They occur under specific conditions of wind, waves, and morphology of the coastline that can lower the elevation of maximum erosion rates, slightly below the mean sea level in sheltered areas.

New chronology scenarios for submerged relict paleoshorelines and associated uplift rates offshore Marzamemi village (Southern Sicily)

Dr. Andrea Giulia Varzi [1], ***Dr. Marco Meschis*** [2], ***Dr. Luca Fallati*** [1], ***Prof. Daniela Basso*** [3], ***Prof. Alessandra Savini*** [1]

1. *Dept. Of Earth and Environmental Sciences (DISAT), University of Milano-Bicocca,* ***2.*** *Istituto Nazionale di Geofisica e Vulcanologia (INGV),* ***3.*** *milano Bicocca University*

Eastern Sicily, along with the Calabrian Arc region, is one of the most tectonically active regions of Southern Italy. Indeed, the tectonic setting of SE Sicily has been adequately studied. The study area of this work is located offshore Marzamemi village, SE Sicily, and it represents the emerging portion of the NE-SW oriented bulge of the African foreland. During June 2021 we performed a multibeam echosounder survey thanks to which we were able to produce a new 17 km2 high-resolution bathymetric map. From a geomorphological point of view, investigation of such an area resulted in the discovery of several relict marine terraces, identified through the mapping of paleoshorelines. These terraced landforms are largely used to reconstruct the Quaternary glacial and interglacial climates, marking different phases of sea-level variations through time. The mean regional uplift rate of this area is of about 0.2 mm/yr since Tyrrhenian time. Despite studies of onshore marine terraces have shown that uplift rates remained constant through the whole Late Quaternary, they have a tendency to vary spatially; higher uplift rates have been observed in the Augusta's area (about 0.41 mm/yr), decreasing southward along the coast. This would suggest a sort of tectonic stability moving even southward, thus in the Marzamemi area. The aim of this work is to (i) trying to refine the chronology of the mapped submerged paleo shorelines, (ii) refining the associated rates of uplift, and (iii) speculate hypotheses on the significance of these offshore preserved marine terraces compared to what is known in the literature in respect to uplift rates, tectonic regional setting, and sea-level variations. Specifically, here we propose two possible scenarios resulting from the application of the synchronous correlation approach, driven by already published age controls.

Reconstruction of the paleo-landscape of Ognina (Siracusa, South-eastern Sicily) during the occurrence of tsunami and storm events

Dr. Giovanni Scardino [1], ***Dr. Angela Rizzo*** [1], ***Dr. Vincenzo De Santis*** [1], ***Mrs. Despo Kyriakoudi*** [2], ***Prof. Alessio Rovere*** [3], ***Prof. Matteo Vacchi*** [4], ***Dr. Salvatore Torrisi*** [5], ***Prof. Giovanni Scicchitano*** [1]

1. *Department of Earth and GeoEnvironmental Sciences, University of Bari,* **2.** *Department of Geology, Ghent University, Belgium,* **3.** *Ca' Foscari University of Venice,* **4.** *Department of Earth Science, University of Pisa, Italy,* **5.** *Studio Geologico Torrisi, Catania*

South-eastern Sicily represents one of the Mediterranean areas most impacted by tsunamis and storm events in the past. These extreme marine events left geomorphic and sedimentary imprints, such as large boulders or high-energy deposits, along the coasts. One of these deposits was reported by previous works along the coast of Ognina, a small residential area located 20 km south of Siracusa. The deposits fill the back edge of a ria incised into Miocene limestones, and are composed of three main stratigraphic units attributed to several tsunami and storm events that occurred along the coasts of south-eastern Sicily since the IV century Common Era (CE). In this work, we use numerical models to simulate the impact of these extreme marine events, at the time of their occurrence, along the Ognina coastal sector, with the aim to: i) better define the tsunamigenic sources responsible for the events found in the deposits, ii) verify if some units could be related to a storm event, iii) investigate constrains on the paleo-landscape of the studied area at the time of tsunami and storm occurrence. We reconstructed the morphology of ancient local landscapes using geological and historical information, together with a detailed topographic and geoelectrical survey. We implemented a modelling chain to simulate the tsunami and storm wave propagation upon the ancient landscapes. Our results highlighted that the use of advanced modeling tools, combined with in situ geological evidence and geophysical survey, has the potential to support the attribution of coastal geomorphic imprints to specific tsunami or storm events, the better definition of the paleo-landscapes, and the identification of the most likely tsunamigenic sources. This last aspect plays a fundamental role in providing more reliable characteristics of the tsunami propagation as well as in the assessing of potential tsunami hazard and related coastal impacts.

Session 44: Environment-human interfaces, new frontiers of consilience in the reconstruction of the past

Unconventional archives of human-environment interactions from Maharashtra, India

Dr. Jill Leonard-Pingel [1]***, Dr. Atreyee Bhattacharya*** [2]***, Dr. Anoop Ambili*** [3]***, Dr. Sudipta Sarkar*** [4]***, Dr. Andrew Michelson*** [5]***, Dr. Praveen Mishra*** [6]***, Dr. Supriyo Chakraborty*** [7]

1. *The Ohio State University,* ***2.*** *CIRES, University of Colorado, Boulder,* ***3.*** *Indian Institute of Science Education and Research - Mohali,* ***4.*** *Indian Institute of Science Education and Research - Pune,* ***5.*** *State University of New York - Maritime College,* ***6.*** *Cluster University of Jammu,* ***7.*** *Savitribai Phule Pune University*

Globally, there is a need to better characterize human-environment interactions as we strive to meet the pressing demands of a changing climate and work towards a more sustainable future; this is especially true for areas that have been pronounced “climate hotspots.” Maharashtra, India, one of these hotspots, is both a critical agricultural hub and a region that experiences pronounced and well-documented impacts of anthropogenic climate change. Combined with rapid population growth, expansion of water intensive cash crop agriculture, and urban development, these droughts have emerged as major stressors on freshwater resources in the region. This combination of factors has led to large-scale social disruptions, including crop failures, rural-urban migration, and farmer suicides. Maharashtra, therefore, provides a perfect case study for characterizing human-environment interactions in the “Anthropocene.”

While long-term climatic reconstructions exist for Maharashtra, there are few records of changes in the human-environment system on timescales of human interest and on localized geographic scales. Here, we investigate the use of unconventional sediment archives – sediments from human-made reservoirs – to determine if they can provide critical information about local climatic and ecological systems through the Anthropocene. We have found that the high-resolution (inter-annual) records preserved in these cores contain records of depositional changes (e.g., sediment grain size, magnetic susceptibility) that can be useful in understanding hydrological changes. We note that regional expressions of the summer monsoon, which may deviate from regional-scale climatological records, are recorded in these cores, providing us with both higher-resolution temporal and geographical records of environmental change and variability. Other proxy records in these cores promise to provide similarly high-resolution records on environmental change within the local watershed and the lake itself. When interpreted in consilience with historical records, these environmental records can provide a context of human interactions with their freshwater ecosystems that can help us better predict the future of these interactions in a changing world.

Past climatic conditions of Northeasthern Nunavik (Canada): Wind and atmospheric temperature from historical sources

Dr. Marie-Michèle Ouellet-Bernier [1], ***Prof. Najat Bhiry*** [1], ***Mrs. Laura Brassard*** [1]

1. *Département de géographie, Université Laval*

Northeasthern Nunavik, like many Nordic environments are facing climatic changes that have major impacts on physical and human environments. Ice melting and temperature rising have many consequences in communities of the North, mobility on ice become a challenge, fauna and flora are changing. To better understand the changing climate, it is important to rely on data from the past. Unfortunately, meteorological data are only available since 1929 in Quaqtaq, and are discontinuous until 1980. The objective of this research is to provide information on past atmospheric temperature and wind conditions based on instrumental, documentary and narrative sources. This work is focusing specifically on land records from southern Hudson Strait, a west to east axis including Kangiqsujuaq, Quaqtaq and Killiniq. Series of instrumental temperature record are available since 1883 until now. Wind strength and direction was extracted from 2 sources: three reports of a Hudson Bay meteorological expedition (1883 to 1886) and post journals of the Hudson Bay Company (1914 to 1940). During the first period, predominant wind was blowing from the north-west (33%), the west (17%) and the north (17%) with south-eastern winds during spring (11%) and eastern winds during summer and autumn (respectively 17% and 10%). The second series showed annual predominant winds from the north (29%) and the west (17%). A temperature index was built based on narrative sources, including travel journals, life stories and novels. The five-point index (-2, -1, 0, 1, 2) distinguished a summer and a winter signal. It shows that winters colder than normal are generally associated with predominance of the west (33%) and the north (27%) winds, with further numbers of very strong winds. Summers warmer than usual were usually described with light winds from the east (34%) and the south (23%). Reconstructed temperature record appears to be in concordance with regional atmospheric circulation patterns notably the North Atlantic Oscillation (in opposite relationship for this region of the North Atlantic).

Interweaving narratives: Understanding the dynamics of human-environment relationships in the Maya region

Dr. Eva Jobbova [1]

1. Trinity College Dublin

Despite extensive research, the relationship between climate change and human societies is still not well understood, especially with respect to how and to what extent climate change can be considered a primary driver in the cultural trajectory of a particular region. Although there are new analytical opportunities provided by methodological developments in various disciplines, little is known about the short- or long-term dynamics of past human-environment relationships. Reasons for this include a lack of, and challenges in, integration between relevant fields, such as archaeology, anthropology, epigraphy, palaeoclimatology and palaeoecology. This paper explores how integrating datasets from different disciplines can lead to a better understanding of the socio-ecological relationship between human societies and their environments and how this drives cultural change.

The paper focuses on the Maya society, whose perceived successes and failures are often linked to their relationship with the local environment and their response to episodes of climate change over a period of nearly 2000 years. The works responds to recent debates and new analytical opportunities in Maya studies, provided by developments such as increased volume of paleoclimatic data, the growing field of settlement archaeology and advances in Maya epigraphy.

An increased interest in climate change within the last few decades has meant that a large amount of paleoclimatic data have been collected from the Maya area, often indicating considerable changes in rainfall patterns during the mid-to late Holocene. These data, beside other things, challenged the general assumption of unproblematic water supply in the tropics. The ethnographic research conducted among contemporary Maya communities supports this new outlook; it showed that "drought" and especially high variability in rainfall patterns are real phenomena with often severe consequences for people's livelihoods. Combined with archaeological and epigraphic evidence, the results also confirmed that both ancient and modern Maya developed a wide variety of strategies to cope with extreme climate events; as well as to adapt to changes in the long run.

By combining range of evidence, the paper looks at the relationships between Maya society and the local environment, on multiple spatial and temporal scales, while also considering socio-cultural agencies.

What can climate-forced vegetation modelling and pollen-based reconstructions tell us about anthropogenic impact on European vegetation of the Holocene?

Ms. Anhelina Zapolska [1]***, Ms. Maria-Antonia Serge*** [2]***, Dr. Florence Mazier*** [2]***, Dr. Aurelien Quiquet*** [3]***,***
Prof. Mathieu Vrac [3]***, Prof. Didier Roche*** [1]

***1.** Vrije Universiteit Amsterdam, **2.** University of Toulouse, **3.** Laboratoire des Sciences du Climat et de l'Environnement*

Assessment of past anthropogenic modifications of landscape dynamics is crucial for understanding the human role in Earth systems, especially to question the natural state of the system. Recent advances in paleoenvironmental sciences allow us to assess the long-term impacts of anthropization on ecosystems, landscapes, and land cover.

Our study, conducted within the framework of the EU-ITN TerraNova project (https://www.terranova-itn.eu/), aims to combine pollen-based vegetation reconstructions and vegetation modelling to highlight the relationship between vegetation changes and anthropogenic activities in Europe throughout the Holocene.

The method is based on a comparison between modelled and reconstructed vegetation cover over 15 time windows from Mid-Holocene to the present day at a 1˚x1˚ spatial resolution for Europe. Modelled vegetation is derived from climate-forced vegetation modelling, using a dynamic vegetation model (CARAIB) forced by the downscaled version of the iLOVECLIM climate model, and represents potential natural vegetation of the past. Climatic variables, derived from the iLOVECLIM are bias-corrected using the cumulative distribution functions transformation (CDF-t) method. Pollen-based reconstructions are obtained by applying the 'Regional Estimates of VEgetation Abundance from Large Sites' (REVEALS) model on pollen records to reconstruct observed vegetation cover across Europe for the last 6.5 ka years.

The comparison is performed using presence fractions for 9 plant functional types, calculated by CARAIB and REVEALS independently. Analysis of the evolution of discrepancies in two datasets allows us to distinguish the role of climatic conditions in pollen-based vegetation reconstruction from other types of impact. The results of our study indicate that the proposed methodology effectively offset the impact of climatic conditions on pollen-based vegetation reconstruction, which allows us to estimate the possible role of anthropogenic factor in European vegetation distribution change over the mid- and late-Holocene.

Further research steps, made in collaboration with other partners of the TerraNova project, will include incorporation of both vegetation datasets in an agent-based model, aimed to assess the role of hunter-gatherer activities in vegetation changes, incorporating anthropogenic land cover change scenarios to the workflow and introducing plant consumption by megafauna, which will allow further analysis of underlying processes behind landscape changes.

“Smoky forests” - The legacy of charcoal production in pre-industrial Central Europe

The human activities related to land use accompanying agriculture have been the main driving force behind the formation of new landscapes. On the other hand, the role of other factors affecting landscape transformation has not been fully identified. Forests, in particular, were exploited not only for timber, but also for other wood-related products (such as charcoal, potash, and tar), but the spatial scale of this activity and its effects are not yet recognized. Charcoal was a very important economic and energetic resource during the pre-industrial period. This is underlined by the fact that, so far, we have mapped more than 600,000 remnants of charcoal hearths in Central Europe. As time progressed, the demand for energy increased until coal began to be used on a wider scale in the late 18th and early 19th centuries. Our goal is to provide a comprehensive understanding of how charcoal hearths functioned and to state what role they played in the evolution of landscapes. For this purpose, research methods typical of biogeography, remote sensing, dendroecology, paleoecology, soil science, botany, onomastics, as well as art history were combined in order to thoroughly understand not only the natural consequences but also the social and economic aftermath of charcoal production. Our paleoecological results show intermediate disturbance connected with charcoal hearths operation affecting the short-and long-term changes in the ecosystems, which had a cascading nature. Charcoal production causes severe consequences to vegetation composition, soil properties, microclimate, water cycle, and finally erosion that, in turn, affects adjacent lake and peatland ecosystems. This research addresses the emerging issue of the impact of charcoal hearths legacies of past human activity and the effect of shaping the trajectory for landscape transformation during the pre-industrial period.

The study is the result of research project No. 2018/31/B/ST10/02498 funded by the Polish National Science Centre.

Historical forest management in central Europe: a multiproxy approach combining tree rings and pollen-based land cover modelling

Throughout history, humans relied on wood for constructions, tool production or as an energy source. Historical timber is therefore a great source of information for studying land use changes related to wood utilization and forest management, which provides further insights into the impact of land use on vegetation and plant diversity over the last millennia.
Here, we focus our study on the last 1000 years and Central Europe. 44 240 precisely dated tree-ring samples from the economically and ecologically most important tree species (spruce, fir, pine, oak, beech) found in historical buildings were compiled and analysed regarding their dendrological characteristics. In parallel, pollen records from 205 sites were used to quantitatively reconstruct the regional plant abundance (25 plant taxa) for a total of 45 1° by 1° grid cells; the REVEALS model is used to transform pollen data into regional plant cover. The different cells were compiled according to their average elevation, lower (below 500m asl) and medium elevation (above 500m asl). Results of both proxies were compared at a temporal scale of 100-year time windows. Our results show that during the period 1150–1850, a steady decline in forest cover and an increase in open land were observed. Land use changes overtime were recorded. At the same time, phases of higher (e.g., after the Thirty Years' War (1618–1648 CE)) and lower (e.g., during the Black Death (1346–1353 CE) and during the Thirty Year's War) building activity were observed. Furthermore, equivalent amount of spruce and oak were used as construction timber, respectively 35% and 32%, whereas conifers overall dominated the wood in buildings. Most strikingly, the diameters of the trees at the time of harvesting were similar (about 25 cm) for all four species (spruce, fir, pine and oak), while the age and growth rate varied, indicating a selection of wood based on the diameter criterion throughout the period.
This study reveals that human selection of suitable trees for timber construction based primarily on tree species and diameter coupled with exploitation policy resulted in changes in plant abundance and forest structure.

Understanding the relationship between humans and the coastal environment in the deep past: the consilient approach of SPHeritage Project

An interdisciplinary approach is necessary to investigate the relationship between human peopling and the coastal environment during Prehistory. We present the challenges faced and the strategies adopted in the framework of the SPHeritage Project, which aims to understand how Palaeolithic groups living along the Ligurian-Provençal coastal area, in the NW Mediterranean, responded to Pleistocene sea-level fluctuations and the related changes in the littoral environment. The Balzi Rossi study area contains a unique complex of Palaeolithic sites of archaeological significance, as well as sea-level indicators of the last 3-4 interglacials, within a rocky coast geomorphological setting.The evidence of Palaeolithic settlement and exploitation of marine resources provides opportunity for the study of human adaptation associated with sea-level change.

A number of major challenges had to be tackled, though, to achieve the goals of this Project. Large portions of the local archaeological sequences were removed in earlier investigations that began at the end of the nineteenth century, during which time an integrated approach of natural and human sciences was lacking. Moreover, a standardized assessment of the palaeo sea levels had never been performed in the area, hampering the possibility to reconstruct the geographical and ecological characteristics of the environments associated with early human settlements. Finally, the age constraint of the investigated sequences was mostly based on old technologies, with consequent limitations in reliability and accuracy of chronology.

The strategies adopted to overcome these issues were based on the synergic work of a multidisciplinary team with diverse expertise. Strategies included novel stratigraphic correlation between sites, new and extensive age constraint of the marine and terrestrial deposits using multiple and innovative methods, and the detection of past shorelines on the continental shelf through geophysical surveys and sediment coring.

Our preliminary data are promising, and suggest that a cosilient approach can provide valuable insight on how relative sea-level change and consequent shoreline fluctuations can drive settlement strategies and human migration/dispersal patterns.

Session 45: Plants as Resources for Early Humans – Availability and potential exploitation of useful wild plants through Pleistocene human history

PlantBITES – A database for Plant Resources in Early Human Environments

Dr. Angela Bruch [1]***, Dr. Karen Hahn*** [2]

1. ROCEEH Research Centre, Senckenberg Research Institute, Frankfurt/M, 2. Institute for Ecology, Evolution and Diversity, Goethe University, Frankfurt/M

Studies on possible plant food and its availability for different groups of early humans so far usually consider only a pre-selected set of plant species often based on the scarce archaeobotanical record. In contrast, the database PlantBITES is a tool to consider the full range of potentially available, dominant plant species in vegetation units. It serves assessing the amount and variety of obtainable food (and other) resources for early humans. Data collected in PlantBITES comprise information mainly on edibility and other uses of plants that occur in natural environments as well as their relevant botanical traits. Based on such records it is possible to analyze and quantify plant resources and their seasonal availability for humans in a given environment.

The availability of plant resources is considered taking into account not only natural aspects but also the different levels of cultural capacities necessary for the utilization of plants – as it is usually not included in ethnobotany. Cultural capacities of different hominin groups regarding the exploitation of plant resources change considerably through time with respect to the use of tools and fire, and especially the capability to process and store plant materials. Therefore, the PlantBITES database facilitates the evaluation of the relevance and impact of climate or other environmental changes as well as of cultural developments on the resource availability for early humans through time.

PlantBITES provides a range of applications for exploring the resource space of early humans. This will be highlighted by examples of exploring the database to quantify the spatial and seasonal availability of plant food resources for early *Homo* in the South of the Iberian Peninsula, as well as the availability of plant food resources in relation to changing cultural performances of early *Homo* in Southern Africa.

First evidence of plant use in Tagua Tagua 3, a Late Pleistocene site in central Chile: Cultural and environmental implications

Dr. Carolina Godoy-Aguirre [1]***, Dr. Rafael Labarca*** [2]***, Dr. José Blanco*** [3]***, Prof. Jose Iriarte*** [4]***, Dr. Matías Frugone Álvarez*** [5]***, Dr. Erwin González-Guarda*** [6]***, Prof. Claudio Latorre*** [2]

***1.** Núcleo Milenio UPWELL, Chile, **2.** Pontificia Universidad Católica de Chile, **3.** Sociedad Chilena de Arqueología, **4.** University of Exeter, **5.** Universidad Católica de la Santísima Concepción, **6.** Universidad de O'Higgins*

The ancient Tagua Tagua Lake is one of the oldest archaeological localities in central Chile (34S), with at least three well-controlled late Pleistocene anthropogenic deposits. The hunter-gatherer tradition of its inhabitants has been well documented. However, the scarce preservation of organic evidence in central Chile has mostly prevented the study of plant resources of these early occupants.

In this contribution we present the first evidence of plant remains from the archaeological site Tagua Tagua 3. We study the stratigraphic sequence of phytoliths in the sediments throughout the occupation, spanning from the Late Pleistocene to the beginning of the Middle Holocene. In addition, we focus on the plant micro and macro fossils recovered directly from the earliest occupation of the site. We studied plant microfossils gleaned from seven lithic artifacts, whereas the macrofossils correspond to charred seeds recovered from a hearth dated c. 12,500 cal BP.

Our results show an evolution of the vegetation landscape through the occupational sequence that is complementary to pollen studies and new sedimentary biomarker analyses carried out on the site. Preliminary results of cultural evidence show an assemblage of microfossils composed of highly fragmented phytolith, starch grains, trichomes, pollen and indeterminate plant tissue.

Five artifacts showed evidence of plant use, including geophytes (typically rich in starch) and leaves of cf. Nicotiana sp. In addition, remains of feathers were found in one of the sharp-edged flakes, implying that these instruments were versatile. The material recovered from the hearth provides new insights into the cultural uses of plant and animal species, but also into the prevailing environmental conditions. Despite its small volume, the rich assemblage recovered shows a surprising diversity of plant species that can be linked to the bones of micro and megafauna, insects, eggshells, and possible remains of ostracods that were also recovered.

This new evidence shows the need to expand our records of local reference collections for the study of the plant remains. Comparison of our results with synchronous occupations will be of vital relevance for understanding the uses of plant resources by these early hunter-gatherer groups of Tagua Tagua and South America.

Early hunter-gatherer sites in the Atacama: living under the trees in the most arid desert in the world, 13,000 - 11,200 cal BP

Dr. Paula Ugalde [1]***, Dr. Delphine Joly*** [2]***, Dr. Calogero Santoro*** [3]***, Dr. Vance Holliday*** [1]

1. *The University of Arizona,* ***2.*** *University of York,* ***3.*** *Universidad de Tarapaca*

Humans arrived in the Atacama Desert 13,000 years ago, facing one of the harshest landscapes on Earth. They settled in a rainless stretch of land with scattered patches of biotic resources fed by increased rainfall in the Andes. They established social networks with people from different environments, creating essential bonds to maintain viable populations. However, we do not understand how they inhabited this forbidding landscape to make it their home. We propose that, aside from water sources, groves of phreatophyte trees, especially *Prosopis tamarugo*, were important when choosing locations for residential camps. These trees not only provided shade and endured droughts but fostered a more fertile environment by improving soils and attracting fauna. These groves would also have been visible landmarks in an otherwise barren landscape, promoting social aggregation. Based on ethnographic data, soil analyses, taxonomic identifications, and over 100 radiocarbon dates on preserved *in situ* tree stumps and charcoal associated to Paleoindigenous sites, we propose that the first peoples of the Atacama did not always interact with trees through exploitative ways. We posit that Paleoindigenous peoples of the Atacama made efforts to preserve a specific genus of tree: *Prosopis*, preferring other species for firewood and tools (e.g. *Schinus molle*), transforming the enduring *Prosopis* groves into focal points for inhabiting the Atacama both by the end of the Pleistocene and the beginning of the more hyperarid Holocene. To our knowledge, this is the first study that presents preserved evidence of tree groves contemporaneous with early (i.e. Paleoindigenous/Paleolithic) hunter-gatherer sites in the world.

Vegetation reconstruction and plant food availability for Homo sapiens in the highlands of Ethiopia since the Last Glacial Maximum

Dr. Manuel Casas-Gallego [1]***, Dr. Angela Bruch*** [2]***, Dr. Katharina Neumann*** [3]***, Dr. Stéphanie Bodin*** [3]***, Dr. Marco Schmidt*** [4]***, Dr. Karen Hahn*** [1]

1. Institute for Ecology, Evolution and Diversity, Goethe University, Frankfurt/M, 2. ROCEEH Research Centre, Senckenberg Research Institute, Frankfurt/M, Germany, 3. Department of Paleoanthropology, Senckenberg Research Institute, 4. Palmengarten der Stadt Frankfurt am Main

The Ethiopian highlands are a hotspot of archaeological and palaeoenvironmental interest as they have potential to shed light on the Late Pleistocene and Holocene cultural evolution and expansion of *Homo sapiens*. A number of archaeological sites in the SW Ethiopian mountains provide evidence of discontinuous occupation over the last 22 ka. In order to identify possible links between humans' dispersal across the region and past environmental habitats it is crucial to understand how plant ecosystems changed since the Last Glacial Maximum (22 ka BP). To do so, we have modelled past vegetation distributions in Ethiopia using detailed maps of modern potential vegetation combined with high-resolution palaeoclimatic data. The modelled distributions show significant changes in the extent of the main vegetation units through time which are validated by regional pollen records. One of the most remarkable findings of the simulated vegetation distributions is the expansion of areas with high climatic suitability for Afromontane forests during the late glacial. This inference is in contrast with long-standing hypotheses that suggest that savanna and grasslands became more predominant in the Horn of Africa during the Last Glacial Maximum. The series of vegetation belts that nowadays characterise the south-western Ethiopian highlands are estimated to have migrated downslope between 500 and 600 m during cold periods of the Late Pleistocene. We are aiming to assess the impact that the altitudinal shifts and the geographic distribution of vegetation units may have had on the amount and variety of food resources available for human populations inhabiting the Ethiopian mountains. An extensive database currently under development (*Plant-BITES*) compiles information on the edibility, nutritional value, accessibility through the year and other uses of plants that occur in each vegetation unit. The combined analysis of the availability of plant resources and the pattern of occupation of the montane archaeological sites show the relevance of habitats distribution to provide suitable settings for occupation to humans in the region throughout the last 22,000 years.

Use of plants for medicinal and edible purposes during the Upper Paleolithic and Neolithic Period in the territory of Georgia according to palynological research

Dr. Inga Martkoplishvili [1], ***Dr. Eliso Kvavadze*** [1], ***Dr. Natalia Togonidze*** [2]

1. Georgian National Museum, 2. Institute of Botany, Ilia State University

The palynological research of the cultural layers of 4 Upper Paleolithic caves (Dzudzuana, Satsurblia, Kotia Klde and Bondi) and two Neolithic settlements (Gadachrili Gora, Shulaveri Gora) in the territory of Georgia showed that people of that time used dozens of fruits, seeds, leaves, shoots and bulbs of plants in their diet and medicine.
As the researched material shows, in the Upper Paleolithic people store supplies in caves, where they often kept nuts (*Corylus*) and wild cereals (Poaceae), the pollen of which always prevails in the layers of the cave where they lived. Palynological research showed that at that time people ate beech (*Fagus*) fruits, picked wild grapes (*Vitis silvestris*), constantly consumed walnut (*Juglance regia*) and chestnut (*Castanea*) fruits, collected horsetail (*Hippophea*), asquil (*Roza canina*), cornus (*Cornus*). From grasses, in addition to cereals, *Malva*, *Plantago*, and *Carduus* were used as food.
As for medicinal plants found in the Upper Paleolithic cave materials, people used several antipyretic and anti-inflammatory remedies, such as lime (*Tilia*), which is still used in phytomedicine today. In the list of medicinal plants, there are also many pollen grains of pain-relieving and anti-bleeding plants, such as *Centaurea jacea*, *Ephedra*, *Campanula*, *Trifolium* and others. During the research of the Upper Palaeolithic samples, a total of 32 medicinal plants were identified.
In the Neolithic Period, the human diet improved as it began to cultivate cereals and other plants, and folk medicine developed more. Compared to the Upper Paleolithic, the Neolithic people studied and consumed much more medicinal plants. 56 medicinal plants have been identified from the Neolithic layers, almost twice as many as from the Paleolithic.
The study of material from the Upper Palaeolithic and Neolithic periods clearly illustrates the Neolithic revolution, which is manifested by a radical increase in food and medicinal plants in the archaeological material.

Vegetation dynamics and the origin of proto-cereals in Eastern Mediterranean from pollen and NPPs during the last 3 Ma: the case of Lake Acigöl and Lake Burdur in Turkey

Dr. Mary Robles [1], ***Dr. Valérie ANDRIEU*** [1], ***Prof. Pierre Rochette*** [2], ***Dr. M. Cihat Alçiçek*** [3], ***Mrs. Eliane Charrat*** [4], ***Mr. François Demory*** [1], ***Dr. Jérémy Jacob*** [5], ***Dr. Odile Peyron*** [6]

1. *Aix-Marseille Univ., CNRS, IRD, INRAE, Coll France, UM 34 CEREGE, Aixenrovence, France,* ***2.*** *Aix Marseille University, CNRS, IRD, INRAE, College de France, CEREGE, Aix-en-Provence, France,* ***3.*** *Pamukkale University, Department of Geology, Denizli, Turkey,* ***4.*** *Aix-Marseille Univ., CNRS, IRD, UMR 7263 & 237 IMBE, Aix-en-Provence, France,* ***5.*** *Univ. Versailles Saint-Quentin, CEA-CNRS, UMR 8212 LSCE, Gif-sur-Yvette, France,* ***6.*** *Univ. Montpellier, CNRS, IRD, EPHE, UMR 5554 ISEM, Montpellier, France*

The Eastern Mediterranean is a key region on the crossroad between Europe, Asia and Afrique. The first hominins are out of Africa at least around 1.8 Ma and the Eastern Mediterranean is the cradle of agriculture at the beginning of the Holocene and a major center of crop plants diversification. The domestication of Poaceae by humans and thus the apparition of cereals is attested at around 11,000 years BP in the Fertile Crescent. However, the presence of pollen of Cerealia (proto-cereals) is attested in Lake Acigöl, South-Western Turkey, between 2.3 Ma and 10 ka. As proposed in previous work, the appearance of proto-cereals could be linked to the pressure of large herbivore herds on steppic ecosystems around the Lake Acigöl, leading gene mutations of Poaceae. Proto-cereals and other edible plants from Acigöl may have been part of the diet of early hominins present in South-Western Turkey between 1.6 and 1.2 Ma.

In the framework of the ANR project FOOD-RE, the BS 87 series of Lake Burdur, located at around 30 km West of Lake Acigöl, is currently being studied. The aims of this study are to (1) reconstruct the vegetation dynamics based on pollen between 3 and 2.5 Ma around the Lake Burdur to complete the previous study carried out on Lake Acigöl between 2.3 Ma and 10 ka (2) identify pollen grains of Cerealia-type and perform measurements (3) understand more precisely the mechanism at the origin of presence of pollen of proto-cereals in this area.

The first analyses show an open landscape dominated by a steppe Poaceae, *Artemisia* and Chenopodiaceae. Pollen of proto-cereals have been also recorded before 2.5 Ma and measurements of pollen grains show large grain size, annulus and pore diameter. The mechanisms of the apparition of pollen of proto-cereals will be analyzed and compared to coprophilous spores and mammalian fauna in South-Western Turkey.

Setting the table in Sangiran: Availability of food resources for Hominids in Java at 1 Ma

Mrs. Susanne Krüger [1], ***Dr. Angela Bruch*** [2], ***Dr. Christine Hertler*** [3], ***Dr. Mika Puspaningrum*** [4], ***Mr. Iwan Pramesti Anwar*** [4]

1. ROCEEH Research Center, Senckenberg Research Institute, Frankfurt am Main, Germany, 2. ROCEEH Research Centre, Senckenberg Research Institute, Frankfurt/M, Germany, 3. ROCEEH Research Centre, Senckenberg Research Institute, Frankfurt/M, 4. Bandung Institute of Technology

This study focuses on available edible resources for hominids in Sangiran by the time of the Grenzbank formation. At that time at least two hominids, *Homo erectus* and *Meganthropus paleojavanicus*, inhabited the Sangiran area. These hominids differ in their dentognathic morphology and therefore presumably in their dietary strategies. In order to reconstruct the diet composition of both kinds of hominids, the reconstruction of the available resource space is crucial. Do their diets differ due to the exploitation of different vegetation units? Or does the difference relate to physiological or socio-technological factors? This study establishes the basic framework to answer these questions.
We identify five distinct vegetation units within a 50 km radius around Sangiran. These units are reconstructed on the basis of palaeotopographic and climatic maps. The majority of this area is covered by Lowland Monsoonal Forest (LMF) and freshwater habitats.
The resource space includes all edible resources and is divided into five categories: plants, insects, aquatic resources, as well as small and large vertebrates. The actual diet of hominids comprises a selection from the resource space based on the abundance and seasonal availability of resources on one side and the socio-technological skills of hominids on the other side. A rare resource, which is only available during few months of the year is less likely part of the diet than an abundant aseasonal resource. If this resource requires for instance heat treatment to be consumable, only hominids with the technological skill to use fire can include this resource into their diet.
Therefore for every edible species in each vegetation unit data on abundance, seasonality and required processing are collected. In this way the different vegetation units can be compared in terms of their resource availability of each category in the dry and wet season. The LMF for instance offers more fruits in the dry season than in the wet season, but more edible plant parts in total than freshwater habitats.
In this way, we describe and analyze the resource space of hominids at Sangiran and provide insights into resource availability and potential subsistence strategies of *Homo erectus* and *Meganthropus paleojavanicus*.

Session 46: Application of biomarkers and CSIA in Pleistocene archaeology

Plant-wax biomarkers in the Quaternary sediments of Deserts: Implications for human-environment reconstructions

Dr. Deepak-Kumar Jha [1], ***Dr. Robert Patalano*** [2], ***Dr. Patrick Roberts*** [2], ***Prof. Michael Petraglia*** [3]

1. *Department of Archaeology, Max Planck Institute for Geoanthropology,* ***2.*** *isoTROPIC Research Group, Max Planck Institute for Geoanthropology,* ***3.*** *Australian Research Centre for Human Evolution, Griffith University*

The preservation of plant-wax compounds over millions of years has provided an opportunity to develop fresh insights into past climatic and environmental conditions. These compounds have been found to be well-preserved in a wide variety of archaeological and palaeoenvironmental sediments. Temperate palaeosols and lake sediments have shown particular promise for preserving plant-waxes. However, the potential of plant-wax biomarker analysis in desert environments has yet to be explored, with general assumptions that these compounds, and organics in general, would be less likely to be preserved in sandy sediments, while low abundance of vegetation on the landscape would further minimize expected concentrations.

In this study, we evaluate the preservation of straight-chain alkyl lipid compounds such as *n*-alkanes and *n*-alkanoic acids (fatty acids) in desert sediments collected from 4 different archaeological sequences in the Nefud Desert, Saudi Arabia (n=2) and in the Thar Desert, India (n=2). The Nefud and Thar Deserts are selected given that they are geographically situated on one of the pathways of human dispersals from Africa to Asia, making them important sites for studying past human-environmental interactions. The samples were selected to represent both the Pleistocene and Holocene epochs to facilitate study of the effects of age on the preservation of these compounds.

We studied the preservation of plant-wax biomarkers using distribution patterns, carbon preference indexes (CPI), average chain lengths (ACL) and compound concentrations (ng/g dw). We also analysed samples for bulk $\delta^{13}C$ values and total organic carbon (TOC, %) to understand organic preservation and dominant vegetation contributors to the plant-wax organic pool in these desert environments. The results of molecular indices such as high odd over even preference (OEP) in *n*-alkanes, even over odd preference (EOP) in fatty acids, high CPI (Alk≥2.9 and Acid≥4.4, and high ACL (Alk ≥29.9 and Acid ≥27.4) indicate that plant-wax compounds are well-preserved across the studied desert sequences. This study provides a platform for applying this methodology to contexts where the impacts of climate and environmental change on past human societies during the Quaternary period is a question of high priority.

Plant Wax Biomarkers Reveal Late Pleistocene-to-Holocene Climatic and Ecological Change and Afromontane Human Adaptations in Lesotho, Southern Africa

Archaeological and paleoecological studies seeking to understand the climatic and ecological conditions associated with human expansion into African montane environments are often limited by a lack of proxy data obtained directly from archaeological sites. Although numerous proxy archives exist for southern Africa for the Quaternary, many of these are distal to archaeological sites (i.e., off-site) and obscure the ecological complexity that on-site records can provide for areas of past human activity. Here we present a ∼58-thousand-year vegetation and precipitation record using molecular $\delta^{13}C$ and δD values of plant wax *n*-alkanes directly from archaeological sediments collected at the Ha Makotoko rockshelter in western Lesotho, which extends from Marine Isotope Stage 3 through to the Holocene.

Stable carbon isotope ratios from terrestrial plant wax biomarkers indicate a constant C_3-dominated ecosystem from ∼58 to 5.0 ka, followed by C_4 grassland expansion due to increasing Holocene temperatures. Meanwhile, hydrogen isotope ratios indicate a relatively wet later Holocene compared to a drier, yet stable, Pleistocene and early Holocene. The results from Ha Makotoko demonstrate that the resource-reliable, Pleistocene environments incentivized persistent upland habitation likely due to generally uniform precipitation and dependable freshwater reserves that supported rich terrestrial food resources along perennial water courses. The added ability to catch fish may have underpinned the ability of hunter-gatherers to survive in highland Lesotho by compensating for significantly reduced availability of terrestrial plant foods when colder conditions prevailed. In particular, our data contributes to debates concerning the adaptive capacities of humans in upland environments and how they may have acted as key refugia or conduits for the biogeographic dispersal of humans during periods of climatic stress that impacted lower-altitude biomes.

One Toba, Different Tales: Assessing variability in environmental impact of ~74ka Toba super eruption on South Asian mosaic

Mr. Gopesh Jha [1], ***Dr. Deepak-Kumar Jha*** [1], ***Dr. Robert Patalano*** [2], ***Dr. Patrick Roberts*** [2], ***Prof. Krishnan Krishnan*** [3], ***Prof. Nicole Boivin*** [1], ***Prof. Michael Petraglia*** [4]

The ~74ka Toba eruption is considered the largest explosive volcanic event of the last 2 million years, with a Volcanic Explosivity Index (VEI) of 8.8. It is thought to have caused global havoc, leading to drastic global cooling and population bottlenecks for many species, perhaps including humans. Many global climatic records and simulation studies have shown that ~74ka Toba eruption had severe impact on the northern hemisphere and may have affected hyper-arid zones of southern hemisphere as well. Current research is framed around the idea that Toba event had highly variable regional environmental impacts, and regions such as South Asia may have been completely unaffected despite their relative proximity to the eruption. Nevertheless, the manifestation of Toba on local environments in South Asia has been difficult to explore due to a lack of chronometric ages and terrestrial environmental record. Our current work focuses on the well dated YTT sequences from central, western and Southern India, and seeks to create a paleoenvironmental transect to explore Middle-Late Pleistocene environmental change and the possible impacts of the Toba eruption across different biomes in South Asia. To do so, we employ analysis of plant wax biomarkers (n-Alkane) and compound specific isotopes ($\delta^{13}C$ and $\delta^{2}H$) for assessing paleovegetion and paleohydrological responses and subsequent habitat transformation. Our novel biomarker records promise the possibility of more detailed insights into the environmental change encountered by human populations in South Asia at the time of the Toba eruption and the Late Pleistocene more widely.

Palaeoenvironment during the Middle Stone Age in interior South Africa based on n-alkane stable isotope records

The Middle Stone Age (MSA) between 300 and 30ka in southern Africa is associated with complex cultural innovations by anatomically modern humans. While archaeological sites in caves and rockshelters along the coast provide a MSA cultural record predominantly after 160ka, sites in the Kuruman Hills in the arid interior of South Africa have evidence for occupations that focus on the earlier part of the MSA. Associated palaeoenvironmental records show wet phases during these occupations at Wonderwerk Cave, Kathu Pan and Ga-Mohana Hill rockshelter based on reconstructions using sediments, tufas and organic remains. However, beyond these exceptional sites, organic preservation is rare in the southern Kalahari during the Pleistocene. Sediment biomarkers are an innovative method that can create palaeoenvironmental records directly at archaeological sites, in addition to or despite of the lack of other suitable proxies. Leaf wax n-alkane records, tracking changes in the proportion of C_3 trees with C_4 grasses, are particularly promising biomarkers to study in the savanna environment of the Kuruman Hills. We present n-alkane carbon and hydrogen stable isotope measurements from sediment samples taken from the MSA layers at Wonderwerk Cave (240-150 ka) and Kathu Pan 6 (156-74 ka, minimum age). The results are compared to other proxy records from these sites and to modern transects of leaf wax n-alkanes in South Africa to assess the preservation and strengths of the method both in cave and open air sites. Our results show evidence for phases of increased humidity and shifting concentrations of C_3 and C_4 plants at both sites. Through the integration of environmental proxy studies and archaeological analyses from these sites and other newly published early MSA records in the area we can build a regional picture of palaeoenvironmental change during the earlier phases of the MSA in the arid interior.

Isotopic Evidence for Human Microhabitat Use Within and Across an Ecological Refugium, Panga ya Saidi, Kenya

The Panga ya Saidi (PYS) cave site of coastal Kenya has been instrumental for understanding long-term human occupation and resource procurement in a climate resilient tropical deciduous forest within a larger wooded and grassland biome. The site is best known for containing the earliest known human burial in Africa, the oldest stratified evidence of marine engagement in eastern Africa, and an ~80-thousand-year sequence of technological innovations and material culture traits that encompass the MSA-LSA-Iron Age transitions. Because PYS as possibly a Late Pleistocene environmental refugia buffered against dramatic climate shifts and exhibits the earliest known appearance of the LSA in Africa, it presents a unique opportunity to test hypotheses centered on the adaptability of hominins across spatially and temporally variable plant landscapes.

We compare a new □62-thousand-year vegetation and precipitation record obtained from molecular $\delta^{13}C$ and δD of plant wax *n*-alkanoic acids extracted directly from PYS archaeological sediments to existing bulk carbon and oxygen faunal isotope data to highlight human resource acquisition strategies across plant-landscape microhabitat variability. Overall, the $\delta^{13}C$ data from the C_{28}-C_{32} *n*-alkanoic acids indicate a C_3 dominated environment over the past ~62 ka, while δD values suggest an increase in precipitation over time, with a relatively drier Late MIS 4 and Early-to-Mid MIS 3 compared to the LGM, Terminal Pleistocene, and Holocene. Interestingly, separating these two phases was a comparatively intense, yet short-lived, dry period to which the plant landscape, and $\delta^{13}C$ values, did not respond. Our data also suggests differences between the immediate PYS forest environment and those within the human hunting range, as indicated by the bulk faunal isotope data. The reliable coastal PYS forest would therefore have been particularly alluring to Pleistocene human populations during periods of climatic stress or resource instability, specifically as it was able to withstand relatively extreme, at least short-term, climate anomalies.

Abrupt change and feedbacks of precipitation, vegetation, and fire in the Turkana Basin during the early Acheulean

Dr. Rachel Lupien [1]***, Dr. Kevin Uno*** [2]***, Ms. Maria Kuzina*** [2]***, Dr. Matt Grove*** [3]

***1.** Aarhus University, **2.** Lamont-Doherty Earth Observatory, Columbia University, Palisades, NY, **3.** University of Liverpool*

Abrupt changes in environment have significant impacts on the humans living in and depending on the landscape. The amplitude and rate of climate changes have been shown to affect evolutionary changes in hominins, including the development of stone tool technology. However, it has been historically difficult to reconstruct past climate and ecosystem change at timescales that can resolve these transitions, which is crucial for testing hypotheses on the nature of this relationship. Further, the interplay between various ecosystem parameters, namely precipitation, vegetation, and fire, may have nonlinear interactions that are important for our understanding of evolutionary responses. Here, we present new ultra-high-resolution leaf wax hydrogen and carbon isotope and fire (PAH) biomarker data from the HSPDP WTK13 sediment core in the Turkana Basin, Kenya, a region containing multiple Acheulean sites known for their multi-purpose handaxes. Our West Turkana record spans a single high-amplitude insolation cycle (~21 kyr) just after 1.76 Ma, which accords well with the timing of the earliest evidence for Acheulean technology found in the nearby Kokiselei assemblage. We find that while precipitation responds with a simple nonlinear response to the relatively gradual orbital forcing, changes in vegetation and fire are more complex. On millennial timescales, there is coherency between ecosystem parameters, but the overall structures differ, indicating the prominence of feedbacks within the system. Multiple abrupt, oscillatory transitions occur in vegetation structure, which likely had a large effect on humans by exerting selection pressures favoring greater behavioral plasticity. It is possible that these patterns were exacerbated by the high-amplitude, orbital scale changes occurring during this time period. With higher-resolution, multi-proxy data, we are better able to focus on climate feedbacks and their impact on our hominin ancestors.

A biomarker and stable isotope approach to detecting climate-mediated site occupation patterns – a proof-of-concept study from La Ferrassie, France

Human responses to climatic shifts are central to understanding key developments throughout our evolutionary history, including the disappearance of Neanderthals ~40 ka ago. Indeed, the archaeological record of late Neandertals shows a substantial amount of variability that has been discussed in the context of shifting climates. Yet, establishing links between these climatic and archaeological changes remains challenging due to a lack of climatic data that can be sufficiently related to archaeological evidence of human activities. Generating climatic data directly at archaeological sites is therefore key.

Diverse sample types from archaeological sites, from sediments to faunal remains, generate distinct types of climatic insights, offering different time resolution and varying relationships to past human activity. Here, we purposefully exploit such differences in an approach employing the stable isotope analysis of both 1) n-alkanes from sediment samples and 2) faunal tooth enamel from the Late Pleistocene Neanderthal occupations (MIS 5 – 3) of La Ferrassie, southwest France. In a previous study we documented a divergence between warm-climate faunal stable isotope signatures and sedimentary markers of freeze-thaw processes within a single layer of La Ferrassie. Here we explore this further by providing highly resolved climatic data from n-alkane biomarkers which are then compared to the faunal isotope data. The sequence of n-alkane ('leaf wax') δ^{13}C and δ^{2}H measurements we generate permit the inference of climatic conditions during the sedimentary formation of the site deposits – that is, a site-specific and naturally accumulated archive. We then contrast this with δ^{18}O and δ^{13}C data generated from tooth enamel and bone collagen of large bovids that represent the remains of Neanderthal hunting activity – an anthropogenically accumulated archive with a direct connection to Neanderthal occupations of the site.

Using this comparison, we demonstrate how deviations between natural accumulations and anthropogenically-related climate archives can be used to explore the different time scales and climatic conditions of sedimentary deposit formation versus the specific climatic conditions surrounding human activity at a site. Finally, we explore if this approach could be used to highlight climate-mediated site-occupation patterns, characterize conditions during occupation hiatus and thus explore potential climatic preferences of Pleistocene humans.

Session 47: The geological record of capable faults

Tectonic Geomorphology and Characteristics of the West Ilocos Fault System (Philippine Fault Zone) in the Eastern Solsona Basin, Philippines

The Philippine Fault Zone (PFZ) is a 1200-km-long tectonic feature that transects the entire Philippine archipelago from northwestern Luzon to southeastern Mindanao. The PFZ consists of predominantly left-lateral strike-slip faults that have generated strong to major earthquakes in recent years, notably the Mw7.7 1990 Luzon Earthquake, and more recently, the Mw7.0 2022 Northwestern Luzon Earthquake. In northwestern Luzon, a network of strike-slip, reverse, and normal fault segments associated with the PFZ comprises the West Ilocos Fault System (WIFS). In this study, strands of the WIFS east of the Solsona Basin in Ilocos Norte were examined through geomorphological analysis, ground penetrating radar (GPR) surveys, and paleoseismic trenching. Morphotectonic features such as offset streams, truncated spurs, and subtle elevation changes were interpreted from anaglyph images and high-resolution digital topography data. In the municipality of Marcos, geomorphic markers indicate a general sinistral movement of the fault, with the fault scarp trending N20-35°E and dipping northwest. Ground penetrating radar surveys conducted along and across the fault scarp reveal discontinuous reflectors, corresponding to minor faults at a depth of about 5 m. A paleoseismic trench was then dug across the fault scarp, revealing the main fault, its splays, and displaced stratigraphic units. At least ten (10) stratigraphic units were delineated and described based on color, thickness, and sedimentological characteristics (e.g., texture, sorting, composition). Stratigraphic units are generally composed of muddy to silty sand and sandy gravels with angular to sub-rounded clasts of volcanic rocks sourced from the Ilocos Foothills (i.e., Bojeador Formation). Initial interpretation of the trench wall stratigraphy reveals at least two (2) faulting events that show normal displacement of stratigraphic horizons. These displaced horizons within alluvial deposits further imply recent movement along this segment of the WIFS, which we refer to as the East Solsona Basin Fault. The timing and recurrence of these faulting events have yet to be established through radiocarbon dating of charcoal samples collected from the stratigraphic horizons.

Paleoseismological studies along the Eastern Southalpine front revealing evidence of recent tectonic activity: implication for the seismic hazard assessment of NE-Italy

Prof. Maria ELIANA POLI [1], ***Dr. Giulia Patricelli*** [2], ***Dr. Giovanni Paiero*** [1], ***Dr. Emanuela Falcucci*** [3], ***Dr. Stefano Gori*** [3], ***Dr. Giovanni Monegato*** [4], ***Prof. Adriano Zanferrari*** [1], ***Dr. Andrea Marchesini*** [1]

__1.__ University of Udine - Department of Agricultural, Food, Environmental and Animal Sciences - Udine, Italy, __2.__ University of Udine - Department of Agricultural, Food, Environmental and Animal Sciences, __3.__ Istituto Nazionale di Geofisica e Vulcanologia (INGV), Italy, __4.__ CNR - IGG

The numerous paleoseismological investigation conducted in north-eastern Italy during the last 10 years allowed us to characterize the active front of the Eastern Southalpine Chain (ESC): a polyphase S-SE verging fold and thrust belt confined to the West by the sinistral Schio-Vicenza Fault System and to the East by the dextral strike-slip fault systems of western Slovenia and eastern Friuli. The main development of the ESC is associated to the messinian-pliocenic compressive event, which affected the inherited Dinaric structural architecture. Since Pliocene-Quaternary times the study area is subjected to a N-S compression and deformation is presently accommodated with velocities of the order of 2-3 mm/yr. The distribution of seismicity matches the arcuate shape of the Eastern Southalpine front, which is characterized by NE-SW to WNW-ESE and NW-SE trending structural features. Particularly, the strongest earthquakes (Mw ≥ 5.5) which affected the Veneto-Friuli region are located along the Venetian, Carnic and Julian prealpine border (1511 Mw 6.3; 1695 Mw 6.4; 1776 Mw 5.8; 1794 Mw 6.0; 1836 Mw 5.5; 1873 Mw 6.3; 1936 Mw 6.0 and 1976 Mw 6.5). Despite this, the active external thrust systems of the ESC are generally considered blind and the record of coseismic effects associated to seismic events are scarce. In this work we present a collection of 4 paleoseismological case studies, located all along the arcuate prealpine border, investigating the Bassano-Valdobbiadene, Meduno, Susans-Tricesimo and Colle Villano-Borgo Faris-Cividale Fault Systems. Our investigation documented many coseismic effects, both primary and secondary, mainly dealing with vertical displacement along shear planes, extrados secondary fractures and paleoliquefaction features, highlighting the recent tectonic activity of the investigated thrust faults. Particularly, the results we collected demonstrated that the frontal thrust systems of the Eastern Southern Alps, responsible of Mw ≥ 5.5 seismicity, are capable to generate permanent surficial deformation effects in occurrence of their activation.

The Kachchh Mainland Fault's Late Quaternary-Holocene Earthquake History: Evidence from Optically Stimulated Luminescence (OSL) Dating and Paleoseismology

Mr. Eshaan Srivastava [1]***, Prof. Javed Malik*** [1]***, Dr. Mahendrasinh Gadhavi*** [2]***, Mr. Nayan Sharma*** [1]

1. *Department of Earth Sciences, Indian Institute of Technology Kanpur,* ***2.*** *L. D. College of Engineering*

The Kachchh region has had at least four destructive moderate-to-large earthquakes in the past 500 years. With the exception of the Allah Bund earthquake in 1819, none of these earthquakes were, however, accompanied by surface rupture. Even the recent Mw7.6 Bhuj earthquake in 2001 took place on a blind fault with a sizable deformation zone that was reflected in the form of lateral spreads and had significant liquefaction and hydrological consequences. Previous research revealed that a number of faults in the Kachchh, including the Island Belt Fault, the Kachchh Mainland Fault (KMF), and the Katrol Hill Fault, were active during the Late Quaternary. But there is little supportive evidence available in the form of qualitatively reported recent Quaternary-Holocene rupture events and the nature of the active fault (Morino et al., 2007; Morino et al., 2008a, 2008b; Malik et al., 2008). As a result, nothing is known about the regional paleoearthquake events. This makes it more difficult for us to comprehend the tectonics of the area and the seismic risk. To address this issue, we investigated the fault exposures associated with the Kachchh Mainland Fault (KMF) near the Jhura dome using geomorphological data, near-surface geophysical surveys, and paleoseismological trenching. The tectono-geomorphic landmarks close to the dome, such as strath terraces, cut-fill terraces, alluvial fan surfaces, and north-facing fault scarps, were also thoroughly studied. We discovered deformation features that might have been brought on by multiple earthquakes between 9.7 and 6.4 ka in a paleoseismological trench that crossed the fault track. When compared to the archeoseismic and climatic records, the chronological order of the geomorphic markers also suggests a few recent event occurrences between 4.1-0.9 Ka. Given the interval between recurrences of 1000–1500 years, it is not unlikely that an earthquake of a moderate to large magnitude may strike KMF.

Re-characterizing a capable fault in Alaska, USA; How lidar and trenching data forced a reinterpretation of the Ragged Mountain fault

Dr. James McCalpin [1]

1. *GEO-HAZ Consulting, Imc.*

The 33 km-long Ragged Mountain fault (RMF) forms the northwestern corner of the Yakutat microplate, which is colliding with the North American plate in south coastal Alaska at □5.5 cm/yr. The most prominent evidence of postglacial faulting is a zone of nearly-continuous antislope scarps cutting the colluvial-alluvial apron at the range front, documented by USGS in 1976. These extensional scarps were interpreted as 180 m of normal fault slip on a shallow (13 degrees) west-dipping former reverse fault (fault inversion). If true, this would make the RMF the fastest-slipping normal fault in the world (15 mm/yr). However, the microplate is in a highly compressional setting; how could the world's fastest extensional fault exist there? In 2005-06 we remapped the central part of the RMF from lidar DEMs and excavated five trenches. New observations: (1) downslope from the antislope scarps lay a subtle, semi-continuous reverse fault scarp, not recognized in 1976, and (2) strata in the footwall had been folded to near-vertical and contained multiple, parallel, postglacial flexural-slip faults. A trench across the antislope scarp exposed evidence for three displacements: at 0.5–3.9 ka; slightly younger than 8.3 ka; and at 18.1–21.8 ka (recurrence intervals 4.4–8 kyr and 9.8–13.3 kyr), with displacements per event ranging from 15 to 40 cm. In the thrust trench ruptures were dated at 2.8–5.9 ka; 5.9–17.2 ka, and 17.2–44.9 ka (mean recurrence intervals 7.2 kyr and 19.5 kyr). Displacements per event ranged from 26 to 77 cm. We interpret the thrust fault as the primary seismogenic structure, and the antislope normal faults as secondary collapse structures in the fault tip. The largest reverse trench displacement (77 cm) equates to average displacement expected for a 33 km-long reverse rupture, and a slip rate of > 0.08 mm/yr. Our revised characterization was based on the suite of surface-rupture features observed in several post-1976 reverse surface ruptures, especially the 1980 M7.1 El Asnam, Algeria, earthquake, which occurred four years after the USGS characterization. When assembling databases of surface rupture, compilers should be aware of possible defects in interpretation in these older reconnaissance studies.

Fault Parametrization for Probabilistic Fault Displacement Hazard Analysis. Case Study from the Upper Tiber Valley

Fault displacement can be particularly risky for critical infrastructure located in the nearby of a capable fault. Usually, this issue is dealt with zonation and avoidance strategies, but sometimes this option is not feasible for existing facilities. Probabilistic Fault Displacement Hazard Analysis can address this problem, assessing the likelihood of exceeding a certain level of displacement at the site of the infrastructure. Since the early 2000s, several authors proposed different methodologies for different kinematic contexts. Using databases of coseismic ruptures of past earthquakes, empirical regressions have been proposed to assess the probability of occurrence and the probability of exceedance of certain values of displacement, for both Primary and Distributed faulting.

The probability of exceeding a certain value of displacement at the site of interest is also related to the probability of occurrence of a surface faulting earthquake on a certain fault. To perform the PFDHA, the fault parameters and earthquake rates are needed.

We propose the results of PFDHA applied to the Anghiari Fault, a poorly constrained normal fault located in the Upper Tiber Valley (Italy), and the methodological approach used to gain the fault parameters needed to perform the PFDHA.

The Anghiari fault is an 11 km-long, NE-dipping, highly segmented normal fault bounding the western side of the Sansepolcro basin. It is one of the synthetic splays of the Altotiberina low-angle normal fault system.

We started with geological survey, morphotectonic analysis and geophysical investigations to accurately map all the fault segments and to select sites suitable for paleoseismologic trenching. To assess the capability of the fault and its rate of activity we carried out a paleoseimic campaign, investigating several segments of the Anghiari fault. To obtain a multiscale evaluation of the fault slip rate, we collected samples to date paleosurfaces displaced by the fault with the cosmogenic nuclides methodology.

At the end we performed the PFDHA obtaining curves and maps of hazard for both primary and distributed faulting.

The San Ramón thrust fault and the sustainability of Santiago, Chile: Increasing seismic risk and recommendations for public policy

Dr. Gabriel Easton [1], ***Dr. Rubén Boroschek*** [2], ***Prof. Sofía Rebolledo*** [1], ***Dr. Jorge Inzulza*** [3], ***Prof. Daniela Ejsmentewicz*** [4], ***Prof. Paulina Vergara*** [5], ***Mr. Eduardo Giesen*** [6]

__1.__ Departamento de Geología, Facultad de Ciencias Físicas y Matemáticas, Universidad de Chile, Santiago, Chile, __2.__ Departamento de Ingeniería Civil, Facultad de Ciencias Físicas y Matemáticas, Universidad de Chile, __3.__ Departamento de Urbanismo, Facultad de Arquitectura y Urbanismo, Universidad de Chile, __4.__ Facultad de Derecho, Universidad de Chile, __5.__ Instituto de Asuntos Públicos, Universidad de Chile, __6.__ Colectivo Viento Sur, Observatorio Precordillera

The San Ramón thrust fault system is located at the west foot of the main Andes Cordillera, along the piedmont of a more than 2000 m high mountain front that limits the central valley where Santiago, capital city of Chile, inhabited by more than 7 millions of persons, is located. Paleoseismological and seismological results evidence that this is an active fault capable to produce large earthquakes with superficial rupture. Its potential activation constitutes a challenge for the city of Santiago as well as for the entire metropolitan region. The eastern border of the city has experienced an accelerated urbanization in the last four decades with respect to the previous four centuries, with increasing seismic risk. This is a risk element not yet included in Chilean public policies, whose consideration is essential regarding the sustainability of the city, since a growing population of people lives directly on its trace as well as in its surroundings.

We conclude with seven recommendations for public policy: (1) to define the San Ramón Fault as an active fault; (2) to restrict the foundation of any infrastructure in a 300 m wide fringe along the San Ramón Fault trace, with the possibility of carrying out studies to specify the location of this fringe at surface, including it as a constitutive element of local and regional urban planning policies; (3) to modify the Chilean Seismic Code to incorporate active faults; (4) to carry out hazard studies related to landslides susceptibility, given the potential activation of the San Ramón Fault and incorporating these areas into regional and urban planning instruments; (5) to make available accurate and pertinent information to the public regarding the location and seismic risk of the San Ramón Fault; (6) to define the restriction fringe along the San Ramón Fault trace (300 m), as an area of environmental protection and natural conservation along the Andean piedmont; and (7) to define and to implement a governance strategy for the design, implementation, monitoring and evaluation of sustainable urban planning, in coherency with the Sustainable Development Goals, and the national and global policy on Disaster Risk Reduction.

New Observations of the Surface Slip Distribution of the Ruptures to the 24th and 25th February 1981 Ms 6.7 and 6.4 Earthquakes, Pisia and Skinos Fault, Greece

Earthquake surface ruptures are the surface expression of coseismic slip on a fault produced during large magnitude earthquakes. Extensive field observations of these ruptures can provide important insights into fault kinematics and relationships between regional tectonics, faulting processes and seismic hazard. However, only a few well-documented examples of normal faulting surface ruptures exist in the literature. The 1981 eastern Gulf of Corinth seismic sequence generated ruptures on the Pisia and Skinos Faults, however, only a few offsets were recorded immediately after the earthquakes, with measurements spacing hundreds to thousands of metres apart. The 41-year-old rupture is still well preserved along the Pisia and Skinos normal faults, both as bedrock fault plane lichen stripes and ruptures in colluvium. We re-visited sites close to those measured in 1981 and found offsets only slightly larger or smaller than those measured in 1981 (± < a few decimetres even for sites that had over a metre of slip in 1981). We found no clear evidence of an overall increase in slip due to post-seismic motion, so the 1981 slip distribution is relatively-well preserved. We mapped the ruptures, taking measurements at 223 sites spaced tens of metres apart or less along strike, and have produced detailed surface slip distributions, recording strike, dip, plunge, plunge direction, slip, heave and throw. Kinematics obtained along the two faults display asymmetric bell-like slip distributions that, when summed across strike between the two faults, reveal a double-humped, symmetric slip distribution. The two maxima in slip on the summed profile occur at two along-strike bends in the ruptures where strike and dip values on the fault planes vary. The bend for the Pisia example is also associated with an abrupt change in the slip-vector azimuth despite the lateral continuity of the rupture. These kinematic observations provide insights into possible geometric barriers to rupture propagation and how these relate to surface slip distributions and fault scaling relationships. Detailed measurements like those herein are key to understanding faulting processes and fault-slip hazard on capable faults, which has important implications for seismic hazard.

Updated regressions on the likelihood of surface faulting

Dr. Francesca Ferrario [1], ***Dr. Marco Pizza*** [1], ***Dr. Frank Thomas*** [1], ***Dr. Giorgio Tringali*** [1], ***Dr. Franz Livio*** [1]

1. *Università degli Studi dell'Insubria, Como*

Several factors define if an earthquake will rupture all the way to the topographic surface, including moment magnitude, earthquake kinematics, local lithological characteristics. Surface rupture starts to occur for earthquakes of Mw 5 (or even lower in peculiar context like volcano-tectonic settings) and becomes more and more likely for higher magnitudes.

The likelihood of primary surface faulting as a function of magnitude is the first branch in the logic trees currently adopted for fault displacement hazard assessment and thus has a paramount role, especially for probabilistic evaluations. Nevertheless, the scaling equations currently adopted were developed several years ago; we attempt to update such relations by exploiting more recent earthquakes. We selected from the ISC-GEM seismic catalogues the earthquakes with Mw higher than 5.5 occurred between 1992 and 2018 and with epicenter located onshore and hypocentral depth lower than 20 km. We build a homogeneous dataset categorizing the events as having or not having ruptured the surface (88 and 276 events, respectively).

Then, we compute empirical regressions of the likelihood of primary surface faulting as a function of magnitude on the entire dataset and on subsets for the different earthquake kinematics. Overall, we found a general agreement with existing equations, except for reverse earthquakes; we discuss possible causes related to the dataset or adopted methods. We argue that the documentation of surface faulting gained an increased attention in the last years, given the critical role posed by fault displacement hazard for high-risk plants. New techniques that are nowadays routinely adopted (e.g., InSAR, optical image correlation) allow to investigate in an unbiased manner the entire earthquake population, thus providing sound results. The methodological choices in the first stages of dataset implementation (e.g., depth threshold) may affect the final result; in this sense, we define clear thresholds, to assure repeatability of the procedure.

The equations derived in this study can be used together with existing equations, handled in a logic tree structure; similar equations can be derived for different seismotectonic settings or geographic regions, whenever a sufficient earthquake dataset is available.

Session 48: Quaternary climate, landscape and surface processes in mountain belts

Geomorphic settings of wetlands on quaternary volcanoes in the humid tectonic zone: Recharge water characteristics and responsiveness to climate change

Dr. Natsuki Sasaki [1]***, Dr. Masatsugu Yasuda*** [2]***, Prof. Toshihiko Sugai*** [3]

1. *Chuo Univeristy,* ***2.*** *Asia Air Survey Co., Ltd.,* ***3.*** *The University of Tokyo*

In northeastern Japan (Tohoku region), numerous wetlands are on a backbone range (Ou Mountains), and northwestern winter monsoons bring in a large amount of snow. In this study, we comprehensively examined the landforms, climate, and hydrological settings of wetlands on the volcanic surface of the Ou Mountains. Additionally, we clarified that the responsiveness to climate change differs depending on the local geomorphic and hydrologic conditions.

Wetlands of various geomorphological origins are formed in the study area. The tectonic lineaments due to east-west compression and the gravitational deformation, including landslides and linear depressions, are representative sites of wetlands. On the original volcanic surfaces of high-elevation areas, the tectonic lineament and linear depressions are covered with snow drift. Furthermore, wetlands are formed on the saddles with less snow accumulation.

We observed soil temperature, moisture, and electrical conductivity in three peatlands along a tectonic lineament and on the saddles from 2018 to 2019. The peatlands were formed during Holocene warming and humidification. In the lineament, the annual change in electrical conductivity was small. The soil remained moist for approximately 1.5 months after the snow has melted completely and then changed according to the season—dry or wet. In the saddles, the electrical conductivity fluctuated wildly, increasing during the snow-covered periods and decreasing after the snowmelt season. In addition, the soil moisture content also fluctuated wildly with precipitation. Groundwater generally has higher electrical conductivity than precipitation. Therefore, the peatland along the tectonic lineament is mainly recharged from snowmelt runoff. Precipitation and shallow groundwater from the surrounding slopes contribute to recharging in the peatlands on the saddles.

With the long-term warming trend in the Tohoku region, a reduction in snow accumulation and melting of snow at an earlier stage will significantly impact wetland environments. Using aerial photographs taken in 1976 and 1998, we measured the area for each wetland type and found that snow-fed type areas have shrunk, while those on saddles have increased. Therefore, it was revealed that the responsiveness to climate warming depends on the characteristics of the recharge sources that reflect the landform.

Evolution of the polygenetic Frébouge Cone during the Holocene (Val Ferret, Mont Blanc Massif)

Dr. Catharina Dieleman [1], ***Dr. Philip Deline*** [2], ***Prof. Susan Ivy-Ochs*** [3], ***Ms. Patricia Hug*** [4], ***Prof. Jordan Aaron*** [5], ***Dr. Marcus Christl*** [6], ***Dr. Naki Akçar*** [1]

1. *Institute of Geological Sciences, University of Bern,* ***2.*** *Université Savoie Mont Blanc, CNRS, EDYTEM,* ***3.*** *ETH Zurich,* ***4.*** *Department of Earth Sciences, ETH Zürich,* ***5.*** *Geological Institute, ETH Zürich,* ***6.*** *ETH Zurich, Laboratory of Ion Beam Physics, Zurich, Switzerland*

Proglacial settings in the Alps are typically polygenetic, often characterised by a complex and discontinuous interplay between glacial, fluvial, and gravitational processes. These processes yield high volume of sediments, which usually exceeds the transportation capacity. The overshoot proglacial sediment load leads to accumulation on slopes, and thus, to failures such as rock avalanches or debris flows. Such failures can occur unexpectedly and harm the villages and infrastructure in the vicinity of proglacial environments. The northern slopes of the Ferret and Veny valleys in the Mont Blanc Massif are home to several polygenetic cones and portray a stunning field laboratory for the exploration of the interplay between the glacial, fluvial, and gravitational processes. This study investigates one of the active and well-preserved polygenetic cones in these valleys, namely the polygenetic Frébouge Cone, in order to disentangle the geomorphic processes that contributed to its formation, and to reconstruct its evolution. To achieve these goals, detailed field and remote mapping, ^{10}Be surface exposure dating of different geomorphic features, and runout modelling with DAN3D® were applied. The geomorphological map revealed complex interactions of glacial, fluvial, debris flow, and rock and snow avalanche processes. The established chronology indicates two major fluxes of debris flows, the first one at ca. 2 ka, and the second at ca. 1 ka. In addition, a rock mass with a maximum volume of to 12 Mm^3 collapsed in the upper reaches of the cone at ca. 1.2 ka and overran the cone by travelling more than 100 m up onto the opposite valley slope. Afterwards, the Frébouge glacier overrode the cone several times leaving moraines and striated boulders, reaching its maximum extent ca. 300 years ago. This study underscores the untwisting of complex interaction of surface processes in the Alpine valleys, which are prone to hit the urban areas and infrastructure.

Late-Quaternary Glacial History of the Milang Sub-basin, Lahaul Himalaya, Western Himalayas

Mr. Sandip Tanu Mandal [1], ***Prof. Milap Chand Sharma*** [1], ***Dr. Madhav Krishna Murari*** [2], ***Dr. Pankaj Baghel*** [3], ***Dr. Pavitra Kumar*** [4]

1. *Centre for the Study of Regional Development (CSRD), Jawaharlal Nehru University, New Delhi, 110067, India,* ***2.*** *Geochronology Group, Inter-University Accelerator Centre (IUAC), New Delhi, 110067, India,* ***3.*** *Inter University Accelerator Centre, New Delhi,* ***4.*** *National Geochronology Facility, Inter University Accelerator Centre, New Delhi -110067, India*

Glacial and Geological studies investigate the pieces of evidence to understand the timing and extent of glaciation of the late Quaternary period. Studying past glacial records can also be helpful to reconstruct the effects of environmental change in the region. The study of the Quaternary glaciation in the Himalayan and Tibetan regions has remained the focal point of several scientific research. The palaeo-glacial and palaeo-climatic reconstruction of the Milang watershed (MLW) has been done with the help of using geomorphic mapping and cosmogenic 10Be surface exposure, and Optically Stimulated Luminescence (OSL) dating. The MLW is a sub-basin of the Chenab basin in the Lahaul region of the Western Himalayas. It lies in the zone of transition between the arid regions of Spiti, Ladakh, and Tibet and the monsoon-influenced regions south of the Pir Panjal in Himachal Pradesh. This study reports the first 10Be dates for the MLW watershed and tries to co-relate the results with a regional framework for palaeo-glaciation in the Lahaul Himalaya as given. Based on the Landform Mapping, ^{10}Be exposure and OSL ages the palaeo-glacial extent of the MLW has been reconstructed. Three major palaeo-glacial stages, namely, Chandra (~81.5 ±3.94 ka), Darcha (12 ka to 15.5 ka) and Mulika (~8 ±1.47 ka) have been identified. The Chandra stage of glaciation refers to a massive valley glaciation influenced by the Monsoon. The glaciers occupied the Chandra and Bhaga valleys. The Darcha stage represents a valley-wide glacier extended in the main Milang valley. It coincides with the regional glacial stages of SWHTS (Semi-arid Western Himalayan-Tibetan Stage) 2A, SWHTS 2B, and SWHTS 2C influenced by Westerlies. The Mulkila stage was a major glacial advance stage that occurred during the early Holocene. It is represented by well-preserved glacial trimlines and sharp-crested moraine ridges. During this stage the South Asian Monsoon moisture was dominant and glaciers were more sensitive to precipitation.

Multiple glacier river-blocking events on the southeastern Tibetan Plateau in response to climate changes since the last glacial maximum

The detailed evolution of valley-damming by glaciers on the southeastern Tibetan
Plateau, including the very large Gega dammed lake, is reconstructed based on observed sediment sequences, and optically stimulated luminescence (OSL) dating. In total, six main lithofacies associations are inferred that represent three relevant sedimentary environments associated with the dammed lakes, i.e. lacustrine, deltaic and fluvial. Since the local last glacial maximum (LGM), there have been at least three river-blocking events and consequent phases of lacustrine development in the Gega and Jiedexiu dammed lakes. They occurred at ca. 25–17 ka, 14–11 ka, and ~4 ka. Sedimentological evidence shows that the glacier-dammed lakes were not stable; they experienced oscillations of lake level through short-time drainage events. The damming events and subsequent
outburst floods were likely triggered by changes in the extent and thickness of glaciers, caused by rapid climatic changes.

“Morphotectonic evolution of the Albanian Dinarides belt from preliminary meteoric 10Be/9Be denudation rates”

Mrs. Chiara Bazzucchi [1] ***, Prof. Claudio Faccenna*** [1] ***, Prof. Paolo Ballato*** [1] ***, Dr. Silvia Crosetto*** [2] ***, Dr. Hella Wittmann*** [2]

1. Dipartimento di Scienze, Sezione Geologia, Università Roma Tre, Roma, Italy, 2. Helmholtz Centre Potsdam, German Research Centre for Geosciences (GFZ), Potsdam, Germany

The Albanian Dinarides correspond to the central part of the Dinarides – Hellenides orogen, a SW-vergent fold-and-thrust belt resulting from the convergence and the collision between the Adriatic and European plates. Prominent topographic differences reflect the geologic organisation of the belt into NW-SE-oriented structural domains, which can be summarised into an external compressional zone, and the extensional continental interior, characterised by graben basins.

Modern seismicity (e.g. 1979, Mw 7.1 Montenegro, and 2019, Mw 6.4 Durres earthquakes) together with geomorphic features such as marine and river terraces, endorheic basins, wind gaps, hanging valleys, suggest that this region has been tectonically active since at least late Quaternary. Despite this evidence, a thorough understanding of the morphotectonic evolution of the area is still limited. Since deformation style and rock erodibility are the primary factors controlling the evolution of the topography, we aim at reconstructing the Quaternary morphotectonic evolution of the Albanian fold-and-thrust belt by using geomorphic markers. We first focused our attention on drainage network analysis: rivers are able to respond quickly to tectonic and climatic changes, becoming good candidates to investigate how the landscape reacts to external forces, and how tectonics, climate, and surface processes are related. Here, river denudation rates will be used to quantify Quaternary erosion rates, which will in turn serve as proxies for uplift rates. We calculate river denudation rates by employing the innovative technique of meteoric 10Be. Unlike the well-known in situ Be technique that can be exclusively employed in quartz-rich lithologies, with this new technique also quartz-poor lithologies can be processed; this is particularly useful in Albania, where carbonate rocks and ophiolites predominate.

After morphometric analysis and remote mapping of all the major drainage basins of Albania and western Macedonia, twenty basins were chosen for sampling. These basins are in equilibrium, develop on a unique lithology, lie in the proximity of the main tectonic structures, are spatially distributed to cover all the main tectonic domains. We expect variable uplift rates over different sections of the belt, reflecting different tectonic activity across the NW-SE-oriented structural domains, and evidences of the contribution of deep processes to landscape evolution.

Session 52: Eurasia, one continent one common past: cross-continental stratigraphical correlations

A potential second stage for the Middle Pleistocene Subseries based on the Mid-Brunhes event

Prof. Martin Head [1]

1. *Department of Earth Sciences, Brock University*

The Global boundary Stratotype Section and Point (GSSP) at Chiba, Japan defines the base of the Middle Pleistocene Subseries and Chibanian Stage with an astronomical age of 774.1 ka. This boundary represents the approximate midpoint of the Early–Middle Pleistocene transition, a 1.4–0.4 ka interval marked by a progressive increase in the amplitude and asymmetry of climate oscillations and a shift towards quasi-100 ky periodicity. Both units currently extend upwards to the base of the Upper Pleistocene Subseries dated provisionally at ~129 ka. The Middle Pleistocene with a 645 kyr duration is the second longest subseries of the Quaternary. Introducing a second stage, beginning at the approximate mid-point of this subseries, would provide a useful division. The 'Mid-Brunhes Event' (MBE) more recently termed the 'mid-Brunhes Transition' is an abrupt step-change to increased amplitude of the quasi-100 kyr cycles and to warmer interglacials from MIS 11 onwards, as revealed by Antarctic ice core records, the LR04 benthic foraminiferal isotope stack, and a recent long alkenone paleotemperature record from the central Mediterranean Sea. Other long-term changes at this time include an abrupt weakening of the East Asian Summer Monsoon, suggesting an increase in average Northern Hemisphere ice volume. The base of this new stage would reasonably be placed at around the MIS 12–MIS 11 transition (Termination V, ~420 ka), an interval of rapid change clearly recognised in the marine record. This level appears to approximate the bases of the Holsteinian, Hoxnian, Likhvinian, and Zavadivian regional stages across northwestern and central Europe, the Russian Plain, and the Ukrainian Loess Plain; and can be traced across the Chinese Loess Plateau. Climatostratigraphic signals associated with Termination V (~420 ka) would serve as the primary guide to this proposed new stage for the Middle Pleistocene. The 'Bermuda' geomagnetic excursion occurring within a prominent relative paleointensity minimum at ~412 ka in MIS 11 offers additional stratigraphic characterization. Such a second stage would terminate the Chibanian, eliminating its redundancy as the sole stage of the Middle Pleistocene.

The stratigraphic subdivision of the Late Pleistocene in the Northeastern European margin

Dr. Nataliya Zaretskaya [1]***, Dr. Olga Korsakova*** [1]***, Mr. Dmitrii Baranov*** [1]***, Mr. Maksim Ruchkin*** [1]***, Dr. Andrey Vashkov*** [1]

1. *Individual researcher*

We present new results obtained on the eastern White Sea coast in the Kuloi Plateau area (Northeastern Europe). Lithostratigraphic studies of sedimentological successions, OSL dating, foraminifera and malacofaunistic analyses, as well as correlation of available continental and marine palaeoarchives were carried out to reconstruct the chrono- and event stratigraphic sketch reflecting the relationship of glaciations and marine transgressions in the region. A composite sequence of the Upper Pleistocene lithological units linked to the Late Pleistocene sedimentation environments in the southeastern White Sea region was resulted.

In the southeastern White Sea coast, Upper Pleistocene composite sequence includes Mikulino, Chermen, Kalinin, Leningrad and Ostashkov Groups (Horizons in Russian lithostratigraphy). Mikulino Group is composed of silty clay with rounded clasts, shells and benthic foraminifera, overlain with sub-supralittoral sandy sediments, OSL-dated to 138-103 ka. They correlate with Eemian Stage (MIS 5e) and Boreal glacioeustatic transgression which was succeeded by eustatic less active Belomorian one. The sediments of Belomorian transgression ESR- and OSL-dated at 92-77 ka and correlated with Early Weichselian Stage (MIS 5d-a) and Chermen Group are composed of silty sediments with shells and thin-layered sandy deposits. This transgression could be triggered by changes of relative sea level due to the Early Weichselian cool-warm rhythms and evolution of the early Late Pleistocene glaciations centered in the Barents-Kara region. Kalinin Group is composed of solid silty clay without any paleontological remnants overlain by the sub-supralittoral sandy deposits with shells and shell detritus, and gravel beds. They have been ESR- and OSL-dated to 77-52 ka (MIS 4-3); both clay and sandy-gravel beds were accumulated during the Mezen marine transgression, which took place in the Middle Weichselian. Corresponding marine deposits were earlier described only in the eastern part of the region (Jensen et al., 2006). Ostashkov Group is composed of till, glaciofluvial and glaciolacustrine deposits correlated to LGM and initial deglaciation of the Late Weichselian Stage. Our data evidence that marine environments prevailed on eastern White Sea coast throughout the Late Pleistocene, with the exception of MIS 2.

This research is funded by RSF, project 20-17-00081.

Obliquity-driven magnetic susceptibility cycles in a long-term Quaternary fluvial fan in the Pannonian Basin - and their prospects in terrestrial stratigraphic correlations

Fluvial fans are controlled by variations of physical processes in the catchment and of distributive avulsion dynamics, thus can give complex response to climate changes. The Maros Fan is a long-term, Late Miocene–Quaternary fluvial fan accommodated by the continuous subsidence of the Békés Basin. A high-resolution stratigraphic investigation of the Quaternary Maros Fan is performed based on wireline log correlations, completed by measured and logged magnetic susceptibility (SUS) records. The interpretation is supported by analyses of the magnetic granulometry based on frequency dependent SUS measurements, and on magnetic mineralogy based on scanning electron microscope and hysteresis investigations.

The time-series analyses of the Maros Fan SUS records reveal the reliable occurrence of the ~41 ka frequency, together with the customary ~100 ka cycles. Towards the source-distal sections the intensity of the ~41 ka cycles decreases, while that of the ~100 ka cycles remains strong. In spite of the apparent stratigraphic and spectral similarities of fluvial fan and loess SUS records, the magnetic phase of the Maros Fan sections is expressly related to the detrital magnetite that originates from the catchment during early postglacial permafrost degradations; the latter following climatic amelioration into interglacial events.

The recording of the ~41 ka cycles cannot be attributed to the high sedimentation rate, since it is similar in the Körös Basin and Makó Trough; however the cycles cannot be detected in these source-distal fluvial settings. It is a particular stratigraphic feature of source-proximal fluvial settings, i.e. the climate controlled rearrangements of the distributive drainage on the fluvial fans, in concert with the climate-controlled occurrence of the permafrost-related magnetite fraction, derived from the catchment, which is responsible for the excellent amplification and preservation of the ~41 ka SUS variations.

As a local phenomenon, this is significant since it records the obliquity-driven variations of permafrost development in the Carpathians. However, fluvial and alluvial fans are recent widespread depositional landforms within the Eurasian Mountains and were possibly the same during the repeated Quaternary deglaciations. Thus, obliquity-driven SUS variations of source-proximal fluvial settings, attached or adjacent to regions of loess deposition should also be assumed when explaining Quaternary SUS records.

Proposal for the lower boundary of the late Middle Pleistocene stage in Central Europe

Prof. Leszek Marks [1]

1. Polish Geological Institute - National Research Institute

The late Mid-Pleistocene is roughly correlated in the European Quaternary with stratigraphical units from the Holsteinian Interglacial to the Saalian Glaciation that is with the marine isotope stages from 11 to 6. A stratigraphy of this part of the Quaternary in Europe is far from being clarified, regarding the interaction between the environmental processes and climate. Stratigraphical subdivisions of the northern, glaciated part of the continent contain hiatuses or units with incredible setting and it makes interregional correlation difficult. On the other hand, stratigraphical schemes of the extraglacial area, based on sites with fluvial, lake and loess sequences, are much more convincing and complete. Combining the schemes from these two regions still remains a challenging field in the European stratigraphy. Among the main limitations, there is a lack of good dating methods that could be applied to deposits of this part of the Mid-Pleistocene whereas correlation of the terrestrial sequences with high-resolution oxygen isotope deep-sea curves can solve only partly the dating problems. Starting from the bottom of late Mid-Pleistocene, a deglacial part of the Elsterian Glaciation is represented by widespread glaciolacustrine sediments deposited in vast proglacial lakes of the retreating ice sheet. These sediments were identified from the Netherlands and the Lower Elbe region in the west to Poland and eastern Belarus in the east. They pass upwards into the sediments, either of the Holsteinian sea in northern Germany and the Kaliningrad District of Russia or into fluvial deposits in other parts of this region. Location of the glaciolacustrine sediments and their draining towards the Holsteinian sea in the north played a principal role in establishing the modern fluvial pattern in the northern part of continental Europe. Thus, the lower boundary of the second Mid-Pleistocene stage in Central Europe could be set at the Elsterian/Saalian boundary, at the top of the late Elsterian glaciolacustrine series that forms a key horizon in a considerable part of northern continental Europe. It could be also indicated by the Chegan palaeomagnetic excursion. The research was done within the project no. 2017/27/B/ST10/00165, funded by the National Science Centre in Poland.

An update of the Late Pliocene and Early Pleistocene vegetation and climate stratigraphy of NW Europe

Dr. Timme Donders [1], ***Dr. Alexander Houben*** [2], ***Dr. Kim M. Cohen*** [3], ***Dr. Freek Busschers*** [2], ***Mr. Dirk Munsterman*** [2], ***Dr. Mark Dekkers*** [4], ***Dr. Francien Peterse*** [1]

1. Utrecht University, 2. TNO Geological Survey of the Netherlands, Utrecht, Netherlands, 3. Dept. of Physical Geography, Faculty of Geosciences, Utrecht University, 4. Utrecht University, Faculty of Geosciences, Department of Earth Sciences

Studies into the chronostratigraphy and climate record of the Late Pliocene and Early Pleistocene in northwest Europe was spurred by pioneering work of Waldo Zagwijn. This period of Earth history is particularly important because of the inception of ice sheets in the Northern Hemisphere. However, Zagwijn's classic stratigraphic framework based on palynology is difficult to correlate to the Marine Isotopic Stages (MIS) due to a lack of independent dating of the terrestrial deposits. The type area in the Dutch-German border region is characterized by a complex local stratigraphy and represents an incomplete sedimentary record.

We aim to reconstruct a new stratigraphic composite reference section for the Late Pliocene and Lower Pleistocene of the shallow marine to deltaic deposits of the western Netherlands and North Sea. We present a new 380-m deep borehole from Petten and an updated record from Hank to construct a composite record for the late Pliocene and early Pleistocene vegetation and climate changes. The shallow-marine to deltaic facies are logged in detail and yield well-preserved and diversified pollen and organic-walled dinoflagellate cyst associations. New onshore and offshore paleomagnetic data enable a refined correlation of the terrestrial pollen zones to the MIS. Sedimentological analyses from these boreholes reveal the local depositional environment and aid in identification of hiatuses in the record. Organic geochemical biomarker data provide a quantitative paleotemperature record. Combined, they show clear late Pliocene to earliest Pleistocene interglacial-glacial cyclicity, expressing variation in sediment supply, large-scale landscape reorganization and terrestrial temperature variation.

A spliced record is constructed and evaluated using the global glacioeustatic and paleoclimatic record. Comparison of the splice to the upland type area data provides new insights in the timing and duration of the classic regional terrestrial stages – Brunssumian, Reuverian and Tiglian – and highlights remaining gaps in the record. An integrated multiproxy framework for the Late Pliocene and Early Pleistocene of the Netherlands, in a scientific drilling framework, will lead to improved reconstructions of climate, sea-level and sediment provenance.

Eurasian peatlands as valuable deposits of the synchronous Anthropocene Signal

Dr. Barbara Fiałkiewicz-Kozieł [1]***, Prof. Beata Smieja-Król*** [2]***, Prof. Edyta Łokas*** [3]***, Dr. Marcin Siepak*** [4]***, Dr. Paweł Wąsowicz*** [5]***, Prof. Kunshan Bao*** [6]***, Dr. Jüri Plado*** [7]

Peatlands, spanning 3% of the Earth's surface, are crucial archives of stratigraphically defined "Great Acceleration" of human impact and are valuable deposits of the Anthropocene evidence. In our study, we would like to answer the question of what is the synchronous anthropogenic marker in selected Eurasian peatlands, which could allow for distinguishing new epochs. 50 cm-long peat cores were collected from the Sudetes in Poland, near Tomsk city (Russia), China, the NW part of Iceland, the western part of Estonia and Spitsbergen to identify trace elements, isotopic signature of Pb and 239 + 240Pu concentration in the peat (except for China, where Pu was not measured).

The maximum concentration of Pb (from 4 – 360 mg kg-1) is strongly distinct between investigated sites and, together with the first appearance of spheroidal aluminosilicates, differs with the deposition time. Comparison of industrially driven Pb deposition in archives from different countries indicates regional or local differences due to the individual history of industrial development. However, the rise in trace metal inputs for Pb in the 1950s does appear to be synchronous for all studied peat deposits. A pronounced peak in 239+240Pu level, which refers to 1952 and 1963, was established.

While individual peatlands differ with industrial Pb history, a substantial upturn of Pb concentration in the 1950s and a clear nuclear weapon test signal were determined in all the profiles, confirming the value of peatlands as archives of globally expanded human-driven changes of the Earth.

The study was supported by grant no. 2017/27/B/ST10/00428 from National Science Centre

Session 55: Understanding the human-animal-environment interface in Quaternary South Asia

Palaeolithic assemblages, raw materials, palaeoenvironments and landscape adaptations in the Lower Son Valley, Uttar Pradesh, India

This study highlights recent explorations undertaken to investigate the palaeoanthropological potential of the Lower Son Valley. During these investigations, 61 new Palaeolithic and microlithic sites have been identified along with three vertebrate fossil sites in the valley. The valley preserves multi-technological (probably transitional) phases starting from Late Acheulean(?), Middle Palaeolithic, Upper Palaeolithic and microlithic. The Palaeolithic and microlithic artefacts were collected from seven different sites probably spanning from ~140 ka to 48 ka based on currently-known evidence (i.e., Patpara, Bamburi, and Dhaba etc). The valley's assemblages have the potential to shed light on global questions, such as the end of the Acheulean, and local debates, such as the position of the Indian Upper Palaeolithic. The raw material utilised in the valley is primarily porcellanite which is derived from exposures of the Semri Group of the Vindhayan Supergroup and is quite versatile and unique in nature which allowed Late Acheulean to microlithic populations to exploit it for artefact production. Other raw materials like chert, chalcedony, quartz, quartzite, limestone and agate are also utilised. The Quaternary sediments in the valley have also yielded mammalian fossil specimens such as long bone fragments, dental specimens and antler fragments. Late Acheulean to Upper Palaeolithic sites are generally located on the south side of the Son River, while microlithic sites are found throughout the study area. Furthermore, a ~11-meter-deep geological excavation was also conducted to reconstruct the regional Late Pleistocene palaeoenvironmental framework and date the associated sediments. Preliminary analysis indicates that the sampled sediments at that specific location date back to ~57 ka and grain size analysis shows an increase in coarser deposition after ~30 ka, probably indicating an increase in precipitation. Broadly, the valley has potential for more multi-proxy studies to understand hominin adaptations, technological transitions (Late Acheulean to microlithic) and palaeoenvironments in this north-central region of India.

Reconstructing the genetic ancestries of Neolithic and Megalithic Populations of Burzahom, Kashmir using Ancient DNA Analysis

***Mrs. Aparna Dwivedi* [1], *Ms. Richa Rajpal* [1], *Dr. Maanasa Raghavan* [2], *Dr. Niraj Rai* [1]**

***1.** Birbal Sahni Institute of Palaeosciences, 53-University Road, Lucknow-226007, India, **2.** Department of Human Genetics, University of Chicago*

Burzahom is a unique archaeological site in Kashmir, India that demonstrates successive transitions from the Neolithic era, to the Megalithic era, to the early historic period in south Asia. There is evidence of cultural interactions between this site and neighboring regions such as Central Asia and the rest of South Asia. However, more than five decades after the excavation, questions on the genetic identities and genetic interactions of the people who resided in Burzahom remain unanswered. This study is an attempt to characterise the genetic ancestry of individuals from Burzahom through ancient DNA analysis. DNA was extracted from petrous bones and teeth of seven individuals from the site and sequenced on the Illumina HiSeq platform. Five out of the seven samples yielded authentic ancient DNA, as confirmed by DNA damage patterns using the software MapDamage. Of these five samples, two had sufficient data for downstream analyses including genetic sex assignment, which showed that both samples belong to male individuals. One of these samples was dated using Accelerator Mass Spectrometry to 2027-1778 BCE, while results from the other are awaited. These individuals were assigned to mitochondrial haplogroups M65a and U2b. Both these haplogroups are found in south Asia today. Haplogroup U2b has been found previously in an ancient individual from the Harappan site of Rakhigarhi, India. Autosomal data analyses for both samples will help us further understand the genetic ancestry and migratory history of residents as well as their genetic relationships to contemporary and later populations in South and Central Asia. This study represents one of the oldest ancient genomic datasets from South Asia thus far and is a milestone for ancient DNA analysis in the Indian as well as broader south Asian context.

Investigating the palaeoecological implications for hominin occupation in the Pinjore Formation (2.58-0.63 Ma), Siwalik Hills, northern India

Ms. Anubhav PreetKaur [1]

1. *Indian Institute of Science Education and Research Mohali*

Role of environmental stimuli in human evolution, expansion, speciation, adaptation and extinction has been highlighted time and again by scholars. Global climate change from forest-dominated to grassland-dominated environment in the Plio-Pleistocene period has been identified as an important factor for hominin dispersal around the Old World. However, in light of recent researches this priori is being questioned and debated. The fossils of *Homo erectus*, one of the first known early human species to expand outside of Africa, has been discovered from Early Pleistocene deposits of East Europe, West Asia, and Southeast Asia, thereby placing Indian Subcontinent in general- and the Siwalik Hills in particular- as an important dispersal route. However, apart from the chronologically and taxonomically ambigous Hathnora cranium, no unequivocal fossil hominin remains have yet been reported from the region. Based on the presence of fauna often associated with *Homo erectus,* like *Theropithecus oswaldi, Hippopotamus,* and *Megantereon* in the Early-Middle Pleistocene deposits of the Siwalik Hills, scholars have predicted the presence of hominin remains in the region, yet none have been found. Currently, lithic artefacts are the only known signatures of hominin occupation in the region, primarily occurring as surface deposits without secure dates. The Pinjore Formation (2.58-0.63Ma), north of Chandigarh represents the most extensive and the only continuous Early-Middle Pleistocene deposit in the region with a rich record of fossilised vertebrate remains and recently, Ostrich eggshells. In light of absence of stratified lithic deposit and secure dates, palaeoecological and faunal analogies with other Early-Middle Pleistocene hominin bearing sites, can provide an adequate explanation for presence/ absence of hominins in the region.

Late Pleistocene Archaeological Records of Luni-Sukri Basin in the Thar Desert, Rajasthan,India

***Dr. Chintan THakar* [1], *Mr. Ravindra Devra* [2], *Dr. Ritesh Purohit* [3], *Dr. Punaram Patel* [3]**

***1.** Department of Ancient Indian History,Culture & Archaeology, Madhav University,Rajasthan, **2.** Department of Humanities and Social Sciences, IISER-Mohali, Punjab, **3.** Mohanlal Sukhadia University, Udaipur, rajasthan, India*

South Asia is one of the major geographic regions to address research questions related to, Paleolithic archaeology and Quaternary environments, such as climate change, landform evolution, human occupation, adaptation, dispersal, and cultural transitions. Its northwestern parts encompass the continuation of mid-latitude deserts. Thar, or the Great Indian Desert, is spread over 5000 sq km from the Lower Indus valley to the Aravalli Hills range. Its dynamic palaeo-geographical setup acted as a barrier or corridor for the Paleolithic hominins. However, it represents rich lithic artifact assemblages from the Mid to Late Pleistocene geological context. Culturally, these findings from the Lower Paleolithic onwards until the Late Paleolithic provide key information on hominin occupation and regional technological development while highlighting other critical research problems. Our focused area is the Luni-Sukri river basin, a unique geographical area located on the southeastern edge of the Thar Desert.The present study addresses the hominin landscape adaptability of a select ecozone relating to the lithic cultural traditions. Over the past several decades, multidisciplinary research projects have revealed archaeological and geochronological records in the other Parts of the Thar Desert. We conducted primary field observations and pilot studies in the relatively unexplored region and came up with new insight related to earlier hominin presence here. We have adopted a multiproxy approach to evaluate the recent findings,including geo-archaeological explorations. The study investigates the Paleolithic sites' formation processes, spatial distribution patterns, and stratigraphic association.The lab methods include detailed lithic analysis to understand reduction sequences and petrographic analysis of identical rock types for raw material characterization. The lab methods include detailed lithic analysis to understand reduction sequences and petrographic analysis of identical rock types for raw material characterization. The use of selective cryptocrystalline raw material and technological aspects indicates the presence of advanced middle to late Paleolithic, emphasizing regional cultural diversity.The under-processing sample for dating will confirm the chronological frame of these sites.So this attempt will help to understand questions related to the Palaeolithic cultural sequence of the Thar Desert and subordinate areas of the western margin of the Aravalli range based on raw material variability and lithic strategies in different regions.

Out of the Glue: Unravelling fossil localities in the cemented bed of the Bearma, a lesser-known river valley in Madhya Pradesh, Central India

Mr. Yezad Pardiwalla [1], ***Prof. Vijay Sathe*** [2]

1. Indian Institute of Science Education and Research Mohali, 2. Deccan College Postgraduate and Research Institute, Pune, India

Fossilised faunal remains from peninsular India generally occur within a few river valleys notably the Narmada, Son, Belan, Godavari and Krishna and its major tributaries like Manjra, Bhima, Ghod, Wardha, Penganga, and Tungabhadra. Associations with Pleistocene archaeological assemblages are therefore generally rare and challenges exist in correlating the lithic material with fauna. Here we present three localities, two previously unreported, that have yielded several faunal remains within an approximately 5km stretch of the River Bearma. The Bearma is a tributary of the Sonar which in turn discharges into the Ken, a major northeast flowing Central Indian river. The faunal fragments found along this portion of the Bearma consist both cranial (including teeth) and post-cranial elements belonging to mammalian species within families of Bovids, Cervids, Proboscids and Equids. A fossilised mollusc has also been recovered from one of the localities adding to the taxonomic diversity of the overall assemblage. States of preservation vary depending on the duration of exposure, with some specimens being patinated and rolled. All samples were recovered from the active channel of the Bearma, however some seem to have been recently eroded from yellowish-brown silty sediments flanking the river. The presence of cemented gravels at all three localities is noteworthy, with some of the fossils being adhered to these outcrops in the stream bed. While artefacts, mostly small flakes and tools on crypto-crystalline material, have been identified along with the fossils, straightforward associations are challenging owing to the secondary nature of deposits within fluvial contexts. A rich Acheulean locality was also found along the Bearma, an anomaly on this river, just downstream of the fossil localities and associated with the cemented gravels but devoid of faunal remains. Previously researchers have tried to co-relate the Bearma fossiliferous sedimentary sequence with the Central Narmada and Middle Son formations roughly 250kms to the southwest and northeast respectively, bracketing them between the Late Middle and Terminal Pleistocene. Thus this small yet important assemblage from district Damoh holds the possibility to fill in both key geographical and temporal gaps in the paleoanthropological research of Central India.

Human-animal relationships: A Case Study of Dimasa community interpreting their ethno- cultural history & folklores through study of utilitarian involvement of wild and domestic faunas

Ms. Atashi Maitra [1]

1. North-Eastern Hill University

The northeastern region of India has diverse ranges of cultural affinities of indigenous ethnic communities. They share a varied quantum of knowledge related to traditional practices, zootherapeutic knowledge and their own curetted hunting and butchering skills of wild faunas. The ethnic community of Dimasa has a close-knit world with the utilitarian concept of involving wild and domestic faunas in their everyday life. The people of the Dimasa community are adept in using animals in every facet through their beliefs of superstations, hunting for, subsistence, pride and security thus making them prone to the modernization surrounding them.

The research focuses on the utilization and valorization of wild and domestic faunas by the Dimasas in traditional zootherapeutic practices, butchering patterns, and mummification of the hunted animals. Along with it usage of animals are also seen in ontological aspect which is an eminent part of their religion, culture, and traditional ethnozoological approaches adopted by the ethnic community. The study aims to draw analogies from the modern hunting activities of the Dimasa which implies primitive practices inherent from previous hunters and gatherers. The social entanglement of the Dimasa society with the animals in ritualistic measures is crucial for the themes of relational archaeology which interprets the connection between the material and human world stating on the cohabiting nature of human and animals evolving from ancient time period. Increasing advancement in the economic sphere has increased their dependency on wildlife resources creating imbalances in the ecological sphere with a decline in the faunal diversity as well. Ethnographic observation of contemporary societies aided with geographical and ecological aids can help us to understand the cultural continuity with respect to the status of conservation of the present species correlating them with the past faunal resources by tracing local ecological diversity of the region.

Dynamic adaptability of core-and-flake technologies: discussions on the evidence from the Indian Subcontinent

Dr. Vivek Singh [1], *Ms. Anubhav PreetKaur* [1]

1. Indian Institute of Science Education and Research Mohali

It is postulated that early hominins had behavioural and anatomical capacities to adapt to new situations with their Mode 1 technology, and hence, Mode 1 or simple core-and-flake technology is considered to be a powerful adaptive tool for the hominins. Ecological studies undertaken at various Mode 1 occurrence across the Old World attest to the proposition that a simple 'core and flake' toolkit was an excellent adaptive tool to cope with unfamiliar terrain, wide resource variability and uncertainty. Therefore, such 'opportunistic' and 'least effort' technology continues to appear in the archaeological record along with other advanced technologies and is associated with the earliest occupation of a region. In the present research, we represent evidence from two distinct regions in the Indian Subcontinent: Siwalik Hills (northern India) and central Narmada Valley (central India). The results indicate that at both these locations, local fluvial clasts (pebbles and cobbles) were utilised for the production of lithic artefacts. The primary technology at both these locations is observed to be core-flake, possibly related to the form of locally available raw material. Currently, there are no chronological data from these locations; however, according to previous academic research, there is a hint of Mode 2/Mode 3 in the evidence from Siwalik Hills. Through this research, we try to understand the significance of core-and-flake technology in terms of hominin behaviour and their adaptiveness to various landscapes in the Indian Subcontinent.

Understanding the Palaeolithic occupations of the eastern Thar margins, Chittorgarh, Southeastern Rajasthan, India

Ms. Swati Verma [1], *Dr. Vrushab Mahesh* [1]

1. Department of Archaeology and Ancient History, The Maharaja Sayajirao University of Baroda, Vadodara, Gujarat, India

Chittorgarh, located on the eastern margins of the Thar desert, reveals the highest concentration of Late Acheulean sites in the Indian subcontinent. This region represents evidence of enduring climate change and is presently characterised by diverse climatic zones, ranging from arid to semi-arid environments. The undulating topography of this semi-arid region is characterised by the Aravalli, Vindhyan, and Bhilwara supergroups, which are drained by the Berach River and its tributaries. Adequate water, food, and raw materials resources made this area habitable during the Pleistocene. Previous research in this critical geographical region has been limited to restricted surveys along the river banks and lacks a multidisciplinary approach. Despite studies on Palaeolithic occurrences being investigated here since the 1950s, the potential to answer significant questions concerning hominin adaptations in South Asia is less explored, with most studies being restricted to typo-technological studies and descriptive notes of their distributions. Rich and continuous Palaeolithic records ranging from the Acheulean to the Late Palaeolithic have been reported here at various sites. Recent explorations in this area have resulted in the discovery of several Lower and Late Palaeolithic sites in various geological contexts primarily in colluvial deposits of Semri, Kaimur and Bhilwara formations. These sites are spatially distributed in three distinct clusters -Eastern, Western and Southern. In terms of technology, raw material preference, artefact density, and preservation status, each group is distinct from the others. The western cluster represents Late Palaeolithic technologies, while the eastern and southern clusters represent Late Acheulean and prepared core technologies. This paper highlights the lithic variability observed within these clusters of sites as well as the core reduction strategies employed on various sites using the *Chaîne- opératoire* method. Further, it presents the results of the morphometric analysis of the bifacial tools along with a comparison of the results with contemporary assemblages from neighbouring valleys (Luni, Banas, and Narmada) to better understand subsistence strategies, raw material preferences, and adaptation.

Agricultural strategies and adaptation during Indus era in north-western India: implication to human-environment interactions

Dr. Shalini Sharma [1], ***Dr. Anil K. Pokharia*** [2], ***Dr. Rajesh Agnihotri*** [2], ***Dr. Sanjay Kumar Manjul*** [3]

1. Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Beijing, China, 2. Birbal Sahni Institute of Palaeosciences, 53-University Road, Lucknow-226007, India, 3. Archaeological Survey of India

The onset of agriculture is one of the most important event for an ever-intensifying human-environment interactions in prehistory. Though agriculture is a human effort but, it has intimate link(s) with contemporary environment. Fossilised organic plant remains recovered from archaeological excavations reveal wealthy information about past agricultural practices and contemporary environment. Macro-botanical analysis along with stable carbon isotope from an Indus era (~2900−1800 BCE) in north-western India revealed how agricultural strategies at these settlements shifted in response to the changing climatic (monsoonal) conditions. The results revealed the transition in the agro-ecological conditions i.e. wetter to drier (arid) during the period of weakening of monsoon (aridity). All together the data revealed that the agriculture during early phase (~2900−2400 BCE) mainly rely on winter season crops facilitated with the winter precipitation, however, the later phase (~2200−1800 BCE) revealed enhanced proportion of drought resistant crops owing to the declining India Summer Monsoon (ISM). $d^{13}C$ of plant remains and soil organic matter also revealed the similar transition in agricultural strategies owing to the aridity ~2200 BCE and later. Abundance of millets at these archaeological settlements might have played an important role in the subsistence economy as an adaptations to the deteriorated climatic conditions due to prolonged weakening of ISM. Overall subsistence pattern indicates continuity and change in temporal domain likely owing to changing environmental conditions over time ~2900−1800 BCE. The cultural adaptation enables consideration of issues related to adaptation and resilience in the face of changing economic and environmental conditions. We surmise that the adverse climatic conditions (declining monsoon) might have compelled settlers to opt for alternative crops resilient to prolonged drought conditions. Present study provides a valuable template for modern societies in exploring plausible strategies to tackle future climate change.

Playas, Fossil dunes and Palaeolithic sites of Thar desert: Geoarchaeological survey in Central Rajasthan, India

Mr. Ravindra Devra [1]

1. *Department of Humanities and Social Sciences, IISER-Mohali, Punjab*

The eastern margins of the Thar Desert have revealed a significant amount of archaeological data related to the Middle and Late Pleistocene phases. During this period, the region experienced sub-humid to arid climatic fluctuations. We have a sporadic presence of artefacts through the desert landscape, whereas high-concentration cultural complexes are only limited to certain pockets. The Late Acheulean and Middle Palaeolithic hominins were probably adapted to grassland-type open-air environments and micro ecozones around lake shores. Some of the previous studies suggest lake shore occupation by Acheulean (e.g., Singhi Talav) and Middle Palaeolithic cultures. Stable dunes are another landform type which was sometimes preferred for habitation (e.g., 16R). This study refers to the previously known context of Palaeolithic sites and seeks to identify new sites within the region. A detailed field survey was conducted to understand the nature of the site distribution pattern. As a result of exploration in associated areas, we found up to a dozen new sites. Our findings confirm that Palaeolithic cultures flourished around the natural pond-like setups and some other sites found in the stable dune deposits. The lithic findings were associated with ecofacts, i.e. fossil bones and bird egg shells, including ostrich and mollusc shells. Further, the study confirms the geological formations of calcrete deposits and fine sediment associated with the archaeological sites. The cultural material exhibits the presence of Acheulean bifaces in a semi-primary context and Middle Palaeolithic artefacts, including tanged points and Levallois core. The most peculiar phenomenon is the miniaturization of lithic objects like diminutive handaxes and micro Levallois cores. This work confirms the presence of palaeolithic sites from previously unknown areas and their firm associations with the paleo landscape and ecofacts. Identifying stratified context, which is rare in the desert landscape, opens up the possibilities of relative dating of the archaeological remains.

Session 56: The Palaeolithic of the Americas: population dynamics, behavioral variability and techno-cultural diversity around the Last Glacial Maximum (MIS 2-3)

The Indigenous Paleolithic of the Western Hemisphere (the Americas)

Dr. paulette steeves [1]

1. Algoma University

The archaeological evidence for human settlement of the Western Hemisphere (the Americas) during the Indigenous Paleolithic (prior to 12-15 k years ago) has been growing for the last century, despite the overly aggressive political debates that created the field as an archaeological research area discussed as an area of academic suicide. Reviewing paleoenvironmental and mammalian migration evidence, it is clear that during numerous interglacial events (2.1M to 24 K years ago), land-based migration routes between the Eastern Hemisphere (Asia) and the Western Hemisphere (the Americas) were available. The evidence from open water crossings on a global scale also supports the possibility of human migrations between land masses prior to 24 K ago. Reviewing published academic literature, I built a database of over five hundred pre-Clovis (pre-11,200 YBP) archaeological sites in North and South America dating from 11.2 k – 200 k years ago. The archaeological record of the Western Hemisphere (the Americas) during the Pleistocene is strikingly diverse, providing evidence of distinct cultural groups' adaptations to varying environments across time and space. I argue that the archaeological, paleoenvironmental and paleontological evidence supports a human presence in the Western Hemisphere prior to 24 K (MIS 2-3) years ago. Recent research has challenged decades-old assumptions regarding early human evolution and migrations in Africa, Europe and Asia. The archaeological, paleontological, and paleoenvironmental evidence that informs our understanding of human settlement in the Western Hemisphere (the Americas) during the Pleistocene is well documented. It is long past time to update the Pleistocene (Indigenous Paleolithic) history of humans in the Western Hemisphere.

New data on Santa Elina rock shelter, Brazil: highlighting its importance for the peopling of the Americas and paleoecology of megafauna around the LGM

Ms. Thaís Pansani [1]***, Dr. Briana Pobiner*** [2]***, Dr. Águeda Vialou*** [3]***, Dr. Denis Vialou*** [3]***, Dr. Pierre Gueriau*** [4]***, Dr. Mathieu Thoury*** [4]***, Dr. Paul Tafforeau*** [5]***, Dr. Emmanuel Baranger*** [6]***, Dr. Cormac McSparron*** [7]***, Dr. Alexander Cherkinsky*** [8]***, Ms. Lidiane Asevedo*** [9]***, Dr. Mariela Castro*** [10]***, Dr. Mário Dantas*** [11]***, Dr. Loïc Bertrand*** [6]***, Dr. Mírian Pacheco*** [1]

1. *Federal University of São Carlos,* **2.** *Smithsonian Institution,* **3.** *Muséum National d'Histoire Naturelle,* **4.** *Université Paris-Saclay, CNRS,* **5.** *European Synchrotron Radiation Facility,* **6.** *ENS Paris-Saclay,* **7.** *Queen's University Belfast,* **8.** *University of Georgia,* **9.** *Federal University of Sergipe,* **10.** *Federal University of Catalão,* **11.** *Federal University of Bahia*

Santa Elina, in Central Brazil, is an important archaeological site in South America. It records successive human occupations from the Late Pleistocene to the Early Holocene with an abundance of megafaunal remains, lithic industry, fire structures, and exceptional rock paintings on the limestone walls of the shelter. Archaeologists have been documenting the site and its material culture for the past 40 years. Here we share new data that reinforce Santa Elina as critical to the debate on peopling of the Americas and their interaction with the now-extinct Pleistocene megafauna. A recent Bayesian age model confirms the well-defined stratigraphy and ancient chronology of Santa Elina; the oldest archaeological unit (III4) is reliably dated to before the Last Glacial Maximum (LGM), around at least 27–25 ka. This unit preserves abundant spatially and temporally associated megafaunal remains (giant sloth bones, *Glossotherium phoenesis*) and cultural remains (stone tools and other lithic industry elements). Isotopic analyses ($\delta^{13}C$, $\delta^{18}O$) performed on teeth fragments of *G. phoenesis* from Santa Elina (unit II2 and III4) reveal their generalist diet and contribute to the paleoenvironmental reconstitution of the site. New AMS radiocarbon dating on bioapatite material of *G. phoenesis* reinforces that unit III4 is dated to around the LGM. Deep investigations using established methods (stereomicroscope, scanning electron microscope) and advanced imaging techniques (microtomography, Photoluminescence, X-Ray Fluorescence) reveal that three ground sloth dermal bones (i.e., osteoderms) of a ground sloth from unit III4 were human-modified into personal ornaments. They present stone tool marks, rim perforation, polish aspect, attachment system, and use-wear traces. Novel analyses indicate that these bones were modified while fresh. This demonstrates the contemporaneity of humans with the Pleistocene megafauna around the LGM. Unfortunately, despite the growing evidence for the peopling of the Americas starting much earlier than ~16 ka, several pivotal Latin American sites (including Santa Elina in Central Brazil and the Serra da Capivara complex in northeast Brazil) are still regarded as contentious, despite their solid evidence. We assert that Santa Elina is a key piece in the puzzle debate of the Paleolithic of the Americas.

Santa Elina rockshelter, or living in the center of South America at the beginning of MIS2

***Dr. Águeda Vialou* [1], *Dr. Denis Vialou* [1], *Dr. Antoine Lourdeau* [1]**

1. *Muséum National d'Histoire Naturelle*

The Santa Elina site lies in western Brazil, in the state of Mato Grosso. It is a rockshelter located in a vast crevice of the limestone massif of the Serra das Araras. In a stratigraphy more than 3 m thick were recorded the testimonies of successive passages of human groups over a temporal depth of nearly 30 ka. The oldest archaeological level is located in the lower part of stratigraphic ensemble III, composed of sandy sediments and limestone blocks (layer III3/III4). It is dated by several direct methods between 25 and 27 kyrs BP. Human presence is attested by a few hundred lithic pieces associated with the remains of an individual of the genus *Glossotherium* (giant sloth), including several dozen bone fragments and thousands of osteoderms. Three osteoderms show the marks of anthropogenic modifications, particularly by perforation.

The oral contribution that we propose here will be an opportunity to present the first results of a new ongoing study of the lithic industry of this level, all in the general context of this archaeological level. The collection consists of flaked remains of different raw materials, among which dominates very clearly a detrital limestone of a different nature from that of the walls of the shelter. The main objective of this production is to transform fairly standardized light plates, mostly between 5 and 12 cm long, into tools by means of short retouching sequences. The edges and volumes are varied, highlighting different functional intentions. Some recurrences appear, however, such as a particularly marked taste for notches and beaks. These flaked plates represent more than half of the collection. The rest is composed of flakes, most of which seem to come from the retouching of the plates. Some of these flakes have also been turned into tools.

To date, Santa Elina is the only archaeological site with such ancient dating in central South America. Its existence encourages us to no longer look only at the coasts (Pacific or Atlantic coast) to fully grasp the settlement processes of the continent.

Stratigraphy, radiocarbon ages, archaeology, paleontology, and astrophysics: 15 years of research about First Nations in the Pilauco Site, Northwestern Chilean Patagonia.

Prof. Mario Pino [1], ***Dr. Antonio Pérez-Balarezo*** [2], ***Dr. Francisco Tello*** [1], ***Dr. Ana M. Abarzua*** [1]

1. Universidad Austral de Chile, 2. Université Paris Nanterre

Prior to the discovery of the Monte Verde (MV) sites, the only validated archaeological evidence in the Americas was related to "Paleo-Indians", < 12,800 years. Research at MV overturned finally the Clovis-First paradigm, at the Taitao bar, not far from MV, on January 12, 1997. Since then, we have learned much about the lifeways of our true First Nations.

The Pilauco site, located in Osorno, ~100 km north of MV, presents another body of evidences of Pleistocene human presence in northwestern Chilean Patagonia. Here, our objective is twofold: to summary more than a decade of research, and to offer some reflections on Pilaucos' place in Patagonian and continental peopling.

The site was formed on an alluvial plain carved on ancient volcanoclastic strata, where a seasonal wetland was formed. The organic sediments deposited here preserve fossils and archaeological evidence. The latter is made up of cores, flakes, debitage and highly effective stone tools associating affordance, debitage, and shaping. Also, there are two human footprints, perforate seed and stones, and ocher.

This record represents continuous human evidence for 4,800 years between 17,600 and the beginning of the Younger Dryas (YD) chronozone (12,800 cal BP), when the fall of an impactor produces significant environmental, faunal, and floristic changes.

The fossil fauna is composed of extinct (mainly gomphotheres, cf. Notiomastodon platensis) and extants micromammals, accompanied by extinct and extant coleopteran species. The first group disappears from Pilauco site around 12,800 cal BP, the second group lives in northwestern Patagonia until today.

As with the fossil seeds, fruits, and cuticles, pollen assemblages below 12,800 cal BP are diverse and abundant, indicating moderately dense, mostly non-tree, herb-dominated vegetation. This assemblage is formed by mostly hygrophilous and cold-resistant plants, typical of the northern Patagonian Forest.

The consequences YD impact hypothesis are well documented by a significant maximum abundance of platinum, gold, iron spherules and high-temperature iron-chromium particles. A geologically instantaneous sharp increase in charcoal abundance records an unparalleled episode of biomass burning.

15 years of research and a growing corpus of multi-proxy information make Pilauco a key site for the understanding human paleoecology in the Americas.

Away from the coasts and high up in the mountains: cultural and chronological significance of Mexico's Chiquihuite Cave and Sima de las Golondrinas highlander sites within the LGM population dynamics

Prof. Ciprian F. Ardelean [1]

1. *Universidad Autonoma de Zacatecas*

Cueva del Chiquihuite (Chiquihuite Cave) and Sima de las Golondrinas (Chasm of Swallows) — two ancient caves located 100 km apart in northern Zacatecas, Mexico — are among the oldest archaeological sites in North America, with well-dated stratified deposits of Late Pleistocene age. Chiquihuite Cave yielded a long occupational history that draws back to the onset of the Last Glacial Maximum (LGM), and is characterized by an interesting lithic industry manufactured on locally-available, recrystallized, fine-grained limestones. Sima de las Golondrinas has so far revealed a younger occupation, spanning from the LGM to the Younger Dryas, in the form of cut-marked bones and possibly the oldest symbolic expressions in North America. Interestingly, the two sites cannot be compared on the same bases, as they don't share the same types of evidence. The artefact assemblages at these localities are relevant for the discussion of cultural diversity in Americas during the LGM. The modified bones inform both of the diet and paleoenvironment, but also of the ideological and behavioral aspects that seem to connect far beyond the American continent. The lithic artefacts have recently started to reveal similarities with other old sites in both North and South America, such as the well-known prehistoric localities in Brazil. Both caves are located on the Northern Mexican Highlands, on different mountain ranges, and at considerable distances from both western and eastern coasts (350-600 km in straight lines), on the central north-south axis of the continent. Chiquihuite and Golondrinas are equally intriguing in the debate of the earliest human colonization of the continent. Were these groups adapted to highland and mountain landscapes instead of riverine and coastal areas? Do they reflect vast migratory cycles that only returned to northern Zacatecas every generation? Are they testimonies of inland peopling routes? Can they be finally related to specific North/South American and (why not?) Eurasian cultural traditions? Were the inhabitants of the two caves the same or at least related groups? And finally: are we looking at the ancestors of later Pleistocene populations or rather at extinct groups that died out?

From MIS 2 to MIS 1 in Colombia : technical and technological data in postglacial times

Mrs. Marina González [1], ***Prof. Carlos López Castaño*** [2]

1. ArScAn-Équipe AnTET, UMR 7041, CNRS, Université Paris Nanterre (UPN), France., 2. Universidad Tecnológica de Pereira, Colombia

The Pleistocene-Holocene boundary (PH) in the Americas is widely characterized from archeology as a transition. However, this notion has been built from geological, geographic and paleoenvironmental/paleoclimatic information. What does it mean first at the archaeological level, and then at the cultural level? Is this "transition" a historical entity in itself? Some of these questions have been raised in North America, but rarely in South America. On a continental scale, this period, roughly between 13,000 BP and 9,000 BP, is synonymous of technical diversity, but where does this supposed diversity begin and end? Overcoming this terminological repulsion by comparing all available data (beyond classical fossils directors such as projectile points) from different disciplinary axes, would lead to a more detailed understanding of Late Pleistocene technical phenomena. This research proposes a critical review of the notion of transition in northwestern South America based on available data and new analyzes of Colombian lithic industries. Human presence in Colombia is recorded in a discontinuous way from 18 k.y. BP. Within the PH boundary, a great technocultural variability is observed, composed of different unifacial and bifacial lithic traditions, different patterns of subsistence and plant settlements/manipulation and domestication. Likewise, from MIS 2 to MIS 1, the Colombian territory is testimony of the succession of several episodes such as the Fuquene stadial (21-14 k.y. BP), the Susaca interstadial (14-13 k.y. BP), the Ciega stadial (13-12.5 k.y. BP), the interstadial Guantiva (12.5-11 k.y. BP), and the stadial Abra (11-10 k.y. BP). These changes added to volcanic eruptions of the last 20,000 years undoubtedly shaped the archaeological record that reaches us to the present. How, then, do human occupation fall within this paleoenvironmental/paleoclimatic context? Can we speak of a causal relationship between technical, cultural and climatic facts? Colombia, formed by a diversity of biomes that transcend current political limits, is key to the understanding of the first South American settlements. From the technical recurrences and differences, preliminarily identified, between recently studied lithic assemblages, a set of technological hypotheses are proposed about the PH boundary's meaning within the context of South American early prehistory dynamics.

Inhabiting the Puna de Atacama before and after MIS 2: the evidences from Cacao 1.A. (Antofagasta de la Sierra, Argentina)

***Prof. Carlos Aschero* [1]*, Dr. Lucinda Backwell* [2]*, Dr. Federico Bobillo* [1]*, Prof. Eric Boëda* [3]*, Prof. Christelle Lahaye* [4]*, Dr. Christine Hatté* [5]*, Dr. Jorge Martínez* [6]*, Dr. Antonio Pérez-Balarezo* [7]*, Dr. Marcelo Zárate* [8]**

***1.** Instituto Superior de Estudios Sociales (ISES, CONICET), **2.** Evolutionary Studies Institute, University of the Witwatersrand, Johannesburg, South Africa, **3.** ArScAn-Équipe AnTET, UMR 7041, CNRS, Université Paris Nanterre (UPN), France., **4.** Université Bordeaux Montaigne, UMR 6034, Archéosciences-Bordeaux, **5.** CEA-Universite Paris Saclay & Silesian University of Technology, **6.** Instituto Superior de Estudios Sociales-CONICET, Instituto de Arqueología y Museo-UNT, **7.** Université Paris Nanterre, **8.** INCITAP-UNLPam-CONICET*

Cacao 1A (25° 54´46” S, 67°20´27.1” W) is an archaeological site located at 3780 masl near the confluence of Cacao and Curuto ravines, north of Antofagasta de la Sierra (W Catamarca, Argentina). It is a rockshelter developed in early Pleistocene ignimbrites with rock art representations spanning the entire Holocene. The site includes a protected area of 20 m^2 as well as an outer esplanade of loose sand bounded by a silghty sloping semicircular stone wall with a 15 m radius including abundant lithic artifacts on the surface and the subsurface.
The rockshelter sedimentary filling (~1m thick) is composed of a lower layer, archaeologically sterile, made up of loose fine sand deposits, overlain by a compact unit (layer 5) mainly composed of plant remains from megafauna feces disaggregation (Megatherium, Mylodon and Hippidion). Layer 5 which includes the oldest archaeological evidence (mainly lithic artifacts), is dated between 38 000 BP and 40 000 BP. Since 2020, within the framework of a Franco-Argentine archaeological mission, French and Argentine specialists have collaborated closely on two aspects: specialized studies of the material collected during previous excavations and a vast geochronological program whose objective is to confirm the existence of Pleistocene archaeological levels in the region as well as understanding their geomorphological context.
In this work we detail the latest advances corresponding to this collaboration. This site has a complex history, which is why we debate about the position of archaeological materials in the interior of a Pleistocene layer; which will give ages of more than 50 000 BP. Based on the study of typological characteristics of lithic artifacts, the geomorphological context of the deposit and dates obtained in a hearth located at the rockshelter's mouth (15 000 BP and 10 000 BP) we deepen aspects of the associations documented so far, considering the processes of human-megafauna occupation-unoccupation recorded and the role of Cacao 1.A as a refuge in the Puna of Argentina.
These results are compared with other sites at a regional and continental scale, in order to assess the relevance of Cacao 1.A in the Puna de Atacama and in the South American Pleistocene.

Revisiting ancient and new lithic collections from classic South American sites: critical assessment and contributions to early peopling of South America

Dr. Antonio Pérez-Balarezo [1]

1. *Université Paris Nanterre*

The initial peopling of the Americas is a matter of ongoing debate. In an attempt to renew this discussion, we focus on the South American record, generally relegated from continental debates. In this communication we present a revision of the lithic industries of eight archaeological sites (Toca dos Coqueiros, Piauí, Brazil; Cacao 1.A., Antofagasta de la Sierra, Argentina; Arroyo del Vizcaíno, Canelones, Uruguay; Monte Verde, Puerto Montt, Chile; Pilauco and Los Notros, Osorno, Chile; Pikimachay, Ayacucho, Peru; Huaca Prieta; La Libertad, Peru), among the most ancient and significant sites in South America. Based on the 3D technicofunctional analysis of these assemblages dated between 40,000 BP and 13,000 BP, we address the assumed techno-cultural homogeneity assigned to the South American Pleistocene and propose a new conceptualization. Our review mostly deals with: a) chrono-stratigraphy, b) methodological approach for the study of the assemblages, c) the geofact/artifact protocol approach, and the d) technological, evolutionary, and historical interpretation of technical phenomena. Taking into account these and other archaeological and paleoenvironmental data available in South America thus renders currently technical traditions not heuristic at different scales and allows us to propose elements for a more logical paleolithic research in technical and cultural terms. The geochronological, paleoenvironmental and paleogenetic contextualization of our results at the hemispheric level indicates an internal variability in each South American region, allowing us to rethink the role of South America in the first dispersals of *Homo* across the American continent. We finally propose a micro-regional approach to American prehistory, from our perspective the only solution way to address in the medium and long term the Americas population dynamics during the Late Pleistocene.

Bluefish Caves Revisited: A Geoarchaeological and Paleoenvironmental Assessment of a Potential Pre-Clovis Site in the Yukon territory of Northwestern Canada

Dr. Rolfe Mandel [1], ***Dr. Lauren Norman*** [1], ***Dr. Lauriane Bourgeon*** [1], ***Mx. Caroline Kisielinski*** [1], ***Dr. Justin Holcomb*** [1], ***Dr. Dennis O'Rourke*** [1]

1. *University of Kansas*

Bluefish Caves, a cluster of four small rockshelters in the Yukon Territory of NW Canada, was excavated during the 1970s and 80s under the direction of Jacques Cinq-Mars. Caves I, II, and III yielded faunal remains dating to ca. 30-10 ka contained in loess, plus artifacts. Also, AMS ^{14}C ages determined on cut-marked bones identified during a recent taphonomic analysis of the faunal assemblage suggests that humans occupied the site as early as 24 ka. Hence, Bluefish Caves may be the oldest recorded archaeological site in North America, and the findings support the "Beringian standstill hypothesis," which proposes that a genetically isolated human population persisted in Beringia during the Last Glacial Maximum (LGM) and subsequently dispersed from there to North and South America. However, the stratigraphic context of the artifacts and evidence of anthropogenic bone modification have been challenged.

Here, we report results of our recent investigations at caves III and IV. In 2019, limited archaeological testing was conducted at Cave III to gain a better understanding of site formation processes. Also, soil/sediment samples were collected for ancient DNA (*sed*aDNA) analysis to determine the feasibility of isolating and sequencing ancient genetic material of transitional late Pleistocene/early Holocene flora and fauna from subarctic loess. Following initial processing of *sed*aDNA samples, sequences suggest recovery of sufficient nucleic acids for identification of multiple taxa in those samples, thereby providing a more robust picture of LGM and post-LGM paleoenvironments in the region. Also, we relocated Cave IV, which was not excavated by Cinq-Mars. The entrance and interior of Cave IV are almost filled with sediments. In July 2022, we tested the area in front of the cave, exposing a ~1-m-thick deposit of loess containing remains of horse, caribou, and other late-Pleistocene fauna. Many of the bones are being ^{14}C dated, and sediment removed from the test units will be fine-screened for micro-debitage. Also, soil/sediment samples were collected for ancient DNA (*sed*aDNA) analysis, and ongoing micromorphological and sedimentological analyses of the loess will help us gain a better understanding of site formation processes and the spatial integrity of any cultural deposits found in Cave IV.

Distribution of Upper Paleolithic human fossil footprints from White Sands National Park

Mr. David Bustos [1]***, Prof. Matthew Bennett*** [2]***, Dr. Thomas Urban*** [3]***, Dr. Jeff Pigati*** [4]***, Dr. Kathleen Springer*** [4]***, Dr. Daniel Odess*** [1]***, Dr. Vincent Santucci*** [1]

In the American southwest conformation for the presents of people from the upper Paleolithic has been obtained from fossil prints of both human and late Pleistocene megafauna. The wet dry episodic events of dry lake beds and salt flats that were once pluvial lakes and ice age wetlands have provided ideal conditions for creating an incredible record of human trace fossils.

This paper will focus on the distribution, abundance, and composition for a variety of fossil prints that have been preserved for over 23,000 years at White Sands National Park. The site at White Sands is important, in that it provides an analog for other pluvial systems that may be preserving fossil prints from the American Southwest or other arid regions of the world. At the upper lake margins there are several meters of stratigraphic sediment containing fossil prints and organics. On the basin floor there are only one to two thin layers with fossil prints. As moisture within the soil is being reduced by persistent droughts and rising temperatures, the prints are rapidly being exposed and lost to soil erosion. For this reason, there is an urgency to document the fossil prints at White Sands and examine other dry lake beds from around the world before the record is lost.

Arroyo del Vizcaíno site (Uruguay): a contribution to the debate of early peopling of the Americas

Dr. Richard Fariña [1], ***Dr. P. Sebastián Tambusso*** [1], ***Mr. Luciano Varela*** [2]

1. Servicio Académico Universitario y Centro de Estudios Paleontológicos (SAUCE-P), Universidad de la República, Santa Isabel s/n, 91500 Sauce, Departamento de Canelones, Uruguay., 2. Servicio Académico Universitario y Centro de Estudios Paleontológicos (SAUCE-P), Universidad de la República, Santa Isabel s/n, 91500 Sauce, Departamento de Canelones, Uruguay

In recent years, several sites vied for adding evidence of human colonisation of the Americas prior to the Last Glacial Maximum. Among them, the 30-kybp Arroyo del Vizcaíno site (AdV) in Uruguay yielded over 2,000 remains mostly of megafaunal species. Among other evidence, some of the fossil remains present cut-marks, which further challenges the already dwindling Clovis-first paradigm. Criticisms on the validity of the site as a potential contribution to such debate have centred on the age of the site, the nature of the bone surface modifications (BSMs), the formation of the site and the scarcity of lithic remains. In this presentation, we discuss our research on those controversial aspects. New dates are being obtained in order to improve the chronology of the site to test our hypothesis of a single depositional event. The BSMs have been the subject of careful research since the AdV was first thoroughly described in 2013 through 3d reconstruction. The results were compelling about their human agency, which was further assessed in later studies about possible equifinality as well as approaches that incorporate the use of Artificial Intelligence. The other lines of evidence are admittedly weaker, as a whole model of site formation has not yet been published. Moreover, the lithic remains are still the subject of on-going research. However, these studies are in the process of being completed and the preliminary results suggest that they are consistent with the hypotheses proposed.

Session 58: The new challenges for luminescence dating

A detailed luminescence chronology of the Late Quaternary Caspian Sea history (Lower Volga region, Russia)

Dr. Jan Pieter Buylaert [1], ***Dr. Redzhep Kurbanov*** [2], ***Ms. Pia Højsager*** [3], ***Dr. Thomas Stevens*** [4], ***Prof. Andrew Murray*** [5]

1. *Technical University of Denmark,* ***2.*** *Institute geography RAS, Moscow; Institute of water problems, hydropower and ecology, TNAS, Dushanbe,* ***3.*** *Aarhus University,* ***4.*** *Department of Earth Sciences, Uppsala University,* ***5.*** *Department of Geoscience, Aarhus University*

In the last decade, loess-palaeosol sequences and alluvial sediments of the Volga River in the northern Caspian Lowland have been intensively studied. In the Lower Volga valley, a 400 km long outcrop reveals the Middle and Late Quaternary sedimentation history of the whole Caspian Basin. The stratigraphy and paleontology of many reference sections (e.g. Srednyaya Akhtuba, Raygorod, Seroglazovka, Kosika) in this area have been described but most sections still lack a reliable independent chronology. Here we present the first high-resolution luminescence chronology for the 18 m thick Srednyaya Akhtuba section. The section represents the most complete Late Quaternary sedimentation history of the Lower Volga region and is made up, from bottom to top: estuary sediments of the Late Khazarian transgression, a thick (~8 m) loess-palaeosol sequence (Atelian stage), three Volga alluvium units (~4 m), the Late Khvalynian Chocolate Clay unit (~3.5 m) and the modern soil (~1 m thick). Ninety luminescence samples were collected over the entire sequence and both multi-grain quartz OSL and feldspar post-IR IRSL dating was applied. We present extensive luminescence laboratory tests to support the reliability of both the quartz and feldspar ages. A time-dependent water content model was developed taking into account the complex drainage history of the site. The dating results reveal that the last ~130,000 years of sedimentation is recorded at Srednyaya Akhtuba. The resulting age-depth model shows that there were no significant breaks in sedimentation and that there is a clear dust accumulation peak at ~65 ka (MIS4).

A revision of the British Chronostratigraphy within the Last Glacial-Interglacial Cycle based on new evidence from Arclid, Cheshire UK.

Prof. Mark Bateman [1], ***Ms. Charlie Rex*** [2], ***Dr. Eva Panagiotakopulu*** [3], ***Dr. Stephen J. Livingstone*** [1], ***Prof. Paul Buckland*** [4], ***Dr. Mark Hardiman*** [5]

1. Sheffield University, 2. University of Glasgow, 3. University of Edinburgh, 4. non affiliated, 5. University of Portsmouth

There is large uncertainty regarding the timing and nature of British interstadials during the Last Glacial-interglacial cycle (LGIC) due to the fragmentary preserved evidence. Of the 24 Greenland interstadials (GI) in the LGIC only five are formally recognised in Britain. Sites which do detail British interstadials during this period are spatially disparate and often lack a robust chronology relying on biostratigraphy or radiocarbon ages based on old techniques. Where sites do span the LGIC and have good chronological control sedimentation appears to have been episodic rather than continuous.

This paper aims to improve understanding of the LGIC in Britain by focussing on a site at Arclid, Cheshire where thick aeolian and fluvial sediments (>25m) containing organic deposits have the potential to cover the entire LGIC. The site sediments were characterised, luminescence dated and organic deposits underwent fossil insect analysis. The stenothermic species from the latter were compared to other sites in England to better understand similarities between interstadial conditions . Results show sand was deposited at the site initially by aeolian but later by fluvial and then fluvioglacial transportation between 77-33 ka ago. Coleoptera and Diptera from an organic lens provided a reconstruction for a heather rich heathland environments grazed by large herbivores, with summer temperatures between 13-18° C, and winter temperatures between -14 and 1°C.

Stenothermic beetle analysis from Arclid indicate similarities with results from other British mid LGIC sites, some of which are at or beyond the limit of radiocarbon dating and may instead be of a similar age to Arclid. A revised British chronostratigraphy places the Chelford, Brimpton and Cassington Interstadials within GI 22/23, GI 21 and GI 20/19. Basal organic sediments found at Arclid are assigned to GI 16 with the Arclid mid and upper peats tentatively assigned to GI 14 and GI 13. This removes the gap in interstadials between the Brimpton Interstadial and the Upton Warren Interstadial complex within the British chronostratigraphy.

Feldspar luminescence dating sheds new light on Pleistocene depositional sequence in an uplifted coast, eastern Japan

Dr. Toru Tamura [1], ***Dr. Tomonori Naya*** [1], ***Dr. Rei Nakashima*** [1], ***Dr. Koji Seike*** [1], ***Dr. Hiroko Okazaki*** [2], ***Dr. Hiroomi Nakazato*** [3], ***Dr. Jun'ichi Okuno*** [4]

Feldspar post-infrared infrared stimulated luminescence (pIRIR) dating is a popular method for determining sedimentary ages that range from a few thousand to several hundreds of thousands years. Its potential is however yet to be fully explored for a range of sedimentary archives. We hereby document a thorough application of feldspar pIRIR dating to depositional sequences in an uplifted coast, eastern Japan and how it refines our understanding of stratigraphic evolution in responses to glacial sea-level changes and tectonics. The depositional sequences are present beneath the Last Interglacial raised marine terrace in the Kanto Plain, eastern Japan, corresponding to transgressive-regressive cycles since the Middle Pleistocene. In the northeastern Kanto Plain, the marine terrace has been believed to represent a coastal barrier during the MIS 5e sea-level highstand, whereas the chronology of the underlying stratigraphy has not been constrained. Our new investigation of two drill cores and four outcrops identified c. 30-m-thick depositional sequences of sandy and/or gravelly marine and terrigenous sediments. More than 50 sediment samples were collected from the sequences for pIRIR dating. According to pretests, the pIRIR at 225□ after a prior infrared stimulated luminescence at 50□ was found to be optimal and thus used for the age determination. The lower part of the sequences consists of MIS 7 shallow-marine deposits, MIS 6d shallow-marine deposits, MIS 6a–c fluvial deposits, thin MIS 5e shallow-marine deposits, and MIS 5d fluvial to brackish deposits, being overlain by coastal barrier deposits with the maximum elevation +30 m. Ages of the coastal barrier deposits are around 110 ka, most likely correlated with MIS 5c rather than 5e as considered previously. This revision revises up the regional uplift rate as c. 0.5 m/ky. The marine deposits in relation to the interstadial sea level in MIS 6d has rarely been identified elsewhere and its elevation is consistent with the revised uplift rate. Our pIRIR ages define 100-ky glacial cycles of depositional sequences since the Middle Pleistocene and provide unpreceded insights on stratigraphic evolution in relations to higher-frequency sea-level oscillations younger than 200 ka.

Application of Rock Surface Luminescence dating on different Pleistocene rocky shore marine features.

Dr. Giulia Cossu [1], *Dr. Daniele Sechi* [1], *Prof. Vincenzo Pascucci* [1], *Prof. Stefano Andreucci* [2]

1. University of Sassari, 2. Università degli Studi di Cagliari

Rocky coasts are erosional environment resulting from the landward retreat of bedrock cliffs at the shoreline. These represent over 80% of continental and island coasts and consist of mixed consolidated or unconsolidated gravel sediment, abrasional shore platform and marine terraces. Despite their wide distribution and importance for the sea-level history and tectonic reconstruction, the chronology of their development remains poorly constrained and understood because of insufficient investigation and the limited available direct dating method. In the last ten years, a new luminescence method called Rock Surface Dating (RSD) has been developed to date of last exposure to the daylight of cobbles and rock surfaces. In this work, we test the performance and relaibility of RSD method on different Marine Isotopic Stage MIS5e (117-126 ka) Sardinian marine terraces. Specifically we aim to compare the results from abrasional shore platform, cobbly beach outer frame and the imbricated zone/beach berm deposits. Preliminary results on the abrasional shore platform show good luminescence performance and promising profile shapes. Despite cobbles from the outer beachframe suffer of an important partial bleaching, leading to a high rate of cobble rejection, a reliable burial age of 131 ± 8 ka has been gained. The cobble of storm berm shows the best luminescence performance with a fully reliable final age of 126 ± 9 ka. Results suggest the dependency of RSD performance on the shore environment related to a complete or incomplete exposition of the cobble or erosive surface to sunlight. However, obtained ages are in good agreement with previous ages for the sites, which confirms the good performance of RSD for dating Pleistocene rock surfaces and different rocky shores forms.

Construction of a Bayesian chronology for ocean core LC31 using radiocarbon and luminescence ages to aid the identification of tephra and sapropel marker horizons

***Ms. Shuang Zhang** [1], **Prof. Simon Armitage** [1], **Prof. Simon Blockley** [1], **Dr. Chris Satow** [2], **Dr. Christina Manning** [3]*

***1.** Centre for Quaternary Research, Department of Geography, Royal Holloway University of London, Egham, UK, **2.** Department of Geography, Royal Holloway University of London, London, United Kingdom, **3.** Department of Earth Sciences, Royal Holloway University of London*

The Eastern Mediterranean is an important region for palaeoenvironmental research because it is sensitive to a complex pattern of climatic and environmental change, influenced by orbital forcing and multiple feedback mechanisms, during the late Quaternary. It is also a key region for understanding the dispersal of humans out of Africa. Consequently, it is essential to develop robust chronologies for palaeoclimatic, environmental and archaeological records in the region, to allow synchronisation and comparison between records and hypothesis testing. Event horizons, such as tephra and sapropels in marine sequences, play an important role in correlating and synchronising the regional palaeoclimatic, palaeoceanographic and archaeological archives.

We have constructed a Bayesian age model for a marine core LC31 based on radiocarbon and luminescence dating. This is the most thoroughly dated and integrated late Quaternary marine sequence in the Eastern Mediterranean basin, which provides opportunities to investigate the event horizons (tephra and sapropel) for the region. Our results suggest that correlation of event horizons can sometimes be ambiguous, leading to erroneous interpretations of palaeoenvironmental data. Tephra representing unknown eruptions could be mis-identified as previous known eruptions if identification is based solely on their geochemistry. Sapropels, unique stratigraphic markers deposited and developed across the Eastern Mediterranean, suffer from ‘’ghost” (invisible) and/or missing sapropels, due to complex depositional and sedimentary processes. Consequently we propose that direct dating of deep-sea sediments via luminescence techniques is an important tool in validating chronologies produced using “known age” horizons such as sapropels and (crypto)tephra.

Post Violet-Infrared Stimulated Luminescence (pVIRSL) Dating: A new luminescence protocol for dating K-Feldspars

***Ms. Monika Devi* [1], *Dr. Naveen Chauhan* [1], *Prof. Ashok Singhvi* [2]**

***1.** AMOPH Division, Physical Research Laboratory, Ahmedabad, Gujarat, India; cIndian Institute of Technology, Gandhinagar, Gujarat, India, **2.** AMOPH Division, Physical Research Laboratory Ahmedabad -380009, India*

Luminescence dating using quartz provides reliable ages up to ~50-100 ka beyond which, the luminescence signal saturates. Feldspar provides an attractive possibility due to its higher luminescence sensitivity and high saturation dose of ~1000Gy. These offer prospects of a continuous dating range from a few years to up to a Ma. However, a key stumbling block in the use of feldspar luminescence has been athermal loss of luminescence due to quantum mechanical tunnelling (also termed as anomalous fading). This leads to underestimation of ages and thence limits its applicability. Current correction procedures for such fading can deal with sediments up to 40-50ka. For older sediments procedures are still under development.

We explored an alternative route to isolate non-fading component from feldspar luminescence and reported that post violet IR stimulated luminescence (pVIRSL) has a near zero fading (g=0.0 ± 0.1% per decade; Devi et al. 2022). This presentation extends this work and will discuss results on experiments to characterize of centres participating in pVIRSL and properties of pVIRSL in respect of dating applications. An optimized protocol for equivalent dose estimation has also been developed.

pVIRSL shows a rapid bleachability (<10% in 60 min), high saturation dose (~1000 Gy), low recuperation (<5%), high signal reproducibility (<5-10%), good dose recovery (within 10%) beside near zero athermal fading. Use of optimized regeneration protocol on feldspars from samples from diverse environments gave pVIRSL doses in the range, 11 - ~ 500 Gy (ages in range 4- 270ka). These accorded with geological/archaeological reasoning and independent age controls.

Insights from playing with portable luminescence readers in two continents and four laboratories.

Dr. Abi Stone [1]***, Mr. Shashank Nitundil*** [1]***, Prof. Mark Bateman*** [2]***, Prof. David Sanderson*** [3]***, Dr. Alan Cresswell*** [3]***, Dr. Aayush Srivastava*** [4]

Portable luminescence (port-OSL) readers are powerful tools within trapped charge dating. High-resolution profiles with depth can contextualise sediment stratigraphy, with insights into (i) relative age, including the position of depositional unconformities, and also: (ii) variations in sediment composition (owing to provenance and/or weathering), (iii) variations in the completeness of luminescence signal bleaching (signal resetting before transport). In simple sedimentary systems, with broadly homogenous sediment provenance, it is possible to produce generalised chronologies that approximate sediment burial age.

Our approach is to compare port-OSL signals with established ages using standard luminescence dating protocols and construct calibration curves (e.g. work published in 2019 by Stone et al.). Dryland dunefields have well-bleached aeolian sediments, making them an ideal testing ground. In southern Africa, we have found these port-OSL calibrations are region specific, with consistent and coherent grouping of samples from the Namib Sand Sea (n=26) and for three different parts of the Kalahari (n=66, n=38 and n=18). The calibration approach also shows promise in the Thar Desert, India (n=44) (research by Nitundil as part of MSc dissertation). A change to the approaches taken in the port-OSL sequences and data processing during our investigations means the available portion of the southern African samples are being re-measured to facilitate an intercontinental comparison. We aim to present this intercontinental comparison.

Our experiences with port-OSL measurements on lake shoreline sediments in the middle Kalahari show weaker correlations than for dunefields and suggest sediment characteristics other than burial age drive differences in port-OSL signals in this setting. To test this, we have made measurements on a range of the subsamples from southern Africa to establish the response of bulk sands to a known 4 Gy dose in order to examine whether samples between regions have different inherent luminescence sensitivity. This may also give insights into sand provenance and sediment pathways.

Climate variability in a subtropical desertic area: Lanzarote over the past 125 ka

Mrs. Myriam Francesca Stelletti [1], ***Prof. Stefano Andreucci*** [2], ***Dr. Giulia Cossu*** [1], ***Dr. Mario De Luca*** [1], ***Mrs. Giulia Laura Faedda*** [1], ***Mrs. Federica Perazzotti*** [1], ***Mrs. Nicole Ruberti*** [1], ***Dr. Antonio Santonastaso*** [1], ***Dr. Daniele Sechi*** [1], ***Prof. Vincenzo Pascucci*** [1]

1. *University of Sassari,* ***2.*** *Università degli Studi di Cagliari*

Lanzarote is the easternmost volcanic island of the Canary Archipelago located in the Atlantic Ocean with a subtropical hot desert climate (BWh). The very low precipitation (100–250 mm/a) is related to its geography (130 km off the coast of NW Africa) and to the low elevation of the island (~670 m a.s.l.).
Despite the dry conditions, a suite of colluvial fans eventually evolving in debris-flow and water-flow dominated alluvial fan systems developed along the flank of the Famara cliff and on the eastern side of El Jable Plain (NE part of the island). The alluvial fan deposits are partially covered, lateral or cut by wind-blown sandy sediments becoming dominant toward the centre of the plain. Fans merged in a low-land depositional area identified as a possible ephemeral lake.
Lanzarote past climatic evolution was detected through the sedimentological study of alluvial fan and associated dunes. The depositional events were dated using both luminescence and radiocarbon ^{14}C dating techniques.
Results show that depositional area of Famara evolved from the beginning of the Last Interglacial (Marine Isotopic Stage-MIS 5) to the Holocene (MIS 1). A first generation of dune system was present at the base of the escarpment during MIS 5e, whereas through MIS 5d and MIS 5a alluvial fan developed partially covering and/or cutting the aeolian system. A well-developed second generation of dunes (mostly climbing) and a minor development of alluvial fans dominate the first part of MIS 4. Alternate of alluvial and aeolian deposits mostly characterized the MIS 3. During MIS 2 alluvial fans become the dominant depositional system.
The geochronological reconstruction of El Jable depositional system allows the following climatic consideration: wetter conditions are observed during the climate deterioration phase occurred during MIS 5d and MIS 2 glacial periods. During MIS 4 dry climate dominate. High frequency climatic oscillations are the main depositional motive of MIS 3 during which alternate of wet and dry conditions occurred. These allowed the formations in the central part of the plain of ephemeral lakes and, therefore, of mud deposits that where substituted by and sand-sheets during the dry, possibly colder phases.

Session 59: Past, present and future ice-ocean-atmosphere interactions between the Southern Ocean and the Antarctic Ice Sheet

Last Interglacial subsurface warming on the Antarctic shelf triggered by reduced deep-ocean convection

Dr. Laurie Menviel [1]***, Mr. Nicholas Yeung*** [2]***, Prof. Katrin Meissner*** [2]***, Dr. Dipayan Choudhury*** [3]***, Dr. Tilo Ziehn*** [4]***, Dr. Matthew Chamberlain*** [4]

1. *Climate Change Research Centre/ESSRC, The University of New South Wales,* ***2.*** *University of New South Wales,* ***3.*** *NSW department of planning and environment,* ***4.*** *CSIRO*

The global mean sea-level was likely 3 to 6 m higher at the Last Interglacial (LIG) compared to pre-industrial (PI), with an Antarctic contribution estimated at 3 to 5 m sea-level equivalent. Antarctic ice-sheet modelling studies suggest that such an ice-mass loss from Antarctica requires a subsurface warming on the Antarctic shelf of ~3°C compared to PI. Here we show that such a subsurface warming is simulated in an equilibrium experiment of the LIG performed with a comprehensive Earth System Model. Reduced deep-ocean convection in the Weddell and Ross Seas, arising from reduced sea-ice formation, are the primary drivers of this subsurface warming, reaching 2.4°C at 430 m depth. The associated changes in meridional density gradients and surface winds lead to a weakened Antarctic Circumpolar Current but strengthened Antarctic Slope Current, which further impact subsurface temperatures around both East and West Antarctica, with a maximum warming of 3°C at 125 m depth on the East Antarctic shelf. Higher SST and reduced sea-ice formation in the Southern Ocean thus increase ocean stratification and lead to a subsurface warming on the Antarctic shelf, with the potential to trigger ice-mass loss from the Antarctic ice-sheet.

Warm water inflow induced Holocene deglaciation in Lützow-Holm Bay, East Antarctica

Dr. Yusuke suganuma **[1]**, ***Dr. Moto Kawamata*** **[2]**, ***Dr. Kazuya Kusahara*** **[3]**, ***Dr. Nathaniel Lifton*** **[4]**, ***Dr. Takeshige Ishiwa*** **[1]**, ***Dr. Kota Katsuki*** **[5]**, ***Dr. Masakazu Fujii*** **[1]**, ***Dr. Motohiro Hirabayashi*** **[1]**, ***Dr. Jun'ichi Okuno*** **[1]**

1. *National Institute of Polar Research,* ***2.*** *Civil Engineering Research Institute for Cold Region,* ***3.*** *Japan Agency for Marine-Earth Science and Technology,* ***4.*** *Department of Earth, Atmospheric, and Planetary Sciences, Purdue University,* ***5.*** *Estuary Research Center, Shimane University*

Recent observations and model simulations show that the inflow of warm Circumpolar Deep Water (CDW) causes rapid melting and thinning of the ice shelves of the West Antarctic Ice Sheet, contributing to the ongoing increase in discharge of grounded ice and to sea-level rise. This process is also thought to contribute to the deglaciation of the West Antarctic Ice Sheet after the Last Glacial Maximum (LGM) ca. 21 ka. However, unlike West Antarctica, the role of the CDW in a potential large-scale ice-mass loss in the East Antarctic is largely unknown. In this study, we present a new, well-constrained ice retreat history for the period since the LGM for Lützow-Holm Bay, East Antarctica, based on a detailed geomorphological survey and ^{10}Be and ^{14}C surface exposure dating of erratics and bedrock. The results show that ice sheet melting in Lutzow-Holm Bay began in the southeastern part of the bay along the Shirase submarine valley from ca. 9 to 5 ka and eventually spread to the northeast ca. 8–4 ka. Regional high-resolution oceanographic modeling shows that the current warmer ocean temperature in the southeastern part of the bay results from the inflow of warm CDW via the submarine valley. Thus, these oceanographic and bathymetric characteristics likely caused the asymmetric early to mid-Holocene deglaciation in Lützow-Holm Bay, East Antarctica.

High precision reconstruction of δ13C-CO2 and major greenhouse gas concentrations (CO2, CH4 and N2O) over marine isotope stage 9 – first application of a novel method

***Mr. Florian Krauss* [1], Dr. Lars Mächler [1], Dr. Daniel Baggenstos [2], Dr. Bernhard Bereiter [3], Dr. Béla Tuzson [3], Dr. Lukas Emmenegger [3], Dr. Jochen Schmitt [1], Prof. Hubertus Fischer [1]**

***1.** Climate and Environmental Physics and Oeschger Centre for Climate Change Research, University of Bern, Switzerland, **2.** Australian Antarctic Division, Kingston TAS, Australia, **3.** Empa, Laboratory for Air Pollution / Environmental Technology*

Ice cores are natural archives preserving valuable information of past atmospheric greenhouse gas concentrations (CO_2, CH_4, N_2O) and the changing climate system. To understand how the complex changes of biogeochemical cycles will respond in the future, we need to decipher the role of changing greenhouse gas concentration and the rearrangement within the major carbon reservoirs (ocean, atmosphere, terrestrial biosphere, and sediment) in the past.
Due to the differences in the carbon isotopic composition of the major carbon reservoirs, respectively the carbon fractionation occurring during exchange processes between the reservoirs, $\delta^{13}C$-CO_2 measurements are a useful tool to help disentangle the causes of CO_2 variations driven by biogeochemical processes.
Here we present the first application of a novel extraction and analysis system for simultaneous quantification of CO_2, CH_4, N_2O as well as $\delta^{13}C$-CO_2 in ice core samples. This is achieved by a semi-continuous laser-induced sublimation extraction technique, developed to liberate 100% of the trapped gases from the ice, followed by the analysis of the extracted air samples by a custom-made Quantum Cascade Laser Absorption Spectrometer (QCLAS), especially designed for small air samples of 1–2 mL STP. While achieving a very high vertical continuous sampling resolution of 1.5 cm of ice, equivalent to a 10–15 g ice core sample, our measurements demonstrate an excellent reproducibility (1σ) for CO_2, CH_4, N_2O as well as $\delta^{13}C$-CO_2 (1 ppm, 4 ppb, 2 ppb and 0.03 ‰). Both methods and instruments were developed to achieve such high vertical resolution and highest precision, imperative, to decipher high-resolution carbon cycle changes in the extremely thinned sections of the future Beyond EPICA – Oldest Ice Core (BE-OIC).
Using the novel method described above, this work will present the first high-resolution $\delta^{13}C$-CO_2 record covering the glacial – interglacial termination (T_{IV}) of marine isotope stage (MIS) 9c–10a (332–345 kyr BP). In addition to that, the major greenhouse gases CO_2, CH_4 and N_2O were measured simultaneously. The results of this study will shed light on the mechanisms behind the CO_2
overshoot during early MIS 9.

Glacial to interglacial ocean circulation, sea ice and ice sheet dynamics over the last 140 k y in the Adélie Land region, East Antarctica

Dr. Lea Pesjak [1], *Prof. Andrew McMinn* [1], *Prof. Zanna Chase* [1], *Dr. Helen Bostock* [2]

1. Institute for Marine and Antarctic Studies, University of Tasmania, 2. The University of Queensland

Present-day observations suggest global warming is influencing Southern Ocean circulation and the duration of sea ice, which is contributing to enhanced Antarctic ice sheet melt. Therefore, understanding the functioning of these three parameters, atmosphere-ocean-sea ice, during past climatic transitions, deglacials and glaciations, may provide clues to the extent of future ice sheet stability. In this study we analyse two sediment cores collected from off Adélie Land, one from the continental shelf and the other from the slope. The shelf core presented a sequence of sedimentary facies, and based on the Antarctic ice sheet retreat model (glacial till-glacimarine sediment- open ocean sediment), it revealed the ice sheet retreat from the outer continental shelf in the region occurred at ~14 k yr, giving way to a prolonged ice shelf calving stage which occurred from ~12 k yr- ~8 k yr. Based on the grain size, ice shelf calving had given way to strong bottom currents which were potentially propelled by the initiation of Adélie Dense Shelf Water. The slope core showed a pattern of glacial to interglacial facies changes, including deglacial and glaciation. Based on diatom assemblages, and the presence of *Thalassiosira lentiginosa*, we suggest the last glacial (MIS 4-2) offshore Adélie Land is characterised by an open ocean environment with respect to sea ice. However, based on the increasing presence of *Fragilariopsis obliquecostata*, we conclude the last glacial had a gradual build-up of sea ice. This sea ice duration reached its maximum at the end of MIS 2, before it rapidly vanished. Following this event, based on the presence of *Thalassiothrix antarctica* within the deglaciation facies, we conclude Circumpolar Deep Water (CDW) influx increased over the slope. Finally, based on the ice rafted debris- rich interglacial facies above, we conclude the CDW increase occurred prior to regional ice sheet retreat. Together these datasets suggest major sea ice changes occurred during the last glacial and its end, followed by oceanographic changes, and then by ice sheet retreat, suggesting a progression of events may influence the demise of the East Antarctic ice sheet.

Tracking Antarctic Intermediate Water dynamics in the South Atlantic through the ‘cold water route’ during the last deglaciation

Dr. Rebecca Parker [1], ***Dr. Zoë Thomas*** [2], ***Dr. William T Hiscock*** [1], ***Dr. Christopher Marjo*** [1], ***Dr. Chris SM Turney*** [3], ***Dr. Victoria Peck*** [4]

1. Chronos 14Carbon-Cycle Facility, Mark Wainwright Analytical Centre, University of New South Wales, NSW, 2052, Australia, 2. Division of the Deputy Vice-Chancellor, Research, University of Technology Sydney, Sydney, NSW 2017, Australia, 4. British Antarctic Survey, High Cross, Madingley Road, Cambridge, CB3 0ET, UK

The circulation of intermediate waters play an important role in global heat transport and carbon storage in the ocean. Changes in their distribution are closely tied to glacial–interglacial climate change. The oceanic gateways of the Drake Passage and Agulhas Current are critical locations for the inflow of intermediate-depth water masses to the Atlantic, which contribute to the shallow return flow that balances the export of deep water from the North Atlantic. Despite being one of the most important water masses of the world’s ocean, the role of the Antarctic Intermediate Water (AAIW) in the Atlantic Meridional Ocean Circulation during various climate states is yet to be fully understood, particularly the cold, low salinity limb that flows through the Drake Passage, known as the ‘cold water route’.

We present a reconstruction of AAIW dynamics through the cold water route over the last ~25 kyr from IODP Site U1534C, located on the Falkland Plateau, which is today bathed in AAIW. We take advantage of ultra-small sample (6-8 specimen) benthic-planktic foraminiferal-derived radiocarbon ages, coupled with benthic foraminiferal $\delta^{18}O$ and Itrax elemental data to track sub-millennially-resolved changes in water mass distribution and ventilation, as well as bottom water current strength at the core site. Using the MICADAS accelerator mass spectrometer at UNSW, our small-sized graphitised foraminiferal samples (200-300 µgC) show precision and reproducibility comparable to full sized (1000 µgC) targets. Results suggest substantial changes in AAIW dynamics and water mass ventilation during the last deglaciation, impacting Atlantic Meridional Ocean Circulation and underscoring the critical role that the Drake Passage plays in global climate during glacial-interglacial transitions.

Antarctic Peninsula surface mass balance since 1600 CD

Dr. Liz Thomas [1]***, Dr. Dieter Tetzner*** [2]

1. *British Antarctic Survey (BAS), Natural Environmental Research Council (NERC), High Cross, Madingley Road, Cambridge CB3 0ET, UK.,* ***2.*** *British Antarctic Survey*

Antarctic snowfall, or surface mass balance (SMB), has a direct and measurable impact on global mean sea levels (GMSL). The snow accumulation recorded in Antarctic ice cores has been used to demonstrate a significant increase in SMB during the 20th century, enough to mitigate sea level rise. However, the role of SMB on future ice sheet dynamics is not well understood. Some studies predict that increased SMB may compensate for future Antarctic ice loss, while others predict greater discharge resulting from increased SMB.

One of the most dramatic 20th century SMB increases is observed in the Antarctic Peninsula. In this study, we present an updated record of SMB from the Antarctic Peninsula, including four new ice cores from Palmer Land, the English Coast and Ellsworth Land. This new compilation extends our understanding of SMB variability back to 1621 CE. We also include the first snow accumulation record from Peter 1st island, providing a unique opportunity to explore SMB variability across the Bellingshausen Sea over recent decades. We demonstrate that the role of oceanic and atmospheric dynamics is different at different elevations, highlighting the importance of investigating SMB variability at local and regional scales. The increased SMB over low elevation sites, and a steepening of the SMB gradient, has implications for dynamic ice discharge and future sea level predictions.

Session 60:
Geoarcheology and paleoenvironmental evolution of the coastal areas

The first extensive groundwater-harvesting agriculture in aeolian sand? Early Islamic Plot-and-Berm agroecosystem by ancient Caesarea, Israel

Prof. JOEL ROSKIN [1], ***Mr. Lotem Robins*** [2], ***Mr. Adam. Ostrowski*** [3], ***Prof. Revital Bookman*** [3], ***Dr. Naomi Porat*** [4], ***Dr. Itamar Taxel*** [5]

1. Bar-Ilan, 2. Department of Geography and Environment, Bar Ilan University, Ramat-Gan, Israel, 3. University of Haifa, 4. Geological Survey of Israel, 5. Israel Antiquities Authority

The "Plot-and-Berm" (P&B) agroecosystem at the southern outskirts of the ancient town/metropolis of Caesarea, Israel, appears to be one of the earliest administrative efforts to cultivate inert aeolian sand. P&B agroecosystems are agricultural utilizations of a shallow water table within loose, aeolian sand, comprised of a checkerboard array of ~hectare-size agricultural plots sunken between 3-10 m high berms. They were developed in agricultural hinterlands with arid to Mediterranean climates. Beyond the southeastern Mediterranean coast, P&B agroecosystems sporadically appear in Iran, Turkmenistan, and Iberia. They are abundant in two regions of Saharan Algeria. Historically dating to the Middle-Ages to early Modern times, some are partly active. Based on a survey of modern-day analogues – Massieras in northwest Portugal, it seems that the plots usually enable 3 agricultural cycles per-annum yielding a wide range of vegetables. The wind-shielded plots probably enhanced micro-climatic conditions for agriculture.

We summarize surveys and three geoarcheological excavations of the Caesarea agroecosystem. Imported fine-grained refuse from adjacent dumps of Caesarea enrichen the plot sand forming 30-50 cm thick, grey anthrosols. The anthrosol level enables year-round access by wells to ~1 m deep groundwater for manual irrigation. OSL ages of the anthrosol suggest a ~250-yr span of agriculture practice during Early-Islamic to early Crusader times (9th-early-12th centuries a.d.).

An anthrosediment made of sand mixed with refuse and hand-size artifacts dating to Early-Islamic times coat and protect the berm from erosion. The berm interior includes sand mixed with small amounts of refuse. POSL profiling indicates a single-stage construction effort. A limekiln and small structures on the berms possess similar OSL chronologies of the berm interiors and anthrosols. Sparse artifacts were found in these features.

Medieval Arabic agricultural manuals and other literary sources lack documentation of this agrotechnology. Based on geospatial-based calculations of the volumes of sand needed to be transported, ~1 million working days was required to construct the agroecosystem. A regional governance probably supported the development of these agroecosystems, possibly in response to religio-administrative calls for *mawāt* (Arabic: "dead") land reclamation. This effort was probably combined with an economic incentive and/or growth of a rewarding crop.

A multi-proxy paleoenvironmental study of a Neolithic coastal landscape. The case of the Cagalell littoral marsh (Barcelona, NE Iberia)

__Ms. Ana Pena Pérez__ [1], ***Dr. Francesc Mesquita-Joanes*** [2], ***Dr. Ramón Julià Brugués*** [1], ***Ms. Gloria Alejandra Rodríguez Abaunza*** [3], ***Dr. Xavier Armengol*** [2], ***Mr. Carlos Javier García López*** [4], ***Dr. Santiago Riera Mora*** [1]

The study of the past relationships between human communities and their environment is a complex task itself. In coastal areas, this becomes a challenging endeavour since coastal environments are especially dynamic, highly sensible to climate-related environmental changes and they record continuous land use since ancient times. The PaleoBarcino project explores these transformations in Barcelona city from a transdisciplinary, multi-proxy and microscale approach in order to overcome the fragmentary recovery of paleoenvironmental and archaeological data associated to the characteristics of the urban context under study. Furthermore, the project studies human adaptations to coastal changes during the Holocene.

Paleogeomorphological studies performed in the Barcelona Plain have contributed to identify the existence of ancient marshes along this narrow coastal plain during Neolithic times. Understanding the relationship between Neolithic communities and these littoral water bodies is crucial, due to their potential to shape settlement distribution, land use and the availability of freshwater resources. At the same time, marsh records register the impacts and transformations triggered by these farming communities at a microlocal scale. The Cagalell is one of these littoral paleowetlands, with lacunar deposits dating back to 8260-7070 cal. yr BC. It was located between two littoral promontories, the *Mons Taber* (NE, 16 m.a.s.l.) and Montjuïc (SW, 185 m.a.s.l.), and had a maximum expansion of 20-25 ha. Prehistoric occupations are recorded in the area surrounding the wetland from the Early Neolithic to the Iron Age.

We present the paleoenvironmental and paleogeomorphological study of the Cagalell marsh deposits integrated with the surrounding archaeological data. Multi-proxy paleoenvironmental analyses include pollen, non-pollen palynomorphs, ostracods and other micro- and macroremains. The geomorphological and sedimentary studies integrate paleoenvironmental sequences, geotechnical records, and archaeological deposits. A chronological framework for the evolution of the lacunar environment is defined by 16 radiocarbon dates.

This study offers a comprehensive description of decadal to centennial coastal and landscape transformations occurred at the arrival of the first farming communities in the Barcelona Plain. For the first time, both non-pollen palynomorphs and ostracod analyses complement the fossil pollen record from the Barcelona Plain, furthering the understanding of the relationship between coastal wetland environments and these societies.

Modelling the chronologies for the origins and spread of agriculture in the East Asian coastal regions

Dr. Tengwen Long [1], **Dr. Christian Leipe** [2], **Prof. Mayke Wagner** [3], **Prof. Pavel Tarasov** [4]

1. University of Nottingham Ningbo China, 2. Freie Universität Berlin; Max Planck Institute for Geoanthropology, 3. German Archaeological Institute, 4. Freie Universität Berlin

After the rise of eustatic sea level slowed down in the early Holocene, coastal wetlands developed across the globe and attracted early communities to settle down, benefitted from the prograding shorelines, increasing land area, readily available water resources, and transitional habitats across a wide range of salinity. East Asia is a prime example of such coastal settling, where two global centres for agriculture – the Bohai Coast and Hangzhou Bay regions – appeared along the coasts in, respectively, northern and southern China since the early Holocene. The current study examines the chronologies for three key domesticates, rice (*Oryza sativa*), millets (*Panicum miliaceum* and *Setaria italica*), and wheat (*Triticum* spp.), in East Asia, to map the establishment of agricultural societies, applying Bayesian and spatio-temporal modelling techniques on radiometric dates. The earliest evidence (ca. 7430 BCE) of rice exploitation appeared in the southwestern margin of the Hangzhou Bay region. Rice appeared in the middle Yangzi River and the Huai River in, respectively, ca. 6680 and 6650 BCE, possibly indicating an expansion of farming communities. Two other major episodes of spread of the crop took place in the period between 4th and 3rd millennia BCE and the period between 1st millennium BCE and 1st millennium CE. The latter episode, including a northeastern spread of rice to the Korean Peninsula and Japanese Archipelago following the coastlines, is linked to major cultural transitions, e.g. the transition from the Jomon to the Yayoi. Millet-based farming seems to have started from the East Asian fertile crescent in the Bohai Coast around 5800 BCE. The spread of this crop should have shaped the formation of the Sino-Tibetan language family. Wheat, a Southwest Asian domesticate, is likely to have been spread to China through the Eurasian steppe and first appeared in the Bohai Coast around 2600 BCE, as an exotic good for the elites. The proposed chronologies refine our understanding of the developments of agriculture and provide essential data for examining the interactions between prehistoric societies and Holocene environmental changes in East Asia.

Pollen and Non-Pollen Palynomorphs to detect the anthropogenic impact in the Mar Piccolo (Taranto, Southern Italy) during the Late Holocene

Mr. Gabriele Niccolini [1]***, Mr. NICCOLO' DEGL'INNOCENTI*** [1]***, Prof. Adele Bertini*** [2]***, Prof. Giuseppe Mastronuzzi*** [1]***, Prof. Massimo Moretti*** [1]

1. *Department of Earth and GeoEnvironmental Sciences, University of Bari,* ***2.*** *Dipartimento di Scienze della Terra, Università degli Studi di Firenze, Via La Pira 4, I-50121 Firenze, Italy*

The Mar Piccolo area has been settled since the Bronze Age whereas the history of its more close center Taranto dates back to the 8th century BC when it was founded as a Greek colony (Taras). Pollen and Non-Pollen Palynomorphs from a core (S05B, 29.49 m thick)) retrieved in the Mar Piccolo basin allow to investigate the paleoenvironmental changes, including those associated to the progressive increase of the anthropogenic impact, during the Late Holocene. Palynological data provide indication on the crops (e.g., Cereals), land use (e.g., *Olea*), farming (e.g., *Sporormiella*-type) and human/domestic animals presence (e.g., *Trichuris* sp.). They are expressed as: i. percentage of single taxa (e.g., *Olea*, *Vitis*, Cereals), ii. anthropic indexes (e.g., Regional Pastoral Index; Anthropogenic Nitrophilous Herbs), iii. concentrations of NPPs having a clear anthropic origin (e.g., *Trichuris*, *Ascaris*). Starting from 10.74 m a concomitant presence of Cereals, *Trichuris* and *Ascaris* attests the presence of settlements in the Taranto area at least since the Bronze Age. The continuous increase in *Olea* and anthropic NPPs highlights an increase in human activities around the basin possibly during the Greek and Roman periods. A subsequently notably increase of agriculture and herding activities during the Middle Ages is attested by both the great abundance of *Olea* and high concentration in *Trichuris* and *Ascaris*. During this time, historical events as famine, wars, or barbaric invasions are in fact well expressed by the percentage changes of some key taxa (e.g., *Olea*). The regional anthropic impact during the historical time, is also evaluated and compared to that recorded in the closest areas (e.g., Lago Alimini Piccolo). Worthy of note is the finding of pollen grains such as *Daphne caucasica* and *Citrus medica* which provide relevant information on chronology and trade.

Living in a coastal swamp: from a dynamic natural to a dynamic cultural landscape

Dr. Harm Jan Pierik [1]

1. *Cultural Heritage Agency of the Netherlands*

In the wide Dutch coastal plain, peat swamps dominated throughout a major portion of prehistory. Still the role of peat growth and subsequent peat degradation in the geological evolution and habitation history is not well known. For this, new palaeolandscape reconstructions were made, integrating new and existing (geo)archaeological and geological data for two estuaries in the western Netherlands.

The occurrence of peat types around the Old Rhine river and the Oer-IJ estuary could be related to environmental factors, such as tidal and fluvial influence. It is shown that peat formation, in return, strongly determined tidal basin infilling, tidal creek position and fluvial style, all strongly steering habitation and land use possibilities. Habitation and initial reclamation often started on higher tidal creeks or on drained edges of the swamps in the Iron Age, and was often followed by local land subsidence and even drowning. Archaeological, historical and geomorphological evidence shows that peat compaction and excavation over the past 2000 years led to subsidence on an increasingly larger scale. This marks the transformation to new human-dominated landscape. It famously put much of the Netherlands below sea level, which led to increased vulnerability of storm-surge ingressions and current sea-level rise.

These insights help to understand reclamation and subsidence history, and furthermore to learn from past adaption strategies to environmental changes that lay ahead.

The ancient Ancylus Lake and Littorina Sea shores of the Vidzeme coast of Latvia, Eastern Baltic: A foundation for coastal Stone Age settlement suitability modelling

Mr. Edijs Breijers [1]
1. *Faculty of Geography and Earth Sciences, University of Latvia*

Due to the glacio-isostatic adjustment (GIA) of the Baltic basin region and the global water level fluctuations, the ancient shores of the Baltic Sea development stages can be discovered both underwater and elevated well above the present day sea-level. Throughout Holocene, the dynamics of the ancient coasts have affected the inhabitants of the territory of Latvia; recurrent occupation of several suitable stone age settlements has been noted in previous research, but no notable discoveries have been made on the ancient shores of the Vidzeme coast of Latvia, Eastern Baltic Sea. Since the distance to the coast has often been set as a determinant for the development of early settlements due to the available resources of the sea, e.g., fishing grounds, it is crucial first to reconstruct the possible configurations of the ancient shores. Only several geomorphological studies from the past century have indicated the approximate locations of some of the possible shoreline positions, but a detailed assessment of the past dynamics of the shorelines is lacking.

By implementing a previously developed automated free and open source software workflow (*QGIS*, *SAGA GIS*, *GRASS GIS* and *WhiteboxTools*) on a LiDAR-derived digital elevation model, the traceable ancient ridges of the Vidzeme coast of Latvia are detected and adjusted in raster format according to a GIA model and a relative sea-level (RSL) database for Ancylus Lake and Littorina Sea stages. Each of the adjusted rasters is clustered for trend surface analysis to obtain several ancient water levels per development stage, which are then analyzed for coherence with the input data and general validity with the development of the Baltic Sea.

Similar approach has already aided with archaeological interpretations elsewhere on the coast of Latvia, where settlement sites have been discovered and dated, and it is believed that it could help with interpretations of stone age settlement sites inland, relatively near the Vidzeme coast, where, e.g., seal remains have been discovered. The reconstructed ancient shore models, consisting of several RSL height models, could potentially aid in settlement suitability modelling and lead to discoveries in a relatively unknown land.

Neoarabia, a diachronic multi-scale and multi-proxy approach to East Arabian climate-environmental variability in the Middle Holocene: impacts on coastal Neolithic societies and socio-environmental responses.

NeoArabia is an interdisciplinary and multi-scalar project, dealing with the very long term of the Arabian coastal Neolithic (6200-2800 BC) by a latitudinal transect of ~1000 km. Focused on environments/landscapes reconstructions and the mobility of human communities, it intends to test the societal resilience at scales from the site to the region, using socio-environmental scenarios. It simultaneously studies paleoclimatic, paleoecological and archaeological changes and variabilities allowing the reconstruction of environmental and societal changes during the Eastern Arabian Neolithic (8500-4500 cal BP). This study is therefore multi-site, multi-scale temporal (seasonal, interannual, millennial, orbital…) and spatial as it is based on a 1200 km latitudinal transect between the southern Arabian Gulf and the southern Arabian Sea (Dhofar) (25.5°N-55.6°E to 16°N-53.45°E).
Our work is based on the simultaneous analysis of several continental, coastal and marine sedimentary systems (archaeological sequences of shell middens, palaeobeaches, lagoons/sebkhas and oceanic sequences), and on several carbonate supports (speleothems, shells…). We will also discuss several periods of increased detrital activity, seen at archaeological sites, in lagoons, in karst speleothems and in the Arabian Sea, associated with discontinuous aridification stages in eastern Arabia since the Middle Holocene and a probable change in tropical storm frequency.
They are looking for the connections of terrestrial-marine signals, at very high chronological resolution (10-50 years), in order to discuss their spatio-temporal correlations and causalities, responsible for the evolution of plant and animal biomass, and the adaptation strategies of coastal human communities. Based on the resilience model, we intend to explore the process of reorganisation of the eastern Arabian Neolithic communities in terms

of geographic location strategies, economic and technological adaptations, evolution of social structures, and behaviour aimed at avoiding or reducing impacts.

River mouth mobility during the Ist millennium BCE: The case of the Po and the Etruscan city of Spina (Ferrara, Italy)

Mr. Joé Juncker [1]***, Dr. Ferréol Salomon*** [1]***, Prof. Andrea Gaucci*** [2]***, Prof. Laurent Schmitt*** [1]***, Mr. Enrico Zampieri*** [2]

1. *Laboratoire Image, Ville, Environnement (LIVE UMR 7362), Université de Strasbourg, 3 rue de l'Argonne, 67000 Strasbourg, France,* ***2.*** *Dipartimento di Storia Culture Civiltà, Alma Mater Studiorum-Università di Bologna*

During the first millennium BCE, the main mouth of the Po River was located at the central part of the delta in the area of Comacchio (Province of Ferrara). The river mouth formed a promontory with several beach-ridges well preserved and visible on aerial photographs. The fortuitous discovery of the Etruscan site of Spina in the first part of the 20th century in this deltaic context raises many questions about the resilience of the city in this geomorphological configuration. The connections with the Mediterranean basin, the Po Valley and the Alps and Apennines mountains makes it a privileged commercial hub. For several decades, the issue of proximity to the river and the coast has been central to understanding its commercial dynamism but also the risks that may lead to the decline of this short-lived city (6th-3rd century BCE). This ancient deltaic lobe has been little explored regarding the Late Holocene and offers limited dates except for major trends obtained by interpolation. The chronology of the local succession of the ancient coastline is based on tangible archaeological evidence providing a coastline in the archaeological sense and a *terminus ante quem*. However, numerical geochronological tools have never been used to date these deposits. A French-Italian core drilling campaign was conducted as part of a project called “EOS-Etruscan on the Sea” (2020-on) in 2022. This new sedimentary data, based on an innovative sampling strategy with systematic drillings on the paleochannel and the beach-ridges, will be studied by a multiproxy approach combining several dating techniques (^{14}C, OSL, and portable OSL reader) with various sedimentological analyses. We explore, thanks to a high-resolution analysis, the river mouth deposits over time and space, as well as their relationships with the city.

New chronological evidence reveals a continuously inhabited Neolithic–historical settlement in south China

Dr. JIANHUI JIN [1]

1. School of Geographical Sciences, Fujian Normal University

The Xindian Ancient City (XAC) site is the most complete and frequently excavated urban site in the lower reaches of the Minjiang River. Archaeological and chronological research of this area helps clarify the history of human activity at the site and restore the geographical background of the ethnic minority regimes who lived in the coastal areas of south China during the Eastern Zhou dynasty and the related influence on regional civilisation. Dating results suggest that the site was built during the Spring and Autumn and Warring States periods (3.2–2.4 thousand years ago), which can reasonably explain the presence of relics from the Warring States period on and within the wall. Our dating results are also consistent with the late Neolithic stone tools and pottery fragments found in the area, suggesting that the site was an ideal settlement before castles were constructed. Based on the spatial distribution of the Neolithic sites and Holocene transgression records in the Fuzhou Basin, it was found that coastline advance and retreat were the main factors affecting the paleo-human activity in the Fuzhou Basin during the late Neolithic period. Previous studies showed that the seawater gradually withdrew from the basin around 2 ka BP. Before this, humans mainly lived in the crescent-shaped area on the west side of the Fuzhou Basin, close to the ancient coastline. Based on existing archaeological results and chronological data, it can be shown that the lower reaches of the Minjiang River, where Fujian Province's capital is located, has long been the centre of ancient human activity in the coastal areas of south China, with a civilisation history of 6–4 ka and a city construction history of at least 2.9 ka.

Crovani lake as a natural laboratory to test man-climate-environment interactions in island ecosystems of Mediterranean during the last six millennia

Dr. Federico Di Rita [1], ***Dr. Matthieu Ghilardi*** [2], ***Prof. Matteo Vacchi*** [3]

1. *university of Rome Sapienza,* ***2.*** *CEREGE – AMU-CNRS-IRD-Collège de France-INRAE, Europôle de l'Arbois BP 80 13545 Aix-en-Provence CEDEX 04, France,* ***3.*** *Department of Earth Science, University of Pisa, Italy*

Islands of the global oceans are experiencing destructive impacts of climate that deeply affect ecosystems stability. This is of particular concern for the large Mediterranean islands, which are considered both hotspots of biodiversity and world's most vulnerable areas to climate change. Understanding the long-term effects of climate and human impact on such island ecosystems is fundamental for the development of any conservation strategy. To this regard the use of palaeoecological research methods has the potential value to identify key periods where human societies and climate changes transformed the island ecosystems in different ways.
Corsica is one of the most interesting places of the Mediterranean to investigate with this approach. This island was crossroad for many populations in the conquest of the Mediterranean and is one of the major plant biodiversity hotspots in Mediterranean. Recent palynological and geoarchaeological investigations opened a new era in the study of this island allowing to refine the knowledge on environmental dynamics and to question former paradigms.
We carried out a multidisciplinary investigation on the sediment cores extracted from the Crovani coastal lake (NW Corsica) in order to define the action of climate, geomorphological processes, and land-use on the landscape changes over the last 6000 years. The results highlight that anthropogenic and climate-induced fires favoured the development of Mediterranean maquis, dominated by *Erica* and *Quercus ilex*, from ca. 6000 to 3350 cal. BP. A change in arboreal vegetation triggered a short but intense sediment input into the pond between ca. 3350 and 3200 cal. BP. This is chronologically consistent with runoff events recorded in several coastal sites of western Corsica, possibly related to a climate change occurred in sites of the western Mediterranean. The evidence of agriculture in pollen record is earlier than any archaeological evidence previously available in this part of Corsica and dates from 3900 cal. BC. Human impact has been responsible for the degradation of the maquis only from approximately 1000 cal. BC, and it intensified during Roman times, when the area experienced the first phase of galena exploitation. Our findings further suggest an influence of solar activity on centennial-scale forest cover variations.

New evidence suggesting human arrival in Mallorca prior to 5000 cal BP

Prof. Bogdan P. Onac [1]***, Prof. Joan J. Fornós*** [2]***, Dr. Angel Ginés*** [2]***, Dr. Joaquín Ginés*** [2]***, Dr. Victor Polyak*** [3]***, Prof. Jerry Mitrovica*** [4]***, Prof. Yemane Asmerom*** [3]

1. *University of South Florida,* ***2.*** *University of Balearic Islands,* ***3.*** *University of New Mexico,* ***4.*** *Harvard University*

There is no agreement on the timing of human colonization of the Balearic Islands. Three arrival models consist of: 1) Early (~9000 cal BP) without permanent habitation, 2) Classical (~7500 cal BP), and 3) Late (~5000 cal BP). Although the last two models suggest the existence of stable settlements, only the third one has been deemed plausible. Here, we present archeological and new sea-level data that imply human colonization on Mallorca before 5000 cal BP. Genovesa Cave (also known as Cova de'n Bessó) is located in the eastern part of Mallorca at ~400 m from the coast. It is a typical littoral cave with dry passages and galleries/chambers flooded by the sea-level rise. Genovesa Cave hosts abundant pottery and stone constructions. The latter includes a stone-paved path connecting the cave entrance with the first underground lake, a wall of cyclopean technique parallel to the foregoing path, and a stonewall built by placing large boulders on top of each other without mortar or cement in the entrance lake (~1.5 m deep) to bridge the only two dry chambers in the cave. This walkway, which is 0.5 m high and its top is presently submerged by 1 m, provided access to an inner chamber, where pottery attributed to the Naviform Culture (ca. 3500 cal BP) was discovered. This structure was thought to have been constructed around this time. However, the western Mediterranean deglaciation sea-level curve based on phreatic overgrowths on speleothems from coastal caves of Mallorca, suggests that by 3500 cal BP, the water depth in the lake would have been 1.25 m. Building a bridge that remains 0.75 m underwater is highly improbable. Using the same sea-level curve, we suggest that the bridge was constructed as early as 6000 cal BP (when sea level first encroached this part of the cave), but not later than 5500 cal BP (when the water in the lake was 0.5 m deep). If this scenario is correct, the possibility that stable human settlements existed in Mallorca prior to ~6000 cal BP should be reconsidered.

Burial Dynamics and Abrupt Climate Change at the Shell-Midden Site of Canímar Abajo, Matanzas, Cuba

Dr. Matthew Peros [1], ***Dr. Yadira Chinique de Armas*** [2], ***Prof. Silvia Hernández Godoy*** [3], ***Prof. William Buhay*** [2], ***Prof. Eduard G. Reinhdardt*** [4], ***Prof. Mirjana Roksandic*** [5]

1. Bishop's University, 2. The University of Winnipeg, 3. Universidad de Matanzas, 4. School of Geography and Earth Sciences, McMaster University, 5. University of Winnipeg

Archaeological and paleoclimatic data provide unique insights into societal resilience, adaptation, and transformation in the face of abrupt climate change, but few studies have examined such responses through the lens of prehistoric burial dynamics. The purpose of this paper is to examine the role that abrupt climate change had in influencing the timing of site abandonment and the shaping of cultural practices (e.g., diet, burials) at Canímar Abajo, an extensively studied site on the north-central coast of Cuba. A minimum of 220 individuals have been exhumed from two separate cemeteries at Canímar Abajo, which are stratigraphically separated by a shell midden. Radiocarbon dating of the human remains indicates that the older cemetery dates to at least 3300-2750 cal BP and the younger cemetery to 1590-1000 cal BP. Starch grain and isotopic analysis indicates that these populations depended on marine and terrestrial resources, including cultigens.

A new synthesis of paleoclimate data from Cuba, consisting of high-resolution analyses of speleothems, and pollen, isotopic, and foraminiferal data from lagoons and cenotes, shows that the timing of the older cemetery aligned with the "pan-Caribbean drought," and that its termination at ~2750 cal BP is closely associated with the 2.8 kyr event, an episode of cold SSTs in the North Atlantic and very dry conditions in the Caribbean. The younger cemetery was also associated with a relatively dry climate from ~1600-1000 cal BP, and that the end of its use is coincident with the abrupt onset of humid conditions beginning 1000 cal BP. The data from Canímar Abajo reveal a close correspondence between the termination of the large cemeteries and abrupt and high-magnitude climate changes, suggesting a causal link between the two such that settlement demography was affected by sudden stresses to critical freshwater, terrestrial, or marine resources.

Interdisciplinary research of buried ancient settlements and agricultural fields in Jägala Jõesuu, northern Estonia

Palaeosoils of buried historical agricultural fields, as well as Stone (ca. 3100 BC) and Bronze Age (ca. 700 BC) settlement sites were studied in northern Estonia using a set of archaeological, palaeobotanical and geoarchaeological methods, including sedimentological and soil geochemical analyses, AMS radiocarbon and luminescence dating, and ground penetrating radar study. The National Geographic Society funded the research. According to radiocarbon dates, this area was used for slash-and-burn agriculture from ca. 2000 BC until ca. 1400 AD. Fields were arranged on top of the mid-Holocene coastal landform system, consisting of seaward□dipping beach deposits and covered by coastal dunes, which developed during the coastal retreat at ca. 5500–5000 BC. Sandy palaeosoils of agricultural fields are characterized by low organic C content, depleted P, Sr and Fe concentrations, and well-developed soil profiles suggesting podzolisation. Palynological and phytolith analyses showed that wheat, barley, rye, millet and perhaps hemp or hops were grown there. Up to 3-m-thick layers of dune sand covering the fields accumulated rather quickly and were probably not related to intensive agricultural land use. According to the combined luminescence age, based on seven datings, this took place around 1524–1581 AD. The development was most likely caused by catastrophic deforestation due to tree felling and/or forest fires, followed by reactivation of old dune sands. It is possible that the complete destruction of forests in the area was the result of the raid or siege of the nearby town and castle of Tallinn by the troops of the Grand Duchy of Moscow during the Livonian War (1558–1583) between 1560 and 1577 AD.

Resilience and Political Ecology of Human-Geological Environment Relationships: the case of Helike, Greece

Ms. Amanda M. Gaggioli [1]

1. Brown University - Joukowsky Institute for Archaeology

Single-event environmental phenomena endure as explanations of widespread social catastrophe across time and space. In particular, earthquakes have been linked in various places throughout the past with large-scale social downturn, most notably at the end of the Late Bronze Age (LBA) (c. 1200 BC) and in the late Roman period (fourth to sixth centuries CE) in the eastern Mediterranean. This paper shows how earthquakes traditionally perceived as 'natural' disasters are not merely 'natural' but social and a critical factor in political ecological relationships. This argument draws from advancements in geoarchaeology and soil micromorphology and soil and architectural material collected and analyzed from Helike, Greece–leader of the Achaean League and infamous victim of the 373 BCE earthquake disaster. The soil micromorphology of seismically triggered soft sediment deformation structures (SSDS) allows for the identification and interpretation of earthquakes and other geological hazards in direct association with settlement architectural remains. The integration of this micromorphological data together with geomorphological, paleoseismological, FTIR, and architectural data from excavations of 16 sites belonging to six occupation phases spanning the third millennium BCE to fifth century CE within the 15 km2 delta plain of Helike shows the interrelations of earthquake deformation and other environmental changes, such as flooding and rapid coastal change, and technological innovation and invention in the human-built environment. Material-geological patterns indicate settlement-wide efforts aimed at resilience–the prevention of social disruption, or disaster–in not only earthquakes but also other environmental hazards, including flooding and rapid coastal change. Changes in the material-geological record from the level of the settlement, to private and public structures, and to particular structural elements indicate distinctive human strategies in resilience through time. The development of resilience in human-geological environment relationships involved decisions that confronted not only immediate geological conditions and change but also negotiations with the constraints of and opportunities afforded by political leadership and organization, economic resources and production, and cultural values and associations, revealing not only resilience, but also more significantly, a political ecology of human-geological environment relationships.

Microfossil investigations as part of multiproxy analyses in ancient harbour sediments – the Roman Harbour of Ephesos versus the Hellenistic Harbour of Elaia

Dr. Anna Pint [1]***, Prof. Peter Frenzel*** [2]***, Dr. Martin Seeliger*** [3]***, Dr. Friederike Stock*** [4]***, Prof. Helmut Brückner*** [5]

1. *University of Jena,* ***2.*** *Friedrich Schiller University Jena, Institute of Earth Sciences,* ***3.*** *Institute of Physical Geography, Goethe-University Frankfurt,* ***4.*** *Bundesanstalt für Gewässerkunde,* ***5.*** *Institute of Geography, University of Cologne*

The complete understanding of human and landscape history and their complex interactions is a highly topical desideratum of modern science in general, and, in particular, of landscape archaeology and geoarchaeology. A variety of specialized scientific disciplines focuses on the investigation of different aspects of past societies and palaeo-environmental changes and conditions. The complexity of the coastline is of crucial importance for the existence of harbours. On the west coast of Turkey, the well protected and deeply incised embayments provided ideal locations for harbours during antiquity. Their connection to the hinterland *via* rivers made these locations even more attractive. However, the enormous fluvial sediment supply led to the siltation of the harbours in relatively short times. Concerning the microfossil inventory, harbours are very similar to lagoons in habitat type and ecology due to their protected position. In harbour basins, eutrophication is common, caused by the input of human waste and the reduced exchange of water. This is reflected by a ubiquitous faunal association, adapted to temporary deficiency in oxygen. Often, the sedimentation rate is higher than in natural lagoons. Silting up of a harbour leads to the separation from the sea followed by a freshening of the water body with a characteristic freshwater fauna during the final phase. This marked change in the faunal composition indicates the disconnection to the sea and the end of the harbour activity. Comparing the Roman Harbour of Ephesos and the Hellenistic Harbour of Elaia the key difference between the two harbour sites are the various sedimentation rates. In Elaia the sedimentation rate was low that caused the present position of the harbour close to the coast, whereas Ephesos was subject of a very high sementation rate causing fast siltation and separation of the Roman Harbour from the sea. Also, stronger sedimentation rates caused stronger human impacts those as dredging, which is reflected in a mixture of microfaunal assemblages.

Session 62: Paleoclimate, paleoweathering, paleoprovenance and machine learning on sediments during Late Quaternary Period

Paleomonsoon variability of the past 2000 years - a high-resolution record from a coastal lake in Southern India

Dr. Anish Warrier [1]***, Ms. Yamuna Sali A.S.*** [2]***, Dr. Sandeep Kizhur*** [3]

1. *Associate Professor, Manipal Institute of Technology, Manipal Academy of Higher Education,* ***2.*** *CSIR-Senior Research Fellow, Manipal Institute of Technology, Manipal Academy of Higher Education,* ***3.*** *Department of Geology, Central University of Kerala, Kasaragod, India*

Extreme weather events are more frequent across the globe. To understand the direction of the changing climatic conditions, the underlying mechanisms need to be addressed. This study aims to reconstruct the paleoclimatic variability of southern India during the past two millennia by adopting a multiproxy approach (geochronology, environmental magnetism, sedimentology, and loss-on-ignition). The study was conducted on a 154 cm long sediment core retrieved from Lake Ramasamudra, Southern India. The multiproxy data spans 1566 years (from 2005 to 439 cal yr BP). The environmental magnetic data reveals the strength of the monsoon in terms of fluctuating magnetic mineral concentration. The magnetic mineralogy of the lake is composed of magnetite (mean S-ratio value = 0.9). The magnetic grains present in the sediments are a mixture of medium to fine-grained, indicating a stronger intensity of pedogenesis in the catchment in response to the enhanced monsoonal conditions. Four distinct climatic phases were identified from the reconstructed paleoclimatic record viz. Phase I: 2005-1550 cal yr BP; Phase II: 1550-1000 cal yr BP; Phase III: 1000-500 cal yr BP, and Phase IV: 500-439 cal yr BP. High values of χ_{lf}, χ_{fd}, χ_{ARM}, and SIRM in phase I suggest a high influx of terrestrial sediments (including fine-grained magnetite), implying stronger monsoon and pedogenesis. A high lake level was also inferred from the low per cent values of sand, as finer particles get deposited far from the shore within the lake, where the hydrodynamic conditions are weak. In phase II, there is a cyclic variability in the concentration-dependent magnetic parameters indicating a strengthening of monsoon, which attains its peak at around 1200 cal yr BP and starts declining to a less humid climatic condition. The monsoonal intensity was the weakest in phase III and shows a further weakening trend indicated by decreasing χ_{lf} value. Phase IV is characterised by low values of concentration-dependent parameters, and high values of sand fraction and organic carbon (OC), suggesting a stronger monsoon. The high values of OC significantly dilute the magnetic properties. Spectral analysis of the χ_{lf} data reveals periodicities of 526, 226, and 67 years, attributed to the solar origin.

Decadal- to centennial-scale periodicities in the Indian summer monsoon in southern India: Evidence from spectral and wavelet analysis of multi-proxy data

Dr. Sandeep Kizhur [1], Mr. Aravind G H [2], Mr. Abdul Rafaz [3], Dr. Anish Warrier [4]

__1.__ Assistant Professor, Department of Geology, Central University of Kerala, Kasaragod, India, __2.__ Research Scholar, Department of Geology, Central University of Kerala, __3.__ Junior Research Fellow, Department of Geology, Central University of Kerala, __4.__ Assistant professor, Manipal Institute of Technology

The objective of the present study is to document variations in the Indian summer monsoon and its inherent periodicities during the past 2000 years based on multi-proxy investigations on sediments deposited in Madagadakere (MK) Lake in southern India. For past rainfall reconstruction, proxies like rock magnetics, particle size, diffuse reflectance spectroscopy (DRS), and Fourier-transform infrared spectroscopy (FTIR) have been employed on MK lake sediments. The chronology of the Madagadakere sediment core (MK1) is constrained by seven AMS (Accelerator Mass Spectrometer) ^{14}C dates. The maximum ^{14}C age obtained for the trench samples collected is 2130 ± 30 years with a mean sedimentation rate of 1 mm/year. The down-core variations of rock magnetic parameters ($\chi_{lf,}$ χ_{fd} %, IRM, SIRM, and interparametric ratios), principal component scores of FTIR spectra, as well as second derivative values of DRS spectra, are used to assess the variations in detrital input, pedogenesis, and chemical weathering intensity in the catchment area of the lake.

Based on changes in different proxy parameters, the paleo-rainfall history in the area can be split into four phases..

Phase I (2100–1600 cal. years B.P.): Higher terrigenous influx, strong pedogenesis, and chemical weathering associated with an intensified monsoon were documented, followed by a steady decrease.

Phase II (1600–900 cal. years B.P.): There was a sudden increase in rainfall conditions during the commencement of this phase.

Phase III (900-200 cal. years B.P.): Cyclic variation in rainfall is observed during this period, with alternating dry and wet periods.

Phase IV (200 cal years B.P. to present): An increasing trend of rainfall (resulting in increased detrital influx and strong pedogenesis) towards present is documented during this phase.

Spectral analysis and wavelet of rock magnetic data reveal the presence of periodicities like 296, 72, 60-54, 45, 39-36 years in the palaeorainfall data. The shorter periodicities (60-54, 45, 39-36 years) were predominant during intervals 400-Present, 700-500, 1100-1250, 1800-1400 and not so significant during the intervening periods. Whereas, the longer periodicity of 296 years was predominant throughout the last 2000 years. These periodicities are also observed in other paleoclimatic records from the region, which are ascribed to solar origin.

Paleo-temperature inferred from brGDGTs over the last 18 cal ka BP from Lake Barrine, tropical NE Australia

Terrestrial temperature exerts a major control on vegetation distribution, the hydrologic cycle and many biogeochemical cycles. Yet little research into terrestrial paleotemperature reconstruction has been conducted covering the Holocene in northern Australia and recent global surface temperature reconstructions include no data from northern Australia. Branched glycerol dialkyl glycerol tetraethers (brGDGTs) are increasingly used to reconstruct terrestrial temperature because of their ubiquity and a preservation window of at least tens of millions of years. Here, we fill this spatial gap through reconstructing mean annual surface water temperature in Lake Barrine in tropical NE Australia from 18.3 to 1.7 cal ka BP using separated 5- and 6-methyl brGDGTs. A 7.2 m master core from the centre of the lake was extracted, along with 5 surface lake sediment samples and 7 soil samples in the catchment area. The result showed that the fractional abundances of all brGDGTs in the catchment soils, surface and downcore sediment in Lake Barrine were closely correlated, with dominant tetramethylated brGDGTs, especially Ia. We applied a global calibration to reconstruct the temperature using lake sediment samples and a binary mixing model to correct the temperature bias caused by different portions of soil-derived brGDGT input. The corrected temperature record compares favourably with independent temperature records from a broader region, with lower temperatures than modern in the late Glacial and higher ones than modern in the early to mid-Holocene.

Luminescence chronology of loess-palaeosol deposits in the Central Shandong Mountains region: Provenances and paleoclimate implications

Dr. Qiuyue Zhao [1]

1. Taishan University

The loess-palaeosol deposits of the Central Shandong Mountains (CSM) to the east of the Chinese Loess Plateau (CLP) potentially provide valuable archives for the reconstruction of East Asian monsoon patterns. However, compared to the abundant attention given to the loess layer, fewer studies have explored the palaeosols documentingthe processes and characteristics of interglacial climate changes. The high-resolution chronologies and provenances of the palaeosol in the CSM area are still unclear. In this work, the luminescence ages and paleoclimate proxies in the Shaozhuang (SZ) and Focun (FC) sections were studied, by combining detrital zircons U–Pb ages from the loess-palaesosol in Jingbian, Licheng, Focun, Pianguan and Dongming Yellow River sediments. Quartz single-aliquot regenerative dose protocol (SAR) and K-feldspar post-infrared IRSL (pIRIR290) dating results were obtained in the SZ (8.0 ± 1.1 ka − 50.8 ± 2.7 ka) and FC (3.8 ± 0.3 ka—144.0 ± 7.8 ka) sections to develop the most detailed CSM region chronologies to date. The analyzed grain sizes and detrital zircon U–Pb ages suggest that the provenance of the CSM loess was dominated by local Yellow River sediments. The palaeosols observed in the ffeld in these two sections were composed of both aggradation soils deposited in the interglacial period and non-aggradation soil formed by the weathering and leaching of the underlying loess. We found evidences for the presence of non-aggradation soils as indicated the relatively high 5–16 μm particle percentages, relatively low chemical index of alteration (CIA) values and the percentages of >63 μm particles compared to those of the overlying palaeosol layers. Nevertheless, the loess-palaeosol deposits in the CSM are still the product of the East Asian monsoon and global climatic variations, as the deposits have recorded the glacial-interglacial cycles.

Geochemical and Clay Mineralogy Characterization of Ganga Flood Plain Sediments: Insights to Weathering and Sediment Provenance

Dr. Anupam Sharma [1], ***Mr. Mukesh Yadav*** [1], ***Dr. Gurumurthy GP*** [1], ***Dr. UMA KANT SHUKLA*** [2]

1. Birbal Sahni Institute of Palaeosciences, 2. Department of Geology, Banaras Hindu University, Varanasi 221005

Ganga Flood Plain is one of the most fertile land in the world. The Ganga Flood Plain receives sediments from the Himalayas and the Peninsular region through the Himalayan and Peninsular Rivers. Few smaller rivers (Gomati and its tributaries) which originate in the plainer region of the Ganga Basin carry sediments from older flood plain and converge with the major trunk rivers, the Ganga and the Yamuna. During the monsoon season, Gomati and its tributaries receive surface water from different parts the flood plain in the form of surface runoff. Hence, these rivers play a crucial role in sediment recycling and elemental redistribution. In this study, the sediment samples from cliff sections of the southern Central Ganga Plain along the Ganga, Yamuna and Loni Rivers have been studied for clay mineralogy and major elements geochemistry to evaluate the chemical weathering, elemental characteristic and climatic impact in the Ganga plain. The clay mineralogy data suggests that sediment from the Himalaya region is dominated by illite and chlorite, and the peninsular river sediments are dominated by smectite. In Yamuna River, smectite, chlorite and illite are observed in decreasing order. Whereas, the plain fed river sediments show illite and chlorite. The absence of smectite in the plain fed river sediments suggest that there is negligible sediment contribution from peninsular region. The major element geochemical data suggests that the CaO and Na_2O are relatively less mobilized from the Plainer River sediments suggesting low chemical alteration compared to the Yamuna River and Ganga Rivers due to aridity and low fluid replenishment in the plainer region.

Vegetation dynamics and hydroclimate variability since the LGM from the core monsoon zone of India

Dr. MD FIROZE QUAMAR [1]

1. Birbal Sahni Institute of Palaeosciences, 53-University Road, Lucknow-226007, India

Palaeopalynological study of 2.25 m long, lacustrine sedimentary profile from the Koriya District of Chhattisgarh State, core of the monsoon zone (CMZ), central India revealed that between ~22,200 and 18,658 cal yr BP, open vegetation occupied the landscape under a cool and dry climate, probably indicating a reduced monsoon precipitation. This cool and dry climate, influenced by weakening of the Indian Summer Monsoon (ISM), globally matches with the Last Glacial Maximum (LGM). Between ~18,658 and 7340 cal yr BP, under the influence of a warm and moderately humid climate with increased monsoon precipitation, the open vegetation was succeeded by open,mixed tropical deciduous forest. This open,mixed tropical deciduous forest continued to grow in the region, with an increase in the frequency of some of the tree taxa especially, between ~7340 and 1961cal yr BP under a warm and relatively more humid climate with increased monsoon precipitation, correlatable with the Holocene Climatic Optimum (HCO)/Holocene Thermal Maximum (HTM). Between ~1961 cal yr BP and the Present, dense, mixed tropical deciduous forest came into existence under a warm and relatively more humid climate with further increase in monsoon precipitation. The present study provides an unprecedented record of the vegetation dynamics, climate change and the ISM rainfall variability since the LGM from one of the poorly understood areas of the tropics where rainfall is essentially controlled by the monsoon variability.

Session 63: Late Quaternary fluvial archives from the time of Homo sapiens: Stratigraphical, sedimentological, palaeontological and georchaeological records

Role of the paleo-Yamuna River in riverscape evolution in northwest India during Late Quaternary and its non-contemporaneity to Harappan Civilization

Dr. Imran Khan [1], ***Prof. Rajiv Sinha*** [2], ***Dr. Mayank Jain*** [3], ***Dr. Andrew Sean Murray*** [4]

***1.** Aligarh Muslim University, **2.** India Institute of Technology Kanpur, **3.** Technical University of Denmark, **4.** Department of Geoscience, Aarhus University*

The avulsion of major rivers has often been linked to the decline and abandonment of the Bronze Age Indus (Harappan) urban centers (~4.6–3.9 ka BP) in northwest (NW) India. It has been documented that a large river system, the Ghaggar-Hakra system, used to drain parts of NW India until the Early Holocene and was fed by two major tributaries, paleo-Yamuna from the east and paleo-Sutlej from the west. Recent work has demonstrated that the paleo-Sutlej was defunct shortly after ~8 ka. However, the role of avulsion of the paleo-Yamuna has remained unresolved because of very limited and fragmented subsurface stratigraphic and chronological data. This work presents high-resolution chrono-stratigraphic data well-supported by 47 optically stimulated luminescence (OSL) ages from six sediment drill cores (~50 m deep) raised across a series of paleochannel traces of the Yamuna in the Haryana, NW India. Our detailed sedimentological analysis shows multi-storied channel sand bodies separated by muddy intervals typical of repeated avulsions and compensational filling in a fan setting. This study exclusively suggests that the avulsion of the paleo-Yamuna River occurred ~18 ka ago. This implies that the Ghaggar-Hakra system draining this region was already weakened during the post-LGM period, and the avulsion of the paleo-Sutlej at ~8 ka resulted in its final abandonment. Since both these avulsions occurred significantly earlier than the expansion and decline of the Indus Civilization in this region, it reaffirms the non-contemporaneity of the Harappan civilization with a large river system draining this region.

Post-LGM fluvial archives and human activity in the NE piedmont of the Pennines

Prof. David Bridgland [1], ***Dr. James Innes*** [1], ***Prof. Antony Long*** [1], ***Dr. Wishart Mitchell*** [2], ***Dr. Charlotte O'Brien*** [1], ***Ms. Mairead Rutherford*** [3], ***Mr. Blaise Vyner*** [4]

1. *Durham University,* **2.** *University of Dundee,* **3.** *Oxford Archaeology North,* **4.** *Blaise Vyner Archaeological Consultancy*

Study of the post-glacial evolution of the piedmont reach of the River Ure–Ouse in North Yorkshire, UK, reveals a drainage system that is incised into the landscape, in part re-excavating the MIS 2 infill of a pre-existing valley. This incision is manifest in the profusion of gorges and terraced reaches characteristic of this and other eastern Pennine rivers such as the Wharfe, Swale, Wear and Tyne (and also in the deeply incised minor valleys known as 'denes' that drain to the North Sea coast). A similarity between all these systems is that the glaciated landscape into which they are incised is typically ~30 m above their modern channels, while evidence for terrace ages range, from highest to lowest, from Lateglacial to Late Holocene (post-Medieval). The Ure sequence is one of the best developed and best dated amongst such archives. Evidence for human occupation of the eastern Pennines during the latest Pleistocene and the first half of the Holocene is uncommon and tends to be on the uplands; in the valleys themselves such evidence is perhaps largely buried by later sediments. There is abundant activity evident from the Late Neolithic, however, extending from the effects of early agriculture to the construction of henge monuments. Later prehistoric archaeology is plentiful, especially on the interfluve between the Ure and its northern neighbour, the Swale, although there is considerable indication of Iron Age to Romano-British occupation of the valley floors. On the lowest terraces the abundant Medieval archaeology includes remains from shoemaking at Ripon. In addition to a terrace staircase declining from the deglaciation level (+ ~30 m) to the modern river, the fluvial archives include cut-off channels filled to levels comparable with terrace sediments of similar age.

Developments in mapping, dating and quantitative reconstruction of Lower Rhine river activity in the last 3000 years (Niederrhein and upper Rhine delta; Netherlands and Germany)

Dr. Kim M. Cohen [1]

1. *Dept. of Physical Geography, Faculty of Geosciences, Utrecht University*

The river Rhine grades from valley to delta plain in the Dutch-German borderlands: an apex bifurcation situation that established and evolved in the Late Holocene, in prehistoric and historic times. This densely populated, long and heavily man-used region has been intensively studied from quaternary geological, geomorphological, archeological and historical viewpoints. New findings append and upgrade the state of mapping and dating of morphological features such as alluvial ridges and oxbow channels. Such resolves details of regional landscape genesis and evolution and allows to identify human occupation of the river banks along contemporary channels and their interaction with activity of the river. Maintaining geographical overview and interdisciplinary collaborative networks is essential to keep track and course in this situation of rapidly growing availability of barge loads of diverse and detailed geological-geomorphological, geoarchaeological and paleoenvironmental mixed bags of information.

Critically, the state of research reached in the last decades has allowed for quantitative reconstruction of the activity of the Lower Rhine river: insight in the pacing of meander migration (i.e. paleo-morphodynamics), insight in the heights that extreme floodwaters occasionally reached and the peak-discharges associated with those (i.e. paleo-hydraulics). In turn, that information feeds into actual issues. One of these is flood safety, where the information feeds in to work on recurrence times of large floods, besides on human landscape alteration effects vs. historic climate variability vs. Anthropocene present and near-future conditions. Another one is heritage management through multiple time frames: e.g. connected to UNESCO world heritage status of *Limes* roman empire military border sites, to interest in the Dark Ages, to interest in High-Late Medieval urbanization, to medieval embankment, to 18th century early river engineering.
The contribution will provide a condensed overview of the new insights, focusing on the Dutch-German Rhine river borderlands, citing regional reports and recent international publications.

The relative importance of geomorphic processes and anthropogenic activities in the organic carbon storage of temperate floodplains

Prof. Gert Verstraeten [1], ***Dr. Ward Swinnen*** [1], ***Ms. Renske Hoevers*** [1], ***Dr. Nils Broothaerts*** [2]

1. KU Leuven, Department of Earth and Environmental Sciences, Division of Geography and Tourism, 2. Thomas More University of Applied Science

River systems convey organic carbon and mineral sediment through the landscape, but also store a significant proportion in their floodplains for varying amounts of time. A proper quantification of the floodplain storage component is required to gain insight in the land-ocean transfers and cascades of organic carbon and mineral sediment at Holocene timescales. In this study, the Holocene floodplain carbon and sediment storage was quantified for five medium-sized rivers in contrasting environments. The study sites consist of a mountain river (Upper Dee, Scotland), lowland rivers in the European sand belt (Grote Nete and Zwarte Beek, Belgium) and loess belt (Dijle and Mombeek, Belgium).

The Holocene stratigraphy was reconstructed using 1246 soil corings across 131 river valley cross-sections. Combining these reconstructions with radiocarbon dates and measured sediment properties allowed to quantify the total sediment and carbon storage. The results indicate that in the high-energy river system of the Upper Dee, the total storage of mineral sediment and organic carbon is largely dependent on the local geomorphology, with the local storage being largely determined by the river dynamics. In contrast, the observed differences in floodplain storage in the studied lowland river basins is strongly linked to the history of human impact in the region. Sediment storage is on average 4.4 times higher in the loess belt river catchments compared to those in the sand belt. Similar differences, although less pronounced, can be observed for the storage of organic carbon, with floodplains in the loess belt containing 2.6 times more organic carbon than floodplains in the sand belt. This difference can be attributed to the inherent erosion sensitivity of loess soils and an opening of the landscape and increased hillslope erosion since the Bronze Age. This resulted in the deposition of large amounts of mineral sediment in the river floodplains. As a result, the alluvial peat layers were buried and protected from oxidation and human activity. As such, the Holocene trajectory of river floodplains, determined by the interplay of geomorphic and anthropogenic factors determines the current floodplain stock and its potential for future storage.

Multi-proxy palaeoenvironmental reconstruction of two fluvial systems in the United Arab Emirates and implications for human dispersal

Ms. Kira Raith [1]***, Dr. Gareth Preston*** [1]***, Dr. Ash Parton*** [1]***, Prof. Adrian Parker*** [1]

1. *School of Social Sciences, Oxford Brookes University*

Rivers are important terrestrial archives to reconstruct the palaeoenvironment. The investigation of rivers in dryland environments is challenging due to the sporadic and high variable precipitation, triggering fluvial activation which often occurs as high energy events. However, they are important additions to other proxies like speleothems, lake sediments or phytoliths indicating wet periods, to reconstruct environmental change and climate. The study region in the northern United Arab Emirates located at the edge of the largest sandy desert on earth, the Rub' al Khali, is sensitive to climate change and experienced pronounced shifts between wet and dry periods in the past. Today the climate of the region is influenced by the mid-latitude Westerlies, the Indian Ocean Summer Monsoon as well as tropical cyclones and lies north of the current summer position of the ITCZ. Although both investigated ephemeral river systems of Wadi Dhaid and Wadi Iddayyah are directly adjacent to each other and both originate in the Hajar Mountains, they show different characteristics of source material and river morphology. In this regard, they find different ways to adjust their course to reach a maximum flow efficiency and an equilibrium form. The sedimentary structures identified, range from scour-and-fill structures, cross-stratification, planar bedding to structureless sediments and inform on different flow conditions through a comparison with sedimentary investigations of modern rivers, other palaeorivers and flume experiments. In addition, Wadi Dhaid and Wadi Iddayyah are further explored using remote sensing and by the construction of longitudinal profiles. The dating by optically stimulated luminescence (OSL) and radiocarbon of different stratified sections along the course of the rivers allow together with sedimentological and geochemical investigations to reconstruct the environmental change over the last 160 ka in the region. Over this time scale different phases of increased erosion and deposition are recognised. Moreover, it is shown that fluvial activity occurred partly contemporaneous with aeolian deposition and was almost continuously. Finally, the palaeonevironment investigations are linked to the debate about human dispersal in which Southeast Arabia is recognised as a key region.

The Mid to Late Pleistocene Atbara River basin in eastern Sudan as a habitat for hominins

Dr. Robert Bussert [1], ***Mr. MOSAB MOHAMMEDNOOR*** [1], ***Dr. Ali Eisawi*** [2], ***Prof. Omer El Badri*** [3], ***Dr. Anne Delagnes*** [4], ***Dr. Brian Kraatz*** [5], ***Dr. Khalafallah Salih*** [2], ***Dr. Sumiko Tsukamoto*** [6], ***Dr. Faysal Bibi*** [7]

The Atbara River, as the northernmost major tributary of the Nile and connecting the Ethiopian Highlands to the Nile, may have played an important role in the question whether the Nile functioned as a faunal and cultural dispersal route or as an ecological refuge during the Pleistocene. About 50 m of alluvial deposits, exposed over more than 200 km along the middle Atbara in eastern Sudan, document the river history and the environmental conditions in this region for the last ~250 ka, according to our new age dating. The sediments contain abundant fossils, including hominins, and stone tools. The sedimentary succession, divided in a previous study into two major sedimentary units, the Butana Bridge Synthem (BBS) and the Khashm El Girba Synthem (KGS), each with three sub-units separated by erosive unconformities, consists of river channel deposits and floodplain sediments with intercalated paleosols. The units differ in the grain size of the channel sediments, in width-to-depth ratios and vertical and lateral connectivity of channel elements, the ratio of channel to floodplain deposits, the internal architecture and sedimentary structures in the channel sediments, and the type of paleosols.

Gravel-dominated deposits of wide-but-shallow channels with intercalated floodplain sediments in the oldest unit (BBS; ~250 to ~160 ka) represent poorly confined braided channels with highly variable but sometimes high runoff. Overlying floodplain sediments contain Calcisols and Acheulean stone tools; apparently the floodplains were visited by hominins. Sandy-gravelly channel sediments with lateral accretion deposits in unit KGS1 (~160 to ~130 ka) represent deposits of meandering rivers. Near a point bar, hominins produced abundant Acheulean tools. Skeletal finds also show that hominins inhabited the area. The mostly sandy channel sediments of unit KGS 2 (~130 to ~60 ka) with high width-to-depth ratios and frequent lateral accretion deposits intercalated in thick floodplain deposits including Vertisols indicate well-confined meandering channels, with the internal channel architecture suggesting a pronounced seasonal or intermittent discharge. In unit KGS3 (~30 to ~15 ka), laterally and vertically amalgamated sandy-gravel channel deposits represent deposits of shallow, poorly confined braided channels. The paleoclimatic and tectonic controls on the depositional processes will be discussed.

Holocene dynamics of fluvial systems in the Moulouya basin (Morocco) : questioning the role of climate changes in river morphogenesis

Dr. Bruno Depreux [1], ***Dr. Jean-François Berger*** [2], ***Dr. David Lefèvre*** [3], ***Prof. Larbi Boudad*** [4], ***Prof. Abderrahmane El Harradji*** [5]

1. *Archéorient, UMR 5133, University of Lyon 2-CNRS, 7 rue Raulin, 69007 Lyon, France,* ***2.*** *Environnement, Ville et Société-IRG, UMR 5600 CNRS, Univ. de Lyon 2,,* ***3.*** *Université Paul Valéry Montpellier 3, CNRS, UMR 5140 Archéologie des sociétés méditerranéennes, Campus Saint Charles,* ***4.*** *Mohammed V University, Faculty of Sciences, Rabat, Morocco,* ***5.*** *University Mohammed Premier Oujda*

The dynamics of fluvial systems and their responses to different forcing during the Holocene are still poorly documented in North Africa. In the Moulouya basin, the main Mediterranean catchment in Morocco and one of the largest in the Mediterranean, pioneering studies had already suggested the role of climatic control and revealed the potential of the alluvial archives of its upstream basins.

This strong potential led us to develop a comparative and systemic approach to the Holocene evolution of the alluvial plains in two sub-basins of the Moulouya. With this regional approach, coupled with high-resolution multiproxy analyses and numerous radiocarbon dates, this work confirms the potential for palaeoenvironmental reconstruction of the alluvial archives and allows us to build a robust morphosedimentary and palaeoenvironmental framework for the Holocene of the upstream basins of the Moulouya and northeast Morocco.

This work also reveals the predominant role of climatic forcing, on multi-millennial to centennial scales, on the dynamics of Holocene fluvial systems in the Moulouya basin. Two morphosedimentary units (MSU) of regional extent, characterized by a strong homogeneity of the hydrosedimentary and morphogenic dynamics, have been highlighted. A fluvio-palustrine formation (MSU 1, 10800 - ~6000/5000 cal. BP) appears strongly controlled by the orbital variations of the last African Humid Period. This formation was then eroded during a period of hydrogeomorphological instability associated with strong fluvial activity (8200 - 6200 cal. BP). A new multi-millennial period of aggradation (MSU 2, 5200 - ~2000/1000 cal. BP) marks the lasting transition to a hydrological regime characterised by intermittent flow and strong flood dynamics, linked to the progressive aridification experienced by North Africa and the southern Mediterranean during the Late Holocene.

On a millennial to centennial scale, this work also highlights the sensitivity of the Moulouya alluvial archives to rapid climatic changes (RCCs) during the Holocene, e.g. two phases of major incision followed by strong fluvial activity reflecting the responses of the hydrosystems to the 8.2 and 7.6-7.3 ka RCCs. Finally, this work suggests that solar forcing could have acted as a factor of morphogenesis in the upstream basins of the Moulouya.

Changes in the Magnitude and Frequency of Holocene Monsoon Floods on the Mahi River, Western India

Prof. Pramodkumar Hire [1] ***, Dr. Archana Patil*** [2] ***, Ms. Gitanjali Bramhankar*** [1]

1. *Department of Geography, HPT Arts and RYK Science College, Nashik – 422005 (India),* ***2.*** *Department of Geography, RNC Arts, JDB Commerce and NSC Science College, Nashik Road, Nashik – 422101 (India)*

During the past seven decades, the monsoon-dominated Mahi River of western India has experienced extraordinarily large magnitude floods that rank among the highest recorded rainfall-runoff discharges per drainage area in the world. The large magnitude floods on this river are a direct outcomes of severe tropical cyclones implanted within the Indian summer monsoon. The cluster of extreme floods in the past few decades represents an inconsistent strengthening in both the magnitude and frequency of large floods when compared with the 17 ka record of palaeoflood deposits in the basin. Scour line, shrub line, trimlines resulted from erosion of largest(s) floods on the channel margins of the river and its tributaries have served as palaeostage indicators of the recent floods. An investigation of relative magnitude for modern, historical and palaeofloods shows that the present and last century is characterized by very large magnitude floods. The study demonstrates that most of the historical floods and palaeofloods, for which there is some evidence, were smaller in magnitude than the modern floods. The examination further reveals that the floods are clustered in distinct time intervals. There is evidence of clustering in five different periods - (a) 9000 - 7000 BCE, (b) 3000 - 0 BCE, (c) between 1520s - 1720s, (d) Around 1920s, and (e) between 1960s - 1990s. The largest floods between 1960s and 2020s modern record of the Mahi River at the Wanakbori site is 120 yr flood and its tributary the Som River at Rangeli site is 720 yr flood in a probability distribution. A comparison between palaeofloods and gaged record demonstrating the enormous recent increase in the magnitude and frequency of severe floods. This cluster of severe floods of current and last century could reflect changes in either climate or land use or construction of dams. These post-1950 CE floods are thus the largest at least in the Holocene. Numerous palaeoflood studies in tropical-storm regions reveal a similar increase in high-magnitude floods within the past seven decades, suggesting a widespread climatic cause for this pattern.

Session 64: Mapping Ancient Africa: Climate, Vegetation & Humans

When the desert was a lake: Providing context for Homo sapiens development in the northern Kalahari

The Okavango rift zone and delta, and the Makgadikgadi paleo-megalake form a dynamic system in northern Kalahari, where tectonic activity, climate change, sedimentation, and biota have interacted in a complex pattern. Paleogenomics and regional climate modeling studies recently suggested that the region may have been a hotspot for *Homo sapiens* evolution.

Here we present results from the first scientific deep drilling project (OKAMAK) in the northern Kalahari, Botswana. Two drill cores, OKA (230 meters) and MAK (210 m), were drilled in the Okavango delta and Makgadikgadi paleolake, respectively. Cores recovered shallow and deep-water sands, muds and evaporitic lithologies of the Cenozoic Kalahari Group extending across the unconformity into the pre-Cenozoic Karoo Group sandstones.

Focusing on the Quaternary, we discuss stratigraphy and initial multiproxy data, developing chronologies and interpreting the complex climate of the region, history of river piracy, evolution of the delta and infilling phases of Makgadikgadi and assess the international collaborative potential of this yet to be fully understood region.

Paleolakes and socioecological implications of glacial "greening" of the South African interior

Dr. Brian M. Chase [1]***, Dr. Andrew Carr*** [2]***, Dr. Stephen Birkenshaw*** [3]***, Prof. Peter Holmes*** [4]***, Ms. Mulalo Rabumbulu*** [5]***, Ms. Angela Feak*** [6]***, Dr. Brian Stewart*** [6]

1. *Centre National de la Recherche Scientifique, Institut des Sciences de l'Evolution-Montpellier,* ***2.*** *School of Geography, Geology and the Environment, University of Leicester,* ***3.*** *School of Engineering, Newcastle University,* ***4.*** *Department of Geography, University of the Free State,* ***5.*** *Department of Geography Environmental Management and Energy Studies, University of Johannesburg,* ***6.*** *Department of Anthropology and Museum of Anthropological Archaeology, University of Michigan*

Determining the timing and drivers of Pleistocene hydrological change in the interior of South Africa is critical for testing hypotheses regarding the presence, dynamics and resilience of human populations. Combining a suite of new OSL ages and radiocarbon dates with hydrological modelling, we demonstrate the presence of several late Pleistocene palaeolakes and infer regional-scale invigoration of hydrological networks in the South African interior during Marine Isotope Stage (MIS) 3 – particularly 55-39 ka and 34-31 ka – and during MIS 2. The climatic changes required to sustain these hydrological systems would likely have resulted in the replacement of xeric shrubland by more productive higher grass cover vegetation, capable of supporting increased ungulate diversity and biomass. Some support for the latter is found in the existing fauna records. A well-known feature of many of these interior landscapes is the abundance of Middle and Later Stone Age lithic (surface) assemblages. Together these observations contribute to a growing recognition that that Pleistocene interior of South Africa provides an important counterpoint to coastal archaeological and palaeoenvironmental records, and must be considered in wider understandings of climate and human population dynamics through the Pleistocene.

Evaluating refugia in recent human evolution in Africa

Dr. James Blinkhorn [1], ***Ms. Lucy Timbrell*** [2], ***Dr. Matt Grove*** [2], ***Prof. Eleanor Scerri*** [1]

1. *Max Planck Institute for Geoanthropology,* ***2.*** *University of Liverpool*

Homo sapiens have adapted to an incredible diversity of habitats around the globe. This capacity to adapt to different landscapes is clearly expressed within Africa, with Late Pleistocene Homo sapiens populations occupying savannahs, woodlands, coastlines and mountainous terrain. As the only area of the world where Homo sapiens have clearly persisted through multiple glacial-interglacial cycles, Africa is the only continent where classic refugia models can be formulated and tested to examine and describe changing patterns of past distributions and human phylogeographies. The potential role of refugia has frequently been acknowledged in the Late Pleistocene palaeoanthropological literature, yet explicit identification of potential refugia has been limited by the patchy nature of palaeoenvironmental and archaeological records, and the low temporal resolution of climate or ecological models. Here, we apply potential climatic thresholds on human habitation, rooted in ethnographic studies, in combination with high-resolution model datasets for precipitation and biome distributions to identify persistent refugia spanning the Late Pleistocene (130–10 ka).We present two alternate models suggesting that between 27% and 66% of Africa may have provided refugia to Late Pleistocene human populations, and examine variability in precipitation, biome and ecotone distributions within these refugial zones.

Homo sapiens behaviour and adaptation in East Africa. New evidence from an open-air site in a modern Ethiopian savannah environment: the GOT10 site.

Ms. Caterina Aureli [1], ***Mr. Seminew Mogesie*** [1], ***Ms. Marianna Fusco*** [2], ***Mr. Sahleselasie Melaku*** [3], ***Prof. Enza Elena Spinapolice*** [1]

1. *Dipartimento di Scienze dell'Antichità, Sapienza Università di Roma, Italia.,* ***2.*** *Dipartimento di Scienze dell'Antichità, Sapienza Università di Roma, Italia; Department of History and Art History, Universitat Rovira I Virigili, Tarragona, Spain.,* ***3.*** *Authority for Research and Conservation of Cultural Heritage (ARCCH), National Museum of Ethiopia, Addis Ababa, Ethiopia*

The preservation of *in situ* open-air archaeological contexts is often rare, especially for arid landscapes. In East Africa erosion caused by environmental phenomena is one of the principal events that make difficult the preservation of organic and, sometimes, inorganic remains. Moreover, these phenomena may affect the conservation of archaeological stratigraphies making extremely hard the analysis of human occupations. For this reason, when found, organic remains in arid eroded landscapes represent an extremely important proxy for the reconstruction of past human behaviour and occupation dynamics. However, it is still difficult to combine the data with the lack of a secure stratigraphic archive to compare with. The site named GOT10, in the Gotera area, southern Ethiopia, shows a stratigraphic deposit located in a depression of modern savannah environment rich in artefact and faunal remains in primary deposition in association with fireplaces, dated to MIS 3 (ca. 45-42 ka, AMS). The analysis of the GOT10 archaeozoological record - one of the few open-air sites that have faunal remains fairly conserved in the savannah environment - is fundamental to include Ethiopia in the broader debate about site functionality and seasonality, mobility, and environmental exploitation during the late Pleistocene. The faunal remains from GOT10 site come both from the stratigraphic layers (2018 and 2022 fieldwork) and from the collection of surface material (2017, 2018, and 2022 fieldwork) within the Gotera area. Despite the difficult conservation of the faunal remains due to the weathering and the surface contexts, the state of preservation of these materials is good. We propose the case study of GOT10 faunal assemblage for the reconstruction of past human occupation dynamics in a problematic context characterized by both deposits in situ and surface eroded materials.

Pan-African Climate and Vegetation over the Quaternary and Implications for Human Distribution

Dr. Miikka Tallavaara [1], ***Dr. Edward Armstrong*** [2], ***Dr. Kenji Izumi*** [3], ***Prof. Paul Valdes*** [3]

1. *Department of Geosciences and Geography, University of Helsinki,* ***2.*** *Department of Geosciences and Geography of the University of Helsinki,* ***3.*** *School of Geographical Sciences, University of Bristol*

We have constructed a climate-vegetation dataset that spans the Quaternary period using the HadCM3B-C coupled climate model and the BIOME5 vegetation model. We use this to explore the key mechanisms that determined Pan-African precipitation and vegetation change over the Quaternary which we reconcile against observations. We focus on the interconnection of precession-induced North/South variability that constitutes the North African Humid Periods, and East/West precipitation variability which has been hypothesised to be driven by changes in the tropical Walker circulation. We identify the impact from the three key forcings: orbital variations, greenhouse gases, and the ice sheets, and explore how these change through the Quaternary. In addition, based on information on how climate affects hunter-gatherer population densities in modern ethnographic data, we use our climate-vegetation-model data to simulate changes in distribution and abundance of humans in Africa between 400 and 10 ka. Assuming that climate was the main driver of human distribution in the Pleistocene, we explore the idea that there could have been number of core population areas across Africa that have been variously interconnected depending on the prevailing climate conditions.

Middle Pleistocene Vegetation dynamics at Yiapan, a high elevation extra-basinal Site complex: Significance to human behavioral adaptations

Dr. Rahab Kinyanjui [1], ***Dr. Veronica Waweru*** [2], ***Dr. Christine Ogola*** [3], ***Dr. Christine Omuombo*** [4], ***Ms. Husna Mashaka*** [5], ***Ms. Sylvia Wemanya*** [2]

1. Earth sciences department, National Museum of Kenya. Archaeology Department, Max Planck Institute for Geoanthropology, Jena, Germany, 2. Department of Anthropology, Rice University, Houston, TX, USA, 3. Department of Earth Sciences, National Museums of Kenya, 4. Department of History and Archaeology, University of Nairobi, Kenya and Earth sciences department, National Museum of Kenya

Yiapan is a high-elevation mid-Pleistocene site complex dated between ca. 500ka and 60ka. Sedimentary units observed here indicate that the site was near a large water body. At the same time, lithic artifacts point to several technological phases found in multiple successive layers of occupation. The lowest layer is composed of large cutting tools of the late Acheulean period, the middle and upper layers are characterized by smaller tools consistent with hafting (tools with handles) and the use of obsidian sourced from non-local sources. This toolkit shift signals an important behavioral adaptation and cognition that increases as early modern humans emerge. The toolkit choice is often associated with availability/access of raw materials. Prolonged occupations such as the one depicted at Yiapan the suggests stability and accessibility of valuable resources. In this paper, we seek to determine habitats associated with site occupation between ca. 500ka and ca. 400ka during Acheulean phase, which are attributed to archaic Homo sapiens.

We present archaeological and paleobotanical data collected from two occupational layers identified in the stratigraphy profile

Phytolith data from the lower occupational layer is dominated by a mixture of woody- and grass- derived morphotypes. Palms and sedge phytoliths coupled with fresh water diatoms are significantly present in specific levels. This suggests terrestrial landscapes covered with wooded grasslands vegetation type. Fresh water habitats were also present on the landscape that could either be swamps/wetlands or lake, consistent with the preliminary geological data. In the upper layer, woody-derived morphotypes decreases with increased grass phytoliths suggesting reduced canopy habitats associated with MSA toolkit.

Currently, we have zero zooarchaeological data that could shed light on faunal community in the basin. It is not yet clear whether this was just a raw material sourcing- and tool making-site or it is due to taphonomic challenges that did not favor bone preservation at the site. However, this is work in progress, and we hope to get faunal data that can enrich the current palaeobotanical data to accurately determine the kind of ecosystem that is associated with the technological shift noted at the site.

An astronomical age model for Lake Bosumtwi (Ghana) to reconstruct West African climate and environmental change in the last million years

Mr. Mathias Vinnepand [1]***, Dr. Christian Zeeden*** [2]***, Dr. Anders Noren*** [3]***, Dr. Stefanie Kaboth-Bahr*** [4]***, Prof. William Gosling*** [5]***, Dr. Jochem Kück*** [6]***, Dr. Thomas Wonik*** [2]

1. *LIAG, Leibniz Institute for Applied Geophysics, Hannover, Germany,* ***2.*** *Leibniz Institute for Applied Geophysics, Hannover, Germany,* ***3.*** *University of Minnesota, Continental Scientific Drilling Facility, Dept of Earth and Env. Sci., USA,* ***4.*** *University of Potsdam, Institute of Geosciences, Potsdam, Germany,* ***5.*** *University of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics, Amsterdam, The Netherlands,* ***6.*** *GFZ Potsdam, Germany*

Lake Bosumtwi evolved in a 1.07 Ma meteorite crater in Ghana. Due to its climatic and environmental sensitivity in the tension field between the North African Monsoon (humid, wet) and the Harmattan (dry and dusty winds from the Sahara), this limnic archive has been intensively studied. Drilling in 2004, supported by the International Continental Scientific Drilling Program (ICDP), recovered core samples from the complete sedimentary archive. Yet, detailed climatic and environmental reconstructions for the time prior to the last glacial cycle have not been completed, mostly due to the absence of a robust age model. In 2022, we obtained core scanning natural gamma ray data of the ~300 m lacustrine sedimentary sequence. Based on this data, we are generating an astronomical age model that can be directly compared to the independently-dated section of the Holocene and Upper Pleistocene, but extends farther back in time. Our age model will provide critical chronologic context for the numerous existing and new proxy data that illuminate past changes in climate, environment, and ecosystems. This breakthrough will considerably expand our knowledge about the environmental conditions in the cradle of humankind beyond the last glacial cycle.

Late Holocene vegetation and climate of Wonderwerk Cave, South Africa, from charcoal

Ms. Busisiwe Hlophe [1]**, *Prof. Marion Bamford*** [2]

1. *Evolutionary Studies Institute, University of the Witwatersrand, Johannesburg, South Africa,* ***2.*** *University of Witwatersrand, Johannesburg*

The Wonderwerk Cave represents one of the rare cave sites in the arid interior of southern Africa that preserve multiple palaeoclimate indicators, such as pollen, charcoal, and phytoliths. Despite the large amount of charcoal excavated from the Holocene strata, pollen has been the most used indicator for Holocene environmental conditions. Pollen is less spatially precise compared to charcoal, hence this study is aimed to reconstruct the palaeoclimate of the area around the Wonderwerk Cave during the late Holocene by studying charcoal from one of the Late Holocene strata, Stratum 2b, which records the time between 2.3- 0.5 ka cal BP. The second aim of this study is to infer the human-plant interactions that were happening at that time. To do this, a sample of 50 charcoal fragments was studied, the wood they originate from identified, and climate and human-plant interactions inferred from the woody species identified. The sample was found to be dominated by shrubs or small trees that can tolerate dry environmental conditions, such as *Ozoroa paniculosa, Searsia lancea, Brachylaena huillensis, Commiphora sp., Maytenus undata, Olea europaea* subsp. *africana* and *Ziziphus mucronata.* This indicates that the environment was mostly dry. However, the presence of taxa that tolerate wetter environments such as *Heteropyxis natalensis, Olinia ventosa,* and *Berchemia discolor* suggests that rainfall patterns may have been variable. The presence of taxa that commonly grow near river banks suggests that there may have been a water source nearby, similar to Boesmansgat found 15 km from the cave. Overall, the results indicate a semi-arid climate and an open bushveld with a grassy layer, and small woody plants that enabled the humans occupying the Wonderwerk Cave to harvest wood, fruits, and medicine from them.

Palaeoenvironments of the Cape Floristic Region: New research & current developments

Dr. Lynne Quick [1]***, Dr. Saúl Manzano*** [2]***, Dr. Marc Humphries*** [3]***, Dr. B. Adriaan Grobler*** [1]***, Dr. Manuel Chevalier*** [4]***, Prof. Michael Meadows*** [5]***, Dr. Phumelele Gama*** [6]***, Dr. Brian M. Chase*** [7]

1. *African Centre for Coastal Palaeoscience, Nelson Mandela University,* ***2.*** *Área de Botánica, Dept. The Cape Floristic Region (CFR) is a key focus area within southern Africa due to its botanical importance in terms of high levels of biodiversity as well as its rich cultural and archaeological heritage. The area is highly sensitive to cycles of regional and global environmental change, and records obtained from the region provide valuable information regarding past climate variability. Prior to the last decade, few high resolution palaeoenvironmental records were recovered from the region, and its environmental history remains relatively poorly understood. This presentation summarises the research initiatives currently being undertaken by Nelson Mandela University's Palaeoecology Laboratory. This ongoing work aims to provide a comprehensive understanding of climate, biodiversity and human-environment interactions within the CFR, with a particular focus on the understudied eastern subregions.

The records presented are derived from unique natural archives found within the CFR including rock hyrax middens and coastal lowland wetland deposits. These archives are being analysed within a multi-proxy, multidisciplinary framework, using pollen, fungal spores, micro- and macrocharcoal, diatoms and geochemistry to elucidate changes in vegetation, herbivory, fire, hydrology and climate.

This work is designed to actively develop regional capacity, using the new Palaeolab and engage students and early career scientists from the area to contribute to the development of fundamental knowledge regarding their environment and history.

Late Holocene palaeoecological studies at Lake St Lucia, KwaZulu-Natal

Ms. Angela Effiom [1], ***Dr. Frank Neumann*** [2], ***Prof. Marion Bamford*** [1], ***Prof. Enno Schefuß*** [3], ***Prof. Matthias Zabel*** [3], ***Prof. Louis Scott*** [4], ***Prof. Marc Humphries*** [5]

1. Evolutionary Studies Institute, University of the Witwatersrand, Johannesburg, South Africa, 2. Geology, School for Geo- and Spatial Sciences, Faculty for Natural and Agricultural Sciences, North-West University, South Africa, 3. MARUM-Center for Marine Environmental Sciences, University of Bremen, 4. Natural and Agricultural Sciences Faculty, University of the Free State, 5. University of Witwatersrand, Johannesburg

Palynological studies were done on lacustrine sediments deposited during the last ~7000 yrs. BP in Mkhuze Swamp, which drains into the most northern part of Lake St Lucia located in the Indian Ocean Coastal Belt Biome of KwaZulu-Natal, eastern South Africa. The aim was to reconstruct the past vegetation and to infer past climate fluctuations as well as human disturbances to complement growing evidence from other disciplines about these questions in the area. Palynological results shows a dominance of *Podocarpus* (yellowwood tree), other forest elements, marine indicators as well as Chenopodiaceae/Amaranthaceae accompanied by a decline in fungal spores between 7000yrs BP and 3500yrs BP indicating a mesic forested environment with marine influence leading to an increase of the water table along the coast. Regionally, pollen records in Lake Eteza shows similar vegetation change during that period. A peak of Fungal spores and grasses with a corresponding decline in *Podocarpus* and other forest elements and the disappearance of marine elements between 3500yrs BP and 2300yrs BP, signals a drop in water table probably due to evaporation, which was due to an increase in temperature. During the last 1000yrs pollen of *Podocarpus* decreased and a peak of pollen of the woodland tree S*pirostachys* (tamboti), together with strong Chenopodiaceae/Amaranthaceae presence and the appearance of marine elements (scolecodonts and foramenifera linings) suggest a change from a forested environment to an open woodland vegetation and an increase in the salinity of the swamp. Similar pollen fluctuations are found in Lake Eteza and Sibaya. The presence of *Pinus* pollen at the top of the profile suggests the onset of European settlement which were introducing pines for timber production. Regional pollen records in the last ~7000 cal. BP shows a general trend from a mesic forested environment towards an open woodland environment.

Holocene palaeoecological reconstructions of landscape dynamics at the year-round/winter rainfall boundary in the Cape Floristic Region (Southwestern South Africa)

Dr. Saul Manzano [1], ***Prof. M. Timm Hoffman*** [2], ***Prof. Lindsey Gillson*** [3], ***Dr. Brian M. Chase*** [4], ***Dr. Lynne Quick*** [5]

1. *Quaternay Palynology Lab. Universidad de León,* ***2.*** *Plant Conservation Unit, University of Cape Town, South Africa.,* ***3.*** *Plant Conservation Unit, University of Cape Town South Africa.,* ***4.*** *Centre National de la Recherche Scientifique,* ***5.*** *African Centre for Coastal Palaeoscience, Nelson Mandela University*

The Cape Floristic Region (CFR) extends over the SW corner of South Africa, encompassing landscapes that fall under the year-round and winter rainfall areas. Alterations of the present-day rainfall seasonality patterns are expected under projected scenarios of climate change. This accentuates the need to address several fundamental issues regarding the ecological present and future of the highly biodiverse heathlands and shrublands of the CFR. In particular, the drivers of internal biome dynamics and the controlling factors regulating the boundaries of the different biomes (namely the Fynbos and Succulent Karoo).

Here we present the results of a multi-site palaeoecological experiment designed to test the impact of long-term seasonality changes on fynbos-succulent karoo boundaries at the boundary between the winter and year-round rainfall areas of South Africa. Our results show a clear relationship between rainfall seasonality and vegetation dynamics in a high-elevation site, whereas at lower altitudes other factors such as local runoff, ground-water supply and underlying geology seem to be more explanatory of the vegetation at local scales. These transitions can be explained from differential responses of taxa to experimental manipulations of summer rainfall.

High-resolution sedimentary charcoal records of fire link burning, vegetation change, climate, and pastoralism in the Cape Floristic Region, South Africa

Ms. Stella Mosher [1]***, Dr. Mitchell J. Power*** [1]***, Dr. Lynne Quick*** [2]***, Prof. Torsten Haberzettl*** [3]***, Dr. Thomas Kasper*** [4]***, Dr. J. Tyler Faith*** [5]

Physical Geography, Institute for Geography and Geology, University of Greifswald, 4. Physical Geography, Institute of Geography, Friedrich Schiller University Jena, 5. Department of Anthropology, University of Utah

Fire is central to the Cape Floristic Region (CFR)'s highly biodiverse and disturbance-adapted Fynbos Biome. However, prehistoric fire regimes and their ecological consequences remain poorly understood. Here, we use high-resolution sedimentary charcoal records to interrogate links between fire, climate, vegetation, and pastoralism in the Fynbos. We reconstruct fire activity using charcoal particles from two coastal, ecotone lakes – Eilandvlei, a Fynbos-Afrotemperate Forest site experiencing year-round rainfall, and Verlorenvlei, a Fynbos-Succulent Karoo site experiencing winter rainfall. Both records provide exceptionally high continuous-resolution data from 4200 cal BP to the present, spanning the arrival of pastoralism into the CFR ~2,000 years ago. Both records are sufficiently high-resolution to interrogate human impacts on fire, with approximately 2-year time steps at Eilandvlei and 10-year time steps at Verlorenvlei. At Eilandvlei, our preliminary results, spanning the period 4250 to 2200 cal BP, show the highest charcoal influx occurs from 4250 to 3500 cal BP, co-occurring with more frequent, higher magnitude fires and 16-25 years between burns. A significant decline in fire activity occurred around 3400 cal BP, after which fire frequency slowed to 33-66 years between events. At Verlorenvlei, results span 4250 to 3350 cal BP and show charcoal influx, peak magnitudes, and fire frequency are considerably lower and less frequent, with fire activity peaking around 3600 cal BP with 40 years between burns. Fire-vegetation links at Eilandvlei suggest that as fire activity decreased into the late Holocene, fire-adverse Afrotemperate Forest vegetation thrived at the expense of Fynbos. Our data suggest Fynbos fire regimes are more dynamic than indicated by historical observations, and points to the importance of using high-resolution fire histories to understand how climate and human impacts shaped disturbance in the CFR over centuries. Both reconstructions are ongoing and being generated in tandem with experimental burning of known vegetation to establish biome-specific charcoal morphotype and morphometric keys and a near-surface, sub-annual fire history calibration study.

Reconstructing the fire history and palaeoenvironment at Thyspunt, southern Cape coast, South Africa.

Ms. Asithandile Ntsondwa [1], ***Dr. Marc Humphries*** [2], ***Dr. Saul Manzano*** [3], ***Dr. Lynne Quick*** [1]

1. *Botany Department & African Centre for Coastal Palaeoscience, Nelson Mandela University, Gqeberha,* ***2.*** *School of Chemistry, University of the Witwatersrand,* ***3.*** *Área de Botánica, Dept. Biodiversidad y Gestión Ambiental, Facultad de Ciencias Biológicas y Ambientales, Campus de Vegazana, Universidad de León*

With climate change and ecosystem degradation at their peak, there is a conscious need to understand both phenomena. This is to better create mitigation, adaptation, and management strategies not only from a global perspective but also from a regional and local one. The southern Cape coastal region forming part of the Great Cape Floristic Region in South Africa is an example of an area with rich biodiversity and ecological history that needs to be explored further. This is to establish ecological baselines for the region and to better inform conservation and management strategies. Palaeoenvironmental studies can play a crucial role in the management and conservation of biodiversity and landscapes. A more comprehensive look at the palaeoenvironments of the Eastern Cape as a subregion of the Cape Floristic Region through fire reconstruction and sediment analysis is necessary. The need for fire reconstructions from the southern Cape coast is because the dominant vegetation (fynbos) is fire-dependent, and thus vegetation changes are shaped by fire. The fire regimes for this study have been reconstructed using sedimentary micro- and macrocharcoal from a sediment core (TP-1) extracted from Langfonteinvlei wetland at Thyspunt, covering the last 5000 years. The sedimentary characterisation is based on loss on ignition and geochemical analyses which provide better insight into the geological and geomorphic setting, climate history, and sediment properties of the area. The preliminary results from the geochemical data indicate high calcium carbonate composition throughout the sequence followed by very high organic content encompassing the last 500 years. The geochemical data also indicate that the sediments are associated with shallow marine and near-shore depositional environments with a sharp increase in clay content at about 4500 cal yr BP representing a low-energy environment. There are prominent macrocharcoal peaks around 4000 and 200 cal yr BP, with the former peak most likely associated with an increase in wildfires (driven by climate change) and the latter possibly reflecting human influence at that time.

Key terms: Palaeoenvironment, fire reconstruction, southern Cape coast, micro- and macrocharcoal, sediment analysis.

Floristic clues to the origins of the Dahomey Gap from the Ewe-Adakplame forest (Benin, West Africa)

Mr. Alfred Houngnon [1]***, Prof. William Gosling*** [2]***, Dr. Kolawolé Valère SALAKO*** [3]***, Dr. Peter Adeonipekun*** [4]

1. *Association de Gestion Intégrée des Ressources (AGIR),* ***2.*** *University of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics, Amsterdam, The Netherlands,* ***3.*** *Laboratory of Biomathematics and Forest Estimations University of Abomey-Calavi Faculty of Agronomic Sciences,* ***4.*** *Laboratory of Palaeobotany and Palynology, Department of Botany, Lagos (Unilag) University of Lagos: Akoka, Lagos*

The Dahomey Gap, a 200 km wide dry corridor separating the West and Central African rain forest blocks is still largely discussed as an important biogeographic phenomenon. Understanding its origin and evolutionary is a fundamental pre-requisite for an effective conservation and management of the vascular plant species hosted by the remaining forest relics and its related biodiversity. Here, we explore the degree to which the Dahomey Gap has formed a barrier between the diverse forest relics to the west and east and we present the floristic similarity between target forest patches from Ghana, Benin and Nigeria. We anticipate that the grassland dominance of the Dahomey Gap is the more persistent state for the region through the Quaternary and therefore that the current forest patch is a 'relic' from a relatively recent (Holocene) and short-lived (few thousand years) connection between the more ancient diverse forests to the west and east. The dataset contains 376 Species ranked in 267 Genera and 74 Families that are heritage plant species belonging to the Regional Centre of Guineo-Congolian Endemism. Jacquard similarity index at Species level, showed the highest values 0.093 within Nigeria and 0.071 (Benin and Ghana). This trend is confirmed at Genera and Family level showing that the forest relics appear to be floristically similar. Interestingly, our analyses suggest that the Dahomey Gap should not be considered as a strong phytogeographical boundary within the West African forest belt. But rather a consequence of combined effects from past climatic and anthropogenic disturbances. These results are consistent with other studies who placed the floristic boundary of the Upper Guinea further at the Cross River area, eastern part of Nigeria. Then, we can consider that floristic diversity is an important palaeoenvironment reconstruction marker. Also, palaeoecological studies combining Fires and Vegetation are needed to assess human impact on this landscape since the development of an autonomous African metallurgy.

Filling the calibration gap: the importance of modern pollen studies from dry and transitional regions in Africa, and a case study from North-East Namibia

Dr. Adele Julier [1], *Dr. Rosemary Shikangalah* [2], *Dr. Ezequiel Chimbioputo Fabiano* [2]

1. School of Biological Sciences, University of Portsmouth, Portsmouth, 2. University of Namibia

Modern pollen-vegetation relationships are crucial for calibrating our understanding of past ecosystem dynamics as inferred from palaeoecological records. By understanding how vegetation responded to factors such as climate and anthropogenic changes in the past, we can make informed decisions about managing ecosystems for future generations. In Africa, these questions are particularly important as climate change impacts ecosystem dynamics, and changing human activities alter traditional management regimes. It has been demonstrated that modern pollen data from dry and transitional regions in Africa are severely lacking, and efforts are needed to set up monitoring over multiple years in these areas in order to inform palaeoecological reconstructions.

In this study, we present modern pollen trap data from Bwabwata National Park (BNP) in North-East Namibia. BNP is located within the Kavango-Zambezi Transfrontier Conservation Area and is the only national park in Namibia which allows people to live within its boundaries, in multiple use areas. BNP lies within the Sudano-Zambezian floristic region, at the southern extent of the broad leaved tree-shrub savannah biome and experiences a semi-arid climate. The area is currently of particular interest due to oil prospecting, with considerable debate around environmental impacts happening in Namibia on this topic. It is therefore very important to understand long term vegetation dynamics in the region; there are some palaeoecological records but no calibration studies from the area. In this study we use modern pollen data in conjunction with remotely sensed estimates of vegetation cover to calibrate pollen-vegetation relationships. This can then be applied to palaeoecological records from the region to improve our understanding of vegetation change over time.

This pilot study presenting 1 year of pollen data lays the foundations for setting up a network of long-term pollen monitoring plots in Namibia across a range of ecosystems. This will enable us to better understand how vegetation responds to climate and management changes in dry and transitional African ecosystems.

Investigating the potential of high-resolution carbon isotopes in archaeological Protea and Podocarpus charcoal as a rainfall seasonality proxy

Ms. Gemma Dimitra Poretti [1], ***Dr. Vincent Hare*** [1], ***Dr. Alisoun House*** [2], ***Dr. Justin Pargeter*** [3]

1. *Stable Light Isotope Laboratory, Department of Archaeology, University of Cape Town,* ***2.*** *Evolutionary Studies Institute, University of the Witwatersrand, Johannesburg, South Africa,* ***3.*** *African Paleosciences Laboratory, New York University*

Tracking changes in rainfall seasonality is difficult using the materials preserved in the archaeological record. Today, South Africa is uniquely positioned at the interface of both the Indian and Atlantic Oceans and the tropical and temperate climate systems. This produces a distinctive seasonal rainfall gradient that extends over the country: a Summer Rainfall Zone (SRZ) to the east, a Winter Rainfall Zone (WRZ) to the west, and the Year-Round Rainfall Zone (YRZ) occupying the southern coast and interior between them. While existing proxy records have helped elucidate broad shifts in these zones over time and space, high-resolution fluctuations in seasonal rainfall are limited and often qualitatively inferred. This study thus explores an alternative approach to quantitatively reconstruct rainfall seasonality from a ubiquitous yet largely underutilised material: archaeological charcoal. We first investigated whether an established seasonal precipitation proxy showing success in both modern and fossil Northern Hemisphere evergreens can be applied to South African evergreen (*Protea* and *Podocarpus*) wood and charcoal across rainfall zones. Using these results as modern analogues, the proxy was then tested on archaeological *Proteaceae* and *Podocarpaceae* charcoal from the Last Glacial Maximum and late Pleistocene. Successive carbon isotope measurements across the growth axes of the modern wood and charcoal samples produce seasonal amplitudes comparable to local climate data, though with some slight offset. This was hypothesised to result from subsampling resolution effects and/or some input of dry season moisture and/or, in the case of the charcoals, depletion in carbon isotope values with carbonisation. Nevertheless, the ratios of summer to winter rainfall calculated for the modern wood and charcoal samples show that the proxy has significant potential to differentiate between seasonal rainfall regimes. These preliminary results demonstrate the potential of using archaeological charcoals to quantify past seasonal rainfall and, in turn, apprehend the nature of climatic shifts over glacial-interglacial cycles, of importance to late Pleistocene human habitation and cultural trends.

Long-term change in the lowland forests of the Yasuní National Park, western Amazon

Ms. Molly Spater [1]***, Dr. Rommel Montúfar*** [2]***, Dr. Carmen Luzuriaga*** [3]***, Dr. Núria Cañellas-Boltà*** [4]***, Dr. Mª Carmen Trapote*** [4]***, Dr. Rachel Smedley*** [1]***, Prof. George Wolff*** [5]***, Prof. Robert Marchant*** [6]***, Dr. Encarni Montoya*** [4]

1. *University of Liverpool, School of Environmental Sciences, Department of Geography and Planning,* ***2.*** *Pontificia Universidad Católica del Ecuador,* ***3.*** *Universidad Tecnológica Equinoccial,* ***4.*** *Geosciences Barcelona (GEO3BCN-CSIC), 08028, Barcelona, Spain,* ***5.*** *University of Liverpool, School of Environmental Sciences, Department of Earth, Ocean and Ecological Sciences,* ***6.*** *University of York, Department of Environment and Geography*

Uncertainty remains regarding the origin of the high biodiversity found within lowland forests of the Amazon Basin, particularly with regards to legacy impacts of human populations, natural disturbance and ecosystem stability. Current research is challenging the idea of Amazonian forests as untarnished, mature ecosystems, suggesting instead that a more complex patchwork of forests exists in varying stages of recovery from previous perturbations. Uncovering the source, duration and extent of past disturbance is key to understanding modern patterns of biodiversity and is vital to inform vegetation and climate modeling, and direct conservation. The Yasuní National Park, located in northeastern Ecuador, holds some of the highest levels of plant and animal diversity on the planet and is also home to several indigenous groups. Despite the ecological and cultural importance of Yasuní, few palaeoecological studies exist within the region. Here we present the pollen and charcoal analyses of a record taken from a *Mauritia flexuosa* palm swamp spanning the last 3400 years. While rainforest elements were constant throughout the record, a replacement of the dominant taxa *Iriartea* by *Mauritia* as well as the rise in Araceae and *Euterpe* occurred over the last 1500 years. We interpret this change as a transition from seasonally flooded forest to a palm swamp and suggest it was driven by shifts in local hydrology. The importance of local hydrology is further highlighted when comparing results with a nearby 6000 year old sedimentary record that exhibits a similar transition from floodplain forest to palm swamp. These cores document late Holocene forest history and river migration or flooding, which in addition to the ecological consequences, could have influenced patterns of human occupation, as human presence is evidenced in local archaeological works nearby.

Human ancestors dispersal : the role of climate changes in Africa during late Pliocene

At the end of the Pliocene, before the triggering of the Greenland ice sheet, while CO_2 was around 400 ppm, we explore the potential dispersal of *Australopithecus* via the Genus' fossil record and climate and ecological niche modeling. In Africa, tropical areas experienced drastic hydrological changes that were mainly driven by precession cycles, which deeply modulate monsoon intensity and patterns. An illustration of such hydrological variability is the evolution of Mega Lake Chad. To explore to what degree strong climate modifications occurring over tropical Africa could have modified hominin dispersal, we simulated the response of climate, vegetation, and hydrological cycles of the mid to late Pliocene (4–3 Ma) to astronomical forcing. We provide a series of Earth System models (IPSLCM5A2) associated with high resolution simulations using only the atmospheric component, coupled with a dynamical vegetation model (ORCHIDEE), both of which were used to estimate ecological niches with a spatial resolution of 50km.
Our results indicate that:
1. Four regions appear as suitable habitats for hominins. Three of them correspond to regions with a documented fossil record: East Africa, the Chad lake basin, and South Africa, whereas, in the fourth, Northern Africa, no hominin fossils have yet been documented for this period.
2. Some regions remain suitable to hominins during full orbital cycles and, therefore, may be qualified as refugia, especially the Turkana region in Eastern Africa and Southern Africa.
3. A corridor between South and East Africa is not always available for dispersal. In contrast, there is a continuity between East Africa and the Lake Chad Basin.
This study pinpoints the important role of the tropics in climate changes over Africa.
We will present the strength and limitations of such approaches, which were made possible through a large trans-disciplinary effort between paleontologists, paleoenvironmentalists, paleoclimatologists, and niche modelers.

Modelling malaria spread in the Late Pleistocene

***Dr. Margherita Colucci* [1], *Dr. James Blinkhorn* [1], *Prof. Andrea Manica* [2], *Prof. Eleanor Scerri* [1]**

***1.** Max Planck Institute for Geoanthropology, **2.** University of Cambridge*

Malaria is a major widespread disease that led to the rise of resistance mutations in the human genome (e.g. sickle-cell disease) and its worldwide incidence is strongly driven by factors contributing to the Anthropocene, particularly in the tropics. These include increasing human population density and urbanisation, with significant impact from environmental factors. For example, changes in environment due to anthropogenic land use and land cover modifications influence the choice of the *Anopheles* vector's breeding location (varying species prevalence, survival, adaptation and proliferation), feeding habits (zoophilic-to-anthropophilic shift) as well as the climate, an important factor for vector's spatial distribution range. Individual sibling complex show different relationships with climatic factors, which affect the development of both the parasite and the mosquito. All these aspects may favour an increase of malaria transmission, yet mutations in the human genome indicate that selection pressures pre-date urbanisation, and originate in an allegedly environmentally "pristine" past.
This paper investigates the possible impact of anthropogenic alterations of the environment on malaria incidence around 25-22 thousand years ago (KYA)/in the late Pleistocene in West and Central Africa. It considers whether human behaviour created the conditions for the *Anopheles* vector species to thrive and, therefore, shaped and catalysed the spread of malaria.
We model the distribution of three vectors (*An. gambiae, An. funestus and An. coluzzii*) and their sibling groups, examining environmental and climate changes and signatures of human activity. This project combines several aspects to model the interactions between the environment, malaria vector and human factors. It brings together paleoclimate and environmental data, epidemiological information, vector and human distribution data, as well as human intervention on the environment, ultimately testing whether a "Deep Anthropocene" in the tropics has shaped a major global health burden.

Uncovering human-megafauna interactions in the drowned caves of the Yucatan Peninsula, Mexico.

Dr. Oscar R. Solís Torres [1], ***Dr. Joaquín Arroyo-Cabrales*** [2], ***Dr. Noel Amano*** [3], ***Dr. Patrick Roberts*** [3]

1. Max Planck Institute for Geoanthropology, 2. Instituto Nacional de Antropologia e Historia, 3. isoTROPIC Research Group, Max Planck Institute for Geoanthropology

The Yucatan Peninsula is a massive, kilometres-thick carbonate platform situated in southeastern Mexico. Drainage systems in the area produce a flat topography where no surface rivers flow. Karstification and surface permeability have led to the formation of one of the most extensive active underground cave systems in the world. During the Last Glacial Maximum the peninsula was higher and the sea level more than 100 m lower than today, meaning that many of these caves were dry and accessible until the middle Holocene. Cold and dry climate conditions prevailed during the LGM and beyond, with a significant reduction of forest biomes occurring at 13000 - 8000 cal BP. From 8,000 years ago, warmer and wetter conditions, alongside a rise in sea level, resulted in cave submergence and an expansion of the present-day tropical and sub-tropical vegetation of the region. Given its record of human presence throughout this period, the sites of this region present the possibility to explore the varying impacts of climatic change and human presence on different megafaunal populations. These caves have been documented as providing well-preserved paleontological records in submerged, secure contexts. Nevertheless, there has been limited taphonomic and scientific work undertaken on these remains. Here we present the preliminary results of a multidisciplinary analysis of megafaunal remains uncovered from the drowned caves of the Yucatan Peninsula. We have applied taphonomy (including cutmark analysis and site formation studies), radiocarbon dating, palaeoproteomics, and stable isotope analysis to megafaunal remains from the caves in the Cenote Iza, Cenote Papakal, Cenote Ziizha, Cenote Izah, Cenote San Antonio, Taj Mahal cave, Cenote Sifa and, Cenote Las Palmas to assess the interactions between our species and megafauna in this region and to build up more detailed records of megafaunal chronology and ecology in a little-studied portion of the Americas. Contextual and geochronology framework for these remains supports the hypothesis that the cave systems in the peninsula were accessible for much of the last glacial period, serving as natural traps for animals and people.

Land-use changes and human-environment interactions in the Maya Lowlands of Belize during the post-Classic and colonial periods

Dr. Shawn O'Donnell [1]***, Dr. Joanna Tindall*** [2]***, Prof. Bronwen Whitney*** [3]***, Prof. Sarah Metcalfe*** [2]***, Dr. Elizabeth Rushton*** [4]***, Prof. Julie Hoggarth*** [5]***, Prof. Jaime Awe*** [6]

1. *Department of Geography and Environmental Sciences, Northumbria University, Newcastle-upon-Tyne, United Kingdom,* ***2.*** *School of Geography, University of Nottingham, University Park, Nottingham, United Kingdom,* ***3.*** *Geography and Environmental Sciences, Northumbria University, Newcastle, UK,* ***4.*** *Department of Curriculum, Pedagogy and Assessment, University College London, United Kingdom,* ***5.*** *Department of Anthropology, Baylor University, Waco, Texas, USA,* ***6.*** *Department of Anthropology, University of Northern Arizona, Flagstaff, Arizona, USA*

The ancient Maya of tropical Mesoamerica are amongst the best-studied cultures across the globe, including research focused on socio-environmental dynamics. Several regional palaeoclimate records from speleothems and lake sediments indicate drought and hydroclimatic instability during the spatio-temporally heterogenous Terminal Classic Decline (TCD) ~750–1100 CE, when monumental construction at many Classic Maya sites ceased. Following the TCD, many populations appear to have shifted to coastal or inland locations with direct access to water. While the Classic Maya are known to have managed scarce surface water resources across this limestone-dominated region to support their cultivation of maize, squash, beans and sweet potato, they also tended and exploited forest and savanna resources including palms and pines for food, construction materials and fuel. How the Maya adapted their land-use strategies in the post-Classic, especially in areas where the archaeological record suggests continuity of habitation, has received little attention. Additionally, in the Belizean portion of the Maya Lowlands, palaeo-data have rarely been used to examine socio-environmental dynamics during subsequent phases of Spanish and British colonialism. During these periods, local economies were driven by extraction and export of forest resources such as logwood, mahogany and chicle, followed in the twentieth century by diversification to include bananas, citrus and sugarcane. Here, we present the first pollen and macrocharcoal records from the Belize River Valley, from a sediment core from Laguna Castillo, a small oxbow of the Mopan River near to the Classic Maya temple and ceremonial centre of Cahal Pech. From these data, and new palaeolimnological and archaeological data, we infer local land-use changes from the Maya post-Classic through the Spanish and British colonial periods. We compare these results with coeval data from the New River Lagoon in northern Belize, location of the Classic Maya temple site of Lamanai which also shows continuity of habitation after the TCD.

An 8,500 year record of vegetation change, climate, and human impacts from Baie des Baradères, Haiti, using pollen analysis and XRF core scanning

Mr. Cesar Arturo Vera Florez [1], ***Dr. Matthew Peros*** [2], ***Mrs. Sydney Moser*** [3], ***Dr. Simon Pendleton*** [4], ***Dr. Jeffrey Donnelly*** [5], ***Dr. André Viau*** [3], ***Dr. Andrea Hawkes*** [6], ***Dr. Chad Lane*** [7], ***Dr. Pete van Hengstum*** [8]

The Insular Caribbean is a region sensitive to multiple climate stressors, including hurricanes, droughts, and sea-level changes. Such is the case for Haiti, a country located in the circum-Caribbean region, that has also been affected by extensive anthropogenic land use, rendering much of its landscape devoid of vegetation, and increasing its vulnerability to erosion and floods. Despite this, there is limited long-term environmental data from Haiti to provide critical baseline data to assess modern-day and future environmental risk.

To address this, pollen identification and analysis was undertaken from a sediment core collected from Baie des Baradères, a shallow bay adjacent to the delta of the Baradères river, to reconstruct vegetation and climate changes, as well as human impacts, in the area during the last 8,500 years. We also used high-resolution XRF core scanning to document the sedimentary context of the core and distinguish between inputs of terrestrial and marine-derived materials. The chronology of the core was established with over 25 AMS dates.

The results show that at the base of the core (from 8,500 to ~4,000 cal yr BP), mangroves and other coastal plants were dominant, whereas they decrease in abundance towards the core top, possibly representing sea level rise and a migration of the coastline farther from the core site. An abrupt increase in elemental titanium occurs in at least seven portions of the core beginning about 2,500 cal yr BP, and may represent an influx terrestrially-derived sediments into the bay from the nearby Baradères river. While our results are still preliminary, these events may be associated with precipitation from hurricane impacts, and the pollen from these sections is associated with high levels of Asteraceae and ferns, reflecting disturbance to the local landscape. Finally, large quantities of fern spores and herb pollen such as Asteraceae, Amaranthaceae, and *Borreria* are dominant in the upper sediments of the core, and likely reflect extensive human-impacts on the Haitian landscape over the last few hundred years. This project represents one of the few pollen records available from Haiti, and helps fill a large spatial gap in such records from the insular Caribbean.

One million years of tropical vegetation and fire from a biological and climate hotspot

Dr. Janelle Stevenson [1], ***Dr. Rebecca Hamilton*** [2], ***Dr. Marco Coolen*** [3], ***Mr. Akhtar-E Ekram*** [3]

The Lake Towuti Drilling Project (Sulawesi, Indonesia) is located in the Indo Pacific Warm Pool, home to the world's warmest oceanic waters and a globally important driver of climate. Sulawesi is also part of Wallacea and a place of enormous biological diversity.

Through the drilling project, we have developed parallel records of palaeovegtation for the last million years using pollen, charcoal, ancient chloroplast DNA (cp aDNA) and compound specific stable isotope analyses of leaf waxes ($\delta 13C_{wax}$).

The early part of record reflects the rifting that took place one million years ago and the evolution of a swampy valley bottom to the deep lake that is modern day Lake Towuti. Importantly it shows a constantly forested landscape with compositional changes appearing to follow orbitally driven changes on glacial interglacial timescales and linked to fire.

Major findings include:

- Forest covered lowland Sulawesi over last one million years.
- Compositional shifts driven by glacial scale climate change and fire.
- Fire is present throughout the record, although most abundant from 60 ka to 12 ka.
- Dipterocarps disappear with an increase in fire at 60 ka
- Implications for understanding their biogeography in the region
- Forest reorganisation and lake level proxies suggest driest conditions from 40 ka to 12 ka.
- 31 ka to 17 ka appears not only drier but more seasonal – contraction of montane gymnosperms.
- The last 45,000 years stands out as different to anything in the preceding ~950 ka.

Food production drove environmental and demographic changes over the Holocene in Western Africa

Dr. Andrea Kay [1]***, Dr. Fabio Silva*** [2]***, Dr. Patrick Roberts*** [3]***, Prof. Jed Kaplan*** [4]

1. Department of Archaeology, Max Planck Institute for Geoanthropology, 2. Bournemouth University, 3. isoTROPIC Research Group, Max Planck Institute for Geoanthropology, 4. The University of Hong Kong

There are strong inferred demographic patterns associated with changes in food-production and environment over the last 5000 years in western Africa. Neither food production strategy nor environment alone are enough to explain past demographics for the entirety of the Holocene. Only when multiple proxies are examined can we tease out the complex human-environment relationships of the past and the shifting locus of anthropogenic activity. Land-use is an often-overlooked aspect of human-environment interactions, which can have significant impacts on both demography and land cover. While the cyclical nature of human-environment relationships can make discussions of causality complex, land use is a critical element to understanding how past societies have left landscape legacies that are still relevant to Earth system's today.

In West and Central Africa, an area with some of the world's most threatened tropical forests, the degree to which climate or humans drove major past changes in vegetation, have been debated. Many scholars have seen humans as opportunistic agents, rapidly moving into areas that were good for farming and avoiding the supposed 'barriers' of rainforests until they were naturally reduced by mid-Holocene climate change. On the other hand, it has been proposed that humans were the cause of major changes in rainforest extent and distribution, including the Late Holocene Rainforest Crisis (LHRC), in parts of West and Central Africa. While the cause is most likely to be some combination of extreme weather events and land-use, the impacts being debated had knock on effects for the continental carbon cycle, soil erosion, vegetation and climate as well as major population movements and the spread of farming to the rest of Africa.

Here, we present a Per Capita Land-Use (PCLU) approach that models the interconnected nature of demographic trends and socio-environmental systems over the long-term in West and Central Africa. We focus on two different but interconnected dynamics: 1) changes in human demography relative to changes in both food-production and climate, and 2) the potential environmental impact of these observed land-use and demographic trends.

Session 80: Magnetostratigraphy and Environmental Magnetism contribution to understand paleoclimatic and paleoenvironmental changes

The use of paleomagnetism as a dating and correlation tool of Quaternary sequences: strengths and limitations

Dr. Leonardo Sagnotti [1]

1. *Istituto Nazionale di Geofisica e Vulcanologia (INGV)*

The Earth's magnetic field variations due to geodynamo processes inside the liquid outer core span time scales of geologic interest, extending from centuries (e.g., paleosecular variation – PSV), millennia (e.g., geomagnetic excursions and polarity reversals), tens of thousands years (relative paleointensity stratigraphic trends - RPI), up to tens of millions years (changes in the frequency of occurrence of geomagnetic field reversals). These variations are recorded and preserved in sedimentary and volcanic rocks. In the past decades, the chronology of peculiar geomagnetic features that occurred during the Quaternary has been defined in an increasing detail, allowing the definition of a "Geomagnetic Instability Time Scale" (GITS) now extending to the last 2.8 million years and thus providing an original tool for dating and correlating Quaternary stratigraphic sequences at high resolution.

Though the mechanisms of acquisition and preservation of a natural remanent magnetization in rocks can be complex and are presently only partly understood (especially for sediments), the reliability of the paleomagnetic signal can be checked and tested through a series of independent rock magnetic and stratigraphic methods.

In this talk, I will discuss some case studies illustrating strength and limitations of paleomagnetism to the development of Quaternary stratigraphy. In particular:

- The use of PSV and RPI stratigraphic records for dating and correlating sedimentary sequences in polar regions (where other classic proxies for dating and correlating sequences may be poorly represented or even totally absent), spanning the last tens to hundreds thousands years;
- The effects of a variable lock-in depth and diagenetic processes in sediments and their implications for achieving high-resolution paleomagnetic dating and correlation;
- The characters and consistency of paleomagnetic records preserving details of fast and wide geomagnetic variations such as geomagnetic excursions and full polarity reversals, with a particular emphasis on the Matuyama-Brunhes reversal, which is the most recent and well documented full reversal of the Earth's magnetic field and has an outstanding importance for the definition of a Quaternary Time Scale.

Paleomagnetic and 10Be records across the Pleistocene and Pliocene geomagnetic polarity transitions from the Boso Peninsula, central Japan

Dr. Yuki Haneda [1], ***Dr. Yusuke suganuma*** [2], ***Dr. Hiroto Kajita*** [3], ***Dr. Masayuki Utsunomiya*** [1], ***Prof. Makoto Okada*** [4]

1. *Geological Survey of Japan,* **2.** *National Institute of Polar Research,* **3.** *Hirosaki University,* **4.** *Ibaraki University*

The geomagnetic polarity reversals have occurred repeatedly in the geological eras, and are recorded in sediments and lavas almost contemporaneously, providing significant stratigraphic markers to constrain ages of strata and correlate strata in remote areas. However, complex structures of the geomagnetic polarity reversals and the process by which sediments acquire remanence would make age offset between remote sites. Therefore, reconstructing past geomagnetic polarity reversals is significant not only for elucidating the mechanism of the reversal, but also improving the age constraint of sediments. Here, we provide preliminary paleomagnetic records with ^{10}Be data which is a proxy of the geomagnetic field intensity across the lower and upper Mammoth transitions (late Pliocene), and lower Jaramillo transition (early Pleistocene) from on-land marine successions in the Boso Peninsula, central Japan. These transitions are known to have occurred during periods warmer than the preindustrial and thus are significant stratigraphic marks for paleoclimatic and paleoceanographic studies. Structures of the geomagnetic polarity transitions will be discussed by comparison to the paleomagnetic and ^{10}Be records across the Matuyama–Brunhes transition in the Chibanian GSSP site.

Can Optically-Stimulated Luminescence (OSL) Techniques Detect Reductions in Geomagnetic Field Intensity? A Case Study from Lake Suigetsu, Japan, across the Laschamp Excursion

Dr. Richard Staff [1]***, Prof. David Sanderson*** [1]***, Ms. Charlie Rex*** [2]***, Prof. Masayuki Hyodo*** [3]***, Dr. Ikuko Kitaba*** [4]***, Ms. Vanessa Nowinski*** [5]***, Dr. Gordon Schlolaut*** [6]***, Dr. Keitaro Yamada*** [4]***, Prof. Takeshi Nakagawa*** [7]

__1.__ Scottish Universities Environmental Research Centre, __2.__ University of Glasgow, __3.__ Kobe University, __4.__ Research Centre for Palaeoclimatology, Ritsumeikan University, __5.__ University of Adelaide, __6.__ Helmholtz Centre Potsdam, German Research Centre for Geosciences GFZ, __7.__ Ritsumeikan University

The most recent polarity reversal of Earth's magnetic field, the 'Laschamp Excursion', occurred ~41,000 years ago, with an accompanying dramatic weakening of the magnetic field intensity during the preceding and subsequent transitions in to and out of the reversal itself. Records of 10Be (principally, the Greenland ice-cores) and 14C (including tree-ring data series), both cosmogenic nuclides, demonstrate increased production rates at this time when the weakened geomagnetic field allowed greater penetration of solar and cosmic radiation into Earth's upper atmosphere. It follows that increased extra-terrestrial radiation receipt would also reach the Earth's surface, and Cooper et al. (2021; Science 371, 811–818) recently postulated that such effects could have resulted in "major environmental changes, extinction events, and transformations in the archaeological record".

In the present study, we investigate whether such an increase in ground-level radiation receipt is detectable in terrestrial sediment records using optically-stimulated luminescence (OSL) techniques. To this end, we utilise the varved sedimentary profile extracted from Lake Suigetsu, central Japan, a truly world-leading archive of palaeoclimatic and palaeoenvironmental change. We present contiguous Portable OSL (POSL) measurements (n = 235) spanning ~45,000 to 35,000 cal BP, and compare these with the published high (21 year) resolution palaeomagnetic dataset from Suigetsu produced by Hyodo et al. (2022; Communications Earth & Environment 3, 79).

Supporting palynological, µXRF, and thin-section microscopy data from Suigetsu support climatic and/or environmental correlations with our POSL dataset, with minerogenic properties controlling the luminescence signal. The most marked single event identified within our dataset relates to a major earthquake ~39,200 cal BP, which resulted in re-routing of inflow to the lake. A superimposed relationship between the luminescence profile and geomagnetic intensity remains tantilising, and we shall focus on this discussion in the conference presentation.

Indian Summer Monsoon variability during the Late-Holocene in southern India: Evidence from lacustrine sediments

Ms. Reshma K V [1], ***Dr. Sandeep K*** [2], ***Mr. Aravind G H*** [3], ***Ms. Gayathri S J*** [4], ***Dr. Anish Warrier*** [5]

1. *Research scholar, Central university of Kerala,* ***2.*** *Assistant professor, Central University of Kerala,* ***3.*** *Research Scholar, Central University of Kerala,* ***4.*** *Student- Central University of Kerala,* ***5.*** *Assistant professor, Manipal Institute of Technology*

Geological archives like lake sediments can provide direct evidence of the past variability of rainfall on a local or regional scale, with a relatively high temporal resolution. In the present study, environmental magnetic (magnetic susceptibility) and Fourier Transform Infrared (FTIR) spectroscopic analyses were performed on sediment samples of Cheppandikere lake (CK), southern India to decipher palaeorainfall variations in the region. The 56.5 cm long sediment core is constrained by 4 AMS ^{14}C dates. The magnetic susceptibility data indicates the fluctuations in the rainfall during the past 1700 years. Some of the mineral components identified using FTIR spectroscopic analysis include quartz, orthoclase, microcline, kaolinite, montmorillonite, hematite, calcite and organic carbon. Principal Component Analysis was carried out on FTIR data from which, three components (PC1, PC2 and PC3) are identified. The variations in the PC1 scores may reflect the changes in terrigenous influx to the lake, which in turn is dependent upon monsoon. PC2 scores are interpreted to be authigenic factor and PC3 is interpreted to be aridity factor. Both rock magnetic and FTIR data indicates the presence of three climatic phases during the Late Holocene period. the period ~1700 - 1250 cal. years B.P. is characterized by high rainfall. During ~1250 to 833 cal. year B.P., moderate rainfall is documented. Whereas, and period ~833 cal. Year B.P. to present are characterized by decreasing trend.

Late Miocene sedimentary chronology and paleoclimate significance of the Jianzha Basin in the northeastern margin of the Tibetan Plateau

***Prof. Chaofeng Fu* [1], *Mrs. Lin Chen* [1], *Mr. Yanfeng Yang* [1], *Prof. Xiaoke Qiang* [2]**

1. School of the Earth Sciences and Resources, Chang'an University, Xi'an City, Shaanxi, CHINA, 2. State Key Laboratory of Loess and Quaternary Geology, Institute of Earth and Environment, CAS, Xi'an City, Shaanxi, CHINA

Jianzha Basin is located in the northeastern part of the Tibetan Plateau and contains a thick sequence of Cenozoic sediments which are crucial for investigating the growth of the Tibetan Plateau and the record of the evolution of the Asian inland arid environment. Magnetostratigraphic results show that Late Cenozoic sedimentary sequence from the Jianzha Basin has recorded a continuous geomagnetic polarity sequence from C5r.3r to C3r, the section spans the interval from 11.8-5.8 Ma in the Late Miocene. Based on the high precision paleomagnetic dating framework and frequency susceptibility index (χ_{fd}), the cycle stratigraphy of Jianzha Basin was studied, whose results show the χ_{fd} of the deposit sediment displays a significant periodic change at around 7.2 Ma, which the record reveals that the East Asian summer monsoon (EASM) is dominated by 41 ka obliquity period before ~7.2 Ma and controlled by 100 ka short eccentricity period after 7.2 Ma. Spectral analysis of oxygen isotope records of benthic foraminifera from the South China Sea shows strong short eccentricity period and weak obliquity period between ~5.8 and ~7.2 Ma, and strong obliquity period and weak short eccentricity period between ~7.2 and ~11.8 Ma, which is consistent with the spectral analysis of frequency susceptibility (χ_{fd}) from the Jianzha Basin. In addition, it is found that the EASM climatic transition from 100,000-year orbital period to 40,000-year obliquity period occurred around 7.2 Ma, which is similar to the climatic transition around 0.9 Ma in the Middle Pleistocene. Therefore, the climate change result will provide a new similar model for predicting future monsoon climate changes. This study was supported by the National Natural Science Foundation of China (Grants 42272221, 41772167); and supported by projects funded by the Second Tibetan Plateau Scientific Expedition (STEP) program (2019QZKK0704); and supported by the Central University Research Foundation, Chang'an University (Grants 300102272901).

Session 82: Data science and paleoecology: current intersections and advances

Applying statistical thinking to palaeo data through generalized additive models

Dr. Gavin Simpson [1]

1. Department of Animal and Veterinary Sciences, Aarhus University

Palaeoecological and palaeoenvironmental stratigraphic data exhibit a number of features that make them complex to analyse; for example they i) are autocorrelated in time (and, potentially, also in space), ii) are generally irregularly spaced in time, and iii) have complex variance properties due to time averaging and sampling processes.

This complexity has some unfortunate consequences. All too often, data are not subject to any form of statistical analysis, and, when they are, often that analysis uses inappropriate statistical methods. Furthermore, analysts will often invent their own ad hoc approaches to get answers to their specific questions. The statistical properties of such ad hoc approaches are rarely known, however.

A number statistical methods have been developed over recent years and decades that can handle the complex needs of palaeo data. Among these methods is the generalized additive model (GAM) and related extensions. The use of GAMs to model temporal trends in palaeo data has increased steadily in recent years, thanks, in part, to the availability of high quality, open source software like the R package mgcv. GAMs are relatively simple models that will be familiar to anyone who has taken a graduate course in ecological statistics, and yet GAMs are incredibly versatile models that can be adapted to suit many pressing questions that palaeo scientists wish to address.

In this talk I will briefly introduce GAMs and show how penalised splines, which underpin the GAM, work, before moving on to cover some recent developments from my own work that extend GAMs to new areas and questions. In particular, I will discuss; i) models that go beyond the mean to investigate trends in other moments, such as variances of palaeo time series, ii) using derivatives of splines fitted in a GAM as estimates of rates of change in palaeo time series, and iii) copula GAMs that can estimate how the correlation between two variables itself changes over time. In each case I present a relevant motivating example and supplement the talk with fully worked examples in R that are available on GitHub.

Understanding the drivers of vegetation change in the Southern Rocky Mountains with paleobotanical records and a forest landscape model

Dr. Paul Henne [1], ***Dr. Robert Thompson*** [1], ***Ms. Laura Strickland*** [1], ***Dr. Lesleigh Anderson*** [1], ***Mr. Richard Pelltier*** [1], ***Mr. Jacob Slawson*** [1]

1. *United States Geological Survey*

The lower montane ecotone of the Rocky Mountains in western North America is a mosaic of forest, woodland, shrubland, and grassland where trees exist near their limits in drought tolerance. Widespread tree mortality during recent droughts and local limitations in regeneration following wildfire may presage extensive conversion of forests to shrublands and grasslands in a warmer and drier future. However, understanding of the temporal dynamics among climate, disturbance, and vegetation is limited by a paucity of paleoecological records from unglaciated lower montane ecosystems. Furthermore, historical records and inventory plots provide a short window to evaluate models capable of projecting vegetation change. We are addressing these challenges by combining new pollen, macrofossil, charcoal, and oxygen isotope data from Blue Lake, Colorado USA (2540 m a.s.l.) with simulations from the LANDIS-II forest landscape model. Our modeling approach tests competing hypotheses that account for past vegetation change to understand long-term interactions among climate, disturbance, and vegetation on a scale that is relevant to ecosystem management. Sediment began accumulating at Blue Lake following a landslide ca. 9000 cal yr BP. Pollen data indicate that mixed coniferous forests with abundant pine (up to 50%) grew near Blue Lake during the middle Holocene. Macrofossils demonstrate the local presence of *Pinus ponderosa*, a species presently limited to riparian settings ~400 m lower in elevation that does not form extensive stands in the interior of the Rocky Mountains today. *Pinus* declined after 6000 cal yr BP, contributing 10 – 20% of the terrestrial pollen sum after 4000 cal yr BP, when increasing Poaceae and *Artemisia* pollen indicate a more open environment with forest patches of *Pseudotsuga* and *Picea.* A contemporaneous decrease in calcite $\delta^{18}O$ may indicate the declining abundance of summer rain. LANDIS-II simulations of vegetation surrounding Blue Lake suggest warmer summers with more abundant summer precipitation supported stands of *Pinus ponderosa* in a mixed coniferous forest before 6000 cal yr BP. Our combined paleoecological/modeling approach implies that future summer moisture availability and the strength of the North American Monsoon will be important determinants of the resiliency of forests in the lower montane ecotone of the Rocky Mountains.

Automatic recognition of pollen and spores in (sub)fossil pollen samples

Dr. Martin Theuerkauf [1]***, Mr. Alexander Gillert*** [2]

1. Institute of Botany and Landscape Ecology, University of Greifswald, Germany, *2. Fraunhofer Institute for Computer Graphics Research IGD, Rostock, Germany*

Manual pollen analysis is labour-intensive and expensive. Hence, attempts to automate pollen analysis have a long history, yet only appear feasible with the advent of modern deep learning techniques. Recent studies report progress in the automated classification, i.e. the identification of prepared pollen grain images.

As one step further, we explore automated pollen and spore analysis in true samples from lake sediments. Such approach requires not only classification but also the detection of pollen grains in the sample matrix. We therefore use a 2-stage artificial neural network model: The first stage, a Faster R-CNN object detector, is trained to detect the location of pollen grains in the sample matrix without further classification. The second stage, a MobileNetV3 image classifier, uses higher resolution image crops to identify those pollen grains located in the first stage.

The algorithm has been trained using ~20,000 manually labelled pollen slide images with about 20,000 labelled pollen grains and non-pollen objects. The images have been scanned as z-stacks with at least 5 focus layers. Our image classifier uses the best focus layers for pollen identification. Tests proof that our approach is well able to locate pollen grains (step 1) while success of identification (step 2) differs among pollen types. Recall and precision are promisingly high (>90%) for the pollen types most abundant in the training data, yet is still poorer for rarer pollen types. We illustrated to usefulness of the approach in two examples. The first is a specialized application, aiming to determine masting years of beech in an annually resolved, 300 year pollen record from Western Poland. In the second example we use automatic pollen counts to refine an existing pollen record from NE-Germany to 1-cm resolution. Based on these result we discuss suitability of our approach to complement manual pollen counts.

Establishing FAIR Data Resources as Key Elements in Data Science Approaches

***Ms. Socorro Dominguez Vidana* [1], *Dr. Simon Goring* [2], *Dr. Jack Williams* [3], *Prof. Jessica Blois* [4], *Prof. Jonathan Nelson* [3], *Mr. Steve Crawford* [5]**

1. HT-Data Consulting, 2. University of Wisconsin-Madison, 3. University of Wisconsin Madison, 4. University of California-Merced, 5. Penn State University

Charles Babbage – one of the founders of modern computing, along with Ada Lovelace – was asked ‘Pray, Mr. Babbage, if you put into the machine wrong figures, will the right answers come out?’ This question highlights an essential and persistent challenge for data science: ensuring transparency of scientific workflows and analyses. Data Science approaches often depend on large volumes of data as inputs, and may involve “black-box” numerical approaches for analysis. Given the data volume and workflow complexity, understanding the underlying data, and the workflows employed within these models is critical for understanding the ultimate output and their interpretive limits. The community-wide push towards FAIR scientific approaches are broadly intended to enhance both data accessibility and transparency, through the specific goals of Findability, Accessibility, Interoperability and Re-Use (Wilkinson et al., 2016).

Paleodata resources, such as the Neotoma Paleoecology Database, the Paleobiology Database, LinkedEarth and the PaleoFire Database, play a critical role achieving transparent and open paleoscientific research by supporting activities including data retrieval and augmentation, stewardship and storage, and laying the foundation for open and well-documented open scientific workflows.

Neotoma’s implementation of FAIR principles extends equally across all aspects of research, data stewardship, citation, and educational outreach. The implementation of Digital Object Identifiers and linked-data landing pages have made data findable and accessible across a number of platforms, including Google’s Dataset Search. Reproducible and accessible online tutorials have improved the delivery and open sharing of educational materials. Investment in open-science workflows as part of the R package development has promoted the use of reproducible workflows in the Quaternary Sciences. As a case study, we will showcase the way each of these elements relate to researchers working with vertebrate fauna. Future steps include efforts to advance the ethical sharing of open data, as elucidated by the CARES principles (Carroll et al., 2020) and enhanced support for additional paleoecological data types such as aeDNA and isotopic data to support multi-proxy ecological research advances in the Quaternary Sciences.

What do we know about mammal diet? How individual diet records can be used to unpack cross-scale processes.

Dr. Dana Reuter [1], ***Dr. Robert Guralnick*** [2], ***Dr. Michelle Lawing*** [3]

1. University of Oregon, 2. Florida Museum of Natural History, University of Florida, 3. Texas A&M University Department of Ecology and Conservation Biology

Organismal diet is an integral part of understanding ecology and evolution because it is how an organism obtains energy. Over the last 20 years, many datasets have provided wide coverage of the diets of mammals. Mammals occupy a wide range of niches, and studying them using these datasets has been instrumental in expanding our knowledge of how diet is related to many ecological and evolutionary processes. These databases have also been key for reconstructing the diets of extinct species and studying community structure changes in the past. These databases, however, do have limitations, as diet is difficult to characterize given the variation in methods, spatial scales, and temporal scales that exist in the literature. Most datasets do not provide the user with the information needed to evaluate questions related to interspecific interactions, intraspecific variation, and diet study variation. Additionally, they often do not have the resolution needed to study processes affecting species that consume a wide variety of foods, such as omnivores. Databases that aggregate individual diet records and incorporate study metadata can be a powerful tool for incorporating these themes into studies of ecological and evolutionary processes. Questions that can be answered using aggregated records are: How many diet studies exist for the mammals of interest? Over how big a geographic area does diet data for a species come from? Does diet vary through time or across space? Aggregated diet records can be used to incorporate sensitivity analyses into projects, study processes across geographic/ecological scales, and find where and on which species new studies should be conducted. To further the utilization of detailed diet records, we aggregated existing diet data for North American mammals in a structure that records study metadata and aligns with databases such as GLoBI, CarniDIET, and the Avian Diet Database. We use case studies to show that by utilizing this data structure from the beginning of a study design, our work on mammal biogeography can investigate diet at various scales (e.g. population vs. continental), allowing for a powerful predictive framework to be unpacked and applied to various ecosystems.

Disruption of trait-environment relationships in African megafauna occurred in the middle Pleistocene

<u>Mr. Daniel Lauer</u> [1]*, Prof. A. Michelle Lawing* [2]*, Dr. Rachel Short* [3]*, Dr. Fredrick Manthi* [4]*, Prof. Johannes Müller* [5]*, Dr. Jason Head* [6]*, Dr. Jenny McGuire* [1]

***1.** Georgia Institute of Technology, **2.** Texas A&M University, **3.** South Dakota State University, **4.** National Museums of Kenya, Nairobi, **5.** Museum für Naturkunde, **6.** University of Cambridge*

Mammalian megafauna have been critical to the functioning of Earth's biosphere for millions of years. However, since the Plio-Pleistocene, their biodiversity has declined, concurrent with dramatic environmental change and hominin evolution. While these biodiversity declines are well-documented, their impacts on the ecological function of megafaunal communities remain uncertain. Here, we adapt ecometric methods to evaluate whether biodiversity losses since 7.5 Ma were coincident with disruptions in the functional link between communities of herbivorous, eastern African megafauna and their environments (i.e., functional trait-environment relationships). Herbivore taxonomic and functional diversity began to decline during the Pliocene, as open grassland habitats emerged, persisted, and expanded. In the mid-Pleistocene, when grassland expansion intensified and Acheulean hominin tools emerged, phylogenetic diversity declined, and the trait-environment relationships of herbivore communities shifted significantly. Our results divulge the varying implications of different losses in megafaunal biodiversity. Only the losses that occurred since the mid-Pleistocene were coincident with a disturbance to community ecological function. Prior diversity losses, conversely, occurred as the megafaunal species and trait pool narrowed towards those adapted to grassland environments.

A 6300 years perspective of climate and human influences on mountain vegetation dynamics in the French Alps: a case study located in the Aiguilles rouges (Mont Blanc area).

Ms. Jet Vessies [1], ***Ms. Andrea Julien*** [2], ***Dr. Charline Giguet-Covex*** [2], ***Dr. Jing Wu*** [3], ***Dr. Pierre Sabatier*** [2], ***Dr. Erwan Messager*** [2], ***Dr. Laurent Marquer*** [1]

1. *Department of Botany, University of Innsbruck,* ***2.*** *EDYTEM UMR 5204, CNRS-Savoie Mont Blanch University, Le Bourget-du-Lac, France,* ***3.*** *Institute of Geology and Geophysics Chinese Academy of Sciences*

Climate change and human activities are highly influencing plant composition/diversity and ecosystems; particularly in mountain areas. It is critical to study how the climate and human drivers affect vegetation composition and plant diversity changes to better i) understand the long-term trend of vegetation dynamics, ii) assess the current status of the ecosystem and iii) get insights into potential future trends of environmental change. Paleoecology is a key discipline to study such long-term perspectives of change. In particular, pollen grains derived from lake and bog sediments can be used as biological proxy to get past vegetation estimates and quantitatively assess vegetation changes from regional to local spatial scales by using Landscape Reconstruction Algorithms (LRA). Pollen-based modelling outcomes can then be compared to paleo climate data and past land-use.

In the present study, sedimentary archives have been collected in the high-altitude Lake Noir (2495 m.a.s.l.). Three cores have been combined and an age-depth model has been created based on 14C dates and XRF analyses for the correlation of cores. The pollen analysis has been conducted on 104 samples, to provide a high resolution record of vegetation history. Then, LRA has been applied to the pollen counts to reconstruct the local (2000m radius around Lake Noir) and regional (20km radius around Lake Noir) plant cover changes over the last 6300 years. Floristic diversity, evenness and Rate of Change have been calculated to assess plant compositional changes and plant-related diversity trends through time.

Between 6300 and 5100 cal. yrs BP, the landscape is dominated by trees and shrubs, with mainly *Abies* and *Pinus*. *Picea* occurs for the first time. From 5100 to 1200 cal. yrs BP an increase of *Picea* and decrease of *Abies* is recorded. We also see the first occurrences of human activity indicators like increased open land taxa. From 1200 cal. yrs BP to present, those open land taxa really increase (Asteraceae, *Plantago,* Poaceae*, Rumex)*, while trees and shrubs decrease, reflecting the opening of lower vegetation belts. Over the last millennium, land use impacts on vegetation compositional indices increase, while climate was the major driver of change over the previous millennia.

Session 83: Quaternary glacier-climate dynamics in the mid & high latitudes of the Southern Hemisphere

Deglaciation of the Hurd Peninsula (Livingston Island, Antarctica)

Dr. Marc Oliva [1], ***Dr. David Palacios*** [2], ***Dr. José M. Fernández-Fernández*** [2], ***Prof. Mehmet Akif Sarıkaya*** [3], ***Dr. Amaneh Kaveh-Firouz*** [3], ***Dr. Attila Çiner*** [3], ***Dr. Irene Schimmelpfennig*** [4], ***Dr. Leopoldo García-Sancho*** [2], ***Dr. Augusto Pérez-Alberti*** [5], ***Ms. Julia García-Oteyza*** [1]

1. Universitat de Barcelona, Department of Geography, 2. Universidad Complutense de Madrid, 3. Eurasian Earth Science Institute, 4. Aix Marseille University, CNRS, IRD, INRAE, College de France, CEREGE, Aix-en-Provence, France, 5. Universidade de Santiago de Compostela

Spatio-temporal patterns of glacial retreat determine the intensity of geomorphological, hydrological and ecological processes prevailing in ice-free areas of the Antarctic Peninsula region. Here, the chronology of glacial oscillations following the Last Glacial Maximum (LGM) of the last glacial cycle is still very poor and mostly limited to a few sites next to research stations. Hurd Peninsula, located at the SW corner of Livingston Island (South Shetlands) is covered by the Hurd Peninsula Ice Cap (HPIC), which leaves an ice-free of ca. 20 km^2 in its southern sector, as well as numerous nunataks, which protrude above the ice cap. Its highest elevation is Moores Peak (407 m a.s.l.). To understand the patterns of deglaciation on the peninsula, 30 samples for cosmogenic radiation exposition dating (^{36}Cl isotope) have been obtained from polished surfaces and moraine and erratic boulders, from the highest peaks of the nunataks to the coast. On the most recent moraines, the boulders stabilization has been dated by the diameter of the 10 largest thalli of *Rizocarpon Geographicum*. In this communication, we will present a multiple-dating approach combining absolute surface exposure dating and lichenometry to reconstruct the spatio-temporal patterns of glacial thinning and retreat in Hurd Peninsula. Ice thinning of the HPIC already started before the LGM at ~31.6 ka when the highest areas of the plateau became exposed, and accelerated during the LGM at 20-18 ka. Between 16 and 14 ka, the high plateaus were fully deglaciated. The HPIC was relatively stable until the Mid Holocene, when Neoglacial advances in their fronts were recorded at ca. 4.5 and 2 ka. Finally, the most recent moraines in the HPIC glacial fronts correspond to a period of glacial stabilization that occurred during the Little Ice Age at 0.2-0.3 ka. The internal moraines built during this period correlate well with the glacial advances revealed by lichenometry dated to 1850-1900 CE.

Approaches to reconstruct the timing and nature of glaciation(s) at sub-Antarctic Marion Island

***Dr. Elizabeth Rudolph* [1], *Prof. David Hedding* [2], *Prof. Werner Nel* [3]**

***1.** University of the Free State, **2.** University of South Africa, **3.** University of Fort Hare*

For paleoclimate studies of the Southern Hemisphere, sub-Antarctic Islands act as important sentinels to assess the nature and timing of Quaternary glaciations. As such, the character and extent of past glaciations on sub-Antarctic Marion Island have remained an important research focus over the last two decades. Here we provide an overview of approaches used to reconstruct the island's past glaciations, starting with a (re-)assessment of geological history and geomorphological evolution. For example, recently available high-resolution satellite imagery and digital elevation data have enabled the detailed mapping of the island's topography and glacial geomorphology. Such spatial data have aided in validating the process-origins of glacial depositional features which can be used to delineate palaeo-ice margins and demarcate possible glacial basins for the reconstruction the island's palaeo-ice extent. Importantly, the application of relative- and absolute-age dating techniques (i.e. rock hardness and cosmogenic 36Cl age dating) have provided exposure ages of glacial features to supplement the spatial data. The combination of mapping and geochronology allowed for the reconstruction of a model showing spatial variation of ice-extent at an island scale since the most recent deglaciation in the Quaternary.

New Holocene glacio-climatic simulations of the Cook Ice Cap on sub-Antarctic Kerguelen Islands

Dr. Deborah Verfaillie [1], ***Dr. Nicolas Champollion*** [2], ***Dr. Vincent Favier*** [2], ***Ms. Joanna Charton*** [1], ***Dr. Vincent Jomelli*** [1], ***Dr. Irene Schimmelpfennig*** [1], ***Dr. Laurie Menviel*** [3], ***Prof. Hugues Goosse*** [4], ***Prof. Stéphane Blain*** [5]

1. Aix Marseille Univ, CNRS, IRD, INRAE, Coll France, CEREGE, Aix-en-Provence, France, 2. Université Grenoble Alpes, Institut des Géosciences de l'Environnement (IGE), CNRS, Grenoble, France, 3. Climate Change Research Centre/ESSRC, The University of New South Wales, Sydney, NSW, Australia, 4. Earth and Life Institute, Université catholique de Louvain, Louvain-la-Neuve, Belgium, 5. Sorbonne Université, CNRS, Laboratoire d'océanographie microbienne (LOMIC), Banyuls sur mer, France

Understanding the mechanisms of global warming and its impact on human societies is one of the major challenges of the 21st century. In this context, glaciers are excellent indicators of climate because their evolution depends directly on atmospheric conditions through for example temperature and precipitation. Like most of the world's glaciers, sub-Antarctic glaciers are currently undergoing a marked retreat. In the Kerguelen Islands (49° S, 69° E), the Cook Ice Cap has undergone a significant and extremely rapid retreat, losing 20% of its surface area in 40 years, associated with some of the most negative mass balance values observed worldwide.
To better assess the current and future evolution of southern glaciers, it is first necessary to study their past evolution, for which the influence of man is considered negligible. The Kerguelen Islands, due to their geographical location and history, are an exemplary case for understanding past climate mechanisms in the Indian Ocean. Indeed, it harbours well-preserved ancient terrestrial moraines that document the past evolution of glaciers and associated regional climate changes over the last 21,000 years and beyond. Unfortunately, these landforms only provide discontinuous information, both in time and in space. In order to trace the evolution of glaciers over the entire archipelago and the last deglaciation, it is necessary to use glacier-climate modelling.
In this communication, we will present new glacio-climatic simulations of the Cook Ice Cap for the Little Ice Age (~1400-1870 CE) constrained by already-dated moraines around the ice cap. Depending on our progress, simulations for the Antarctic Cold Reversal (□14,5–12,9 ka) or for the Early-to-Mid-Holocene (~10 to 3 ka) might also be presented, in order to understand the climatic mechanisms at work in this southern region of the Indian Ocean. Simulations for the end of the century will also be discussed to provide insights into the future evolution of the ice cap. The simulations will be carried out using two different but complementary glacier models, allowing us to assess the uncertainties arising from the glaciological models, while the use of different climate inputs will inform us of the uncertainty associated with the global climate models.

Patagonian Ice Sheet influence on southern South American climate

The Last Glacial Maximum (LGM, between 26.5 and 19.0 ka before present) is the closest period with stable climate different from present-day conditions. Among the most striking features is a more than 5°C decrease of global temperature, ~50% less carbon dioxide atmospheric concentration than pre-industrial recent times, and a ~120 m decrease of sea level related to continental ice sheet growth. In the mid-latitudes of the Southern Hemisphere the Patagonian Ice Sheet (PIS) grew over the southern Andes. The PIS extended predominantly in a north-south orientation along ~2000 km, from 38 to 54°S, reaching a mean thickness of 1100 meters. Based on glacial records such as moraines, it is possible to infer the presence of extended glacial lobes to the east of the Andes. However, on the western side of the Andes there is little or no evidence of glacial lobes. Is this difference related to LGM climate? Some authors have hypothesized that the PIS boosted the rain shadow effect generated by the interaction of the Southern Westerly Winds (SWW), the Southern Hemisphere low-level, sub-polar jet, and Andean topography. Today, this interaction generates a variation of the precipitation rate from more than 5 m/a to the west to less than 300 mm/a to the east of the Andes. To evaluate this hypothesis, we performed a sensitivity analysis of the PIS influence on southern South American climate. For this we are running a coupled land-atmosphere model simulation using the Community Earth System Model 2 (CESM 2) with LGM boundary conditions and PIS elevation variations. Results will be presented and discussed in the session. Analyzing variations on temperature, precipitation, storm track frequency, and winds we expect to assess if PIS could have influenced glacier growth during the LGM.

A refined deglacial chronology and ice reconstruction for the Río Pico and Río Cisnes palaeo-outlet glaciers (44° — 45° S), former Patagonian Ice Sheet

Ms. Emma Cooper [1]***, Dr. Varyl Thorndycraft*** [1]***, Dr. Bethan Davies*** [2]***, Dr. Adrian Palmer*** [1]***, Dr. Juan L. García*** [3]***, Prof. Christopher Lüthgens*** [4]

The onset of deglaciation during the Last Glacial-Interglacial Transition (LGIT) remains unconstrained across large parts of the northeastern sector of the former Patagonian Ice Sheet. Here, we aim to address the timing and structure of ice recession associated with two outlet glaciers which occupied the Río Cisnes and Río Pico (44° — 45°S) valleys during the LGIT, and the implications of this pattern of deglaciation for palaeoclimate. We provide refined phases of outlet glacier and palaeolake evolution based on geomorphological, chronological and sedimentological data. The new reconstruction is underpinned by OSL and 14C ages, and a new 10Be and 36Cl cosmogenic nuclide surface exposure-age chronology sampled from boulders on moraines and subglacial landforms.

The Río Cisnes glacier had receded ~30 km by 20.78 ± 1.8 ka from its local glacial maximum position, damming an ice-contact palaeolake at ~950 m a.s.l. The Río Pico glacier experienced a similar ~40 km frontal retreat back to a raised bedrock pinning point by 19.31 ± 1.7 ka, damming Palaeolake Pico at the ~870 m a.s.l. level. At this time, both ice-contact palaeolakes drained east, towards the Atlantic. As ice continued to retreat west into the Andean Cordillera, a spillway opened northwards towards the Río Pico valley, lowering the Palaeolake Cisnes level to ~860-850 m a.s.l. As ice recession continued, and both palaeolakes duly expanded west, drainage reversals took place, allowing new palaeolake drainage routes towards the Pacific. Palaeolake level lowering was initiated by between 16.34 ± 1.4 ka to 16.26 ± 1.4 ka in the Río Cisnes valley, and 17.47 ± 1.5 ka to 17.18 ± 1.5 ka in the Río Pico valley. In the Río Cisnes valley, the onset of local ice-free conditions was punctuated by a re-advance during the Antarctic Cold Reversal (14.5 – 12.8 ka), potentially as a result of the convergence of multiple local cirque ice sources originating from the north and south of the Río Cisnes. Our data provide new constraints on the timing and nature of the last termination in this region of Patagonia, the structure of ice source unzipping, and the phasing of local ice-free conditions.

Postglacial fluctuations of western outlet glaciers of the Southern Patagonian Icefield (Chile, 50°S)

Prof. Sebastien Bertrand [1], ***Mr. Matthias Troch*** [2], ***Prof. Julia Wellner*** [3], ***Prof. Carina Lange*** [4], ***Dr. Konrad Hughen*** [5]

Postglacial fluctuations of Southern Patagonian Icefield glaciers are well constrained on the leeward side of the Andes, but they remain mostly unknown on the windward side of the icefield, where most glaciers are marine-terminating. Here, we reconstruct the postglacial fluctuations of the HPS19, Penguin, and Europa glaciers along the hyperhumid western side of the Southern Patagonian Icefield using a multi-proxy sedimentological and geochemical analysis of a 12.2 m long sediment core from Wide Channel (50°S). Results show that the glaciers retreated into Penguin and Europa fjords by 11.2 cal. kyr BP and that they were relatively stable and marine-terminating between 11.2 and 5.8 cal. kyr BP. Thereafter, they fluctuated rapidly, with four marked episodes of glacier shrinkage at 5.8 – 4.8, 3.9 – 2.4, 1.0 – 0.2 cal. kyr BP, and during the 20th century. Although the HPS19, Penguin, and Europa glaciers were calving into Penguin and Europa fjords during most of the Holocene, our data suggest that they retreated to land-based positions between 5.8 and 4.8 cal. kyr BP. The comparison of our sediment record with geological archives from both sides of the Patagonian icefields (46° – 56°S) suggests synchronous glacier variability on multi-centennial timescales during the Neoglacial period, which advocates for a regional climate forcing.

Universidad Glacier (34° S) advances during the LGM and late-glacial times derived from a detailed 10Be moraine chronology: paleoclimate implications

Reconstructing the mid-latitude glacier variations is a prerequisite for unveiling interhemispheric linkages and atmospheric-ocean forcings that triggered those changes in the Subtropical Andes. Nonetheless, the timing, magnitude, and structure of the glacier fluctuations in the Andes of central Chile during the late-Quaternary remain poorly studied. We provide a ^{10}Be chronology (n=23) of Universidad Glacier (34° S, 70° W; ~2500 m a.s.l.) based on ages of boulders resting on discrete moraine belts defining former ice margins. Our findings include the mapping of three moraine belts labeled from the distal to proximal position, located ~20 km, 15 km, and 10 km away from the present-day glacier front. The moraine UNI I extends from the mid to the lowest section of the valley as a kame terrace interrupted by mountain talwegs. The moraine UNI II is composed of a sequence of multiple distinct ridges. The moraine UNI III is a well-preserved single latero-frontal moraine. The exposure ages of moraine UNI I range from 135.9±7.1 to 51.4±2.7 ka (n=3). The mean exposure age of the moraine UNI II is 18.2±1.0 ka (n=14; 1-sigma error). The moraine UNI III yielded a mean exposure age of 12.2±0.7 ka (n=6). The moraine UNI I implies the largest ice extent during a pre-Last Glacial Maximum (LGM) time. The moraine UNI II was deposited during the LGM, linked to a northward-shifted Southern Westerly Winds (SWW). Together with other regional glaciers, paleosol, and marine records, we favor the LGM was a cold and wet period in central Chile. The moraine UNI III represents a return to glacial conditions during the Last Glacial Termination, exposing a double-step deglacial trend observed along the southern Andes and New Zealand at the end of the last ice age. We posit that the SWW migrated north once again at this final stage of the last glacial-interglacial transition to trigger this glacial advance. A tropical forcing for this glacial advance should be discarded because, given the latitude of central Chile, our study site lies in the domain of the extratropical SWW. We suggest that the SWW dominated the late-Quaternary glaciations in the Andes of central Chile.

10Be chronology of Late Pleistocene to Holocene glacial fluctuations in the Río Limarí basin (30-31º S) in the Andes of central Chile

Glacier chronologies in the southern mid-latitudes are suitable to track past latitudinal variability of the southern westerly winds (SWW) through the last glacial period and into the Holocene. Nonetheless, most of the available records along the southern Andes have focused on the temperate areas south of 40° S, leaving a gap in the extratropical semiarid Andes at the northern limit of the SWW influence. Here we present a new detailed ^{10}Be chronology of glacier fluctuations in the Río Limarí Basin (30-31° S). We selected four formerly glaciated valleys ranging between 3000 and 5000 m a.s.l.: Toro and Las Arenas (Combarbalá sub-catchment) and El Viento and El Seco (Río Hurtado sub-catchment). Quartz-rich granitic lithologies make up the rocks there. The glacial imprint is conspicuous, typical for a formerly glaciated mountain landscape including u-shaped valleys, cirques, and aretes containing a distinct glacial drift. We mapped multiple moraine belts, up to five in some valleys.

The outermost moraine is preserved as a prominent, elongated boulderly ridge widened at the top. Boulders expose a weathered layer a few centimeters thick and are embedded in the so-called “maicillo” matrix. In some cases, striated boulders are present. The next moraine belt is a prominent hummocky terrain extending along the valley bottom from side to side, better described as a dead-ice moraine. This moraine is punctuated by distinct moraine ridges that represent former active ice marginal deposits, with faceted and striated boulders. In some cases this glacial drift can be tracked to near actual cirques, where Holocene moraines and active rock glaciers are found.

We applied ^{10}Be exposure dating on boulders resting in stable positions on moraine crests of different generations to build a chronology encompassing the last glacial period and its termination. Preliminary ages suggest glacial advances during the pre-last glacial period and the Last Glacial Maximum (c. 26-18 ka). One moraine seems to have been deposited possible during MIS 3 or MIS 4. Finally, we discuss ages and their paleoclimate implications in the light of previous work in the region (e.g., Zech et al., 2007, 2017; Aguilar et al., 2022).

Session 84: Extending the limits of ice core science beyond new analytical, conceptual and inter-disciplinary frontiers

The quandary of detecting the signature of climate change in Antarctica

Dr. Mathieu Casado [1], _Dr. Raphael Hébert_ [2], _Dr. Davide Faranda_ [3], _Dr. Amaelle Landais_ [4]

__1.__ Laboratoire des Sciences du Climat et de l'Environnement, __2.__ 1. Polar Terrestrial Environmental Systems Research Group, Alfred Wegener Institute Helmholtz Centre for Polar and MarineResearch, Potsdam, Germany, __3.__ LSCE-IPSL, Laboratoire des Sciences du Climat et de l'Environnement (CEA-CNRS-UVSQ), Paris-Saclay, __4.__ LSCE

The current global warming driven by human activities has been accentuated in Polar Regions due to the polar amplification, resulting in large releases of ice that have impacts on circulation and sea level at the global scale. In the Arctic, the temperature has increased at three times the global rate, and lead to significant melt of the Greenland ice sheet and sea ice decline. Yet, for Antarctica, the impact of warming is still poorly constrained given the lack of instrumental data and the large decadal climate variability. Using a compilation of 78 ice core records, we provide a high-resolution reconstruction of past temperatures over the last 1000 years for seven regions of Antarctica and direct evidence of Antarctic polar amplification at regional and continental scales. We also show that both the natural and forced variability are not captured by pseudo-proxy experiments using the CMIP5 and 6 ensembles. This that the feedback loops causing the polar amplification are not properly taken into account, leading to an underestimation of the magnitude of anthropogenic warming and its consequences in Antarctica.

New ice core proxy for reconstructing past wind variability in the Atlantic sector of the Southern Hemisphere Westerly Wind belt

The Southern Hemisphere Westerly Winds play a critical role in the global climate system by modulating the upwelling and the transfer of heat and carbon between the atmosphere and the ocean. Since observations started, the core of the westerly wind belt has increased in strength and has contracted towards Antarctica. It has been proposed that these deviations are among the main drivers of the observed widespread warming in West Antarctica. However, the lack of long-term wind records in the Southern Hemisphere mid-latitudes hinders our ability to assess the wider context of the recently observed changes.

Here, we present records of marine diatoms preserved in a series of ice cores from Ellsworth Land, West Antarctic. The diatom abundances and species assemblages from these ice cores represent the regional variability in wind strength and atmospheric circulation patterns. We use this novel proxy to produce an annual reconstruction of winds in the Atlantic sector of the Southern Hemisphere Westerly Wind belt over the last 300 years. This wind reconstruction allows us to track changes in the strength and position of the westerly winds during the Little Ice Age and explore the link between the recent increase in wind strength, greenhouse gases and ozone depletion in the atmosphere.

Improving ice core nitrate interpretation through a decade of monitoring at Dome C

Dr. Pete D. Akers [1], ***Dr. Joel Savarino*** [2], ***Dr. Nicolas Caillon*** [2], ***Dr. Mathieu Casado*** [3]

__1.__ Trinity College Dublin, __2.__ Université Grenoble Alpes, CNRS, IRD, Grenoble INP, IGE, __3.__ Laboratoire des Sciences du Climat et de l'Environnement

Nitrate (NO_3^-) deposited from the atmosphere is one of the most common ions found in Antarctic snow and glacial ice. Recently, we have shown that the $d^{15}N$ isotopic ratio of nitrate can be used as a quantitative proxy for snow accumulation in Antarctica due to isotopic fractionation during post-depositional photolytic mass loss. Here, we expand upon this premise to better constrain the range and drivers of small scale NO_3^- variability across time and space. We achieve this through the culmination of over a decade of monitoring NO_3^- at Dome C comprising 385 weekly atmospheric samples, over 1700 3–5 day snow surface samples, and 132 monthly snow pits. This continuous monitoring program was supplemented by a trench study at Dome C in December 2019 where 1 m vertical NO_3^- profiles were sampled repeatedly along a 50 m transect. We find that atmospheric and surface snow NO_3^- follow clear seasonal cycles with generally consistent mean values from 2009 to 2021. The interannual $d^{15}N$ variability due to variable weather, insolation, and NO_3^- transport for a given week of the year, however, can be as large as 20 ‰ and 60 ‰ for atmospheric and surface snow NO_3^-, respectively. Snow pit monitoring reveals that $d^{15}N$ from equivalent depths may vary by over 100 ‰ between monthly samplings a few meters apart. We find similar observations in our trench study, with same depth $d^{15}N$ values varying up to 150 ‰ in as little as 4 horizontal meters. This small scale spatial variability largely results from local surface features like drifts that affect photolytic activity on a meter to meter scale by altering local accumulation and snow grain character. This observed temporal and spatial variability reveals the need to replicate and aggregate multiple samples spread over an area >100 m^2 if one aims to collect a NO_3^- sample that is broadly representative of a site. Additionally, we expect NO_3^- recovered from ice cores to exhibit artifacts of this small scale variability due to its single point nature, and we argue that high resolution NO_3^- data likely needs some level of aggregation to reduce these artifacts.

Age-depth relationship for Beyond EPICA using radar measurements and ice flow modelling

This work is part of the network of DEEPICE PhD projects associated with the Beyond EPICA drilling project which aims to recover a continuous 1.5 million year old ice core from Little Dome C in Antarctica.
Over the past 5 years, 3 sets of radar measurements were taken (UT, BAS, AWI/CPH/UA) around the area of interest for the Beyond EPICA project. With the preparations of the Beyond EPICA Little Dome C drill site (BELDC) completed in the 21/22 season, we now use a combination of radar observations and numerical models to understand the age-depth distribution and dynamic properties of the ice in the area surrounding the drill site.
Several internal horizons have been traced and dated by linking them to the 800 ka old European Dome C ice core. We combine a 1D numerical model which uses inverse methods, constrained by the traced radar horizons and the AICC2012 EDC core accumulation profile.
Modelled results include the age of ice and thickness of a layer of stagnant ice along the radar lines for each of the 3 radar datasets. At BELDC, the average modelled age 60m above the stagnant was around 1.5 million years. We compare the thickness of modelled stagnant ice with that of the basal layer observed in the most recent measurements, and propose that they are the same.
These modelled results are directly relevant for the Beyond EPICA project and for the Australian team also planning to drill at LDC for the Million Year Old Ice project. With radar measurements from other areas in Antarctica the model could be applied to other planned drill projects such as those of Japan, China and the US. Currently, our 1D model is appropriate around ice sheet domes. We plan to develop a 2.5D model which takes into account horizontal ice flow, so it could model regions of Antarctica with more varied topography.

How to extract climate signals in deep ice through model-assisted exploitation of high-resolution impurity analysis

Mr. Piers Larkman [1]***, Dr. Rachael Rhodes*** [2]***, Prof. Carlo Barbante*** [3]***, Prof. Barbara Stenni*** [1]***, Mr. Nicolas Stoll*** [4]***, Dr. Marco Roman*** [1]***, Dr. Pascal Bohleber*** [1]

Climate signals from ice cores are conventionally extracted through the use of continuous flow analysis (CFA) at centimeter resolution. The European project Beyond EPICA Oldest Ice (BE-OI) aims to retrieve ice from the bottom of the Antarctic ice sheet. It is expected that this ice will contain more than 14,000 years of climate history per meter depth, calling for analysis to be conducted at a depth resolution beyond the limits of CFA. To extract the climate signal while best conserving ice samples we must use micro destructive techniques with high resolution, such as laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS). Images obtained using LA-ICP-MS have shown that the impurity distribution, and therefore the impurity-derived climate signal, is influenced by the various interactions of impurities with the ice matrix. In deep ice with crystal sizes on the order of centimeters or greater the question remains: on which time scale can the climate signal be expected to be preserved?

To both aid the extraction of the climate signal using LA-ICP-MS and secure a link between CFA and LA-ICP-MS output a computational model was developed. The model is based on simple assumptions about ice crystal growth and impurity distribution. Using this model, an artificial ice volume analogous to the samples conventionally melted during CFA is simulated. Interrogation of this system brings insight into the spatial distortion of the climate signal, first and foremost due to the relocation of impurities by grain growth. It also helps us to better understand the similarities and differences between CFA and LA-ICP-MS observed in the model and in laboratory measurements. Through comparison of the model output with experimental results the link between the climate signal, CFA measurements, and LA-ICP-MS measurements will be discussed and the optimal LA-ICP-MS depth resolution for climate signal extraction constrained.

Elemental record of impurities in the Talos Dome ice core: a study on solubility of elements at different depths

Dr. Elena Di Stefano [1], ***Dr. Giovanni Baccolo*** [2], ***Dr. Paolo Gabrielli*** [3], ***Prof. Barbara Delmonte*** [4], ***Prof. Valter Maggi*** [4]

1. *Dipartimento di Scienze dell' Ambiente e della Terra, University of Milano-Bicocca,* ***2.*** *Paul Scherrer Institute, Villigen, Switzerland,* ***3.*** *Byrd Polar and Climate Research Center, The Ohio State University, Columbus, OH 43210,* ***4.*** *University of Milano-Bicocca*

We present a record on the elemental composition of impurities present in the Talos dome ice core at different depths. Insoluble fraction of dust was investigated with low background instrumental neutron analysis (INAA) while inductively coupled plasma mass spectrometry (ICP-SFMS) was applied to two different set of samples to observe both the total composition and the soluble fraction of impurities in the ice. In order to do so, the first set of samples was only leached while the second one was also filtered to remove dust particles > 0.2µm. We determined 45 elements through ICP-SFMS and 39 through INAA, with a good overlapping of the elements between the two techniques. Besides the determination of major elements (Na, Mg, Al, Si, K, Ca, Ti, Mn, Fe), the high sensibility of both techniques also permitted the determination of trace elements. Among these, rare earth elements (REE) are of particular importance as they have been widely used as a geochemical tracer of aeolian dust sources. The wide range of elements considered in this study gives us the possibility to study links between different elements at different depths. Our principal aim was to study the fractionation of elements between soluble and insoluble phase and how this may change at different climatic stages. Shifts in the fractionation of some elements between soluble and insoluble phase can be an indicator of a modification in the dust sources, but may also point to post depositional processes taking place inside deep ice. Overall, the majority of elements showed a minimum in solubility during the last glacial maximum as a result of higher fluxes of mineral dust which were transported to the Antarctic Continent from remote sources. Iron was the only element to display a clear decrease of solubility at increasing depth linked to chemical weathering processes, highlighting the high sensitivity of this element with respect to post-depositional processes.

Origin of last glacial ice core dust in central Greenland

Dr. Gábor Újvári [1]***, Prof. Urs Klötzli*** [2]***, Dr. Thomas Stevens*** [3]***, Prof. Anders Svensson*** [4]***, Dr. Patrick Ludwig*** [5]***, Prof. Torsten Vennemann*** [6]***, Dr. Susanne Gier*** [7]***, Dr. László Palcsu*** [8]

High-resolution ice core oxygen isotope records reveal that the generally cold last glacial climate was interrupted by numerous rapid shifts to warmer interstadial conditions, called Dansgaard–Oeschger (D–O) events. This D–O type climate variability is coupled with variations in dust concentration and particle size, with rapid decreases in Ca^{2+} ions at the onset of interstadials and slower increases following their end. These abrupt variations in dust characteristics have variously been accounted for by changes in transit and atmospheric residence time, transport distance, extent and intensity of the polar atmospheric cell, dust source strength, aridity, and storminess, nevertheless the precise causal mechanisms of these changes remain elusive. The NGRIP ice core record demonstrates synchrony in variations of Ca^{2+} concentration and $\delta^{18}O_{ice}$ indicating that the climate of continental dust sources and Greenland must have been coupled. However, the mechanisms of this coupled response over wide areas of the Northern Hemisphere (NH) remain poorly constrained. Resolving the source(s) of Greenland ice core dust is a key step in resolving the uncertainty over this coupling, as it allows the environmental controls on dust emission to be constrained, as well as providing insight into major dust transport pathways and atmospheric circulation patterns during abrupt climate events of the Last Glacial Period. A multi-technique analysis of Greenland dust provenance is presented, using novel and established, source diagnostic isotopic tracers as well as results from a regional climate model including dust cycle simulations. We show that the existing dominant model for the provenance of Greenland dust as sourced from combined East Asian dust and Pacific volcanics is not supported. Instead, clay mineralogical, Hf–Sr–Nd and D/H isotopic analyses from last glacial Greenland dust and an extensive range of NH potential dust sources suggest three most likely scenarios (in order of probability): direct dust sourcing from the Taklimakan Desert in western China, direct sourcing from European glacial sources, or a mix of dust originating from Europe and North Africa. Furthermore, our regional climate modelling demonstrates, for the first time, the plausibility of European or mixed European/North African sources.

Session 85: Loess and dust deposits: beyond local studies

Paleodust during the last climate cycle: a data-model comparison

Dr. Denis Didier Rousseau [1]***, Dr. Pierre Antoine*** [2]***, Dr. Catherine Chauvel*** [3]***, Dr. Christine Hatté*** [4]***, Dr. France Lagroix*** [3]***, Dr. Peter Hopcroft*** [5]***, Mrs. Segolene Saulnier-Copard*** [2]

The Last Climate Cycle (LCC, 130-15kyr) has shown cold, dusty (GS) and warmer, non-dusty (GI) intervals, when the atmosphere was 2-20 times more loaded with dust than today. The alternations between GS and GI occurred on millennial time scales, involving climate forcings other than orbital. The transition between GS and GI lasted on average 50 yrs, resulting from a complete climate reorganization that is not presently understood. A data-model project, has acquired and investigated European loess sequences to get high-resolution and well-dated paleodust records of the LCC showing Europe experienced millennial paleodust variations through paleosol-loess unit alternations. Similarly, Chinese loess sequence recorded millennial paleodust variations expressed by grain-size oscillations. These are apparently similar to those initially observed in Europe, although the timing of dust sedimentation does not seem to be identical. Earth System Models contribute i) to characterize the source regions of the paleodust and ii) to reproduce past variations in dust deposition for key paleoclimate scenarios. A key component of the project analyses loess samples dated from the last glacial maximum to detect the origin of the deposited material. A first study on the bulk sediment demonstrates that the paleodust deposited over Europe along a long longitudinal transect (about 2000 km) indicates a short distance transport implying local to regional source. Targeting the <2 mm and 2-20 mm grain size fractions and comparing with the previous results from the bulk samples, preliminary results for Western Europe sites, indicate a local to regional origin for the coarse (2-20 mm and bulk) material and a more distant source for the finer fraction (<2 mm), involving longer transport in relation to general atmospheric circulation, for the finer particles. This is a critical new research question because it implies potentially important order of magnitude regional variations in dust radiative forcing that have never been accounted for in simulations of abrupt events.

Evidencing and dating the impact of millennial time-scale climatic events (DO cycles) in Western European Last glacial loess records

The *European Loess Belt* is the most extensive continental archive of the last glacial period (Weichselian / MIS 5d-2) in Europe. Located downwind of Westerlies, south of the British-Irish and Fennoscandian ice sheets and north of the englaciated Alps, this area was ideally located to record the impact of global millennial-timescale climate variations (Dansgaard-Oeschger (DO) cycles, Heinrich (H) events) triggered by the North Atlantic Ocean circulation during the last glacial period. Furthermore, its northwestern part also recorded numerous evidences of permafrost and periglacial processes such as large ice wedge networks or thermokarst erosion processes, which are connected with ice-rich permafrost environmental phases marked by the development of tundra gley horizons. Our high-resolution stratigraphic approach shows that their distribution can be followed over long distances at least to Belgium and western Germany. Moreover, the demonstration of the connexion between millennial-timescale warming events (interstadials) and tundra gley formation is now possible owing to a new ^{14}C dating approach developed by our team on earthworm calcite granules extracted from 15-30cm thick tundra gley horizons. The accurate dating of the tundra gley layers demonstrates the occurrence of several generations of ice-wedge cast networks that appear to have developed and degraded only during short phases ($\leq$ 1 ka) as revealed by detailed correlations with the North GRIP climate record. These features typify specific palaeoclimatic conditions that are however still to be characterised in the frame of a modelling approach involving inlandsis and sea-ice extent, atmospheric circulation and temperature reconstructions. Otherwise, high-resolution sedimentological and malacological investigations combined with earthworm granules ^{14}C dating demonstrated that the response of loess environments to Dansgaard-Oeschger cycles is recorded by the formation of a rich and complex stratigraphic succession of loess-palaeosol cycles corresponding to as many stadial-interstadial cycles between about 50 and 20 ka. These works therefore make it possible to describe, over the long distance, the response of glacial continental environments to past millennial-timescale climate variations and provide a strong database for the discussion of human-environment relationships during the Last Glacial.

The loess-palaeosol section of Baix (Rhône Rift Valley, SE-France): a unique Late-Pleistocene record of the transition zone between the presently temperate and the Mediterranean region of Europe

Prof. Daniela Sauer [1], Ms. Nora Pfaffner [2], Dr. Annette Kadereit [3], Dr. Sebastian Kreutzer [3], Dr. Tianhao Wang [4], Dr. Volker Karius [5], Dr. Thomas Kolb [6], Dr. Pascal Bertran [7], Dr. Mathieu Bosq [8], Dr. Christine Hatté [9]

Loess-palaeosol sections (LPS) provide valuable archives of Quaternary palaeoenvironmental changes over time, and spatial palaeoenvironmental gradients during the same period. Here we present the LPS Baix, located at the western edge of the Rhône Rift Valley in southeastern France, at 44°42'36" N and 4°43'21" E. Already discovered in 1934, this 14 m thick LPS has never been studied employing modern analytical methods. It caught our attention because it is located in the transition zone between the presently temperate and the Mediterranean region of Europe. To our knowledge, no LPS has been analysed yet in such a transitional climatic position. It likely provides a crucial link between the rigorously analyzed LPS in the presently temperate regions further north (e.g., in northern France, the Alsace region and Germany) and the LPS in the Mediterranean region (e.g., in southern France, Catalonia, Italy and Croatia). Therefore, we aimed at deciphering the paleoenvironmental record of the LPS Baix in this particular transitional climatic position. We analysed the LPS Baix by means of sedimentological and palaeopedological methods combined with OSL and ^{14}C dating of mollusc shells. Reddish Btg horizons of a Stagnic Luvisol at the base of the LPS represent the remains of an Eemian to Early Würmian (MIS 5) pedocomplex formed under warm and - at least temporarily - relatively moist conditions. Two brown Bw horizons of truncated Cambisols have been preserved in the overlying early to middle Pleniglacial (MIS 5a/4 and MIS 3) deposits. The upper Bw horizon is associated with large carbonate nodules, indicating that considerable amounts of calcium carbonate were leached from the former middle Pleniglacial Cambisol and accumulated in the underlying loess unit. This truncated middle Pleniglacial Cambisol is very similar to the middle Pleniglacial palaeosol remains in the LPS Collias that we investigated 87 km further south, near Nîmes, in the present Mediterranean climate. No palaeosols were observed in the late Pleniglacial deposits of the LPS Baix.

Quaternary sediment routing: provenance and spatial variation of loess deposits in the East European Plain and Caspian Sea region

Dr. Chiara Költringer [1], ***Dr. Thomas Stevens*** [2], ***Mr. Yunus Baykal*** [2], ***Dr. Redzhep Kurbanov*** [3]

The East European Plain (EEP) is a vast and geomorphologically variable area with numerous interacting climate systems. Widely glaciated by the Fennoscandian Ice Sheet during the Quaternary, it comprises several complex, interacting sedimentary systems, controlled by glacial, periglacial, fluvial, aeolian and marine processes.
Three major river systems drain the current EEP into the Black Sea and the Caspian Sea in the south, the Volga, the Don and the Dnieper, and both Caspian and Black Sea water levels and long-range sediment transport are heavily influenced by their drainage. The EEP is blanketed by extensive loessic and sandy aeolian deposits, as well as marine, fluvial and alluvial sediments and sediment routing may show complex patterns and controls. As a result, the provenance and transport of loess in this complex and highly dynamic environment remains poorly known.

The Quaternary EEP has multiple potential loess sources. In addition to the Fennoscandian Ice Sheet, surrounding mountain ranges as well as more distal orogens to the east and their palaeo-drainage systems may provide extensive sediments and represent loess source regions. Furthermore, desert areas lying to the east of the South Caspian Sea combine the potential of being a sediment sink for material from mountains, as well as a secondary source for the Caspian Sea region and the large loess area in northern Iran.
Here, a first large-scale reconstruction of Quaternary sediment sources, transport pathways and sinks for the EEP and southern Caspian Sea region is established based on large-n U-Pb dating of detrital zircons. Our results reveal that sedimentary sinks in the region are sourced from a range of places and that sediment supply is mainly linked to continental and mountain glaciation. The distribution of the material over a wide area and long timescales is mostly undertaken via rivers prior to near source aeolian and marine reworking and transportation. A strong spatial variability of loess sources, even over small areas, indicates input from multiple local dust sources.

Lower Danube paleoclimate records and rapid climate variability during the last glacial cycle

Here we present results of detailed high-resolution sedimentological, geochemical, and chronological investigations of several long loess profiles from the Lower Danube area. Our loess data show distinct variability that correlate well with shifts in paleoclimate records from Greenland ice cores and Northern Hemisphere speleothem records over the last glacial cycle. These features in loess data, most prominent in the magnetic susceptibility and grain-size data, are complemented by information from geochemical proxies and provide important insights into the nature of the depositional environment.

To assess the paleoclimatic significance of our proxy data results are further compared with regionally representative lake, loess, speleothem and marine stacks from Black Sea, Mediterranean and the Northern Hemisphere. The comparison reveals consistent millennial-scale variability (e.g., fluctuations that resemble stadial-interstadial events) archived within the proxy data and identification of common features that allow for the synchronization of records (aided also by tephrochronology) over the last glacial cycle. Such chronological synchronization of the loess records with other paleoclimate archives with high confidence on millennial time-scales further allowed revealing some less pronounced but intriguing differences. The results illustrate the value of a multiproxy multi-site approach in understanding sediment dynamics and variations in processes influencing/controlling loess-paleosol formation during rapid climate changes such as stadials and interstadials. Hence, loess archives so far widely underestimated are in many aspects directly comparable to well established paleoclimate archives and significantly improve the spatial resolution of Eurasian-wide paleoclimatic data.

Connecting loess archives in the Western and Eastern Mediterranean

Within the broad field of loess research, studies on Mediterranean loess sections are heavily under-represented considering their great value for reconstructing palaeoenvironmental conditions during the Quaternary period. Taking into account the displacement of atmospheric circulation patterns, especially during stadial phases, the Mediterranean realm has often fallen into the transition zone between polar and subtropical air masses. Hence, these areas are particularly suitable for investigating the influence of different atmospheric systems, e. g. the westerlies, on past landscapes and environments.
Here we present the main results of several research projects dealing with loess dynamics in the Western Mediterranean (central Spain) as well as the outermost Eastern Mediterranean (northeastern Armenia, Southern Caucasus). Apart from the most important stratigraphic and geochronologic patterns, we demonstrate selected proxy information that enable a detailed reconstruction of palaeoenvironments linked to loess formation as well as pedogenesis. The integration of regional terrestrial archive information, e. g. on glacier advances or vegetation dynamics, further help to improve the picture of the environmental framework for the buildup of Mediterranean loess sequences.
Finally, the attempt is made to connect both loess archives and also include marine archive information for providing a very general idea of last glacial climate-related environmental changes over the Mediterranean area.

Age and palaeoenvironmental interpretation of the ice-wedge pseudomorphs recorded in the Last Glacial loess-palaeosol sequences in Poland and western part of Ukraine

***Prof. Zdzisław Jary* [1], *Prof. Andriy Bogucki* [2], *Prof. Piotr Moska* [3], *Prof. Przemysław Mroczek* [4], *Mr. Marcin Krawczyk* [1], *Dr. Jerzy Raczyk* [1], *Dr. Jacek Skurzyński* [1], *Dr. Olena Tomeniuk* [2]**

The North European loess belt was formed in cold climatic conditions in the periglacial zone of the Pleistocene continental glaciations. Unlike many others loess areas, periglacial loess was deposited during short but intense sedimentation phases strongly coupled with the dynamics of the glacial system.

Three types of periglacial structures are useful to reconstruct the former periglacial environment: cryogenic wedges with primary mineral infilling, cryoturbation and gelifluction structures, and ice-wedge pseudomorphs. These structures frequently form marker horizons, which suggests their relation with global and/or regional climate changes.

Among many periglacial phenomena, only some indicate unequivocally the presence of fossil permafrost. The most important are ice-wedge pseudomorphs, which are reliable evidence of former permafrost. Each generation of ice-wedge pseudomorphs proves that the temperature thresholds have been exceeded twice. They document significant cooling and subsequent warming of the climate. However, there are still problems with determining the genesis of many pseudomorphs, which complicates the possibility of their reliable palaeoenvironmental interpretations.

Taking into account a spatial distribution of Last Glacial ice-wedge pseudomorphs it can be stated that in the central and eastern part of research area the permafrost had developed at least twice. The older (MIS 4) generation indicate their development in conditions between continuous and discontinuous permafrost. The common occurrence and large size of the younger generation of ice-wedge pseudomorphs (MIS 2) indicate continuous permafrost in this part of the research area. However, there are some evidences of partial decay of permafrost during the early MIS 2 what can be interpreted as a presence of rapid short-term warming around 23 ka years ago. In the western part of Poland the evidence of MIS 4 permafrost were found only in northern part. During the MIS 2 loess area in western Poland were occupied within both continuous and discontinuous permafrost.

Field observations in the extensive exposures of Podolia and Volhynia indicate the presence of more complex ice-wedge pseudomorphs. In addition to epigenetic forms, there are syngenetic forms that more accurately document the subsequent stages of development and disappearance of permafrost.

Presented results were obtained with support of Polish National Science Centre, contract number 2017/27/B/ST10/01854.

Session 87: Prehistoric hunter-gatherers' adaptation during the Last Glacial in Europe

Neanderthals' adaptations during the Weichselian in Central Europe

Dr. Andrea Picin [1], ***Dr. Katarzyna Kerneder-Gubała*** [2], ***Dr. Damian Stefański*** [3]

1. Dipartimento di Chimica G. Ciamician, Alma Mater Studiorum Universitá di Bologna, 2. Center for Interdisciplinary Archaeological Research, Institute of Archaeology and Ethnology, Polish Academy of Sciences Warsaw, 3. Archaeological Museum in Kraków

During the Weichselian (MIS 5d - MIS 3), the climatic deterioration and the rapid decrease of the temperatures caused significant difficulties for Neanderthal groups that had to adapt to new environmental changes. Central European Neanderthals reacted to these cooler ecological conditions by designing a new toolkit composed of asymmetric bifacial knives, bifacial tools, foliate artifacts, and coin-like scrapers (groszaks). This new cultural facies of the Late Middle Palaeolithic is named Micoquian (or Central-Eastern European Micoquian – CEEM) spreading from Eastern France to Poland, Northern Caucasus, and Altai. This paper presents new technological data from several Micoquian sites in Germany and southern Poland. Our results indicate different technological trajectories in the emergence and development of these new stone tools related to the ecological settings, site function, and animal prey. Further comparisons with other Micoquian sites in Central-Eastern Europe and its fringes will reveal the Neanderthals' flexibility in land use during environmental changes.

Neanderthals in changing evironments from the Eemian to the early Pleniglacial – New evidence at the site of Lichtenberg, Germany

Mr. Michael Hein [1], ***Dr. Marcel Weiss*** [2], ***Prof. Brigitte Urban*** [1], ***Dr. Mareike C. Stahlschmidt*** [3], ***Dr. Tobias Lauer*** [4]

Department of Evolutionary Anthropology, University of Vienna, Austria, 4. Terrestrial Sedimentology, Eberhard-Karl University of Tübingen, Germany

The question of how Neanderthals adapted to changing climatic and environmental conditions, and in particular to severely cold climates in northern regions of Central Europe, is far from being resolved. Establishing direct links between occupations and associated environments may be facilitated by the investigation of suitable multi-layered sites that can provide the respective behavioral, chronological and palaeoecological evidence. Here we present the results of our integrative research carried out at the Middle Palaeolithic open-air site of Lichtenberg, Northern Germany. Our set of methods comprises archaeological approaches, luminescence dating, sedimentology, micromorphology, as well as pollen and phytolith analyses. Through an extensive sediment coring campaign, we deliberately included the immidiate surroundings into our investigations, thus gaining valuable contextual information about past landscape-forming processes. These surveys led, among other things, to the discovery of two previously unknown Neanderthal occupations in Lichtenberg.

Our results show that Neanderthals were present in temperate, forested intervals during the Mid-Eemian Interglacial (MIS 5e) and the latest Brörup Interstadial (MIS 5c/GI 22, occupation Lichtenberg II). We further propose a revision of the chronology for the previously known occupation Lichtenberg I: Instead of the early MIS 3 (mean TL age of 57 ± 6 ka), according to our data, the occupation rather took place in the early MIS 4/GS 19 (mean pIRIR age of 71.3 ± 7.3 ka), with dominant cold steppe/tundra vegetation and periglacial characteristics of the embedding sediments.

The artefact assemblages of these temperate to cold environment occupations differ with respect to size, blank production, typology and tool use. We argue that this distinctness can partially be explained by different site functions, tasks and occupation durations, but also by the availability of large and high-quality flint raw material, provided by the respective magnitudes of sediment redeposition from nearby Saalian glacial sediments.

Middle-to-Late Pleistocene magnetostratigraphic records from Loess-Paleosol Zwierzyniec sequence (Krakow, Poland): a correlation between geomagnetic excursions and main archeological levels

Dr. Alessandro Todrani [1], Ms. Serena Perini [1], Dr. Damian Stefański [2], Dr. Andrea Picin [3], Prof. Andrea Zerboni [1], Prof. Sahra Talamo [4], Prof. Giovanni Muttoni [1]

***1.** Department of Earth Sciences, University of Milan, **2.** Archaeological Museum in Kraków, **3.** Dipartimento di Chimica G. Ciamician, Alma Mater Studiorum Universitá di Bologna, **4.** University of Bologna*

We present new paleomagnetic data and rock magnetic results from the sedimentary sequence of the site Kraków-Zwierzyniec 1, located in Krakow, southern Poland. Kraków-Zwierzyniec 1 site represents one of the most important Paleolithic sites of Central Europe, where several archeological layers, respectively associated with Levallois-Mousterian, Micoquian, Szeletian, Zwierzyniecian, and Aurignacian, were discovered. Archaeological levels are embedded into a loess-palaeosol sequence, alternating thick silty layers to shallow soil horizons marked by accumulation of organics, weak weathering, and evidence of frost-related pedoturbation. Continuous wind sediments – as the Zwierzyniec sequence is – are usually considered one of the most suitable deposits for Quaternary paleomagnetic studies, thus we collected a total of 228 superposed paleomagnetic samples to define a high-resolution stratigraphic chronology of the Palaeolithic site. Magnetic directions, dominated by normal polarities, were isolated through thermal cleaning, and were compared with a dated palaeosecular variation (PSV) reference curve from the literature. In addition, samples have also been investigated for relative palaeointensity (RPI) using rock-magnetic parameters (ARM/NRM) at various AF demagnetization steps. The derived RPI curve is then compared to dated RPI records from the literature to augment the chronology of the investigated section. We also investigated the main magnetic assemblages of the loess-palaeosol sequence, as well as the magnetic properties, defining that the magnetization has been mainly acquired by ferrimagnetic minerals (i.e., magnetite grains). Throughout the whole section, several Optically Stimulated Luminescence (OSL) samples were also collected. The ultimate scope of this study is to generate an age model of deposition for the investigated sequence by integrating PSV, RPI, and OSL data, thus offering a fresh geochronological context to archaeological findings.

Comparison of the Neanderthal and Anatomically Modern Human niches in MIS 4 and MIS 2

Mrs. Emilia Hunt [1], ***Dr. Sally Reynolds*** [1], ***Prof. Fiona Coward*** [1], ***Dr. Fabio Silva*** [1], ***Dr. Phil Hopley*** [2]

1. Bournemouth University, 2. University College London

Applying ecological niche modelling to the extinct hominin species is a relatively new approach for increasing the understanding of key pressures involved in evolutionary processes. How have different species of *Homo* dealt with climate changes? Were the extinctions brought about by climate change or only speeded up by it?

As the Neanderthals - *Homo neanderthalensis*, one of the few European species in the hominin ancestry, are the closest to us in a temporal sense and present many similarities to our own species, such as the capacity for symbolic expression (Moncel et al. 2012), and speech (Johansson 2013), they are a valid comparison to Anatomically Modern Humans (AMH).

Their landscapes and climate were unfamiliar to ours as we know them now. The open, steppe-like landscapes that dominated Europe in the prime of the Neanderthals had good exposure to sunlight and rich vegetation that sustained considerable populations of mammoth, bison, deer, horse and reindeer – species fundamental to their diet. Neanderthal and AMH landscapes through various marine isotope stages did differ from each other (Helmens, 2014). However, they were nothing like the barren steppes of present-day Eurasia or any landscapes in today's world.

We have modelled the niches of Neanderthals from MIS 4 (57-71 KYA) and anatomically modern humans (AMH) from MIS 2 (KYA), as both MIS represent cold periods, and then compared these models to each other. These models, created using Maxent (Phillips, 2005), used presence data of sites with a high certainty attribution to the species based on the human remains found at the sites and statistics-based climate reconstruction data (Krapp et al. 2021). The resulting models show the environmental niche of Neanderthals and AMH, which helps us understand them as people, their climatic requirements, and ecological preferences from the glacial periods, those, coupled with geological data, the results can open new prospects for finding additional sites, as well as help us understand possible causes of Neanderthal disappearance.

Spatiotemporal pattern of Neanderthal extirpation and plausible ecological drivers

Ms. Fiona Laviano [1], ***Dr. Frédérik Saltré*** [1], ***Prof. Lee Arnold*** [2], ***Prof. Corey Bradshaw*** [1]

1. Global Ecology, College of Science and Engineering, Flinders University, GPO Box 2100, Adelaide, South Australia 5001, 2. University of Adelaide

Variation in the distribution of ecosystem resources driven by climate shifts have influenced the mobility and dispersal of hunter-gatherer Neanderthals and *Homo sapiens*. Neanderthals disappeared while early *H. sapiens* successfully migrated through Eurasia during marine isotope stage 3 (~ 57,000 to 29,000 years BP). This interstadial phase was characterised by intense, millennial-scale climate variability, with large shifts in winter temperatures and precipitation. Recent attempts to estimate the terminal dates and drivers of Neanderthal extinction support disappearance around 42,000 years BP, with this timing and the relative influence of different extinction drivers varying regionally (e.g., changes in resources availability via changes in ecosystem productivity and competition with *H. sapiens*). However, most of the conclusions for potential drivers rely on mechanistic approaches as archaeological evidence is often sparse and incomplete, thus making the reconstruction of regional patterns of Neanderthal extinction challenging when independent datasets are viewed in isolation. Here, we applied a spatiotemporal statistical model to high-quality Neanderthal fossil records (i.e., suitable dates on securely identified fossils) to generate a spatial and taphonomically bias-corrected extinction map of the chronology of Neanderthal extirpation. We then quantified the relative role of climate change in explaining this pattern of Neanderthal extirpation, by statistically comparing it to regional variation in hindcasted climate conditions derived from climate hindcasts. We show that Neanderthal extinction was a long-term process that occurred from middle and late marine isotope stage 3 (~ 45,000–29,000 years BP), and we identify areas where Neanderthals possibly coexisted with early *H. sapiens*. We discuss how these new timelines provide insights on the extent to which variation in food resources has shaped the Neanderthal population in Western Europe prior to full extinction, potentially promoting the expansion of early *H. sapiens*.

Testing the synchrony between cultural and paleoenvironmental changes in southern France during the Middle-to-Upper Palaeolithic transition

Dr. Tiffanie Fourcade [1]***, Prof. Maria Sanchez-Goñi*** [2]***, Prof. Christelle Lahaye*** [3]***, Mr. Jonathan Lesven*** [4]***, Prof. Anne Philippe*** [5]

1. *University Bordeaux-Montaigne,* ***2.*** *Ecole Pratique des Hautes Etudes, Paris Science Lettres University,* ***3.*** *Université Bordeaux Montaigne, UMR 6034, Archéosciences-Bordeaux,* ***4.*** *Laboratoire Chrono-Environnement, UMR 6249 CNRS, Université de Bourgogne Franche-Comté,* ***5.*** *Laboratoire de Mathématiques Jean Leray, Nantes Université*

Determining the impact of climatic variations on past human cultural changes is a difficult task due to the chronological uncertainties inherent to the dating methods applied to archaeological and paleoclimatic archives, and by the different temporal resolution of both archives.

Here, we present two high-resolution pollen-based palaeoenvironmental sequences from the Bay of Biscay (45°21'N, 5°13'W) and the Gulf of Lion (40°29'N, 4°01'E) plotted against up-to-date chronologies. These sequences unambiguously identify millennial-scale vegetation and climatic changes in southern France in response to Greenland warming and cooling events, *i.e.* Dansgaard-Oeschger (D-O) cycles, and to the North Atlantic major iceberg discharges called Heinrich events (HEs). The chronologies are well constrained by numerical dating (new IRSL ages for the Bay of Biscay deep-sea core) and new age-depth models, based on Bayesian statistics and stratigraphic constrains using ChronoModel software and R-package ArchaeoPhases.

The construction and updating of archaeological databases for the Middle-to-Upper Palaeolithic transition in southwestern and southeastern France has allowed the development of age models based on ChronoModel. These age models provide more reliable chronological windows for the observed cultural changes in Neanderthals and Anatomically Modern Humans (AMH) in Western Europe.

Despite the improved paleoclimatic and archeological chronologies, the identification of a potential synchrony between climate and cultural changes still remains difficult due to new uncertainties. Nevertheless, this study suggests that the progressive opening of landscape since the D-O 12 (~47 ka) favoured the arrival of AMH in Western Europe, leading to competition with Neanderthals for the same ecological niches, and thus to the disappearance of the latter at ~40 ka.

The fundamental role of radiocarbon to forecast possible scenarios of human/environment dynamics during climatic fluctuations.

Prof. Sahra Talamo [1]

1. *University of Bologna*

Chronology is the basal aspect of Paleolithic Archaeology, and precise absolute radiocarbon dating is crucial for understanding the timing of cultural events that occurred in the past. In fact, understanding the timing of dispersals of *Homo sapiens* in Europe, the interaction with Neanderthals, the extent of their temporal overlapping in the different regions, and the interplays between hominins and climatic fluctuations is a research topic that requires high accuracy and precision in radiocarbon dating. Today the radiocarbon dating method is even more intertwined with the field of archaeology and is part of those applied sciences that never stop being improved, to be revolutionized in some way. In fact, for the past 14,000 years, the radiocarbon calibration curve has been highly precise and of high resolution (annual to a decade) due to tree-ring chronologies, but it is still rather coarse in Middle to Upper Paleolithic, where the carbon archives are connected only indirectly to the atmosphere (speleothems, coral reefs, marine and lake sediments). However, the resolution of radiocarbon in the Glacial will be improved by new findings of Glacial trees in New Zealand (Kauri) and in the Mediterranean (Italy, Portugal), linked to the ice-core timescale via another cosmogenic isotope, Beryllium-10. Using these tree-ring-based data, we can begin to calibrate more accurately the 14C ages associated with breakthrough discoveries of human evolution. This study presents new data of high-resolution radiocarbon chronologies of several Middle and Upper Paleolithic sites showing how 14C dates with thigh error ranges could improve the understanding of archaeological human occupations and the association with past climatic fluctuations.

Initial and Early Upper Palaeolithic blade and bladelet technologies in Eastern Balkans (MIS 3): Chronological and climatic indications, taphonomical and techno-economical evidence from Bacho Kiro, Temnata and Kozarnika caves

Dr. Tsenka Tsanova [1]

1. *Paläoanthropologie, Eberhard Karls Universität Tübingen*

The Initial Upper Palaeolithic blade technologies at Bacho Kiro Cave are now securely associated to Homo sapiens dispersal in Eurasia between 45 and 43 ka BP. The chrono-stratigraphic record from the regional benchmark Palaeolithic sites Temnata and Kozarnika caves can be compared and reconsidered. This study assesses contextual information, chronological markers (radiometric dates and Campanian Ignimbrite (CI) Y-5 tephra), lithic technologies, fauna, climatic data and worked bone assemblages to discuss the establishment and duration of the IUP in southeast Europe and the connection with the subsequent Early Upper Palaeolithic bladelet industry from Kozarnika Cave.

This contribution aims to synthesize the pertinent data and expose the coherence and shifts in the archaeological record, which presumably could correspond to new ecological conditions to which humans responded by their behavioural adaptation during the MIS3 in this region.

Key words: Bacho Kiro Cave, Early Upper Palaeolithic, Initial Upper Palaeolithic, Kozarnika cave, MIS 3, Temnata cave, Transition Middle to Upper Palaeolithic.

Palaeoenvironmental changes in the early Gravettian and the Last Glacial Maximum - a comparison of species composition, food webs, and resource use from Lower Austria

Ms. Lilian Reiss [1], ***Dr. Christoph Mayr*** [1], ***Mr. Holger Wissel*** [2], ***Dr. Andreas Lücke*** [2], ***Dr. Andreas Maier*** [3], ***Dr. Thomas Einwögerer*** [4], ***Mr. Marc Händel*** [4], ***Dr. Kerstin Pasda*** [5]

__1.__ Institute of Geography, Friedrich-Alexander-Universität Erlangen-Nürnberg, Wetterkreuz 15, 91058 Erlangen, __2.__ Institute of Bio- and Geosciences, Agrosphere (IBG-3), Forschungszentrum Jülich GmbH, __3.__ Institute for Prehistoric Archaeology, University of Cologne, Bernhard-Feilchenfeld-Strasse 11, 50969 Cologne, __4.__ Austrian Archaeological Institute, Austrian Academy of Sciences, Hollandstrasse 11-13, 1020 Vienna, __5.__ Institute of Pre- and Protohistory, Friedrich-Alexander-Universität Erlangen-Nürnberg, Kochstrasse 4/18, 91054 Erlangen

We present osteoarchaeological and bone collagen stable isotope data of Early Gravettian assemblages (approx. 33 – 29 ka cal BP) from the sites of Krems-Hundssteig, Krems-Wachtberg, and Langenlois, in comparison to Kammern-Grubgraben (Last Glacial Maximum, approx. 24 – 19 ka cal BP). Faunal composition changes substantially over time, from mammoth-dominated assemblages to a dominance of ruminants such as reindeer, horse, and ibex. Additionally, the greater species diversity in the LGM demonstrates a change in the environment or subsistence strategies.

At the Early Gravettian sites, herbivores exhibit $\delta^{15}N$ values of bone collagen of 5.2 ‰ on average. In agreement with previously published data, mammoths had significantly higher $\delta^{15}N$ values (mean: 8.2 ‰). Migration, differences in habitat use, feeding habits and/or physiological factors might be the reason for this anomaly. Among other herbivores, niche partitioning in carbon isotopes between horse and hare (mean: -20.6 ‰) on the one, and reindeer and ibex (mean: -19.3 ‰) on the other side indicate dietary preferences or differential habitat use, with higher $\delta^{13}C$ values being associated with drier ecosystems.

At the LGM site, almost all herbivores (reindeer, ibex, horse, bison, hare, mammoth) show similar $\delta^{15}N$ composition. However, values are generally lower (mean value: 2.5 ‰) than at the Early Gravettian sites. As expected, $\delta^{15}N$ values of carnivores (wolf, polar fox, red fox, wolverine) are at least one trophic level higher than herbivores. Similar to the Gravettian sites, carbon isotopes exhibit a clustering in herbivores, however, mammoth $\delta^{13}C$ values spread between the two herbivorous groups. Wolf and wolverine tend to have higher $\delta^{13}C$ values in both time periods indicating predominant foraging on reindeer or ibex.

In conclusion, our results show a trophic partitioning typical for a tundra steppe-like ecosystem. The study also demonstrates a shift in both, the species composition, and the nitrogen isotope baseline between the Early Gravettian and the LGM. We also show that the exceptionally high $\delta^{15}N$ values for mammoth in the Early Gravettian are not reflected at the LGM site. Moreover, carbon isotopes allow inferring habitat differentiation between herbivores which may give important indications regarding preferred hunting grounds during the Gravettian and LGM.

Characteristics of the Upper Paleolithic lithic assemblages from the Piatra Neamț sites (eastern Carpathians, Romania)

Dr. Elena-Cristina Nițu [1] ***, Prof. Marin Cârciumaru*** [2] ***, Dr. Ovidiu Cîrstina*** [1] ***, Mr. Florin-Ionuț Lupu*** [1] ***, Mr. Marian Leu*** [1]

1. *"Princely Court" National Museum Târgovişte, Museum of Human Evolution and Technology in Paleolithic, Justiției St., no. 7, 130014, Târgovişte, Dâmboviţa County, Romania.,* ***2.*** *Valahia University of Targoviste, Targoviste*

One of the richest areas of Paleolithic findings in Romania is the Bistrița valley, which stands out through a remarkable density of sites (approximately 20 settlements) located on the eastern mountain rim of the Carpathians, in a completely different environment from the region of significant concentrations of Paleolithic sites in Eastern Europe (e.g. Kostenki-Borchevo region). The distribution of the sites is not uniform, with four distinct areas, unevenly researched: the Ceahlău basin, with the largest number of settlements; Bicaz, with an impressive number of lithic materials discovered over time; the Piatra Neamț area, where there are three sites, of which Poiana Cireșului remains a key settlement for the eastern Carpathians, preserving a long chronostratigraphic succession as well as the oldest Upper Paleolithic occupations in this area; and the lower basin of the Bistrița, with two sites, Buda and Lespezi.
Benefiting from recent research, the three sites from Piatra Neamț have a good chronology, several different Paleolithic occupations spanning a long period (between 20 ka cal. BP and 40 ka cal BP) and, unlike most settlements in the east of the Carpathians, the deposits preserve the organic materials very well. To date, eight occupations have been better investigated at these sites, with a chronology between 20 and 30 ka cal BP, therefore overlapping almost the entire Gravettian and Early Epigravettian periods. Being located in the same region, at a very short distance from each other, these sites provide a good opportunity to understand the technical behavior and the exploitation of the similar environment by different Paleolithic communities over a long period of time. Here we present the lithic assemblage from the Piatra Neamț sites, along with the main cultural characteristics of each occupation. Preliminary analysis indicated significant differences between most of the occupations in this area, including in terms of the management of mineral resources, most likely a response to climate change and the environment.

Finding the missing piece but struggling to finish the puzzle: combining off-site and on-site geoarchaeological research in the Swabian Jura (SW Germany) to tackle population dynamics during the LGM

The presence of Palaeolithic foragers in Central Europe during the Last Glacial Maximum (LGM; 25-20 ka cal BP) remains a fascinating and debated research topic, with important implications for the study of the subsequent Magdalenian colonisation of Europe. In Palaeolithic archaeology, phases of de-population are usually inferred from gaps in regional archaeological records. These gaps, however, might also reflect taphonomic processes active at a regional scale, making the integration of on-site and off-site analyses pivotal to tease apart forager behaviours from post-depositional disturbances.

Caves and rockshelters situated in the Ach and Lone valleys (Swabian Jura, SW Germany), show almost no materials and sediments dating between the Gravettian (35-30 ka cal BP) and Magdalenian (17-14 ka cal BP) occupations. This hiatus has been generally interpreted as a phase of human depopulation associated with deteriorating environments during the LGM. With our previous works on linking cave stratigraphic data with open-air geomorphological archives in the Swabian Jura, we proposed an alternative interpretation. We argued that this gap does not necessarily correspond to a phase of depopulation but rather reflects a phase of cave erosion, which was triggered by regional landscape changes. In more recent years, archaeological excavations at the rockshelter of Langmahdhalde, in the Lone Valley, unearthed a 2 m thick sequence composed of sterile loess, dating between ca. 27 and 17 ka cal BP. This discovery is ground-breaking, as it represents the best evidence of deposits dating to the LGM so far unearthed from archaeological sites located in the Swabian Jura. This finding poses new challenging questions: (i) Why erosional processes did not impact on the preservation of LGM deposits at Langmahdhalde? (ii) Are these sterile deposits the final proof that the Swabian Jura was indeed abandoned during the LGM?

To answer these questions, we will present our preliminary results from a new research project, which aims to link off-site geophysical, coring, micromorphological, and luminescence dating with on-site micromorphological, radiocarbon, and microfaunal results from Langmahdhalde. This work gives us the opportunity to showcase the complex interaction between human behaviour, site formation processes, and regional geomorphology in the Swabian Jura during the LGM.

Krotova, Oleksandra (Institute of Archaeology of NAS, Ukraine) Upper Palaeolithic hunter-gatherers' adaptation during the Last Glacial Maximum in Southern Ukraine

Dr. Oleksandra Krotova [1]

1. Institute of Archaeology of National Academy of Sciences of Ukraine

The main results of Amvrosievka site (South-Eastern Ukraine) complex research guided under the author's direction during about the last thirty years are analyzed in the report. The complex consisting of a base camp and bison kill site situated nearby represents a unique Late Pleistocene locality that offers a great deal of information about the Late Pleistocene hunter adaptations.

The paleogeographers argued that the horizon with the densest concentration of cultural remains of the campsite lie in the gray-brown sandy loam below the Holocene horizon. Under this layers are a brownish loam – the Late Pleistocene soil, predating occupation of the camp. The site is dated on the basis of 16 radiocarbon dates from the bone bed (14) and camp (2). Most of the dates are closely related to the value an average of 19,000–18,000 uncal 14C BP.

The bone bed was the kill site for some hunting operations and the place of primary butchering of hunting bag. Secondary carcass butchering, bone processing for making tools, skin processing, and manufacturing of the variety objects also took place at the camp.

During the Late Glacial Maximum (LGM) in territory of the south of continental Ukraine prevailed cold and an arid climate and open landscapes with steppe vegetation. Paleontologists consider that this period was marked by a high density of large herbivores, first of all, the bison.

The rests of a bison averaged 88% of faunal remains in the collections of large herbivores in some main epigravettian sites – Amvrosievka, Anetivka 2 and Velyka Akarzha.

From the ethnographic model, the high density of prey formed the basis of a regular driving seasonal hunting and storage strategy that gave the large hunter groups (to a few communities) an opportunity to live near food storage places during the whole season. Thus, the adaptation of hunter groups in this period are defined by specialized bison hunting, predominance of a logistical mobility in life-style, and a relatively stable social relationship.

Residue analysis for the reconstruction of Late Glacial hunting activities: new data from the Epigravettian series of Grotta della Cala (Campania, southern Italy)

Residue analysis is one of the most promising approaches in dealing with the reconstruction of past human activities, through the identification of ephemeral traces of organic substances by means of cutting-edge techniques capable to characterise ever-smaller samples. In this frame, the use of spectroscopic techniques has proven to be a valuable tool for residue identification, as well as the application of multi-techniques protocols investigating the sample on different levels (morphological, elemental, molecular, structural). In this presentation, the results of the application of residue analysis on a set of more than twenty backed tools retrieved in the entire Epigravettian series of Grotta della Cala (Campania, southern Italy) are discussed and compared throughout the sequence of this technocomplex, which is composed by eight stratigraphic units ascribed to both the evolved (layers P, N, O and M) and final (layers I, L, H and G) phases. From layers N, M and H a series of radiometric dates were obtained which are coherent with the stratigraphic sequence (N: 20826-18819, M: 18978-16863, and H: 14173-13600, 14842-14096, 14226-13598, cal BP - 68,3 %). Over this wide span of time, as is well known, human groups have often faced harsh climatic conditions and rapid environmental turnovers, adapting to the changing surroundings in sometimes unexpected ways. In this frame, the overall analysis of residues coming from the Epigravettian series of Grotta della Cala is meant to provide compelling insights into hunter-gatherers' exploitation of natural resources, with a particular focus on the use of lithic artefacts connected with hunting activities. The workflow applied in the present communication includes complementary techniques like 3D digital microscopy, Fourier Transform InfraRed microscopy, Low Energy X-Ray Fluorescence microscopy and Particle Induced X-ray Emission, which have been already successfully combined by our group in past works to achieve a complete chemical characterisation of each residue.

Technology and subsistence strategies of the Epigravettian groups in southern Italy: new data from layer 9c of Grotta Paglicci (Apulia) and layer O of Grotta della Cala (Campania)

Dr. Matteo Rossini [1]***, Dr. Antonin Tomasso*** [2]***, Dr. Stefano Bertola*** [3]***, Dr. Clarissa Dominici*** [1]***, Prof. Annamaria Ronchitelli*** [1]***, Prof. Adriana Moroni*** [1]***, Prof. Francesco Boschin*** [1]

1. *Dipartimento di Scienze fisiche, della Terra e dell'Ambiente, University of Siena, Via Laterino 8, 53100 Siena, Italy,* ***2.*** *Université Côte d'Azur CNRS CEPAM,* ***3.*** *Dipartimento di Studi Umanistici – Sezione di Scienze Preistoriche e Antropologiche, University of Ferrara, Corso Ercole 1° d'Este 32, Ferrara, Italy*

The Epigravettian is an Upper Palaeolithic technocomplex dated between c. 26-25 ka and 11.9-11.6 ka cal BP, which is well attested in Italy. It developed from Last Glacial Maximum (LGM) to the final phases of the Late Glacial (LG), in a period of remarkable changes in environmental conditions. During the LGM, due to adverse climatic conditions, Epigravettian sites are mainly clustered in 'refuges' such as the southern part of Italy. Our study focuses on the Evolved Epigravettian (c. 16,000 to 15,000/14,500 uncal. BP) of this region in order to achieve new data on possible analogies or dissimilarities in technology and subsistence strategies implemented by hunter-gathers in different environmental conditions. Therefore, we analysed two lithic assemblages respectively on the Adriatic and the Tyrrhenian side of the Italian Peninsula: layer 9c (18,002–18,956 Cal BP) of Grotta Paglicci (Apulia) and layer O of Grotta della Cala (Campania), which can be dated around 21-20 ka cal. BP, based on the date obtained for the immediately overlying layer N (20,826-18,819 cal. BP - 68,3 %).

Human behaviour and environmental change in the upper complex of the Grotta Romanelli (Lecce, southern Italy)

Dr. Fabio Bona [1], ***Dr. Filomena Ranaldo*** [2], ***Dr. Giuseppe Lembo*** [3], ***Dr. Brunella Muttillo*** [4], ***Dr. Beniamino Mecozzi*** [5], ***Prof. Raffaele Sardella*** [6]

1. *Dipartimento di Scienze delle Terra, Università degli Studi di Milano,* ***2.*** *Museo della Presitoria di Nardò, Nardò (Lecce),* ***3.*** *Ministero dell'Istruzione e del Merito,* ***4.*** *University of Siena,* ***5.*** *Dipartimento di Scienze della Terra (PaleoFactory lab.), Sapienza Università di Roma, P.le Aldo Moro, 5, 00185 Rome, Italy;,* ***6.*** *Department of Earth Sciences, Sapienza University of Rome*

Grotta Romanelli is a reference site in the Mediterranean area for the reconstruction of both cultural aspects and environmental changes from the Middle Pleistocene to the onset of the Holocene. Excavations, begun in 1914 by Gian Alberto Blanc and continued intermittently until the 1970s, have revealed a well-articulated stratigraphic sequence. The uppermost part of infilling deposit has provided human remains and thousands of vertebrate remains, lithics and mobiliary art that helped to define the archaeological and paleoecological specifics of the final phase of the Upper Palaeolithic.

When research resumed in 2015, the aim was to update and to investigate in more detail the chrono-cultural framework in the upper complex focusing on the reconstruction of the organisational strategies of the human groups in response to environmental changes, both in the structuring of activities within the site and in the management of the surrounding territory. The current work analyses what has emerged from the recent excavations, specifically considering the studies of those classes of material most represented in the archaeological record of the upper complex.

The analysis of the deposit is based on stratigraphic excavation with integrated computerised data documentation and archiving, this approach incrementing the precision and speed of interpretation and facilitating correlation between spatial data and those arising from the analysis of microfauna, zooarchaeological data and lithic tools.

Within this analytical structure, the study of the small mammals allows us to define the climatic/environmental phases and to put them in relation with the trophic strategies of humans during the phase in which the cave was occupied. The zooarchaeological analysis of the macrofauna and the study of the techniques of lithic production contribute substantially to the reconstruction of human behaviour and spatial use of the cave. The zooarchaeological analysis of the faunal remains provides detailed information on prey exploitation and adds new data regarding the seasonal occupation of the site. Moreover, the study of lithic production shows the systematic introduction of non-local lithotypes and a diachronic tendency towards the creation of products that could be linked to hunting strategies.

Session 88: Human-environmental Interactions Along the Ancient Silk Roads

Ancient hydro-geomorphy in Dunhuang region and the water conservancy facility “HanSaiQiang” before 2000 years

Prof. Xiaoguang Qin [1]

1. *Institute of Geology and Geophysics, Chinese Academy of Sciences, Key Laboratory of Cenozoic Geology and Environment*

Dunhuang was one of the most important sites on the Silk Road. The Shazhou, Yangguan and Yumenguan under its jurisdiction were the famous cities and passes in the Han dynasty. Between the Shazhou oasis along the Danghe River and the Yangguan oasis on the east bank of the Xitugou river, there is a unique relic of the Han Dynasty (~208BC to ~219AD), ‘HanSaiQiang’(HSQ), that means a wall or dam for blocking in Han dynasty. It is 3-5m wide and 1~1.5m high, extending from Danghe Reservoir in the east to Shazaodun beacon tower in the west, with a total length of about 16km. It is a gravel ridge made entirely of gravel on the Gobi Desert, without any sedimentary structure. The role of the HSQ has always been a mystery, and it was guessed to be use for flood protection, or as the sign of the ancient road.

The landform landscape of Shazhou-Yumenguan area shows that the whole area is the Danghe River proluvial fan which east boundary is the current Danghe River and the west boundary is Yangguan-Linchangcun-Erduncun river net. During the Han dynasty, Danghe River floods once rampant in this vast area. The HSQ wall completely isolated the flood northward flowing in the section of the proluvial fan, and forcing the eastern flood into the Danghe river in east to nourish Shazhou oasis, western flood flows to Yangguan, Linchangcun village, Erduncun village to form Yangguan-Erduncun village oasis belt, providing guarantee for the Yangguan-Yumenguan Pass traffic artery. Therefore, it is concluded that the HSQ Wall is a important water conservancy project implemented by the ancients of the Han Dynasty, aiming to completely change the landscape pattern of the Dunhuang area and create an oasis environment conducive to reclamation and defense.

The emergence of rice and millet farming in the Zang-Yi Corridor of southwest China dates back to 5000 years ago

Dr. Xiujia Huan [1]

1. Institute of Geology and Geophysics, Chinese Academy of Sciences, Key Laboratory of Cenozoic Geology and Environment

The Zang-Yi Corridor is of pivotal significance for the interactions between northwest China, southwest China, and mainland Southeast Asia. It has been hypothesized that the formation of mixed farming in this region and its surrounding areas was based on multiple waves of crop dispersal, with foxtail millet and broomcorn millet arriving first from northwest China around 5300 cal. BP and rice from middle Yangtze valley after 4700 cal. BP. Based on the systematic sampling and direct dating conducted at the Guijiabao site, Sichuan Province, this study demonstrates that by no later than 5000 cal. BP, mixed farming had already emerged in the south part of Zang-Yi corridor, which was much earlier than expected before. With this new evidence, it is argued that the transformation into farming in Southwest China was based on the dispersal of a crop package comprising foxtail millet, broomcorn millet, and rice instead of different waves of introduction. A further comparison of all archaeobotanical data in this region revealed that crop patterns varied significantly between different sites because of their diverse environmental conditions.

Nearly 2500 years of precipitation change in the core of Arid Central Asia and its potential impact on Silk Road civilization evolution

Dr. Guoqiang Ding [1]

1. *Lanzhou University*

The ecological environment in Arid Central Asia (ACA) is fragile and sensitive to global climate change. However, there is a lack of accurate quantitative precipitation reconstruction in the study area, which limits the understanding of regional water-heat distribution, and also fails to obtain an in-depth understanding of the relationship between climate change and the Silk Road civilization. In this study, pollen analysis of Sasikul lake on the Pamir Plateau was performed within the framework of six AMS^{14}C ages chronologies and the precipitation change in recent 2500 years was quantitatively reconstructed. Among them, drought-tolerant Amaranthaceae pollen during the MWP reached the highest in the study section, with an average annual precipitation of 115 mm, about 15% lower than modern precipitation, and the climate was relatively dry. During the LIA, *Artemisia*, *Picea* and *Abies* had higher pollen content, with an average annual precipitation of 160 mm (up to 210 mm), about 20% higher than the modern precipitation, and the climate was cold and humid. On this basis, we explore the possible influence of climate change on the evolution of Silk Road civilizations during the historical period, combining regional high-quality temperature records and archaeological data. We believe that the temperature conditions in the water-heat distribution have the most important impact on human activities and the evolution of the Silk Road civilization in ACA. In the Sui-Tang Dynasties, under the warm climate, the melting water of ice-snow increased significantly, the oasis area expanded and the Silk Road civilization flourished and developed; while in the Ming dynasty, the cold and dry climate conditions and the lack of fresh water input led to the reduction of the oasis area, the significant decline of the Silk Road civilization.

Middle Holocene landscape change, climate change and human adaptation in mountainous Central Asia

Dr. Michael Spate [1] ***, Dr. Giedre Motuzaite Matuzeviciute*** [2] ***, Prof. Kubatbek Tabaldiev*** [3]

1. University of Sydney, 2. Lithuanian Institute of History, 3. Kyrgyz Turkish Manas University

The archaeological site of Chap in Kyrgyzstan has been identified as an important centre of prehistoric agriculture in the central Tien Shan. A large archaeobotanical assemblage indicates two periods of intensive occupation and cultivation, ranging ca. 4400-4000 BP and ca. 3000-2800 BP. The occupational layers at the site are separated by thick to very thick bedded fine-grained sediments, absent any cultural materials. Deposition of these sediments appears contemporary with regional climate deterioration, and these conditions have been raised as possible drivers of the ca. 1000-year gap in occupation of the site. This presentation explores the environmental context of human settlement and abandonment of the site through palaeoenvironmental proxies from these sediment layers (including pollen, magnetic and sediment size data). From the data we interpret indicators for anthropogenic and natural processes driving landscape change around the site. We compare these local-scale data with other on-site archaeobotanical remains, and regional-scale palaeoclimate records and archaeological settlement patterns to better understand past human responses to environmental and climate change in mountainous Central Asia.

First paleoclimate calibrations for pollen transfer functions and biomarkers (brGDGTs) covering the Caspian sea to Arid Central Asian area.

Accurate climate reconstructions are important to better investigate the Holocene climate changes mainly because this period appears to be a smooth continuity to the current and the future climate warming and also because the human-societies and climate systems interactions begin from this period to be undeniably ravelled. In this context, an important issue address the understanding of the links between proxies (eg pollen and molecular biomarkers) and environmental forcing (climate…) through accurate calibrations on modern samples. Even if this environment-proxy causal relation has to be studied in a global biogeographical context (flowering plants producing pollen and bacteria or archaea producing biomarkers as Glycerol Dialkyl Glyceryl Tetraethers depend on vegetation, geological bedrock and soils as well as climate), some geographical areas are poorly documented. Among them, the Caucasus lowlands of Azerbaijan and the Touran basin to Pamir-Alay piedmonts and mountains of Uzbekistan and Tajikistan have never been investigated.

In this study, we have collected and analysed new modern samples for pollen and GDGTs from Azerbaijan, Uzbekistan and Tajikistan. Calibrations are then established. The pollen samples have been compared to vegetation *relevés* to better understand the vegetation-pollen rain relation, and then, some transfer function methods (MAT and WAPLS) or machine-learning methods (BRT and RF) have been applied to reconstruct climate parameters from pollen assemblages. A particular focus has been carried on local condition for each surface samples: surrounding vegetation, biome extraction, soil description, sample type (top-core, moss polster or soil), in order to unravel the potential local bias in climate reconstruction. Finally, for both proxies, the discussed results and calibrations will be tested on two paleo-records from lakes Fazilman and Tuya (Uzbekistan).

This study highlight the difficulties raised by the special conditions of these extreme environments (arid to semi-arid context, impact of soil pH, salinity and gypsum content) on pollen and brGDGTs vs. climate calibrations.

Connecting Dots: Human Migration and Trade in Trans-Himalayas based on archaeological evidences in Spiti valley

Dr. EKTA SINGH [1]***, Dr. Nagendra Rawat*** [2]

1. *Shoolini University,* ***2.*** *HNB Garhwal University*

The Hind Kush, the Pamir, the Karakoram, and the Large Himalayas are among the great mountain ranges that make up the western Himalayan region, which stretches from Chitral in the far west to the Uttarakhand Himalaya in the east. Behind it is the Plateau of Tibet, which is connected to the Himalayas through various passes spread across these ranges. The main hub of significant local and long-distance trade networks is located in Ladakh, which is on the upper Indus. Indeed, it is the intersection of several trade routes from Kashmir, Punjab, and Yarkand. At Gartok, the Leh-Lhasa route is joined by many passes from the Uttarakhand Himalaya and passes from Lahul and Spiti in Himachal Pradesh. From the way the western Himalayas look, it is clear that trade with China and Central Asia was important for the area's economy to grow.

The trans-Himalayan region of India has been archaeologically explored earlier in Niti Valley, Uttarakhand, and Kinnaur, Himachal Pradesh shows many interesting aspects of the lives of its inhabitants in these harsh and rugged climatic conditions. The artifacts found at different sites in the Spiti Valley show that a highly developed culture grew and thrived in the first millennium BCE, and that this culture lasted until the historical period. Even though they lived in a remote part of the Trans-Himalayas, you couldn't call them primitive or nomadic. So, the research in the higher Trans-Himalayan region became important because it helped fill a gap in India's higher Himalayan prehistoric archaeology. From a broader point of view, the study has given us new ways to look into other important topics, such as rock art, burial culture and its spread, ceramic traditions, metallurgy, shell beads, and technological advances. This study is an attempt to gather evidence that the Himalayas were never a barrier, as believed. Instead, through its passes, people were well connected through trade and were moving to the faraway places of mainland India and central Asia.

The Entanglement of Landscape: Fire, Climate, and Agro-Pastoralism in the Bronze and Iron Age South Caucasus

***Mrs. Amy Cromartie* [1], *Dr. Odile Peyron* [2], *Prof. Guillemette Ménot* [3], *Dr. Erwan Messager* [4], *Mr. Lucas Dugerdil* [5], *Ms. Kristina Sahakyan* [6], *Dr. Mary Robles* [7], *Dr. Ruben Badalyan* [8], *Dr. Sébastien Joannin* [9]**

This paper investigates how the different social and political structures in Bronze and Iron Age Armenia shaped the surrounding steppe landscape through their agro-pastoral practices. We utilized a series of sediment cores from an altitudinal transect from around Mount Aragats, Armenia in conjunction with multiple biological and geochemical proxies (pollen, non-pollen palynomorphs, XRF, brGDGTs) and the archaeological record to untangle drivers of landscape change. This novel approach integrates multiple lines of evidence in order to understand the complexity of the entanglements of climate, fire, agro-pastoralism, and vegetation in this mountain steppe landscape.

In this paper we focus on the pollen and macro-charcoal results from two sediment cores. One higher in the foothills, published in Cromartie et al. (2020), and a new record located in the valley. We find the markers of human activity corresponds with Early Bronze Age Kura-Araxes expansion of cereal agriculture into this highland region. This is followed by a decline in these markers in the Middle Bronze Age when there is a shift away from permanent settlements and increases in mobile pastoralism. Human indicators of agro-pastoralism land-usage return as communities return to practice settled agriculture from the Late Bronze Age through the Iron Age. Human landscape usage is primarily isolated to the core site in the valley through most of the record, but this changes during the Iron Age when shifts in political structure may have driven communities to utilize wetlands higher in altitude. Macro-charcoal analysis across all cores records a similar fire history which appears to be driven by climate until the last 2000 years but shifts in vegetation in the previous periods suggests humans contributed to declines in the natural fire regime. Overall, our records show that even within a small geographical area, human communities unevenly utilized the landscape and the differing social-political contexts influenced these changes. We highlight that social-political and agro-pastoral change needs to be considered when reconstructing landscape usage and predicting future change.

Session 89: Cenozoic sea-level indicators and ice sheet constraints to global sea-level change

Modeling the Last Interglacial notch formation in Orosei, Sardinia: A Monte Carlo approach

Dr. Nikos Georgiou [1], *Prof. Alessio Rovere* [1], *Prof. Paolo Stocchi* [2], *Dr. Elisa Casella* [3]

1. Ca' Foscari University of Venice, 2. Utrecht University, 3. Leibniz Center for Tropical Marine Reserach (ZMT), Bremen

Imprints that the sea level left during the Last Interglacial (127-116ka BP) are carved on the limestone cliffs of the Orosei Gulf (Sardinia, Italy). Along at least 40 km of almost vertical cliffs and located up to ten meters above modern sea level, several workers described it as a relic tidal notch (Antonioli et al. 2018). Here, we mapped the best-preserved part of this notch using Structure from Motion - Multi-View Stereo (SfM-MVS) techniques, that reveal the details of the hitherto described “double notch” geometry, culminating with an indentation at 10.5m above mean sea level. Although its geometry is laterally constant, the notch's depth differs by 3m, while its base is ranging from well-formed to locally absent, possibly due to local factors that appear to control the notch morphology. In our study, we use a numerical model of tidal notch formation (based on Schneiderwind et al. 2017) that we run using a Monte Carlo approach, with varying erosion rate, bedrock slope, tidal range, tectonics, and relative sea-level (RSL). We discuss under which parameters we obtain the best-matching results between modeled and observed notch geometry. We surmise that this kind of inverted approach might give new insights into classic Last Interglacial relic landforms such as the Orosei tidal notch.

Constraining sea level oscillations in the Last Interglacial by modeling fossil coral reefs

Dr. Denovan Chauveau [1] ***, Prof. Alessio Rovere*** [2] ***, Dr. Anne-Morwenn Pastier*** [3]

1. *Department of Environmental Sciences, Informatics and Statistics, Ca' Foscari University of Venice, Venice, Italy,* ***2.*** *Ca' Foscari University of Venice,* ***3.*** *Helmholtz Centre Potsdam, German Research Centre for Geosciences (GFZ), Potsdam, Germany*

Understanding past sea-level (SL) oscillations is essential to gauge the future patterns of SL rise, in response to warmer climate conditions. Thanks to the good preservation and dating of fossil outcrops, the Last Interglacial (LIG; ~122 ka ago) is one of the best climate analogs to study the possibility of abrupt SL changes within an interglacial. The existence and magnitude of possible intra-LIG SL oscillations is a hotly debated topic. Indeed, some LIG coastal stratigraphic sequences, especially those stemming from coral reef terraces (CRTs), are characterized by abrupt shifts in geological facies or double/multiple stepped stratigraphies, which were hitherto interpreted as proxies for abrupt SL oscillations. To investigate whether these geological formations have an eustatic origin, we focused on modeling the processes and SL scenarios that may contribute to build such reef stratigraphies. For this purpose, we used two models: DionisosFlow software (i.e., a forward stratigraphic model) and the code of Pastier et al. (2019; Geochemistry, Geophysics, Geosystems, 20(8); i.e., a kinematic model based on reef morphology). In our work, we first calibrated the CRT morphogenesis parameters (e.g., carbonate production/reef growth; sedimentation; marine erosion; rock foundation geometry, etc.) based on global reef observations. Then, we tested different SL scenarios (e.g., a stable SL highstand, a stable SL followed by a rapid jump, a double peak SL highstand, etc.). Finally, we compared modeled and observed stratigraphies, and investigated which parameter set, processes and SL scenario are most consistent with observations of double/multiple-stepped reef stratigraphies at different sites globally. Our results highlight that the morphology of CRT sequences provides fundamental observations to unravel past SL, including the possible intra-LIG SL oscillations.

DATED-2: An updated ice-extent chronology for the last Eurasian ice sheet complex, 40-10 ka

Dr. Anna L.C. Hughes [1]***, Dr. Jo Brendryen*** [2]***, Dr. Richard Gyllencreutz*** [3]***, Dr. Evan Gowan*** [4]***, Dr. Jan Mangerud*** [2]***, Dr. John Inge Svendsen*** [2]

1. *Department of Geography, The University of Manchester,* ***2.*** *Department of Earth Science, University of Bergen and Bjerknes Centre for Climate Research,* ***3.*** *Department of Geological Sciences, Stockholm University, Sweden,* ***4.*** *Department of Earth and Environmental Sciences, Kumamoto University*

DATED-1 comprised a fully-documented empirical reconstruction of the changing extent of the last Eurasian ice sheets 40-10 ka (at 1000-year resolution after 25 ka) based on a geological-glaciological assessment of all relevant chronological data (n=5477 dates). All uncertainties within the underlying data are synthesised and expressed in terms of distance; deviation between maximum and minimum limits, and their relative proximity to the extent considered 'most-credible', indicates the degree of uncertainty along the ice margin for each 1000-year time-slice. Explicitly representing all uncertainties in this way provides a straightforward means to compare geological data with results from numerical modelling of past ice extent. Our process created an archive of published dates (and associated data necessary for their interpretation, quality, and recalculation) relating to the build-up and retreat of the British-Irish, Scandinavian and Svalbard-Barents Kara seas ice sheets. Both the time-slice reconstructions and underlying chronological dataset are available via the online data repository PANGAEA. However, new empirical geological data and interpretations are generated almost continually and valuable syntheses such as this run the risk of being frozen-in-time and losing their relevance if not maintained and updated to reflect the latest observations. A decade on from the DATED-1 census of 1 January 2013 the volume of data has grown significantly (>5000 additional dates, >1000 additional sites), and in-tandem with methodological developments in dating procedures and calibrations. Here, we present the second-generation chronological synthesis, DATED-2, which brings the chronological dataset and time-slice reconstructions for the Eurasian ice sheets up-to-date; including all new chronological information published up to 1 January 2023. We highlight the main changes required to satisfy new dates, present a new calculation of the evolution in ice sheet volume and timing of sea level contributions from the Eurasian ice sheets, and discuss implications for, and obstacles to, constraining the timing of ice sheet build-up and demise using empirical geological data.

New dating and elevations constrain the LIG eustatic sea level in south-west Madagascar

Global mean sea level (GMSL) rise is one of the most obvious manifestations of ongoing climate change with major consequences for densely populated coastal regions and islands. However, predictions about the amplitude of the GMSL rise in the future and how it will vary across the ocean are still not accurate enough. To improve the long-term estimates of future sea-level rise, geological records can help to constrain the polar ice-sheet sensitivity to warmer climates. Toward that purpose, the Last Interglacial (LIG, Marine Isotopic Stage 5e, 125 ka) when global mean surface temperature was 0.5°C–1.0°C warmer, and the sea level would have reached elevation of about 5 to 10 m above present, is one of the most appropriate target.

While many sites in West Indian Ocean (WIO) are known to have preserved LIG sea-level indicators, there are far less recent and precise studies dedicated to paleo sea level in WIO in comparison to the Pacific and Atlantic Oceans. Thanks to technical advancements in both survey and geochronology, we aimed to achieve precise paleo RSL reconstructions at the site of Lembetabe, southwest Madagascar, where a fossil reef was first described by the researcher René Battistini more than 50 years ago.

Based on 16 new U-Th ages and a cartography of the fossil reef platform using differential GNSS and drone photogrammetry, we estimate that paleo relative sea level at Lembetabe reached about 3.4 ± 1.4 m above modern between 129 ka and 115 ka. Once corrected for glacial isostatic adjustment, our data suggest that the paleo relative sea level did not exceeded 3 m above modern. Only slight crustal subsidence (that might be related to active faulting) would reconcile our estimate with the 5-10 m often-cited LIG range.

MIS 5 beachrock deposits exposed along the Ujeon beach, Jeungdo, in the southwestern coast of Korea: implications for high relative sea-levels during the last interglacial

Prof. Tae Soo CHANG [1], ***Prof. Kwang Hee Choi*** [2], ***Dr. Jeong-Heon Choi*** [3]

1. *Faculty of Earth and Environmental Sciences, Chonnam National University,* ***2.*** *Department of Geography Education, Catholic Kwandong University,* ***3.*** *Research Center for Geochronology and Isotope Analysis, Korea Basic Science Institute, Ochang, Republic of Korea*

Beachrocks, lithified coastal deposits, have been often used as a powerful marker of relative sea levels like the coral-based records. They underwent almost no post-depositional compaction, thereby recording the position of the shoreline. In this regard, we have examined beachrocks exposed along the coastal dune scarps in the Ujeon beach in order to reconstruct the sea level history during the late Quaternary in the Korean coastal seas. For these purposes, two sections from dune scarps were trenched and four vibracores were taken along the beach-dune transect lines. OSL (optically stimulated luminescene) and ^{14}C-AMS (accelerator mass spectrometry) radiocarbon datings were conducted to determine the ages of the beachrocks, tidal and coastal dune deposits. Additionally, grain sizes and magnetic susceptibility were measured from the trench sections. Sedimentary facies loggings were carried out based on the lithology, structures, colors and biogenic activities. The results show that the Ujeon beach-dune deposits are classified into six major facies types: (1) MIS 5 tidal muds, (2) MIS 5 beachrocks, (3) MIS 4 paleosols, (4) mid-Holocene tidal muds, (5) late Holocene dune sands, and (6) present-day beach sands in stratigraphically ascending order. Of these, beachrock deposits are characterized by laminated, reddish yellow, coarse sands, directly overlying semi-consolidated, older tidal muds dated to MIS 5e. More than 1 m thick of beachrocks display subhorizontal laminations alternating dark and light laminae. Seven OSL samples from beachrocks of two trench sections were dated between 140 and 83 ka, corresponding to MIS 5. They occur ca. 1 m above mean high water level. Considering high elevation of beachrocks and relatively stable tectonic activities from the previous works in the west coast of Korean peninsula, we suggest higher relative sea levels during MIS 5 than those in the Holocene interglacial. This study thus underlines the OSL dated MIS 5 beachrock deposits along the Jeungdo tidal shore in Korea, here documented for the first time in the Yellow Sea.

Constraining the timing and elevation of penultimate interglacial sea levels using submerged speleothems from the Bahamas

Dr. Peter Chutcharavan [1]***, Prof. R. Lawrence Edwards*** [2]***, Prof. David Richards*** [3]***, Prof. Gina E. Moseley*** [4]***, Prof. Jacqueline Austermann*** [5]

1. *Department of Earth and Environmental Sciences, University of Minnesota,* ***2.*** *Department of Earth Sciences, University of Minnesota,* ***3.*** *School of Geographical Sciences, University of Bristol,* ***4.*** *Institute of Geology, University of Innsbruck,* ***5.*** *Department of Earth and Environmental Sciences, Columbia University, Palisades, USA*

Late Quaternary glacial cycles occur at intervals of approximately 100,000 years. They oscillate between warm interglacial periods, with reduced continental ice volume and global sea level comparable to today, and cool glacial periods, with expanded continental ice sheets and sea levels as much as 100 m lower. However, the timing, magnitude, and evolution of each glacial cycle differs and cannot be explained simply by orbital forcing alone. Coastal cave deposits (speleothems) from tectonically-stable islands can provide valuable evidence to constrain the timing and amplitude of sea-level change and complement the existing constraints from fossil coral and marine sedimentary evidence. Speleothems, which form from the degassing of drip waters in caves, must have been subaerially exposed during periods of lower sea levels to allow calcite precipitation, and hiatuses in growth can represent periods of submergence by rising sea levels. Precise U-Th ages for calcite immediately before and after hiatuses in growth can thus be used to “bracket” the timing of sea-level rise and fall during interglacial periods.

We present a new relative sea level (RSL) reconstruction for the penultimate interglacial (Marine Isotope Stage 7), using speleothems from the submerged blue hole Sagittarius Cave, Grand Bahama. The flowstone samples used in our study grew between 13-21 m below present sea level, with multiple phases of growth present in each sample. Detrital thorium contamination poses a challenge for dating speleothems from the Bahamas because the ($^{230}Th/^{232}Th$) activity ratio of drip waters can be an order of magnitude higher than bulk continental crust. Nonetheless, U-series ages demonstrate a hiatus separating two of the growth phases that correspond to MIS 8 and 6. The hiatus contains a thin layer of red, Fe-rich sediment, similar to that found on surfaces below the freshwater mixing zone in submerged caves of the Bahamas today. We interpret this as evidence that the flowstones were submerged below sea level during MIS-7. We will utilize glacial isostatic adjustment modelling to compare our sea level constraints to other RSL records from the penultimate interglacial (e.g., Argentarola Cave, Italy) and draw inferences about global mean sea level change during this period.

Sea-level changes and the closure of Neo-Tethys seaway during the Middle Miocene in the Naga Hills, Indo-Myanmar Range

Abstract

Miocene planktonic foraminifers occur in shale intercalated with thinly bedded siltstone and sandstone of the Surma Group in the foothills of the Naga Schuppen Belt of the Indo-Myanmar Range. These are the first clearly imaged middle Miocene foraminifera from the Surma Group of the Naga Hills. This new M5-M6 assemblage from the upper Bhuban Formation correlates with the uppermost Burdigalian to Langhian age (16-14 Ma). The biostratigraphy, paleoenvironment, sea-level change and paleogeography of the assemblage is significant. It provides a basis for widespread regional and global correlation constraining timing of Neo-Tethys seaway closure. Results indicate that remnants of the Neo-Tethys seaway endured in eastern parts of the India-Eurasia collision zone until the Miocene. This contrasts with the western and Tibetan Himalaya where Neo-Tethys disappeared well before the Miocene. The finding is significant in conjunction with global sea-level change.

Session 90: Ancient DNA from Quaternary and Archaeological Sediments

A sampling strategy to maximize the yield of ancient DNA from archaeological sediments

Archeological sediments represent a nearly infinite source of ancient DNA (aDNA), which, if fully exploited, may revolutionize palaeogenetic research. Current approaches of aDNA analysis from sediments rely on core sampling or loose sediment samples from exposed stratigraphic profiles. Although quite effective, these approaches do not allow us to predict which features of the sediment are most likely to preserve aDNA. A recent study has shown that impregnated blocks of undisturbed sediments, collected for micromorphological analysis, are excellent source of aDNA. Microsampling of blocks from Denisova Cave revealed that mammalian aDNA is not uniformly distributed in the sediment but rather concentrated in small particles, emphasizing the need for further exploration of high-precision sampling. This study also showed that sampling from micromorphology blocks may improve our access to aDNA from rare taxa and single individuals, e.g., hominins, as it reduces the “noise” of high taxonomic diversity encountered when analyzing loose sediment samples. However, micromorphology block samples are unsuitable for routine aDNA screening of archaeological sediments. Here, we propose an approach that combines sampling of loose sediments alongside micromorphology blocks to maximize the recovery of DNA from taxa of interest, while allowing for accurate micro-contextualization of the genetic signal. The loose samples are used for initial broad screening to identify promising areas for aDNA recovery within an archaeological site . The micromorphology blocks from these areas are then used to contextualize the genetic signals and maximize the yield of aDNA from specific taxa through targeted microsampling. We applied this approach to sediments from high altitude tropical environments at three late Pleistocene to Holocene sites in Malawi (eastern Africa), one of which has produced the oldest human DNA recovered from the continent to date. Screening of these samples for aDNA will provide information about the feasibility of this approach in under-sampled geographical regions with challenging DNA preservation conditions, such as the tropics.

Mesolithic-Neolithic Environmental Reconstruction from sedaDNA: Data from the Stonehenge Area and Suffolk

1. University of Southampton, 2. The Arctic University Museum of Norway, Tromsø

The extraction and analysis of sedimentary ancient DNA (sedaDNA) is revolutionising palaeoecology and Quaternary science. It is also making an increasing contribution to environmental archaeology from both off-site and on-site contexts. SedaDNA analysis of two prehistoric archaeological sites in the UK- Blick Mead, Wiltshire and Martlesham, Suffolk, highlight the potential of the method for reconstructing plant and animal communities associated with wetland archaeological activity. At Blick Mead, where there is Late Mesolithic occupation of a floodplain terrace edge for the hunting of aurochs, the sedaDNA reveals open ground conditions typical of a large clearing within the regional forest. At Martlesham, sedaDNA from four domestic mammals: cow, sheep, pig and goat, reveals Neolithic pastoral activity in enclosed woodland (forest farming) surrounding a palaeochannel with trackways. Together, the two sites indicate that sedaDNA can prove a valuable new data on the landscape change and human activity during the critical Mesolithic-Neolithic transition.

Impact of climate and domesticated mammals on Holocene plant richness in the European Alps revealed by sedaDNA

Disentangling the effect of climate change and human activities on vegetation richness is essential to understand and manage ongoing drivers of change. In this study, we reconstruct plant diversity and the distributions of domesticated mammals at 14 lake sites across the Alps during the Holocene, with the aim to explore the relative contribution of climate and land use in shaping the present vegetation. We produce the largest lake sedaDNA dataset of southern Europe, consisting of plant and mammal metabarcoding applied to 705 sediment samples. To disentangle the effects of climate from human impact on vegetation, we studied the influence of temperature, precipitation and domesticated mammals on plant species composition. In total, 747 plant taxa were identified, 43% at species level. Most lakes showed a slowly increasing trend in plant richness since the Holocene. Some lakes have a notable rise at 5,000 years ago, and on the other hand some lakes showed a strong increase in the last 2,000 years. All lakes showed several shifts in dominant growth form, with periods dominated by tree species alternating with periods dominated by forbs. Domestic mammals were identified at all 14 sites, consisting in sheep, goat, cow and horse. Mammal sedaDNA showed the first presence of domestication in the French Alps by the mid-Holocene, which was dominated by goat and sheep. During the Bronze Age, domesticates spread towards the central and eastern Alps, coinciding with the introduction of cows. To further contextualize our results, we will discuss them in light of the regional archaeological data for each period. Our findings suggest both long-term agropastoral activities and climate contributed to the high plant richness of the ecosystems in the European Alps.
.

What else is in the mud? Current status and future potential of environmental DNA in bryophyte research

Dr. Dilli Prasad Rijal [1] *, Dr. Peter Heintzman* [2] *, Prof. Arve Elvebakk* [1] *, Prof. Inger Alsos* [1]

1. The Arctic University Museum of Norway, Tromsø, 2. Centre for Palaeogenetics, Stockholm, Sweden.

Bryophytes are important components of global ecosystems as they influence biogeochemical cycling. The broad geographic ranges and narrow habitat tolerances of most bryophytes make them a suitable group to study the impact of disturbance and climate change on the resilience of northern ecosystems. However, palaeoecological research of bryophytes is largely limited due to their scattered occurrences as macrofossils. To that end, sedimentary ancient DNA (sedaDNA) may provide high resolution taxonomic and occurrence data for bryophytes. Using sedaDNA data from ten lakes covering the time since deglaciation of the Fennoscandian ice sheet to present, we explored temporal diversity of bryophytes and their regional dispersal in relation to different traits. Out of the 77 taxa detected (10% of northern Norway), 42% and 14% were identified to species and genus level respectively, which is better than traditional proxies. Some mosses and liverworts were present already in the earliest samples dated to 16 000 calibrated years before present (cal BP), and the taxonomic richness continuously increased throughout the period in most of the lakes. A short core showed a negative trend for the last 2500 cal BP and two lakes showed non-linear trends. The dispersal ability varied among different orders of bryophytes. Bryophytes that can thrive either in nutrient poor continental acidic soils and tolerate high light irradiance or have no preferences seem to have arrived first after deglaciation. Bryophytes with both sexual and asexual modes of reproductions appeared before those with very common or rare sexual reproductions. Similarly, spore ornamentation seems to have a positive effect on the dispersal of bryophytes. Most importantly, the first appearance time of bryophytes was negatively correlated with spore size, which indicates wind dispersal as an important driver for bryophyte dispersal. We highlight that bryophytes have so far been reported as the by-catch of sedaDNA projects targeting vascular plants and that reference libraries of bryophytes are incomplete as they cover about 57% of bryophytes of northern Norway. Thus, there is a need to develop bryophyte specific markers and expand the reference library to increase detections and fully harness the power of sedaDNA in bryophyte research.

Sedimentary ancient DNA metabarcoding for the recognition of Paleolithic human plant use

Plants have always played an integral part in human life, as fuel, medicine, food and other uses. However, our knowledge of plants used by prehistoric humans is limited by the rare survival of identifiable plant parts in the archaeological record. The application of sedimentary ancient DNA (sedaDNA) provides unique possibilities to analyse DNA also in the absence of any visible remains. Such analyses have been applied to a variety of sedimentary contexts, including cave sediments. With caves often mitigating the full effects of the elements on organic materials accumulated by humans, animals, and other natural agents, they provide an opportunity to study past human presence, their activities and their environments through DNA analyses.
Here we present the potential of sedaDNA analyses of cave sediments to study past human plant use. By combining sedaDNA metabarcoding with pollen data we obtained a temporal reconstruction of plant assemblages that were available to early humans at Aghitu-3 Cave in the Armenian Highlands. This cave contains a detailed record of human settlement and environmental variability between 39,000 and 24,000 years ago. Our sedaDNA and pollen results reveal a stratification of plant abundance and diversity. DNA preservation reflects periods of occupation, with higher diversity in layers with greater activity. Moreover, low pollen concentrations combined with high sedaDNA abundance indicates that plants may have been brought into the cave by animals or humans. The majority of the recovered plants are useful as food, flavor, medicine, or for technical purposes, demonstrating the potential of the environment around Aghitu-3 Cave to support humans during the Paleolithic. This study represented the first application of plant sedaDNA analysis of cave sediments for the investigation of potential plant use by early humans. We now analyse a number of other cave sites from different regions and time periods to expand our understanding of plant use by prehistoric humans.

Sedimentary DNA can reveal past pelagic copepod population dynamics

Dr. Narumi Tsugeki [1]***, Mr. Kai Nakane*** [2]***, Dr. Xin Liu*** [3]***, Prof. Hideyuki Doi*** [4]***, Dr. Gaël Dur*** [5]***, Dr. Michinobu Kuwae*** [2]***, Dr. Syuhei Ban*** [3]

Copepods play a key trophic role as secondary producers in transferring primary production to higher trophic levels such as fish. Copepod production significantly contributes to successful fish recruitment. Despite their importance, knowledge of their dynamics over several decades remains limited due to the difficulty to obtain long-term data series with exhaustive sampling and analysis. However, an understanding of long-term copepod dynamics is urgently required to strive toward better management for sustainable aquatic ecosystems and fish recruitment. Sedimentary DNA (sedDNA) has been developing as a useful tool for reconstructing past plankton dynamics. This study evaluates whether sedDNA targeting the pelagic copepod, *Eodiaptomus japonicus*, in Lake Biwa (Japan) can be an effective tool for elucidating its past population dynamics. We applied a quantitative polymerase chain reaction method targeting the mitochondrial cytochrome c oxidase subunit I gene on two sediment cores and compared the detected sedDNA concentrations with the unique long-term dataset of demographic traits, biomass, specific growth rate, production, subitaneous eggs, and resting eggs of *E. japonicus*. The sedDNA concentration of *E. japonicus* recovered from sediment layers correlated significantly with *in situ* production, biomass, and subitaneous egg production but not with its resting eggs and its specific growth rate. Our results provide evidence for the use of sedDNA as a tracking tool for assessing past copepod production dynamics.

Natural changes and anthropogenic impacts on a Central European lake and its catchment over the past 15,000 years

Lake Constance is a pre-Alpine oligotrophic water body that has a long history of human occupation. Its rich and well-studied archeological record, with a high density of Neolithic and Bronze age settlements especially around the Gnadensee and Überlinger See sub-basins, testify to an early human impact on the landscape. In the past century, the lake was intensively impacted by human activity leading to a distinct period of eutrophication, which has now been reversed as a result of increased management efforts between the bordering countries. However, little is known about previous human impacts on the lake ecosystem, and possible relations to changes in its catchment area. To address this issue, we are investigating ecosystem changes over the past 15,000 years in a sediment core retrieved from the Gnadensee basin, combining data obtained from sedimentary ancient DNA, palynology, and X-ray fluorescence (XRF) analysis. Vegetational zones were reconstructed congruently by both pollen and DNA metabarcoding. The timing of changes and the species composition in the different zones suggest that vegetation was initially determined by climate and postglacial colonization processes, while the human impact has become decisive in the past two millennia. Mammal DNA obtained from the sediments mirror the environmental conditions reconstructed from the vegetation. Ongoing work is targeting the aquatic communities and will allow us to develop a comprehensive understanding of changes in the lake since the end of the Last Glacial.

Tracing species lineages through time and space using multiplexing PCRs

1. The Arctic University Museum of Norway, Tromsø, 2. Université Grenoble-Alpes, Université Savoie Mont Blanc, CNRS, LECA, Grenoble

Sedimentary ancient DNA (*sed*aDNA) has proven to be a powerful tool for the recovery of species level data from a variety of ancient sediments. However, population level data can be more difficult to obtain due to either a lack of taxonomic resolution for the molecular method used or being dependent on a high amount of DNA template and extensive reference material. Here we present the potential of multiplexing different PCR markers together to retrieve population level genetic data from sedaDNA. *Vaccinium uliginosum* (Ericaceae) was chosen as a test species due to its present day intraspecific variation and distribution. It has a circumpolar distribution and can be found at higher elevations south of the Arctic. Within Europe, *V. uliginosum* has three known lineages and multiplex markers were developed to target these based on the chloroplast data generated by the PhyloAlps and PhyloNorway sequencing projects. The resulting 38 markers were tested on lake *sed*aDNA samples from five different sites located in northern Norway, the Alps and the Polar Urals, which contain the extent of present day *V. uliginosum* variation. All main *Vaccinium* lineages and markers could be recovered from the *sed*aDNA data, where for each sample on average 28.4 (+/-9.1) makers were present containing an average of 33 (+/-12.8) marker variants. All samples were dominated by a single population, except one alpine site which had co-occurrence of two different populations in the most recent sample. Multiplexing different markers is a promising tool for generating population level genetic information. The relatively low cost and sensitivity enables the processing of numerous samples, which will allow researchers to track populations through time and space.

A systematic evaluation of hominin and faunal DNA preservation in Pleistocene sediments

Mr. Merlin Szymanski [1], ***Dr. Viviane Slon*** [2], ***Ms. Louisa Jauregui*** [1], ***Dr. Janet Kelso*** [1], ***Dr. Matthias Meyer*** [1], ***Mrs. Sediment DNA Analysis consortium*** [3]

In recent years, sediment DNA analysis has become an increasingly important tool for inferring the past presence of species even in the absence of macroscopically visible remains. The various taxa from which DNA has been isolated from sediment also include Neandertals, Denisovans and modern humans, demonstrating that it may be possible to reconstruct past human occupation at archaeological sites at much higher spatial and temporal resolution than previously imaginable. However, beyond a few proof-of-principle studies, systematic investigations are missing to determine the success rate at which hominin and faunal DNA can be recovered from archaeological sediments and to identify factors that may affect its long-term preservation.

Here we investigate the preservation of hominin and other mammalian DNA in more than 800 sediment samples collected at 148 archaeological sites in Europe, Asia and Africa with evidence of anthropogenic activity, including caves, rock shelters and open air sites. The archaeological layers sampled date mainly to the Middle and Late Pleistocene, but samples from Holocene layers were also included. To determine the taxonomic composition of mammalian DNA at high resolution and to allow the detection also of rare taxa such as hominins, DNA libraries were prepared from each sample and enriched for mitochondrial DNA by hybridization capture. In addition, an improved computational framework was developed to assign the resulting sequences to the biological families (and in some cases the species or populations) they originate from and to evaluate their ancient origin based on the presence of ancient DNA damage patterns.

Tests performed on simulated data indicate that our newly-developed analytical pipeline outperforms existing ones in terms of accuracy and speed. Preliminary data suggest that ancient DNA is, on average, best preserved in sediments from caves, followed by rock shelters and open air sites. Geographic and temporal limits of DNA preservation closely track those previously observed with the analyses of skeletal remains. We hope that the rich empirical data presented here will help to devise optimal sampling strategies in future studies, especially with regards to the number of samples that should be analyzed and the contexts that are most promising for sediment DNA analysis.

Circumarctic changes in herbivore populations over the past millennium

Arctic ecosystems are currently undergoing severe changes due to climate change and direct anthropogenic interference. Numerous Arctic and Subarctic communities directly depend on the herding and hunting of large herbivores. The presence and abundance of large herbivores is a crucial factor and an indicator of ecosystem functioning and community composition. Thus understanding the relative impacts of climate, herbivory and human management on ecosystems, in particular on vegetation, is of paramount importance for their long-term sustainability and conservation, as well as for its inhabitants.

We examined the occurrence and abundances of large and small herbivores (e.g., reindeer *Rangifer tarandus* and Arctic lemming *Dicrostonyx torquatus*) over the past millennium on a circumarctic scale using ancient DNA isolated from sediment cores of twelve lakes situated in Canada, Iceland, Norway (mainland and the Svalbard archipelago), north-western Russia, and northern Siberia. The 137 analyzed samples covered an age range of over 1,000 years in each case. Hybridization capture was used to enrich mammal DNA, and in additional, plant metabarcoding data were used to assess differences in vegetation structure over time and between sites. Overall, sequencing read counts annotated to mammalian herbivores showed contrasting patterns between sites, however, few pronounced changes were observed over time, suggesting that the local signals reflected relatively consistent occurrence of these species over the past thousand years and more. However, a documented near-extirpation event of the Svalbard reindeer population in the early 20th century and its subsequent recovery were reflected in the time series of reindeer read counts from the respective sediment core. The vegetation data supported our conclusion that herbivory related to pastoralism has been an integral component shaping these Arctic ecosystems.

In remote regions with comparably scarce historic documentation of land use and pastoralism practice, well-informed ecosystem management and planning of resource use depend on alternative sources for understanding the history of long-term use. The continuity of herbivory and associated land use over the past millennium reflected by our results provide important decision support data for nature management and will inform scenario building to allow for better adjustments to future large-scale changes due to climate warming and anthropogenic pressure.

Comparison of environmental aDNA methods in late glacial and early holocene samples from Hässadala and Atteköpsmosse (southern Sweden)

Dr. Kevin Nota [1]***, Prof. Barbara Wohlfarth*** [2]***, Prof. Inger Alsos*** [3]***, Dr. Youri Lammers*** [3]***, Prof. Antony Brown*** [4]***, Dr. Laura Parducci*** [5]***, Dr. Benjamin Vernot*** [1]

Environmental DNA extracted from ancient sediments has been increasingly used in paleoecological studies. These studies take advantage of recent improvements in molecular methods and bioinformatic processing of data, but it is unclear whether data can be reasonably compared across methodologies. A question that remains is whether different molecular methods or even similar methods in different laboratories produce consistent results from the same samples. Further, it is unclear which method performs better in terms of detectability and taxonomic resolution, how much overlap exists between them, and how molecular data obtained from new methods is related to traditional proxies such as pollen and macrofossils.

Here we compare published proxy data with three DNA methodologies executed across three independent labs: trnL P6-loop (flora) metabarcoding, shotgun sequencing, and targeted capture. We applied these methods to two well-studied lake sediment archives from southern Sweden, Atteköpsmosse and Hässeldala Port, covering the transition period from glaciation into the early Holocene (15.5 – 10 cal. kyr BP). This period exhibits strong climatic changes of contemporary ecological relevance. We investigate: the difference between single and double-stranded shotgun libraries; molecular data vs published proxy data; and metabarcoding vs capture targeting full vertebrate and invertebrate mitochondrial genomes together with plant barcoding genes (matK. rbcL, ITS1, and ITS2).

Preliminary results show that shotgun metagenomics describes a flora similar to metabarcoding when mapping ancient DNA reads against chloroplast and mitochondrial genomes, while substantially more reads were recovered when the same data is mapped to a nuclear DNA database. Both shotgun metagenomics and metabarcoding recover, in addition to plants, the microalgae Nannochloropsis. Overall, metabarcoding detected few plant taxa, with a large proportion of samples showing no reads, while shotgun metagenomics in combination with the nuclear database, recovered a more complex herbaceous flora with trees/shrubs such as Salix and Betula present already at 14.5 cal. kry BP.

The first look at the data shows that with nuclear databases, shotgun metagenomics might outperform metabarcoding to detect ancient flora, especially with degraded DNA, due to its ability to target shorter DNA fragments (30-45 nucleotides).

Holocene marine ecosystem dynamics off central West Greenland traced by ancient DNA

Dr. Heike Zimmermann [1], ***Dr. Sara Harðardóttir*** [1], ***Dr. Eline Lorenzen*** [2], ***Dr. Sofia Ribeiro*** [3]

1. *Geological Survey of Denmark and Greenland (GEUS),* ***2.*** *Globe Institute, University of Copenhagen, Denmark,* ***3.*** *Department of Glaciology and Climate, Geological Survey of Denmark and Greenland*

The West Greenland shelf is a diverse and biologically unique arctic ecoregion harboring marine areas of international value like the North Water polynya and the Melville Bay Wildlife Sanctuary. Model projections suggest that the shelf will be increasingly affected by sea-ice loss and freshwater discharge from the Greenland Ice Sheet. Large uncertainties prevail on how the regional diversity and ecosystem structure will change in the future, partly because ecological responses are highly complex and because modern long-term observations cover timeframes already affected by climate change. This is raising questions on how to define baselines for evaluating observed changes, and on how to disentangle the effects of human impact and natural climate variability. As ocean sediments are natural archives of the past, they provide vital insights into the natural variability of ecosystems and long-term biotic responses to environmental change. Here, we present a Holocene sedimentary ancient DNA (sedaDNA) record to explore past marine ecosystem dynamics to climate variability off West Greenland over the past 8,500 years. We applied targeted amplicon sequencing of a diatom-specific (rbcL) and a universal eukaryotic (18S V7 region) marker to a well-dated marine sediment core retrieved on the shelf off the Upernavik Ice Stream (AMD14-204C; Lat. 73.261, Long. -57.899, 987 m water depth). Our record revealed a high taxonomic diversity, including many taxa whose body parts are usually not preserved in sediments, such as copepods, polychaetes or jellyfish. Sequence variants representing 251 families in 31 phyla were retrieved for 18S and 19 diatom genera in 14 families for the rbcL marker, respectively. Taxonomic assignments of diatom-derived sequences contain typical cold-water (*Porosira glacialis*, *Chaetoceros socialis*, *Thalassiosira gravida*) and sea-ice associated species (*Nitzschia frigida*), including species indicative of sea ice and brackish water conditions (*Cylindrotheca closterium*, *Pauliella taeniata*). Many sequences remain unassigned, indicating the need for a close collaboration between taxonomists and geneticists to fill this gap for unlocking the full potential of sedaDNA in the future. We will discuss the exceptional potential of ancient DNA to improve predictions of marine productivity and biodiversity, and to support ocean and cryosphere risk assessment and conservation efforts.

Inferences into subsistence strategies at Kirkhellaren Cave, Norway using ancient human and faunal DNA from sediments

Dr. Niall Cooke [1]***, Prof. Johannes Krause*** [2]***, Prof. Bastiaan Star*** [3]***, Prof. Erlend Kirkeng Jörgensen*** [4]***, Dr. Benjamin Vernot*** [1]

1. *Department of Evolutionary Genetics, Max Planck Institute for Evolutionary Anthropology, Deutscher Platz 6, 04103 Leipzig, Germany,* ***2.*** *Department of Archaeogenetics, Max Planck Institute for Evolutionary Anthropology, Deutscher Platz 6, 04103 Leipzig, Germany,* ***3.*** *Centre for Ecological and Evolutionary Synthesis, Department of Biosciences, University of Oslo, 0316 Oslo, Norway,* ***4.*** *Norwegian Institute for Cultural Heritage Research*

Kirkhellaren Cave hosts one of the most spectacular and best preserved archives of integrated cultural and ecological change during the Holocene in Northern Europe. Located 50 km off the Arctic Norwegian coast on the island of Sanna, this site boasts a uniquely rich faunal assemblage of marine species that are frequently underrepresented in deep-time records and terrestrial settings. Recent excavations showcase continuous human presence since 10,000 cal BP, with the identified communities predominantly associated with hunter-gathering and fishing practices. The site has functioned as a significant focal point for communal gatherings throughout time, with evidence of strong network interaction for both Northern Fennoscandic and Southern Scandinavian populations. The cave thus constitutes a rare opportunity to reconstruct long-term marine ecological changes in tandem with human impact. In spite of the cave's detailed archaeological context, no ancient genomics-based approach has yet been attempted to characterize its human and faunal profile, or how these profiles changed over time. One particularly promising method is the prospect of retrieving ancient DNA from sediment samples, which has been previously demonstrated to work successfully in long-occupied cave sites. Here, we report recovery of both ancient human and faunal DNA from several sediment samples, representing a range of layer depths and time periods at Kirkhellaren (approx. 1800-3400 BP with aDNA; samples up to 10000 BP were analyzed). We identify DNA from diverse ancient faunal taxa (*Phocidae*, *Canidae*, *Bovidae*, *Mustelidae*, and *Balaenopteridae*). These findings are generally consistent with the archaeological record and historical interpretation of the site's function; however, we also find the first direct evidence for taxa such as *Canidae*. We also present preliminary population genetics analyses of the identified ancient human DNA, and place it in the broader context of ancient Europe. By retrieving DNA directly from occupational contexts, this study provides the first genetic-based insight into the lives of the ancient Norwegian populations who lived in the region surrounding Kirkhelleran Cave. It also demonstrates the important role that ancient sediment DNA can play in future studies of human prehistory, by enabling genetic material to be analyzed even in the absence of faunal or human remains.

The Dog in my Data: Impact and quantification of faunal aDNA that maps to the human genome

Ms. Stephanie Dolenz [1], Ms. Brooklynn Scott [1], Mr. Robin Warner [1], Mr. Jonas Platzek [1], Dr. Niall Cooke [2], Dr. Kevin Nota [1], Dr. Benjamin Vernot [1]

***1.** Department of Evolutionary Genetics, Max Planck Institute for Evolutionary Anthropology, Deutscher Platz 6, 04103 Leipzig, Germany, **2.** Ancient Environmental Genomics MPRLG, Max Planck Institute for Evolutionary Anthropology, Leipzig, Germany*

The ability to obtain ancient DNA from sediments has dramatically increased the times and archaeological sites available for genetic study. Recent advances have enabled the retrieval and analysis of genome-wide human nuclear DNA, allowing sediment samples to be included in population genetic analyses, and offering population-level insights rather than simply determining the presence and/or absence of taxa or species. One important aspect of sediment DNA is its metagenomic character; a single sediment sample typically contains DNA from multiple species. Although this allows researchers to study many species, even ecosystems, rather than single individuals, it also complicates analyses. In particular, faunal DNA may be challenging to distinguish from human DNA.

This issue is not new to the field of aDNA: the bones and teeth that are typically used in human aDNA studies also contain abundant bacterial DNA. Due to the large evolutionary divergence between humans and bacteria, this non-human DNA is generally removed by a) mapping the DNA to the human genome, and b) restricting to longer DNA fragments.

Here we investigate the extent to which faunal DNA may “mis-map” to the human genome, and the effects this DNA may have on typical population genetics analyses. In short: We find that small amounts of faunal DNA do map to the human genome, and that this DNA can have an outsized effect on analyses. The regions to which this faunal DNA maps are different between different species, frustrating simple solutions such as removing conserved sequences. However, in all tested species, this DNA maps to regions of the genome that are used for typical population genetics analyses. We additionally find that even small amounts of faunal DNA (~2-5% of mapped reads) can dramatically alter basic population statistics such as the f3 statistic, a measure of shared genetic drift between two samples. Finally, we present a simple method for quantifying this mis-mapping DNA that is agnostic to the faunal species, and discuss best practices for identifying samples where faunal mis-mapping is an issue. This method is easily extensible to non-human analyses, making this of general use to the fields of environmental or sediment DNA.

Molecular island archaeology: sedaDNA data from small islands in the Celtic fringe

Prof. Antony Brown [1]***, Dr. Thierry Fonville*** [2]***, Dr. Maarten van Hardenbroek*** [3]***, Prof. Andrew Henderson*** [4]***, Dr. Helen Mackay*** [5]***, Dr. Ben Pears*** [6]***, Dr. Gill Plunkett*** [7]***, Dr. Patrick Gleeson*** [7]***, Prof. Inger Alsos*** [8]

1. *The Arctic Museum of Norway,* ***2.*** *Department of Earth and Atmospheric Sciences, University of Alberta,* ***3.*** *Geography, Politics & Sociology, Newcastle University,* ***4.*** *Newcastle University,* ***5.*** *Department of Geography, Durham University, Durham, DH1 3LE, UK.,* ***6.*** *University of Southampton,* ***7.*** *Archaeology & Palaeoecology, School of Natural and Built Environment, Queen's University Belfast,* ***8.*** *The Arctic University Museum of Norway, Tromsø*

Islands on the Celtic fringe of Europe can be seen as test-cases for investigating the resilience and sustainability of small communities in the face of both climatic and economic change. Were they fragile socio-ecological systems precariously surviving due to economic 'windfalls' or resilient hybrid systems that could respond to changing socio-economic conditions and environmental events? Population levels on these islands generally grew from the medieval periods, when the islands were politically and economically important and sustainable until the 18th centuries after which all suffered depopulation to different extents, and at different rates. Here we use newly developed molecular methods (particularly sedaDNA and lipid biomarkers) to investigate the changing landscapes and life-scapes of four islands, three in the Southern Hebrides and one off the Northern Irish Coast. These islands all share access to marine resources and have strong cultural connections, but our studies reveal divergent histories especially in the post-medieval period. The detection of faecal steroid biomarkers varies between sites, but temporal differences in the initiation and persistence of human occupancy between islands are identified using stanol ratios. Whilst our application of lacustrine faecal steroid analyses successfully extends understandings of the timings of (post)Medieval population and land use change on these islands, it also highlights key areas of uncertainty associated with steroid taphonomy that must be explored before this approach can be used to obtain quantitative population reconstructions. The ability of sedaDNA metabarcoding to reveal cultivars invisible to pollen analyses, such as potato and cereals to species level, makes the technique able to chart the most important socio-environmental events that effected these communities such as the potato famine of the mid 19th century. The data reveals that these islands had periods of convergent and divergent histories and also lends itself to the modelling of combined population-grazing-crop-erosion modelling of catchments on these islands.

Session 92: Zooming into the Quaternary Research in South Asia: Understanding the landscape-cultural-climatic evolution

Terraces, Tools and Time: A Review of Quaternary Environmental Studies in South Asian Prehistory

Prof. Shanti Pappu [1]

1. Sharma Centre for Heritage Education & Krea University

I discuss changes in conceptual approaches in the study of Quaternary environments in South Asian prehistory. Variability in theoretical and methodological approaches adopted by Western and South Asian scholars, along with fluctuating dynamics in the academic interaction between archaeologists and other palaeoscientists, has influenced the interpretation of site contexts and past behaviours. The holistic approaches of the 19th c. were strongly marked by Robert Bruce Foote, whose work drew upon strong geological and ethnographic elements, but contrasted with starker studies during the 1930s, which focused rather on broad correlations between river terraces and cultural sequences. Post-independence developments, such as the decision to incorporate Quaternary environmental sciences into archaeology departments, increasing specialisation, interdisciplinary collaborations, and revolutions in chronometric dating all transformed archaeological studies. Approaches, however, varied greatly depending on the conceptual strategies adopted from the perspectives of archaeologists or other Quaternary scientists, leading to multiple ways of interpreting site contexts, stratigraphy, taphonomy and hominin behaviour. These issues are closely tied to the continuing epistemological reshuffles in the archaeological and Quaternary sciences, with implications for academic curricula, degrees and the categorisation of specialists on the South Asian educational scene. Awareness of these undercurrents is particularly important for appreciating ways in which studies in archaeological sciences are funded in India and by international agencies. In recent years, specialised studies in various fields have driven new dynamics between archaeologists and "palaeo" scientists – each, however, displaying varying degrees of overall understanding of the nature of the archaeological record. On the positive side, this has led to an increase in interdisciplinary collaboration. On the negative side, the application of specific methods without archaeological research questions and the proliferation of publications on archaeological issues that lack "palaeo" specialists is an issue that demands greater attention. I conclude with issues relating to public outreach in the context of studies linking palaeoenvironments to archaeological sites – an aspect of crucial importance when considering the rapid destruction of sites and Quaternary deposits in one of the most densely populated and rapidly urbanising countries on Earth.

Optically stimulated luminescence (OSL) chronometry and environmental context for human occupation during LGM in the Lower Ganga Plains, Eastern India

Mr. Sourav Mukhopadhyay [1]***, Dr. Biswajit Roy*** [2]***, Prof. Satish Sangode*** [3]***, Dr. Manoj K. Jaiswal*** [4]***, Prof. Prasanta Sanyal*** [5]

***1.** Deccan College Post Graduate & Research Institute, **2.** Discipline of Earth Science, Indian Institute of Technology, Gandhinagar, **3.** savitribai phule pune university, **4.** Department of Earth-Science, IISER-Kolkata, **5.** Indian Institute of Science Education and Research - Kolkata*

Lower Ganga Plain (LGP) is covered by fluvio-deltaic deposits formed by the tributaries of Ganga, Brahmaputra, and the rivers of the Chottonagpur plateau. After draining through the Upper Ganga alluvial plains, in the LGP region, several discrete sites of microlithic technology are reported, but information on technological and chronological approaches are restricted from this region. Microliths tools are frequently thought to have been associated with modern human technology along with a combination of tools, including projectile weapons and other effective hunting techniques. Mostly, these small blade lithic toolkits were thought to be used in India, Europe, and Africa to hunt medium- and large-sized grassland and forest creatures, or as adaptations to shifts in environmental conditions during significant climatic change.

The LGP region is well known to have several evidence of modern human occupation, especially through microlithic assemblages. However, the missing vertebrate fossils associated with the stratified horizons and their connections to the environments are yet to be recognized. We report here, for the first time, *in situ* fossils (bones and teeth) of *Bos namadicus* and *Boselaphu stragocamelus* associated with microliths toolkit from a stratified Late Quaternary alluvium sequence at the Barakar region, Eastern India, which indicates human occupation of LGP was most likely constrained between 17 and 18 ka. The paleoclimatic information for this time period has been constrained through stable isotope and mineral magnetic studies. The $\delta^{18}O_{SC}$ value (rainfall proxy) indicates isotopic depletion -6.1‰ during the ~18 to 17 ka period, implying intensification of the Indian summer monsoon (ISM). The co-existence of higher $\delta^{18}O_{SC}$ (-1.4‰) and $\delta^{13}C_{SC}$ values (-2.4‰) suggest that the C_4 plants (grassland) dominated during the ~14.2 ka event, suggesting an impact of the dry climate of the *Bølling period.* Environmental magnetic proxies clearly indicate a shift from the mixed anti-ferromagnetic mineral of the Last Glacial Maximum (LGM) to detrital ferrimagnets post-LGM. These findings contribute to our understanding of human activity in stronger ISM seasonality and have implications for understanding cultural connections and local migration across Eastern India during the LGM period.

Fire history of the western Himalaya and its linkage to climate and human: inferences from the sedimentary black carbon

Dr. Abdur Rahman [1]***, Dr. Rayees Shah*** [2]***, Mr. Siddhartha Sarkar*** [1]***, Ms. Ajayeta Rathi*** [1]***, Mrs. Sangeeta Verma*** [3]***, Dr. M G Yadava*** [1]***, Dr. Sanjeev Kumar*** [3]

***1.** Physical Research Laboratory, Ahmedabad, **2.** Islamic University of Science and Technology, University Avenue, Awantipora -192122, India, **3.** Physical Research Laboratory*

Understanding climate-human-vegetation-fire interaction in the past plays an important role in deciphering modern fire dynamics associated with climate change and anthropogenic perturbation. Fire has played a significant role in the human evolution and its diversification across the continents and hence studying past fire events provides an insight into civilizational imprints in the past. To contribute towards the understanding of the fire history and its linkages to climate change and human evolution in the Himalayas, black carbon (BC)concentrations and its carbon isotope have been analysed in the two sediment cores,extracted from a paleo (Forest Block : FB) and live lake (Wular Lake : WL) in the Kashmir region of India. The chronology of sediment cores has been established using the radiocarbon dating, which covered the last 33 Cal ka BP (FB) and last 4 Cal ka BP (WL) of the Quaternary period. The variation in BC concentrations in the FB sediments showed fireintensity to be many fold higher during the Holocene (after 10 Cal ka BP), possibly due to increased human population and related activities in the region. The BC concentrations in WL sediment showed that the fire history of the last 4 Cal ka BP in the region wasdominantly controlled by the human activities such as agriculture settlement, pastoralism, and smelting of metals. The carbon stable isotopes data of FB and WL sediment cores haveshown change in humidity in the region and its linkage to the strength of westerlies.

The Physical Anthropology of Sri Lankan Vadda People: An Evaluation of Research History

***Ms. Kalangi Rodrigo* [1], *Dr. Wijerathne Bohingamuwa* [2]**

***1.** Department of Prehistoric and Anthropological Sciences Faculty of Humanities, University of Ferrara C.so Ercole I d'Este 32, 44 100 Ferrara, Italy, **2.** Department of History and Archaeology, University of Ruhuna, Matara -81 000, Sri Lanka*

The Vaddas (indigenous forest dwellers) of Sri Lanka have lived in various ecozones and have been linked to the Mesolithic population, dating to ca. 48,000 BP. The tropical rainforest belt of the island, which is home to the last groups of hunter-gatherers, has been their preferred habitat. These 'pristine' habitats have played a key role in their subsistence strategies and behavioral patterns. *Homo sapiens balangodensis*, or Mesolithic man, is considered to be the direct biological and cultural ancestors of Vaddas, since the first physical anthropology and ethnography of Vaddas were undertaken by Sarasins (1892, 1893, and 1908). These studies influenced later researchers (Seligmaan and Seligmaan, 1907 and 1908) to investigate the Vaddas and connect them to the island's Stone Age cultures. Deraniyagala (1953), for example, linked Sarasin's analysis of Vaddas to physical characteristics found in Mesolithic skeletons such as dolichocephalic, thick brow ridged, and the well-worn third molar male. Lukacs and Kennedy (1981) revealed that the protohistoric teeth found in the dry zone are almost identical to Vadda's, which for him explains the similarities in part with cultural practices and certain ecological shifts over time. Many of these studies claim cultural and biological continuity from the Mesolithic population through Vaddas to the modern population of Sri Lanka. On the contrary, the statistical approach adopted by Roberts *et al.* (2018) revealed that the Vadda population significantly differs from Mesolithic foragers, while Ranaweera (2014) confirmed their genetic closeness to the Indian Subcontinent. Thus, the debates continue.

Previous studies, however, paid less attention to the physical anthropology and osteology of Vaddas in a broader historical and evolutionary perspective. No attempts have been made to understand biological evolution and variations and to emphasize the importance of evolutionary history and human genomes that are strongly influenced by the environment. This paper attempts to identify lacunae in previous research and look beyond drivers of change in knowledge to underpin larger historical, ecological, and cultural processes underlying their present and future.

Keywords: Vadda, Indigenous forest dwellers of Sri Lanka, Anthropometry, Ethnography, Physical Anthropology

Late Quaternary Alluvial History and Geomorphological Mapping of Purna River Basin, Maharashtra, India.

Ms. Pushpa Zamarkar [1] ***, Ms. Apurva Fuladi*** [1] ***, Mr. Mahesh Falke*** [2]

1. *Department of Geology, Shivaji Science College, Nagpur,* ***2.*** *Department of Geology, Shivaji Science College of Arts, Commerce and Science Akola.*

The Purna River (PR) originates in the Ajanta Range of hills and is an important left-bank tributary of the Tapti River. Numerous multidisciplinary field and lab studies concentrating on fossil and archaeological localities from the Tapi river valleys of Maharashtra are generating significant findings, enabling researchers to address important evolutionary questions that have long confounded the field, i.e., did technological advancements and symbolism facilitate the dispersal of modern humans in terms of behaviour? What role did major climatic fluctuations and environmental events (e.g., YTT super-eruption) play in the dispersal of modern humans across Asia?

Questions such as these are paramount in understanding alluvial sequence during the Late Quaternary, local geomorphology, and hominin evolution, extensive fieldwork has been carried out along the PR Basin. Based on their lithological, physical, and field properties, provably 74 ka YTT was preserved at two to three different localities in the Late Quaternary Purna sediments, which have been classified as primary and secondary in nature. These ashes are light grey, massive to softly laminated, and they form discontinuous beds that are 10-20 cm thick and extend laterally for >100 m. Pre-tephra successions at both sites preserve a variety of biogenic and non-biogenic structures that are formed in response to specific environmental conditions, such as pedogenic calcretes, and rhizolith balls. Tephra-bearing successions are classified as belonging to four lithofacies: paleosol; planar cross-stratified gravel; matrix-supported massive gravel, and silty clay. In the Kaplieshwar Quaternary formation, previously dated from 70 ka to >100 ka, Gandhigram previously dated >700-800 ka, correlates with the late to middle Pleistocene. Also, the high-resolution satellite data were used to better understand the landforms and their process and drainage pattern demarcation for basin area planning and management.

Long-term (~11,000 cal. years BP) environmental dynamics and apparent carbon accumulation rates (LORCA) in Sebangau peatland, Central Kalimantan.

Ms. Khairun Ramdzan [1]

1. *University of Queensland*

Tropical peatland covers 89 Gt C of the total carbon (C) pool of which 65% are in Indonesia. These peatlands have evolved due to changes in climate and anthropogenic factors. To assess the future of peatlands, establishing the mechanisms of long-term apparent carbon accumulation rates (LORCA) of peat to changes in the peatland ecosystem is needed. Using palaeoecological and geochemical proxies, this study reconstructed the past peatland ecosystem (zones) of vegetation composition, hydrological conditions and peatland disturbances, and evaluated its relation to LORCA and carbon density for the past 11,000 years BP in Sebangau National Park (SNP), Central Kalimantan. The results suggest that the mechanisms of LORCA in each zone depend primarily on vegetation composition which contributed to the amount of recalcitrant organic matter in peat and the frequency of flooding events that influenced the vegetation growth and peat decomposition. The highest LORCA (16.4 g C $m^{-2}yr^{-1}$) and carbon density (332 Mg ha^{-1}) were recorded for ~2300 to 300 cal. yr BP (Zone B) during wet conditions, minimal flooding and with primarily PSF and LMS species (i.e. *Eurya*, *Ilex*, Melastoma, Euphorbiaceae, *Campnosperma* and Myrtaceae). In contrast, the lowest LORCA (7.9 g C $m^{-2}yr^{-1}$) and carbon density (172 Mg ha^{-1}) occurred between ~4500 to 2000 cal. yr BP (Zone C) due to dry conditions with high fire severity events and the transition from PSF to OV species. These conditions were similar to the young peat layer in Zone A (~350 cal. yr BP to present), which points to possible high aerobic peat decomposition and lower LORCA in the long term. Compared with other Indonesian peatlands, this study showed that the LORCA in SNP had similar trends over the past 11,000 cal. yrs BP with the other peatlands sites but was on the lower range in each zone despite having similar vegetation composition. The main reason for different LORCA in these peatlands could be due to flooding tendencies based on its location to the rivers or coastline and the possibility of varying rainfall patterns in Sumatra and Kalimantan.

Evolution of Landscape in the Foothills of Assam- Bhutan Himalayas: An Insight into Climate- Tectonic Relationship

Mr. Belligraham Narzary **[1]**, ***Dr. Manoj Kumar Jaiswal*** **[2]**, ***Dr. Saurabh Singh*** **[3]**, ***Mr. Vibhuti Shivsagar*** **[2]**, ***Dr. Mahadev Rawat*** **[4]**, ***Dr. Atul Kumar Singh*** **[5]**

1. *Department of Earth Sciences, Indian Institute of Science Education and Research, Kolkata, 741246, West Bengal, India,* ***2.*** *Department of Earth Sciences, IISER Kolkata,* ***3.*** *Dr.RammanoharLohia Avadh University, Ayodhya, Uttar Pradesh,* ***4.*** *Inter-University Accelerator Centre (IUAC), New Delhi, India,* ***5.*** *Inter University Accelerator Centre, New Delhi*

Himalaya is formed due to continent-continent collision between the Eurasian and Indian plates. This established a southward propagating fold and thrust belt (FTB) system with major boundary thrusts viz., Main Central Thrust (MCT), Main Boundary Thrust (MBT) and the Main Frontal Thrust (MFT). The MFT is the southernmost fault that separates FTB from the foreland basin, which is a flat alluvial land filled by sediments from the erosion of exhumed FTB. The Landscape at the foreland of the active mountain fronts such as the Himalayas results from the climate and/or tectonic interactions. These are result of crustal movement and erosion or deposition by surface processes. They are important geomorphic archives that preserve information about such changes/activities in the past. Thus, the landscape in the foothills preserves the signature of deformation events and, at the same time, also records changes in the monsoonal rainfall, controlled by glacial and interglacial events. The present study attempts to understand the evolution of alluvial fan deposits in the Assam- Bhutan Himalayan foothills of the Kokrajhar District of North-East India. The study mainly focuses on the uplifted 30 km long fluvial deposition from the Pinkhua Khola River in the west and Leu Pani in the east. The study is critical because it will help understand the southward propagation of the Himalayan fold and thrust belt. The initiation of the faulting events is marked by the clay layers, which were dated using OSL; the dating of clay layers from the hanging wall of three blocks suggests that the FTB was activated ~76 ka and experienced three other phases of deformation at ~45 ka, ~27 ka and 12 ka. These hanging walls also record the monsoon intensification during the MIS3 and MIS1.

Inequality and urbanisation in the landscape dynamics of the Indus civilisation

Dr. Adam Green [1]

1. Department of Archaeology, University of York

As the centennial anniversary of the rediscovery of the Indus civilization approaches in 2024, archaeology has assumed an increasingly important role as a Quaternary science. At this key moment, a growing number of archaeologists are returning to one of the discipline's pressing challenges: the investigation of how inequality has materialized within human landscapes. The Indus civilization provides a key dataset for this investigation. One of the world's first urban societies, the Indus emerged around 2600 BC in South Asia, a pivotal transformation that prompted a dramatic re-organisation of social ecologies. Many scholars have adopted the assumption that the defining feature of urbanization was the dense spatial concentration of consumers, often headed by a politically and economically stratified ruling class. However, archaeological evidence from nearly a century of research at Indus cities challenges this view. It has long been clear that there is no evidence of palaces, elaborate tombs, or individual aggrandizing iconography in Indus cities, and many political and economic benefits were widely available, suggesting a conspicuous absence of stratification among urban communities. However, over the last two decades, our understanding of Indus landscapes has expanded beyond the cities, where archaeologists have traditionally focused their research. Landscape archaeologists in South Asia have documented a substantial and growing number of small-scale settlements, revealing that the Indus was far more extensive that many of its urban contemporaries, connecting diverse communities located far from one another in environments that were as different from one another as the mountainous Himalaya and the arid coasts of Gujarat. In this talk, I will review recent developments in archaeological approaches to inequality at the landscape scale, and discuss how emerging evidence from Indus landscapes can help us rethink one of the most important social ecological transformations known to Quaternary science.

Computational approaches to map Cultural Heritage at risk by recent anthropic activities: examples from South Asian drylands

Dr. Francesc C. Conesa [1], ***Dr. Hector A. Orengo*** [2], ***Dr. Agustin Lobo*** [3], ***Dr. Cameron A. Petrie*** [4]

1. *Institut Català d'Arqueologia Clàssica,* ***2.*** *Catalan Institute of Classical Archaeology,* ***3.*** *Spanish National Research Council,* ***4.*** *University of Cambridge*

The remote assessment and analysis of disturbances and damage affecting the preservation of Cultural Heritage (CH) have become particularly important over the past decade, and has benefitted from improvements in the availability of global geospatial data and innovations in software and satellite to UAV image processing techniques. Moreover, the consolidation of cloud-based data analysis and visualisation platforms, such as Google Earth Engine, offers a game-changing scenario in CH documentation and (geo)archaeological landscape investigations, particularly in remote areas with little or almost no ground information.

In this paper, we will present ongoing satellite-based developments and ready-to-share algorithms aiming at the rapid mapping and monitoring of activities of anthropic origin, such as agricultural development and urban growth, as well as geohazards that pose an urgent threat to site preservation. We will focus on applying AgriExp, a new algorithm and method workflow that uses free and open-source Sentinel-2 satellite imagery to automatically map sites at risk of encroachment by recent agricultural expansion. The algorithm is tested in the fragile archaeological landscape of the Cholistan Desert in eastern Pakistan. The area was central to the development of the Indus Civilisation (c. 3500-1600 BC), and is home to hundreds of well-preserved archaeological mounds. As with many other drylands elsewhere, recent developments in irrigation schemes are threatening the preservation and visibility of many archaeological locations, and often, such new developments are undetected. We will discuss the case study of Cholistan in the context of new appraisals for data sharing and method reproducibility. The availability of the code ensures that this and other similar methods can be rapidly integrated for large-scale new heritage policies on site conservation in similar South Asian drylands and elsewhere.

Reframing the "Proto-indica debate" through a niche-construction framework: the impact of landscapes, plant ecologies, and human lifeways on early rice domestication.

Prof. Jennifer Bates [1], ***Mr. Matthew Conte*** [1], ***Ms. Sung Hui Kim*** [1], ***Dr. Manisha Singh*** [2], ***Prof. Ravindra Nath Singh*** [3], ***Prof. Vikas K. Singh*** [3]

1. Department of Archaeology and Art History, Seoul National University, Seoul, 2. DAV PG College, Department of Ancient Indian History, Culture and Archaeology, BHU, Varanasi, 3. Department of Ancient Indian History, Culture and Archaeology, Banaras Hindu University, Varanasi

The mosaic nature of the South Asian subcontinent, with its diverse environmental, ecological, riverine and climatic zones, make it one of the richest settings for studying changing human lifeways across the Quaternary Period. Change occurred at numerous scales, and the complex interaction between people and their environments is one of the ever-standing challenges facing archaeologists. One debate that remains constant within this is the nature of early agriculture and the shift between hunter-gatherer-fisher-forager lifeways and farming lifeways which developed in numerous forms at numerous times within South Asia, as might be expected of this diverse landscape. The debates are however perhaps most heated in the Ganges Plains, where the nature of early rice use continues as a topic of discussion. Questions remain over whether rice was domesticated in India before, during or after the arrival of Chinese domesticated *Oryza japonica*, what the status of rice in India was (gathered, cultivated or grown) before the arrival of *japonica*, and whether human interactions with *Oryza nivara* (wild rice) led not only to changes in rice, but also to changes in lifeways and the ecologies and environments around sites in the plains. While a lot of debate has been had on the nature of the rice itself, this paper will instead explore the implications of the various rice domestication hypotheses from a broad environmental and ecological stance, asking what impact a local domestication or incoming hybridization model might have had on the changing habitats and niches both plants and humans would have inhabited. Through this niche-construction theory, and incorporating new data from the Sakas excavations, this paper asks what impact might different interactions with rice have had on lives and landscapes, and how might this altered perspective allow us to move the debates around the Mesolithic-Neolithic transition forwards?

Herd management culture and climate: A historical overview from the perspective of biogenic carbon and oxygen isotopes

Dr. Kalyan Sekhar Chakraborty [1], ***Dr. Patrick Roberts*** [2], ***Dr. Thomas Larsen*** [1], ***Dr. Prabodh Shirvaikar*** [3], ***Dr. Sanjay Kumar Manjul*** [4]

1. *Max Planck Institute for Geoanthropology,* ***2.*** *isoTROPIC Research Group, Max Planck Institute for Geoanthropology,* ***3.*** *Deccan College Postgraduate and Research Institute, Pune, India,* ***4.*** *Archaeological Survey of india*

The early Holocene witnessed the beginning of animal domestication in northwestern South Asia. By the mid-Holocene, this practice had spread throughout South Asia into different climatic zones and was incorporated into different cultures. Currently, over 6% of India's population actively engages in specialized pastoralism. However, despite its long history of existence and importance in today's Indian economy, our understanding of how climate and culture influenced the way domesticated animals were raised in this part of the world is extremely limited. This is primarily due to the lack of systematic biogenic isotopic analysis of domesticated animal remains from archaeological settlements.

Recently a few studies were carried out to reconstruct human-animal interaction in South Asia, but unfortunately, they were primarily confined to the Indus region. This has extensively confined our understanding of animal herding practices exclusively within the Indus region. This presentation will showcase the preliminary results of a pan-Indian biogenic isotope project. This is one of the most significant ongoing projects in India that analyses biogenic carbon, oxygen and strontium isotopes from archaeological animal remains. In this presentation, we will discuss the results obtained from cattle and buffalo, the primary domesticates in the Indian subcontinent, in order to understand how rainfall, availability of wild vegetation and agricultural fodder influenced, and historical knowledge and cultural practices determined the way these animals were managed. Along with the cultivation of grains and the production of specialized crafts, different forms of pastoralism also played a significant role in shaping ancient economic and political practices of historical and pre-historical south Asia. Reconstruction of herding practices, therefore, is a crucial step to understanding how ancient Indians perceived and utilized their surrounding environment and herds, and how cultural practices and the interaction between pastorals, cultivators, craft producers and the people in power historically inflicted such perception and utilization of the natural and cultural environment.

Riverine legacies and the archaeology of Jammu in North-western India: a geoarchaeological and remote sensing approach

Dr. Navjot Kour [1], ***Dr. Francesc C. Conesa*** [1]

1. *Institut Català d'Arqueologia Clàssica*

This paper will present the ongoing work of RIVERINE, a research project that aims to investigate the long-term land use and settlement dynamics that shaped the outer plains of Jammu in north-western India. The fluvial complexities in the region are volatile, owing to the erratic and ferocious rivers of the Indus system and its tributaries that drain its vast area. Although these rivers are generally destructive, they are also a major source of fertile alluvium, which contributes to the dense population concentration in these areas. The combination of urban expansion, mechanized agriculture and continuous river shifting and aggravation poses severe threats to the preservation of dozens of archaeological mounds that attest for a long-span occupation ranging from the Early Historic period to medieval times, with the earliest occupation dating back to the Neolithic and Chalcolithic periods. The project integrates 1) archaeological legacy data, in the form of published and unpublished archaeological literature, 2) legacy spatial data, such as historical topographical maps and declassified satellite imagery, coupled with 3) remote sensing observations, to accurately detect the location of ancient mounds and to map and monitoring short to long-term land cover trends, including landscape dynamics such as seasonal flooding, river migration and associated paleochannels. We will discuss our remote-based efforts with the preliminary results of new geoarchaeological and ground-truth surveys, aiming at providing a better understanding of the spatial and chronological relationships of ancient settlements and rivers in the region and in the broad riverine landscapes of South Asia.

Carved by Rivers: Landscape and Environment in Copperplate Land Grant Charters from Deltaic Bengal (c. 600CE–1200CE)

Ms. Samayita Banerjee [1]

1. *Ashoka University*

How can we rethink a landscape that belies cartographic fixity? How does an untameable environment record itself in the historical narrative? This paper looks at epigraphic records preserved in the form of copperplate land grant charters issued over a period of approximately 600 years to understand the shifting fluvial landscape that is the mouth of the Ganga-Brahmaputra-Meghna delta. The riverine topography that marks the southern portion of deltaic Bengal has created an amorphous space in and around the Sundarbans, the largest mangrove forest in the world. While this space has been studied for its unique bioclimate and exotic wilderness what remains largely untapped and disconnected from the scholarship are the remains of its rich material past. This paper is a methodological intervention in looking at epigraphic and archaeological material to understand the very landscape that produced them. An analysis of over twenty copperplatesthat record in minute detail the process of land transfers by the ruling dynasties of southern Bengal portray the region surrounding the Sundarbans as a fluid space, but nevertheless one that was constantly inhabited. It shows that this terrain, which has been and continues to be at the mercy of flood waters and the whims of its rivers, has in fact been constantly reproduced in historical time through human intention and action. Placing water at the heart of this narrative, this paper documents how the landscape inscribed itself on the memory and materiality of its human occupants.

Session 95: Impacts of abrupt climate change on ecosystems, landscapes and societies through INTegration of Ice-core, MArine and TErrestrial records (INTIMATE)

Speleothems as potential chronomarkers of volcanic eruptions and a novel tephrochronologic tool

Mr. Vitor Azevedo [1], *Dr. Andrea Columbu* [2], *Dr. Hu Hsun Ming* [3], *Dr. Emma Tomlinson* [1]

1. Trinity College Dublin, 2. University of Pisa, 3. National Taiwan University

Speleothem records have shown great utility for reconstructing paleoclimate and paleoenvironment age-models based on radioisotopes combined with a series of proxies. However, the use of these records as precise and independent markers of volcanic eruptions is in its infancy. Previous speleothem studies have linked short and long-term changes in climatic proxies to volcanic eruptions while a handful of other studies report direct detection of volcanic aerosols in speleothems and potentially the detection of volcanic tephra. A recent study in Patagonia reported individual tephra shards from found, and analysed in situ within a speleothem. Using trace elements from a speleothem (SA1) from Southern Italy we found a peak in Mg, Sr and Ba/Ca around 15.2 ± 0.1 ka, based on U-Th method, which is statistically synchronous to the age of 14.9 ± 0.4 ka, based on $^{40}Ar/^{39}Ar$ dating of sanidine crystals from the caldera-forming event of Neapolitan Yellow Tuff (NYT), in Southern Italy. This highlights the potential of using speleothems as new contributors to the goals of INTIMATE (INTegration of Ice-cores, MArine, and TErrestrial records) for the last Glacial-Interglacial period. Future aims will be focused on acquiring higher-resolution trace element analysis, further constraining the age-model with additional U-Th ages and testing the potential of finding cryptotephra, which are tephra invisible to the naked eye. Direct detection of volcanic eruptions via tephra chemistry provides independent age markers and extends the tephra lattice into the speleothem record. It will facilitate high resolution correlation of volcanic isochrons in speleothems with those in other climatic records. In addition, preservation of both the volcanic signature and its climatic effect within a single record will permit detailed investigation of the of the lag time and duration of volcanic climate forcing.

A persistent and intimately close relationship between volcanism and climate throughout the Holocene

Volcanic eruptions play a dominant role in driving climate, in ways beyond the established short-term influence on surface air temperatures. The observational record of the timing of volcanic eruptions, their locations, magnitudes of sulfate aerosol injection is incomplete which limits our understanding of the sensitivity of the Earth system to volcanism and the vulnerability of social and economic systems to the climate impact of past and future eruptions.

Here we use an array of synchronized, accurately dated, high-resolution ice-core aerosol records from Greenland and Antarctica to reconstruct the timing, sulfur injections and source locations of 850 volcanic eruptions occurring during the Holocene (i.e., the past 11,500 years). Employing geochemical analyses on recovered volcanic fallout products (i.e. crypto-tephra, heavy metals, halogens, sulfur isotopes) we trace numerous ice-core eruption signals to known volcanic eruptions (including major lava floods from Iceland and caldera-forming eruptions in North America and East Asia).

Using transient climate model simulations including the new volcanic forcing and ultra-long tree-ring chronologies sensitive to volcanic perturbations we can then pinpoint the exact dates of Earth's largest volcanic eruptions since the last ice age, allowing us to analyze the responses of ecosystems, landscapes and human societies following such rare volcanic extreme events.

The persistent and intimately close relationship between volcanism and climate that we identified throughout the Holocene provides strong constraints for the precise timing of rapid climatic events (such as the 8.2 ka event, recently introduced by the International Commission on Stratigraphy as a formal Global Boundary Stratotype Point between the Early- and Mid- Holocene). Going forward, this will allow the paleoclimate community to reconstruct inter-annual to multi-decadal climate variability from a wide range of climate archives that cannot currently be resolved by existing proxy compilations.

A new Lateglacial to early Holocene pollen record from Lake Suigetsu, Japan: Contrast with the N. Atlantic region and implications for human history

Pollen analysis and pollen-based climate reconstruction of the Lateglacial to early Holocene (ca. 16.7 to 10.2 IntCal20 kyr BP) part of the “SG06” core from Lake Suigetsu, Japan has been completed at 1 cm (*ca.* 13 yrs) resolution, yielding a total of 510 pollen spectra. Using the exceptionally precise chronology of the core which is basically coherent with Hulu Cave’s U/Th chronology (Bronk Ramsey et al., 2020), as well as the transfer function between Greenland and U/Th age scales established by Adolphi et al. (2018), the climate reconstruction from Lake Suigetsu has been compared with Hulu, NGRIP, and some other key archives from across the world at multi-decadal precision. The result indicates that the Holocene-like warm and stable mode of the climate in the Far East started as early as 15.0 IntCal20 kyr BP, with added (though much attenuated) influences from the North Atlantic processes such as Lateglacial interstadial (equivalent to the Bølling and Allerød) and subsequent cold reversal (equivalent to the Younger Dryas). Climate became particularly unstable when the N. Atlantic was in the Glacial mode whilst the Far East was already in the Holocene mode, or *vice versa*. Periods of the earliest domestication of plants, origin of agriculture, and the earliest construction of permanent settlements in the Middle East did not show simple correlation with warm or cold periods, but coincided with periods of climate stability. Stability of the climate typical of the Holocene made it meaningful for humans to plan for the future, and may have triggered a fundamental change in human lifestyles. Full details of the results are reported in Nakagawa et al. (2021) Global and Planetary Change.

Quasi-persistent rhythm in the climate and human activity recorded in a varved sediment from Mayan lowland

We discovered varved sediments from a lake within Maya site of San Claudio, southeastern Mexico. This particular setting of the lake strongly implies that the sediment records the detailed history of both natural and human-induced environmental change. We recovered a 6.5 m-long perfectly overlapping sediment cores spanning over the last 5000 years. We performed stable nitrogen isotope ($d^{15}N$) analysis and ultra-high resolution (40 µm stepping; ca. 3 weeks) X-ray fluorescence (XRF) analysis. The $d^{15}N$ data indicate five periods of human occupation, which appear to be followed by abandonment and catchment instability. On the other hand, the XRF data indicated that the climate of this area (most likely evaporation-precipitation balance) exerted persistent cyclicity through the record, though the cyclic signal becomes less distinct and slightly noisier during the period of the Maya civilisation. Many of the detected peaks of the climatic cycles showed agreements with $\Delta^{14}C$ signals of tree rings. The typical interval of the peaks is centered around ca. 200 years. Based on these observations, we may tentatively conclude that the marked oscillation between dry and wet climates in this area was primarily driven by the Suess/de Vries cycle (ca. 200 years) of the solar activity.

The five episodes of human settlement uniformly have their counterparts in the peaks of the 200-year solar cycles, but do not correspond to all of them (albeit, the comparison template of the climatic signal itself becomes less clear – possibly because of the masking effect by human factor). This suggests that the Maya civilisation had certain resilience to the dry-wet oscillations, but climate could nonetheless contribute to significant decline of the civilisation when the resilience had already been undermined by other non-climatic factors, the candidates of which may include epidemy, political instability or unsustainable use of resources.

Atmospheric blocking as a stabiliser during abrupt climate change in eastern Europe during the Last Deglaciation

Abrupt climate change has occurred frequently in Earth history, most notably during the termination of major glaciations in the Quaternary. Changes occurred over decadal timescales and destabilised or transformed landscapes and ecosystems. We use the Younger Dryas as a natural experiment to better understand the regional propagation of abrupt change. We applied hydrogen isotope analyses (δD) of plant wax lipid biomarkers as indicators of hydrological change and moisture origin from five lake records across Central Europe, namely lakes Meerfelder Maar, Steisslingen, Hämelsee, and Rehwiese palaeolake in Germany, and Lake Czechowskie (Trzechowskie palaeolake) in Poland. Using recurrence analysis, a method to detect and classify time-series and characterise dynamical regime shifts (tipping points), we identify the transition from warm to cold states, or from the relatively warm Allerød to the cold Younger Dryas, and return to the Holocene warm state. Further, isotopic gradients from the Allerød, Younger Dryas and early Holocene are compared with modern gradients, revealing spatial differences in the timing of the onset of the Younger Dryas event, in the magnitude and variability of change as well as the structure of the Younger Dryas event. We show that the pattern of δD responses during the YD were not consistent geographically, and that variation at different locations suggests greater climatic stability and smaller degree of change in the east. These spatiotemporal patterns are compared with modelling results and infer that atmospheric blocking over the Fennoscandian Ice Sheet (FIS) was likely the main driver of spatiotemporal patterns, creating a sustained high-pressure system over Fennoscandia deflecting the flow of westerly winds. This blocking effect only happens during summer as there are strong westerlies from September to April or May. Despite the abrupt climate change at the end of the Deglaciation, this resulted in a more stable climate during the YD event in eastern Europe, while western Europe was affected by major climate fluctuations during the second half of the YD because of weaker summer atmospheric blocking at the end of the YD meant more Atlantic inflow reaching MFM in the west but not in the east.

High continentality as a key driver of rapid deglaciation in Europe

The deglaciation process of the Last Termination (17 to 9 ka BP) was largely (~50%) driven by a transient increase in orbital summer insolation over high northern latitudes with additional warming (30%) through greenhouse gases and interacting feedbacks (20%). Excess meltwater fluxes from vanishing ice sheets into the North Atlantic Ocean caused a series of abrupt cooling events (stadials). Simulations of the ~3000-years long Heinrich Stadial 1 (HS1, GS2) and ~1200-years long Younger Dryas (YD, GS1) require a massive, continued influx of freshwater to sustain stadial cooling giving rise to a “meltwater paradox”: most freshwater needs to be produced during the coldest periods. Recent proxy studies show evidence for stronger melting during stadial cooling from the European Ice Sheet (EIS). However, severe cooling registered in ice core and marine proxies requires an atmospheric driver to sustain or increase ice melting during stadial cooling.

In a previous study, we were able to simulate warm stadial summers in Europe during the YD with a high-resolution version of CESM1. However, a solution to the contradictory stadial summer cooling signal in many proxies remained elusive. To classify the type of climate that needs to be reconstructed, we calculated now the continentality of past climate states based on simulations of the period 15 to 9 ka BP. We find that continentality in Europe was generally much higher with shifts to extreme values during stadials. The spatial patterns of European continentality gradients imply westerly flow dominance during interstadials and atmospheric blocking during stadials.

We show that an ensemble of climate reconstructions located south of EIS using chironomids and plant assemblages can reproduce warm stadial summers when continental trainingsets are used. A direct proxy-based reconstruction of continentality confirms simulated values of a highly continental Europe. While vegetation-based coexistence likelihood estimations of Lateglacial summer temperatures show a small dependency on the trainingset, chironomids are highly sensitive to continentality. Due to a much higher signal-to-noise ratio of the ensemble mean, we are now also able to reconstruct the Intra-Bølling and Intra-Allerød Cold Period (IBCP, ~14.2 ka BP during GI-1e?; IACP or Gerzensee-Oscillation, GI-1b, 13.2 ka BP) in S-Sweden.

Geochemical data in the Varved sediment database (VARDA): improving the temporal accuracy and resolution of environmental reconstructions

Ms. Anna Beckett [1]***, Dr. Cécile Blanchet*** [2]***, Dr. Adrian Palmer*** [1]***, Mr. Alexander Brauser*** [2]***, Dr. Rebecca Kearney*** [3]***, Mr. Konstantin Mittelbach*** [2]***, Dr. Celia Martin-Puertas*** [4]***, Dr. Arne Ramisch*** [5]***, Dr. Rik Tjallingii*** [6]***, Prof. Achim Brauer*** [2]

1. *Department of Geography, Royal Holloway University of London, London, United Kingdom,* ***2.*** *Helmholtz Centre Potsdam, German Research Centre for Geosciences GFZ,* ***3.*** *GFZ - German Research Centre for Geosciences, Section Climate Dynamics and Landscape Evolution, Potsdam, Germany,* ***4.*** *Royal Holloway, University of London,* ***5.*** *Institute of Geology, Innsbruck University, Austria,* ***6.*** *GeoForschungsZentrum Potsdam, Projektbereich 3.3, Potsdam, D-14473, Telegrafenberg, Germany*

After launching the Varved Sediments database (VARDA) in 2020 (Ramisch *et al*., 2020), our team has started to collect, harmonize and add geochemical proxy-data from annually-laminated (varved) lakes. The main goal of this exercise is to provide accessible and interoperable data to the paleoclimate and modelling communities, with the specific aim of generating sub-decadal proxy records. Two types of geochemical data have been collected: 1) major elemental composition of (crypto)-tephra layers (Beckett *et al*., in prep.) and 2) stable oxygen and carbon isotopes measured on lake carbonates. The datasets cover the past 35 kyrs with temporal resolutions ranging from 1 to 100 yrs (isotope records). The proxy-records and descriptive metadata were stored in a Neo4j graph database that can be cloned and run locally or accessed via web interface. We collected records from ca. 20 lakes located mostly in Europe and we plan to include lakes from other regions where varved sediments have been identified. Collection and curation of geochemical data of tephra layers is supported by an ongoing PAGES Data Stewardship Scholarship.

Geochemical fingerprinting of tephra layers will enable users to synchronise records with a high temporal accuracy and a better control on tephra attribution (i.e., using both chronological and geochemical information). Stable isotope data obtained on various types of carbonates (biological, authigenic, bulk) will allow users to explore, for instance, the drivers of isotopic fractionation in lake waters at a regional scale. With this contribution, we encourage the wider community to participate in the development of VARDA as well as in data mining and curation. Potential new developments include the addition of other isotope proxies (e.g., deuterium isotopes), bulk geochemistry (e.g., X-ray fluorescence) or pollen data, as well as improving the spatial resolution by adding new locations (including marine varved sediments).

A new varve chronology for the deglaciation of the South Wales sector of the British and Irish Ice Sheet: Implications for glacier and palaeoclimate reconstructions.

Dr. Adrian Palmer [1], ***Dr. Jacob Bendle*** [2], ***Dr. Ian Matthews*** [3], ***Dr. Alison MacLeod*** [4], ***Dr. Richard Staff*** [5], ***Dr. Paul Lincoln*** [1], ***Dr. Wim Hoek*** [6]

Continuous records of palaeoenvironmental and palaeoclimatic change during the Last Glacial-Interglacial Transition (LGIT) from the British Isles are confined to the last 15 ka and do not record the early phases of deglaciation. The chronologies for the deglaciation of the British Irish Ice Sheet after the LGM have been constructed using radiocarbon, OSL dating and cosmogenic radionuclide dates and retreat rates inferred from Bayesian age models. The potential of annually resolved records have yet to be fully explored in the UK. Three glaciolacustrine varve chronologies from the late Dimlington Stadial (GS-2) are available and these short, floating records provide decadal-scale resolution for transient changes in the ice margin position. However, the spatial extent of UK varve archives requires improvement and the floating chronologies to be linked to absolute timescales. This paper presents the first varve chronology for the LGIT in the British Isles from Llangorse Lake, south Wales, that provides a new age estimate for the deglaciation of the southern part of the British and Irish Ice Sheet and yields new insights into palaeoclimate variability during this period.

Microfacies work has produced two varve chronologies from cores extracted from the extant lake and were merged to create a master varve chronology, which has a total duration of 3505 ±143 years. This chronology is anchored to an absolute age scale at the upper end of the varve section using radiocarbon dates and extrapolating the Bayesian age model to date the onset and end of varve formation. The varve data suggests that initially an ice-dammed glacial lake formed at 19.16 cal. ka BP that transitioned into a cold climate lake system around 19.08 cal ka BP. This nival lake persisted for ~3400 years until 15.66 cal. ka BP, after which the lake transitions to non-varved sediments. Variability observed in the varve thickness record is postulated to relate to inter-annual to decadal variability in hydroclimate with three multi-decadal periods of decreased varve thickness below the record's mean. These periods may reflect periods of reduced precipitation in South Wales during the deglaciation of the British Isles.

Session 98: Past vegetation dynamics and their role in climate change

Mapping Holocene Radiative Forcing from Land Cover Change

Dr. Andria Dawson [1], ***Ms. Ruby Morillo*** [2], ***Dr. Bethany Blakely*** [3], ***Dr. Jack Williams*** [4], ***Prof. Marie-José Gaillard*** [5]

Climate-vegetation feedbacks depend on biophysical land cover characteristics such as albedo. This measure of surface reflectance impacts the surface energy balance. However, the narrow temporal extent of direct observations of albedo make it difficult to quantify centennial to millennial scale shifts. Albedo is used to quantify terrestrial ecosystem processes; its magnitude and variability moderate terrestrial biosphere and atmosphere interactions. Networks of fossil pollen data offer an observational constraint on biophysical land cover change that extends throughout the Holocene. We reconstruct Holocene albedo and associated radiative forcing for North America. First, we estimate average monthly blue sky albedo over the 2000-2009 period from MODIS satellite reflectance data products and ERA5 atmospheric reanalysis diffuse and direct radiation. Blue sky albedo –sometimes referred to as actual albedo– represents the overall surface reflectance from combined direct and diffuse incoming radiation. Then using a spatio-temporal network of fossil pollen records and the derived blue sky albedo, we reconstruct albedo. This reconstruction is done in two steps: calibration and prediction. In the calibration step, we develop a statistical model that characterizes the relationship between modern pollen samples and seasonal albedo. In the prediction step, we apply this model to reconstruct albedo from historical pollen records. Finally, these albedo reconstructions are translated to spatio-temporal estimates of radiative forcing using a pre-industrial radiative kernel. This allows us to identify regions that have undergone land cover shifts that have resulted in warming or cooling. This work provides new insight about the nature of climate-vegetation feedbacks and ecotone shifts, and an empirical constraint on ecosystem forecasts.

LegacyBiome 1.0: A global dataset of pollen-based mega-biome reconstructions covering the last 22000 years

Mr. Chenzhi Li [1], ***Dr. Anne Dallmeyer*** [2], ***Prof. Jian Ni*** [3], ***Dr. Manuel Chevalier*** [4], ***Mr. Thomas Böhmer*** [5], ***Dr. Andrei A. Andreev*** [5], ***Prof. Ulrike Herzschuh*** [1]

Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research, Potsdam, Germany

LegacyBiome 1.0 is a new dataset of global mega-biome reconstructions for the last 22,000 years that is particularly designed for the comparison with Earth System Model simulations. With a standard biomization approach we translated pollen data from LegacyPollen 2.0 - a global taxonomically and temporally standardized fossil pollen dataset of 3728 palynological records (3409 in the Northern Hemisphere, 319 in the Southern Hemisphere) - into mega-biomes for 45 time-slices throughout the last 22,000 years with a temporal resolution of 500 years. These mega-biomes have been adapted to the categories used to biomized Earth System Model results so that reconstructed mega-biome estimates can be directly compared to simulations. The accuracy of the new global biomization scheme was determined by comparing the reconstructed mega-biome distribution with the modern potential natural vegetation pattern derived from observations. Then, the distributions of pollen-based mega-biomes were compared against an ensemble of model simulations for the last deglaciation. The overall global mega-biome trend in the reconstruction is in line with the simulations, even if differences are visible at the continental scale. This set of model-based and reconstructed biome trajectories is used to infer the rate of vegetation changes and the stability of the vegetation dynamics on a regional scale. We are now able to identify regions with the greatest disparity between Earth System models and reconstructions, including the Southern Hemisphere, and to discuss better possible reasons for model-data mismatches based on regional characteristics.

Reconstructing biome changes on the Tibetan Plateau since the Last Glacial Maximum using a machine learning method

Dr. Feng Qin [1], ***Prof. Yan Zhao*** [2], ***Prof. Xianyong Cao*** [3]

1. Institute of Geographic Sciences and Natural Resources Research, Chinese Academy of Sciences, Beijing 100101, China, 2. Institute of Geographic Sciences and Natural Resources Research, Chinese Academy of Sciences, Beijing, 100101, China, 3. Institute of Tibetan Plateau Research, Chinese Academy of Sciences, Beijing 100101, China

Tibetan Plateau (TP), as the world's largest plateau, has received much attention on the dynamics of its alpine ecosystems under changing climate. Exploring the historical biome changes on the TP can extend our knowledge of the long-term response of alpine vegetation to climate change. However, the comprehensively quantitative reconstruction of the past TP biomes is not available due to the lack of suitable methods that enable appropriate classification of alpine biomes based on proxy data such as fossil pollen records. We developed a pollen-based biome classification model by applying the random forest algorithm (RF, a supervised machine learning method) based on modern pollen assemblages from the TP and its vicinity (n=1764 sites), and its robustness was assessed by comparing its results with the predictions of the biomisation method. The results indicated that modern biome distributions reconstructed using the RF model based on modern pollen data were in generally good agreement with the observed zonal vegetation. Moreover, the RF model showed a significantly higher accuracy than the biomisation method, indicating the former is a more suitable tool for reconstructing alpine biome changes on the TP. The RF model was then applied to reconstruct the biome changes on the TP over the last 22 ka based on 51 fossil pollen records. A series of biome maps of the TP was constructed at 500-year intervals, and five stages reflecting the major changes in biome pattern since the Last Glacial Maximum (LGM) were recognized, which generally corresponded to contemporary global climate changes and Asian monsoon variations. TP was primarily dominated by deserts with subtropical forests distributed in the southeast in the LGM. During the last deglaciation, the alpine steppe began expanding and gradually became zonal vegetation in the central and eastern regions. Alpine meadows occupied the eastern and southeastern TP since the early Holocene, and the forest-meadow-steppe-desert pattern running southeast to northwest on the TP was established afterwards. Subtropical forests extended north in the mid-Holocene, which reflected the "optimum" condition. During the late Holocene, alpine meadows and alpine steppes expanded southwards at the expense of forest.

Vegetation representation of modern pollen assemblage and long-term change of plant diversity in Nam Co catchment, central Tibetan Plateau

Dr. Quan Li [1]***, Prof. Houyuan Lu*** [2]***, Prof. Yan Zhao*** [3]

Pollen diversity offers abundant clues into the floristic diversity and history of vegetation change. Few palynological studies investigated modern pollen diversity or the past floristic diversity on the Tibetan Plateau (TP). Based on modern pollen assemblages from 37 topsoils and 63 surface lake sediments in the Nam Co catchment on the central TP, this study quantitatively explored vegetation representation of modern pollen assemblages and spatial distribution of modern pollen diversity using Shannon-Wiener index (H) and palynological richness (E(Tn), n=600). Modern pollen assemblages from topsoils of different vegetation had diagnostic features in terms of composition and pollen percentage. The results of boosted regression tree analysis confirmed that source vegetation was the predominant factor (85.8%) responsible for the vegetation representation of lacustrine pollen assemblages, while sedimentary processes accounted for only 14.2%. The results of discriminant analysis indicated that most lacustrine pollen assemblages (90.5%) were representative for the regional vegetation of alpine steppe in the catchment and central TP, while only 9.5% were representative for the local meadow vegetation. Pollen diversity indices showed spatial variability among vegetation types (high values in the domain of alpine steppe, while low values for meadow), reflecting the differences in terrestrial floristic diversity. Therefore, pollen diversity in lacustrine pollen assemblage could be an effective proxy to document past floristic diversity. The past floristic diversity in the lake catchment, recovered from a fossil pollen record of NMLC-1, showed a long-term change of ascending overlaid by several rapid diversity changes during the last 8400 years. This could be attributed to the downward shift of altitudinal vegetation belt driven by a general climatic cooling. The results imply that under the environmental challenge of climate warming and vegetation degradation, alpine vegetation restoration in the central TP should pay attention to altitudinal vegetation belts.

Holocene fire regimes in the Eurasian boreal and boreo-nemoral forest: the first-continental assessment based on charcoal data

***Dr. Angelica Feurdean** [1], **Dr. Chéïma Barhoumi** [2], **Dr. Qiao-Yu Cui** [3], **Dr. Jennifer Clear** [4], **Prof. Marie-José Gaillard** [5], **Dr. Niina Kuosmanen** [6], **Dr. Natasha Mazei** [7], **Prof. Elena Novenko** [8], **Mr. Dmitriy Kupriyanov** [7], **Dr. Normunds Stivrins** [9]*

The Eurasian boreal forest extends over ~15 M km^2. The composition of these forests is spatially heterogenous; the dominant tree species in Europe is distinctly different from Siberia. Fire regimes in Eurasian forests are diverse, but modern fire records are too short to capture patterns, trends, feedback, and drivers of variability. Charcoal records identified from sediment provide valuable perspectives on the centennial to millennia fire regime. Considerable efforts have been made in recent years to fill some gaps in our understanding of the past changes in wildfire regimes; however, the Eurasian boreal region, particularly in Siberia, needs major improvement. Here, we present the first assessment of changes in wildfire regimes, the timing, and drivers of the significant shifts in fire regime during the Holocene at the boreal Eurasian scale based on macrocharcoal records from Europe, Siberia, and subregions within. We found noticeable differences in the Holocene trends and mean fire return intervals among regions in Eurasia. On a Holocene scale, recent fire frequency and severity exceed the long-term Holocene trends or those recorded over the last 4500 years over Eurasia and all its regions except boreal Fennoscandia. At the spatial scale, Europe recorded higher fires and shorter fire rotation than Siberia. In Europe, the mean fire frequency increased along the west to the east gradient from boreal and boreo-nemoral Fennoscandia to European Russia. In Siberia, the mean fire frequency rises slightly from the west to central Siberia. Ongoing analyses indicate that shifts in fire regimes follow trends in large-scale climatic conditions, the dominant tree species composition, and their fire-related traits. The insights will improve our understanding of how Eurasian fire regimes might respond to future climate changes and evaluate the potential of boreal and boreo-nemoral forests to adapt to new fire regimes.

The reconstruction of Holocene spruce migration dynamics in NE Poland using the REVEALS model

Dr. Magdalena Fiłoc [1], Prof. Mirosława Kupryjanowicz [2]
1. Department of Paleobiology, Faculty of Biology, University of Białystok, Poland, 2. University of Białystok

The presence of Norway spruce [Picea abies (L.) Karst.] in north-eastern Poland, in the border zone between the oceanic and continental climates of its boreal range, suggests that even minor, or short-term climate changes in this region may cause (and could have in the past) an increase in the area covered by spruce when changes are favourable (cooling and/or increase in climate humidity) or its decline when changes are unfavourable for this species (warming and/or drought).
The objective of the research was to investigate whether a transient spread of Norway spruce in the late Holocene, reflected in the pollen records from four lakes in north-eastern Poland (Suchar Wielki, Suchar II, Jezioro Ślepe and Szurpiły), resulted from human activity, or whether this process was caused by short episodes of climate cooling dated at about 4200, 3400 and 2800 cal. yr BP. By using regional estimates of vegetation abundance (REVEALS) with reference to palynological data from the investigated lakes in north-eastern Poland, it was possible to reconstruct changes in vegetation in the studied area at chosen intervals. This is important in studies on the succession of spruce, which, because of its heavy pollen grains, may be poorly represented in pollen spectra from lakes, despite the fact that it is found in quite large amounts in the forest communities of the studied region.
The developed model of vegetation cover showed that the expansion of spruce in the studied region correlates very well with the short episodes of climate cooling and increased humidity dated at 4300-4100 and 3500-3300 cal. yr BP. However, contrary to previous expectations, the succession of spruce was inhibited during the climatic oscillation between 2900 and 2700 cal. yr BP. At the same time, anthropogenic plant communities developed during that period, which was associated with settlements of the West Baltic barrow culture at the end of the Bronze Age and the beginning of the early Iron Age.
This study was supported by the National Science Centre (M.F., 2019/03/X/ST10/01114).

Neotropical tree cover response to variation in post-Last Glacial Maximum climate and atmospheric CO2

Senckenberg Biodiversity and Climate Research Centre, Frankfurt am Main; Goethe University, Frankfurt am Main

The post-Last Glacial Maximum period (~ last 19,000 years) was characterised by major changes in the global climate and atmospheric CO_2 concentration. In the Neotropical realm, scattered palaeoenvironment records suggest multidirectional and asynchronous tree cover changes among regions. Local chronological comparisons between vegetation and climate archives suggest that changes in moisture availability during the deglaciation period could be the main forcing. However, the scale and processes of Neotropical tree cover response to post-Last Glacial Maximum climate changes remains cryptic. Here, we modelled the evolution of tree cover throughout this period using the dynamic global vegetation model LPJ-GUESS forced with seven realistic general circulation model palaeoclimate experiments (Last Glacial Maximum, Heinrich Stadial 1, Younger Dryas, Greenlandian, Northgrippian, Meghalayan, and the present). Our high-resolution simulation results (0.5° x 0.5°) are generally consistent with palaeovegetation records and suggest that the average potential tree cover in the Neotropical realm steadily increased from the Last Glacial Maximum (30%) to the present (44%). Variation in climate and atmospheric CO_2 seem responsible for substantial, widespread, and asynchronous increases in tree cover in all regions, which may have strongly affected about a third of the Neotropical realm. In addition, patterns of tree-cover are sensible to variation of intensity and position of the intertropical convergence zone, the South Atlantic convergence zone, and southern westerly winds, which confirm the implication of precipitation changes in Neotropical vegetation evolution throughout the post-Last Glacial Maximum period.

Vegetation and climate changes of the East-European forest-steppe during the last 15,000 years

Ms. Ekaterina Lukanina [1], Dr. Thomas Giesecke [2], Dr. Lyudmila Shumilovskikh [1]

1. University of Göttingen, Department of Palynology and Climate Dynamics, Albrecht-von-Haller-Institute for Plant Sciences, Göttingen, Germany, 2. Utrecht University

Climate change is one of the greatest problems facing humanity. One of the economically important areas potentially threatened by the warming is the East-European forest-steppe ecotone. Located between arid steppe and mesophilic forests, the ecotone combines the most favourable soils and climate conditions for crop production. Higher temperatures change this balance and induce higher risks for agriculture in the region. Palaeoecological studies reflect vegetation changes through time and allow to predict vegetation reaction to climate change. We studied several sediment cores obtained in a north-south gradient across the forest-steppe in the Kursk (Russia) and Kharkiv (Ukraine) regions. Multi-proxy studies including palynology, charcoal, loss-on-ignition and botanical macro-remains' analysis were carried out on these cores. Combining all available records, we reconstruct the forest cover using the modern analogue technique and evaluate possible shifts in the southern treeline and the character of the ecotone since the postglacial. With the use of transfer functions, we explore potential climate forcing that may have changed the vegetation of the ecotone. According to our results, if the current climate warming reaches the Holocene thermal maximum, it might favour arid steppe vegetation and induce risks of drought for agriculture in the region.

Session 99: Lipid biomarkers as molecular archives of human activity from archeological sites

Paleoenvironments and past human activity at the prehispanic cave of Las Estacas (Canary Islands, Spain): A lipid biomarker study

1. *Departamento de Biología Animal, Edafología y Geología, Facultad de Ciencias, Sección de Biología, Universidad de La Laguna, La Laguna, Tenerife,* ***2.*** *Archaeological Micromorphology and Biomarkers Laboratory (AMBI Lab), Instituto Universitario de Bio-Orgánica "Antonio González", University of La Laguna, San Cristóbal de La Laguna, Tenerife, Spain*

Combining lipid biomarkers with compound-specific stable isotope analysis (CSIA) in archaeological sediments provides information about past human activity and their environment. Las Estacas rock shelter (Canary Islands, Spain) is an aboriginal archaeological coastal site with evidence of occupation for the last 1500 years. The cave deposit comprises natural (light brown silts) and anthropogenic (combustion structures or hearths) sediments. We carried out gas chromatography-mass spectrometry (GC–MS) and gas chromatography–isotope ratio mass spectrometry (GC–IRMS) analyses to investigate the natural sedimentary sequences and their correlated combustion structures. Our molecular (*n*-alkane, aromatics, ketones, alcohols, and fatty acids) and isotopic ($\delta^{13}C_{alkanes}$, $\delta D_{alkanes}$, $\delta^{13}C_{16:0}$, and $\delta^{13}C1_{8:0}$) analysis allowed us to reconstruct the paleoenvironmental context and assess landscape anthropogenic transformation, as well as to provide clues about human behavior.

Combined application of lipid biomarkers and soil micromorphology to reconstruct indigenous pastoral activities at the Buracas Cave Complex (La Palma, Canary Islands)

Mr. Enrique Fernández-Palacios [1]***, Dr. Margarita Jambrina-Enríquez*** [2]***, Dr. Antonio V. Herrera-Herrera*** [1]***, Dr. Juan Francisco Navarro Mederos*** [3]***, Dr. Carolina Mallol*** [1]

1. *Archaeological Micromorphology and Biomarkers Laboratory (AMBI Lab), Instituto Universitario de Bio-Orgánica "Antonio González", Universidad de La Laguna, 38206, Tenerife, Spain,* ***2.*** *Departamento de Biología Animal, Edafología y Geología, Facultad de Ciencias, Universidad de La Laguna, 38206, Tenerife, Spain,* ***3.*** *Departamento de Geografía e Historia, UDI Prehistoria, Arqueología e Historia Antigua, Facultad de Humanidades, Universidad de La Laguna, 38206, Tenerife, Spain*

Pastoralism constituted a main subsistence activity among the indigenous populations of the Canary Islands, especially in islands with an abrupt terrain that difficulted the development of agricultural practices. In the case of La Palma, the northwesternmost island of the archipelago, recent archaeological studies indicate that indigenous herders mainly occupied natural caves and rockshelters, leading to the formation of dung deposits inside the cavities. Lipid biomarker analysis focused on steroids has shown great potential to discriminate animal faecal input, and thus, livestock composition. Sedimentary *n*-alkanes can be used to identify plant sources; and in dung deposits, they can shed light on herd diet composition. Combining this approach with soil micromorphology contributes data on the microstratigraphic context. Here, we report preliminary results from a microcontextual geoarchaeological analysis conducted at the Buracas Cave Complex (north of La Palma), a set of volcanic rockshelters occupied during pre-European times. Micromorphological analysis of the studied sequence indicate a sequence of ovicaprine stabling events and episodic burning typical of *fumier* deposits. The lipid biomarker data allows us to identify the origin of the faecal matter and the plant sources used as livestock fodder.

Spatial heterogeneity of biogeochemical properties as a reflection of functional zones within the cultural layer at Upper Palaeolithic site Zaraysk, East European Plain

Mrs. Anastasiia Kurgaeva [1], ***Prof. Michael Zech*** [2], ***Prof. Bruno Glaser*** [3], ***Prof. Eileen Eckmeier*** [1], ***Dr. Sergey Lev*** [4], ***Prof. Sergey Sedov*** [5], ***Dr. Andrey Yurtaev*** [6], ***Dr. Roman Tabakaev*** [6]

The impact of Palaeolithic humans on Pleistocene ecosystems has been considered insignificant due to their low population, non-sedentary lifestyle, and hunter-gatherer activity. However, within settlement the anthropogenic pressure could have been substantial enough to be imprinted in ‘soil-memory’ and variable enough for differentiation of several types of settlement activities, which enables the determination of functional zones within cultural layer through distinctive biogeochemical signatures related to human everyday activities.
The Eastern Gravettian cultural layers at the Upper Palaeolithic site Zaraysk date back to 23-16 uncal ka BP. Various functional zones were sampled: bottom of a flintknapping waste disposal pit, bottom of a hearth, floor of an earth-dwelling structure, surface of a cultural layer, and a reference sample of the contemporary Zaraysk palaeosol from the peripheral area of outside the settlement. To determine the signature of anthropogenic activities and their spatial heterogeneity, we analysed biogeochemical (C/N, biomarkers) and geochemical (elemental composition) data. The results indicated the significant difference between functional zones and the concentration of non-leaf wax-derived organic carbon was calculated, which within the cultural layer was interpreted as a consequence of the anthropogenic activity.
The research was financially supported by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) under Germany´s Excellence Strategy – EXC 2150 – 390870439, RFBR (no.19-29-05267), RSF (no.19-18-00327), NIOKTR 122011200271-7.

A micromorphological and lipid biomarker characterization of the Late Pleistocene sediments of Cave of the Skulls (Israel)

Dr. Natalia Égüez-Gordon [1]***, Dr. Ignacio Lazagabaster*** [2]***, Ms. Micka Ullman*** [3]***, Dr. Uri Davidovich*** [3]***, Dr. Nimrod Marom*** [4]

1. *University of La Laguna,* ***2.*** *University of Liverpool,* ***3.*** *The Hebrew University of Jerusalem,* ***4.*** *Maritime Civilizations Department, L. Charney School of Marine Sciences University of Haifa*

In recent years, advances in biomolecular analyses applied to archaeological research, offer promising insights on climatic-driven hypotheses that can now be addressed with high-resolution paleoenvironmental proxies. Leaf wax carbon and hydrogen isotopic compositions from natural dung deposits, such as those from hyrax middens are key for inferring the palaeoclimate history of a locality or region. Moreover, the integration of these analyses with microstratigraphic analyses, as soil micromorphology, provides robust characterisation of site formation and of post depositional processes that could be affecting the organic remains.
Recently, new research has pointed out an increase in effective moisture during MIS 4 and 3, and ecological modelling has suggested that the Judean Desert was greener in the past. Here we analysed soil sediments and *Hyracoidea* dung pellets from the Cave of the Skulls stratigraphic archaeological sequences in order to elucidate the abrupt, millennial-scale climate oscillations of the last glacial period, also known as Dansgaard-Oeschger cycles, in the Judean Desert. This multi-proxy approach includes 1) soil micromorphology, 2) *n*-alkane hydrogen and carbon isotope ratio analysis, and 3) faecal sterols and bile acids. The results add new data regarding plant water stress, precipitation and aridity, and detect possible shifts in hyrax diet composition during the last glacial period.

Biomarker evidence for the construction and occupation of crannogs in Scotland and Ireland from lake sediment records

Crannogs are artificial islands constructed in lakes and wetlands across Scotland and Ireland from the Iron Age to the Medieval period. Excavations of partially or fully submerged crannog structures are logistically and financially challenging, therefore the timing of crannog occupation and function remains poorly constrained. We present analysis of lake sedimentary archives adjacent to crannog structures as an alternative approach to excavation, to establish construction and occupation histories at two sites: Lough Yoan (N Ireland) and White Loch of Mytron (SW Scotland). Our data provide direct anthropogenic evidence using steroid biomarkers contained within wetland/lake sediments. Evidence of human faecal matter is identified at both sites, demonstrating preservation of faecal steroids within sedimentary environments. The ability of these steroids to provide direct evidence of human occupation is supported by occupation dates independently obtained from archaeological excavations. Steroid ratios indicate the presence of ruminants within the settlements, which is confirmed by sedimentary DNA (*seda*DNA) analyses and supported by palaeoecological-derived nutrient-driven changes in aquatic ecology (diatoms and chironomids). The similarities between faecal steroid records and independent lines of chronological and palaeoenvironmental evidence highlights the ability of lipid biomarkers to provide direct evidence of human occupation from lake sediments, but also demonstrates the ways in which these analyses can be used to characterise occupation phases and advance interpretations of wetland archaeological sites.

Lipid biomarker for diet identification and palaeomagnetism perspective

Dr. Marta Francés-Negro [1]***, Dr. Melanie Roffet-Salque*** [2]***, Dr. Eneko Iriarte*** [1]***, Dr. Angel Carrancho*** [3]***, Dr. Amalia Pérez-Romero*** [1]***, Dr. Miriam Cubas*** [4]***, Prof. Juan Luis Arsuaga*** [5]***, Dr. José Miguel Carretero*** [1]

El Portalón de Cueva Mayor is an archaeological site in the UNESCO World Heritage Centre of Atapuerca (Spain) with a Holocene stratigraphic sequence attributed from the Neolithic to the Roman period. Along these chronologies, this site was used for different purposes: i) habitational where archaeological assemblage shows a mixed economy with similar roles of farming, hunting and gathering strategies; and ii) funerary, due to the presence of tumulus and human remains. Pottery sherds are the main finds, with lithics, faunal remains or metal artefacts.

In this contribution, we present results from lipid residue analysis in pottery samples from different chronologies: Neolithic (*ca.* 5320-3670 cal. BCE), Chalcolithic (*ca.* 3080-2480 cal. BCE) and Bronze Age (*ca.* 2290-1220 cal. BCE), to study changing diet in ancient populations. To address this research question, a total of 104 pottery sherds were originally studied by chromatographic and spectrometric techniques to assess the presence of lipids in samples and characterise the biomarkers. Archaeological lipids were detected in 53 samples and identified as coming from animal fats. Compound-specific carbon isotope analyses was used to identify the source of those animal fats, with the detection of mainly dairy fats and ruminant and non-ruminant carcass fats, in all analysed chronologies.

Milk is one of most impactful food consumption in today's society, since it has been "only" consumed for a few millennia. aDNA analyses carried out in El Portalón shows that the population in Neolithic was lactose intolerant, while but this study reveals the presence of dairy products in pottery.

In order to study the cooking processes, we study for the first time the palaeomagnetic signal within the pottery clay. Using this method, we have identified pots that have been heated up only once (firing) from those that present a firing + cooking signal. This novel approach opens up new avenue of investigation regarding cooking techniques.

Biomolecular evidence for Neolithic cuisine in the Kashmir Himalayas and its potential to support future mountain food security

Dr. Hayley Saul [1], ***Dr. Michael Spate*** [2], ***Prof. Mumtaz Yatoo*** [3], ***Dr. Shinya Shoda*** [1], ***Prof. Oliver Craig*** [4], ***Prof. Alison Betts*** [2]

Recent archaeobotanical evidence from the Kashmir Valley in the Western Himalaya indicates the cultivation of West and East Asian cereal crops and pulses by as early as 4400 BP. At present, little is known about the processing or consumption of these plant foods, while the lack of published comprehensive zooarchaeological data limits our understanding of dairy or meat consumption. For the first time, we present the results of biomolecular analyses performed on absorbed residues from Early and Middle Neolithic ceramics from the Kashmir Valley, dated between ca. 4200-3500 BP. These data are compared with modern experimental references, as well as the archaeobotanical record to interpret patterns of food production and consumption through the Neolithic period in the valley. Palaeoclimate data has characterised this period as one of shifting precipitation regimes and climate instability, following a warm-humid Middle Holocene. We argue that drawing on 'deep time' data from the past, particularly in relation to "neglected" or underutilised food resources, may provide avenues to support food securities for Himalayan populations as they respond to projected climate instabilities in the future.

Identifying the use of marine resources: can shell and shellfish lipids help?

Dr. Jos Kleijne [1]***, Dr. Carlos Simões*** [2]***, Dr. Antonio V. Herrera-Herrera*** [3]***, Dr. Carolina Mallol*** [3]

1. *Groningen Instituite of Archaeology, University of Groningen,* ***2.*** *ICArEHB - Interdisciplinary Center for Archaeology and the Evolution of Human Behaviour, University of Algarve,* ***3.*** *University of La Laguna*

Use of marine resources is attested for prehistoric populations since Neanderthal times. The use of large heaps of shells (so-called shell middens) specifically is first associated with early Modern Humans, but most frequently encountered in Mesolithic and Neolithic contexts, in Atlantic Europe and across the globe. The use of marine resources in general, is regularly documented in early pottery vessels from coastal contexts in Eurasia. Understanding the use of specific marine resources such as shellfish consumption, and shell use in constructions and hearths, is however limited. Not much work has been done on biogeochemical signals, such as lipid biomarkers, of specific marine resources.

In this exploratory study, we analysed local Canary Island shellfish (*Patella ulyssiponensis*). Our research questions are: what lipids do we find in respectively shells and shellfish? Can we characterise the fatty acids, and distinguish them from other marine animals? Thirdly, what is the effect of burning on the lipid composition and quantity in both shells and shellfish? In this presentation we will give first results of this analysis and provide insights into identifying the use of these specific marine resources, in coastal sediments, combustion features, and pottery.

Session 100: Multi-methods geochronological approaches on Palaeolithic sites

Magnetism meeting radioactivity: Lessons from Atapuerca

Prof. Josep M Pares [1], ***Dr. José María Bermúdez de Castro*** [1], ***Dr. Eudald Carbonell*** [2]

The oldest hominid migrations out of Africa into Europe is a controversial debate topic that has ignited heated arguments for several decades. In the northern *plateau* of the *Iberian* Peninsula, the archaeological and paleontological site of Atapuerca is a key locality to contribute to the conundrum, as it holds evidence for the most complete and oldest record of human presence in Eurasia as of today. As such, solid chronologies of both fossils and deposits are of paramount importance to contextualize the hominids within the models of human dispersal into the continent. We will focus on the “Trinchera Atapuerca” sites, a complex of karstic caves developed in Cretaceous limestones partially filled with sediments of both fluviatile and slope origin. The slope deposits, traditionally known in the literature as “entrance facies”, are notorious for containing a rich record of both hominid fossils and lithic tools. Stratigraphic layer TD6 of Gran Dolina has yielded over 170 human fossil remains, more than 200 lithic artifacts, as well as several thousand small and large vertebrate remains. Since 1995, with the discovery and dating of hominid fossils older than the Matuyama-Brunhes reversal (0.78 Ma), numerous studies have progressively provided insights and further refinements on the age of both the fossiliferous and the sterile deposits in Atapuerca. A key issue in the advancement and reliability of the chronology has been the systematic use of complementary dating methods, including paleomagnetism, electron spin resonance (ESR), luminescence (OSL), terrestrial cosmogenic nuclides (TCN), and uranium-series. Each method depends on the available material in the sediments as well as the expected age range. The combination of these geochronology methods allows comparing depositional versus burial ages. The paleomagnetic signal provides the record of the magnetic field at the time of the sediment deposited. On the other hand, exposure and charge particles methods in cave environments, provide the age of the last sunlight exposure of quartz (or feldspar) grains before they were introduced into the cave. Altogether, the current results provide a solid record of human presence in Atapuerca-Trinchera encompassing at least 1.2 Ma, becoming a landmark for the oldest migration pulses into Europe.

Multiple protocols - luminescence dating of the Middle Stone Age deposit at Sibhudu rock shelter (South Africa).

1. *Archeosciences Bordeaux, CNRS Université Bordeaux Montaigne,* ***2.*** *University of Tübingen, Senckenberg Centre for Human Evolution and Palaeoecology, Paläon 1, 38364 Schöningen, Germany,* ***3.*** *Department of Early Prehistory and Quaternary Ecology, University of Tübingen, Schloss Hohentübingen, 72070 Tübingen, Germany*

Sibhudu rock shelter preserves one of the major sequence, over four meters thick, of Middle Stone Age artefacts in South Africa, uncovering pre-Still Bay, Still Bay, Howiesons Poort, and Sibhudan techno-complexes. The first optically stimulated dating chronology performed on single quartz grains by Jacobs et al. in 2008 and 2017 indicated ages between 38 to 72 ka.

While the continuing excavation has uncovered deeper layers, the whole sequence has been re-sampled for optical dating. We applied several protocols on single or multiple grains aliquots of quartz or potassium feldspar grains, including SAR, IR50, pIR-IR290, pIT, and RF[1] , in order to improve and extend the final chronology. Here we show that, other than the RF ages, which overestimate the mean of other age estimates by over 30%, ages for the various protocols are usually within 10% of their mean. Although the excavation has not yet reached bedrock, our results have extended the chronology of Sibhudu back at least until late Marine Isotope Stage 6.
[1] SAR : single aliquot and regenerative dose, IR50: infra-red at 50°C, pIR-IR290: infra-red at 290°C post infra-red at 50°C, pIT: Infrared post isothermal annealing, RF: radiofluorescence.

Geological and geochronological reconstitution of the Cagayan Valley (Luzon Island, Philippines)

The Paleolithic site of Kalinga, in the Cagayan River basin in the Philippines, is associated with the oldest known human occupation traces of the archipelago and dated to 709 ± 68 ka by our research group. This work presents the geomorphological and geochronological study carried out in the region of the site. After the discovery of several surfaces paleontological remains and lithic productions, the region was the subject of numerous excavations from the 1970s, but the chronological framework remained to be specified. In the 2010s, on the Kalinga site, lithic tools and a rhinoceros carcass showing butchery traces were discovered undisturbed in the sedimentary levels, dated afterwards by our team in 2019. Despite these dates, the geomorphological and geochronology of the area are still little known. This work aims to clarify them through the use of ESR dating methods on quartz and $^{40}Ar/^{39}Ar$ on plagioclase. The sedimentary deposits of the Cagayan Basin are mainly composed of fluvial sands partly formed from minerals of volcanic origin. This composition allows the application of these two absolute dating methods. Our results reveal a human occupation between 900 and 400 ka. From a geodynamic point of view, this period is marked by intense tectonic activity with the compression of the structural layers of the sedimentary basin between the two mountain ranges that surround it, the Sierra Madre to the east and the Cordillera Central to the west. This compression resulted in the basin layers folding, causing the appearance of anticlines. The results obtained make it possible to hypothesize a change in the Cagayan River flow direction about 600 ka ago connected to the folding. The latter is supported by the absence of feldspar crystals from later ages as well as the presence of seismites.

40Ar/39Ar dating applied to archaeology: what is new?

The dating of volcanic material including ash layers and lavas using $^{40}Ar/^{39}Ar$ radio-isotopic method is characterized by major technical and technological improvements over the last 10 years which improved both the precision as well as the accuracy of the produced dates. The latest mass spectrometers equipped with high sensitivity multicollectors allow now to date smaller and/or younger K-rich material with precision and accuracy previously unreachable. It is now common with the $^{40}Ar/^{39}Ar$ method to challenge and even in some case improve the accuracy of the radiocarbon dating in the 30-50 ka range period (e.g. Giaccio et al., 2017; Albert et al., 2019) but also to date single 250 microns K-feldspars that are less than 200 ka (e.g. Monaco et al., 2022).

We will take examples of recent investigations to illustrate the new possibilities that are now offered to archaeologists working in geographic areas where volcanic materials could be found together with lithic tools, fauna or human remains. These examples will cover the last 1.8 Ma and will concern various archaeological contexts. Moreover, these cases will illustrate a large part of datable material including K-Feldspars, Plagioclase, lavas, obsidian as well as tektites.

Early hominins are known to have reached western and southern Europe by the Early Pleistocene, but their first appearance elsewhere in Europe is still uncertain due to the lack of solid evidence, as well as the lack of securely dated basal Palaeolithic sites. Korolevo I located in Transcarpathia, western Ukraine, is among the most well-documented, deeply stratified archaeological sites in Europe, with hominin occupation spanning the Early to Upper Pleistocene. At the locus of Gostry Verkh in Korolevo I, the 12m-thick loess-palaeosol profile XIII contained stratified in-situ artifacts from multiple cultural layers spanning the Lower to the Upper Palaeolithic. The site was extensively excavated since 1975, but the Korolevo I chronology remains debatable, particularly below the Brunhes-Matuyama boundary at 7.5 m, with a possible Jaramillo subchron at 10.7 m. Here we constrain burial age of the lowermost artifact level VII (at 11.1–12.0 m) by using in-situ cosmogenic nuclide ^{10}Be and ^{26}Al. Nine cobbles made from vein-quartz, quartzite, and fine-grained sandstone of the level VII were obtained from the collection of Transcarpathian Palaeolithic expedition 1985. The cobbles of high variability (weathering, lithology, mass) went through a challenging quartz purification and Be/Al separation process. The assay of in-situ cosmogenic nuclides ^{10}Be and ^{26}Al was obtained by the Accelerator Mass Spectrometry, followed by numerical modelling of the most probable burial age. Our cosmogenic nuclide burial dating results at Korolevo I are consistent with palaeomagnetic data obtained by previous researchers and represent the earliest securely dated early hominin site in Central Europe. These new dates not only establish the lower layers of Korolevo I as one of the earliest hominin settlements in Central Europe, but also within the same chronological stage reported from southern and western European sites. This research provides critical spatiotemporal data for the paleogeographic scenarios of an early hominin dispersal in Europe and highlights the need for more research in this under-served region.

The significant but little-known Lower Palaeolithic Belle-Roche site (E. Belgium) assigned to MIS 12-11 by a combination of U-series, electron spin resonance (ESR) and single-grain thermally-transferred luminescence (TT-OSL) dating methods

Dr. Gilles Rixhon [1]***, Prof. Lee Arnold*** [2]***, Dr. Martina Demuro*** [2]***, Dr. Mathieu Duval*** [3]***, Prof. Jian-xin Zhao*** [4]

1. *Laboratoire Image, Ville, Environnement (LIVE UMR 7362), Université de Strasbourg, 3 rue de l'Argonne, 67000 Strasbourg, France,* ***2.*** *University of Adelaide,* ***3.*** *CENIEH,* ***4.*** *The University of Queensland*

Although the Belle-Roche site located in the Ardenne Massif (E. Belgium) was unearthed in the early 1980's, its significance in terms of archaeology and palaeontology has remained somewhat unnoticed by the scientific community. This small, fossilised cave is perched ~60 m above the Amblève's current floodplain, i.e. the main sub-tributary of the Meuse River. The 3.5 m-thick sedimentary infill of this karst system consists of fluvial pebbles and sands overlain by 2-2.5 m-thick, coarse-grained slope deposits. Whereas the former are archaeo-palaeontologically sterile sediments, the latter embed no less than 50 different taxa of macro-faunal remains through the entire sequence. These primarily comprise large mammal carnivores such as *Canis mosbachensis, Panthera onca gombaszoegensis, Panthera leo fossilis and Ursus deningeri*, but rodents such as *Arvicola cantiana* are present as well. Equally important is the finding of more than 100 lithic tools at the top of the slope deposit sequence. Due to the lack of their sophistication, these bifaces, choppers and scrapers (along with deep angular notches in bones interpreted as cut-marks) were assigned to a primitive Palaeolithic industry, possibly the Acheulean.

Despite some useful relative (palaeomagnetism) and correlative (biochronology) age constraints on the site and numerical dating of a nearby fluvial terrace (by cosmogenic nuclides), neither the fossil-bearing layers nor the archaeo-palaeontological remains have been numerically dated; likely explaining why this site has remained little-known. Here, we aim to fill this gap by firmly dating this site in a twofold manner. First, fossil bones and teeth from selected large-mammal remains were sampled for U-series and combined U-series/Electron Spin Resonance (ESR) dating, providing consistent age estimates of around 400-450 ka. Second, both basal fluvial sand and the slope deposit fine-grained matrix were sampled for extended-range luminescence dating (single-grain TT-OSL and pIR-IRSL). Analyses are currently ongoing but the preliminary results confirm the status of the Belle-Roche site as a reference for mammal association in NW Europe during MIS12-11 and provide firm constraints on MIS11 human occupation of this region (i.e. oldest site so far in Benelux).

The Quaternary geological, palaeontological and archaeological records in Europe are the most extensively studied in the world, providing a detailed history of the climatic and environmental changes critical to understanding our human story. However, most of the key terrestrial sequences are short, recording only snapshots of time which have little meaning without a securely dated independent timescale. This severely limits our understanding of when early humans may have migrated into and adapted to early European environments, and the effects on their cognitive developments and cultural identities. Differences in tool technologies could be telling us about use, technical evolution, source material, populations or even species differences, but without a secure chronology to tie the archaeological sites together, these fundamental questions cannot be addressed properly.

To help resolve these problems, the EQuaTe project is building on recent discoveries that fossil biominerals provide coherent time signals trapped within their crystals. Commonly-occurring calcitic fossils (snail opercula) provide both closed-system repositories for amino acids (AA) and a stable thermoluminescence (TL) signal that can date events over at least the last 2.6 Ma. We are therefore using both dating methods (AA and TL geochronology) on the same biominerals from a range of archaeological and palaeontological sites to build a dating framework across Europe. Our selected study region ranges from the British Isles to the East European Plain, bounded by the Pyrenees, Alps, Caucasus and Urals; this covers a region beyond potential refugia, where human populations would have been dynamic and highly adaptive, and for which repopulation could have been from different regions. Opercula are often abundant in sediments in this region so form the main study target, but we are also exploring the potential of other biominerals (e.g. tooth enamel, slug plates, worm granules, foraminifera) to expand the environmental scope of the techniques. Here we present the datasets from Britain, France, the Netherlands, Germany, Switzerland and Poland, compare them with other evidence of age, and provide the first integration of these regional frameworks for the basis of a pan-European chronology.

Session 101: Integration of palaeoecological proxy data for the reconstruction of climate and environment dynamics

Sub-millennial scale reconstruction of late Quaternary critical zones in Utah, USA using laminated soil carbonate rinds

__1.__ Washington University in St. Louis, __2.__ Western Colorado University, __3.__ University of Michigan, __4.__ University of Utah, __5.__ Rocky Mountain Biological Laboratory, __6.__ United States Geological Survey, __7.__ Aix Marseille University, CNRS, IRD, INRAE, College de France, CEREGE, Aix-en-Provence, France, __8.__ CEREGE, Aix-Marseille University, CNRS, IRD, INRAE, Collège de France, __9.__ University of Wisconsin Madison

Soil carbonate is calcite ($CaCO_3$) that forms in dryland soils worldwide. It has been widely used as a paleoclimate archive on long timescales (>10^5 yr) because its carbon and oxygen isotope composition are related to vegetation and soil water isotopes during the time of formation. Advances in high-resolution techniques now permit paleorecord development from laminated soil carbonates (also called, e.g., coatings, cutans, pedothems, pendants, rinds) on Quaternary timescales (0–2.7 Ma) with data resolution of 10^2–10^3 yr, as demonstrated by studies in the United States (USA), Syria, Turkey, and Siberia. For example, in our prior work, we generated ^{14}C, clumped isotope, $\delta^{18}O$, and $\delta^{13}C$ transects from a southern Utah (USA) laminated rind. The fidelity of the 35–5 ka records of temperature, soil water, and vegetation is supported by prior regional inferences.

Here, we assess how this novel paleorecord type will provide new kinds of information about ancient critical zones. The western USA had large changes in the geographic and elevational distribution of plants and moisture during the last glacial period, but soil responses remain difficult to assess. We are therefore using a suite of six laminated rinds from southern Utah to explore changes to the critical zone over a ≈750 m elevation gradient. Preliminary radiocarbon dates are in stratigraphic order and rinds grew from the last glacial period into the Holocene (<11.8 ka). Six SIMS-based $\delta^{18}O$ transects range from approximately -15 to -5 ‰ VPDB, with individual transects having internal variability between 3 to 10 ‰. We hypothesize that changes in the seasonal timing of soil carbonate formation (e.g., spring to summer) caused the larger $\delta^{18}O$ ranges, as driven by the interplay of temperature, rainfall, soil respiration, and infiltration. Interestingly, however, elevation is a poor predictor of average $\delta^{18}O$ values and $\delta^{18}O$ variability, which may indicate the importance of site-specific controls. These inferences are intriguing, especially in the context of forthcoming carbon isotope and clumped isotope records (proxies for vegetation and soil temperature, respectively), and highlight the sensitivity and heterogeneous responses of dryland critical zones to small changes in temperature and rainfall.

Palaeoenvironmental and palaeoecological reconstruction during Late Pleistocene-Early Holocene in Mesopotamian and Chacoan regions (Argentina): a mammalian stable isotope approach

Carbon and oxygen stable isotope composition analyses on fossil bioapatite of herbivore mammals allow inferring palaeoenvironmental, palaeoclimatic, and palaeoecological conditions. δ^{13}C values are used to reconstruct the diets of extinct taxa and their preferential habitats, whereas changes in the δ^{18}O values of obligate drinking animals reflect variations in δ^{18}O of meteoric water, which is controlled by temperature and evaporation rate. With the aim to infer these conditions during the Late Pleistocene-Early Holocene in northeastern Argentina, we evaluated a total of 155 tooth enamel and bone samples of representatives from eight families of herbivores: Glyptodontidae, Pampatheriidae, Megatheriidae, Mylodontidae (Xenarthra), Toxodontidae (Notoungulata), Camelidae, Cervidae (Cetartiodactyla) and Gomphoteriidae (Proboscidea). Samples come from the Toropí/Yupoí Formation (Late Pleistocene, Corrientes Province, Mesopotamian Region) and Río Bermejo Formation (Late Pleistocene-Early Holocene, Formosa Province, Chacoan Region).

δ^{13}C values point to the existence of an open environment. Representatives of all families had a preference for mixed C_3-C_4 plant-based diets, including Cervidae that usually show a C_3 plant-based diet. Some individuals of Toxodontidae and Gomphotheriidae retrieved data with a preference for an exclusively C_4 diet, indicating the presence of grasslands in Corrientes and Formosa provinces landscapes. No significant differences have been detected for δ^{18}O values between both Quaternary intervals considered, indicating that all the analysed obligate drinkers may have consumed water subjected to the same temperatures and hydrological conditions. It is remarkable that during the latest Pleistocene-earliest Holocene of Formosa province, Camelidae showed a higher δ^{18}O value than the rest of the families, presenting significant differences particularly with Toxodontidae and Glyptodontidae. Considering that the Camelidae genera here included are *Lama* and *Hemiauchenia* (non-obligate drinkers), we interpret their δ^{18}O values as a reflection of the evaporation conditions of the vegetation and not of the water bodies.

These are the first results of isotope composition applied to mammal communities from the Quaternary of northeastern Argentina. This allows comparisons with other paleocommunities of southern South America to make interpretations on palaeoecological, palaeoenvironmental and palaeoclimatic conditions of the region.

This study was supported by the projects PGC2018-094955-A-I00 (MICIU), PICT 0765/17 (FONCyT) and PI Q002/17 (SGCyT-UNNE). DSP was funded by the predoctoral grant PRE2019-089848.

A one-million-year Molybdenum isotope redox and lake-level record from ferruginous Lake Towuti, Indonesia

Molybdenum (Mo) isotopes are a well-known redox proxy in marine environments and may record redox changes, mixing, and stratification in lake environments. Here we present a ~1 Myr Mo sedimentary record from ferruginous and hyposulfidic Lake Towuti, Indonesia. Lake Towuti is a tectonic lake up to 200 m deep and is weakly stratified and anoxic below ~100 m depth. We performed a source-to-sink approach targeting ultramafic bedrock, lateritic weathering profiles, 37 lake surface sediment samples, and sedimentary drill core records spanning the past ~1 Myr, to better understand Mo variation in this setting.

Larger variations in [Mo] and $\delta^{98/95}$Mo are observed in the lake sediments compared to the weathering profiles. Mo concentration increases with water depth and distance to major riverine inlets suggesting hydrodynamic sorting and Mo enrichment in fines. $\delta^{98/95}$Mo exhibits a pattern with heavier signatures, similar to the lateritic source, in deep anoxic water and substantially lighter signatures in shallow oxygenated water sites. The $\delta^{98/95}$Mo varies from –1.146‰ to –0.135‰ during the past 30 kyr, with the lowest values during the dry and cold Last Glacial Maximum suggesting enhanced climate-driven lake mixing and deep water oxygenation at the deep water coring site. Sediments deposited during the wet and warm Holocene exhibit Mo isotope signatures similar to present-day anoxic deeper water settings thereby indicating persistent water column stratification. These results suggest the potential of Mo as a redox proxy through time. Over the long ~1 Myr time-span, [Mo] and $\delta^{98/95}$Mo show even larger variability potentially recording basin-wide water depth changes and basin evolution. Our results highlight the versatility of Mo isotope compositions for recording both climate- and tectonically driven changes in physicochemical parameters in lacustrine settings.

Analyses of phytoliths and stable carbon isotopes of modern plants and surface soils from the Bengal region: implications for palaeovegetation and palaeoclimate reconstructions

Phytoliths and stable carbon isotopic studies have already been proved as effective tools for understanding past vegetation and climate history. However, to improve the application potential of these palaeoclimatological proxies in past vegetation and climate reconstructions, development of modern analogues that take into account the vegetation's composition, structure, and geographical heterogeneity is crucial. We analyze 243 modern plant specimens and 50 modern surface soil samples from various depositional settings (such as, lake bed, grasslands, open and closed forests) from two distinct forest types (dry and moist deciduous forests) from the western margin of the Bengal Basin in order to build modern reference collections that are essential to these efforts. This study aims to address whether phytoliths and stable carbon isotopes can distinguish the canopy structure and composition of dry and moist deciduous forests, and to document variations in diverse depositional environments within these forest types, if any. We observe that reference collection from modern plants is helpful to identify the plant functional types in surface soil/fossil phytolith assemblages. The results indicate that soil phytolith assemblages can reliably distinguish dry and moist deciduous forest types though, not always clearly discriminate between different depositional settings within these forest types. This incongruity may be attributed to their eolian transport, multiplicity and redundancy among the phytolith morphotypes.Though, stable carbon isotopic ratios ($\delta^{13}C$) of modern plants from the two types of forests exhibit significant differences, the values are not much distinguishable in case of the surface soils from these forests, suggesting that care should be taken when interpreting the $\delta^{13}C$ fossil records. We infer that for reliable palaeo-vegetation/climate reconstructions palaeoclimatological proxies which complement one another should be combined rather than using single proxy.

The 21 m high sediment profile at the Nesseltalgraben site (SE Germany) is currently the best dated, high-resolution lacustrine record of Marine Isotope Stage 3 (MIS 3) in the Northern Alps. A revised age model based on 30 radiocarbon dated plant remains calibrated with IntCal20 dates the record to 50-29 ka cal BP. The Laschamps paleomagnetic event was detected between 1200-1280 cm. The new age model allows the duration and timing of the Laschamps paleomagnetic event to be determined between 40.9 and 42.1 (±0.7) ka cal BP, which is consistent with previously published ages for this event.

The pollen findings indicate repeated changes from tundra to open shrub and forest vegetation. The maxima of shrub and tree pollen coincide with Greenland interstadials 5.1, 5.2, 6, 7, 8, 11, and 12, indicating a substantial increase in (summer) temperatures during these brief episodes. A massive depletion of the flora was accompanied by repeated stadial-interstadial variability, resulting in the complete disappearance of temperate genera, including several shrub and tree taxa.

Additionally, we explored the potential of humic acids for reconstructing Alpine paleoenvironment during the last glacial. Due to their formation humic acids tend to integrate environmental information over longer time periods compared to other organic proxies. In contrast to previously studied materials at the site (bulk organic matter and cellulose of bulk sediment, wood and moss), humic acids have the advantage of being available throughout almost the complete record. Hydrogen, carbon, oxygen, and nitrogen isotope records of humic acids consistently show a major anomaly at 39 ka cal BP, around Heinrich Stadial 4 (H4), and a shift to lower averages thereafter. At the same time, lithologic variability increased and coarse grained layers consistently occur suggesting a more dynamic and unstable hydrologic regime. Thus, all humic acid isotope records suggest a climatic tipping point has been reached after H4. We speculate that these changes around H4 are the result of a change in atmospheric circulation and cooling of the North Atlantic, which is also expressed by increased occurrence of permafrost around that time in Central Europe.

A high resolution multiproxy reconstruction of Late Glacial to Holocene environmental variability of tropical Lake Victoria

The equatorial Lake Victoria (LV), Africa's largest lake, harbors a unique aquatic biodiversity of cichlid fish species that emerged after the lake's last desiccation and subsequent refilling 16,000 years ago. The origin and driving factors of this unique evolution are still not well understood. This highlights the need for a broader understanding of the linkages between paleoenvironmental variability and adaptive radiation.
We present a multi-proxy dataset of bio-geochemical indicators from four long sediment cores retrieved along a depth-transect (near-shore to offshore) in Lake Victoria. Sedimentary pigments and biogenic silica were analyzed to infer aquatic productivity. Changes in sediment composition are supported by micro X-ray Fluorescence (XRF)-derived element geochemistry, ^{13}C and ^{15}N, grain size, and sedimentary phosphorus fraction analyses. In this study, we make use of this exceptionally extensive multivariate dataset to gain a more accurate time- and space-transgressive view on environmental changes in LV. Furthermore, we determine major phases of ecosystem change by using different statistical analyses (e.g. Principal Component, Clustering and Rate-of-change analyses) and uncover their linkage to external and internal forcing factors.
The results suggest three major changes in the lake system since it's last desiccation that follow regional paleoclimate and insolation patterns: (i) the turn from a closed to an open lake system with the establishment of the Nile outflow (~13 kBP), (ii) the onset of the Holocene and the African Humid Period (AHP) (10.7 kBP) and (iii) the gradual termination of the AHP around 5 kBP. This detailed multiproxy record will help to constrain drivers of adaptive radiation and ecosystem development under changing climate boundary conditions.

Multiproxy core analysis of Holocene paleolake sediments in the Prološko Blato karst wetland (Dalmatia, Croatia)

1. *Croatian Geological Survey, Department of Mineral Resources,* **2.** *Croatian Geological Survey, Department of Geology,* **3.** *British Geological Survey*

The Prološko Blato is a seasonally flooded karst wetland situated in the Imotsko polje in the Dalmatian hinterland, Croatia. Recent geomorphological, geophysical, and sedimentological research revealed the presence of Holocene paleolake sediments overlaying the Late Pleistocene alluvial fan deposits. Paleolake sediments were investigated by a multiproxy approach (geochemical, sedimentological, ostracod analysis), constrained by radiocarbon dating, to reconstruct paleoenvironmental evolution during the Holocene.

The paleolake sequence is comprised of three zones. The first zone is represented by the Early Holocene blackish-brown clayey silt, with a high amount of siliciclastic material (high magnetic susceptibility), high TOC, and low $CaCO_3$, and fragments of the juvenile candonid ostracods. Overall, this zone is thought to represent a time of wet and waterlogged conditions during the initial stage of the paleolake development around 9000 cal BP. The second zone marks the formation of the lacustrine environment at ca. 8000 cal BP. It is characterized by pale-colored sandy silt high in $CaCO_3$ (likely endogenic carbonate), rich macro- and microfaunal remains (gastropods, ostracods, Chara gyrogonites), and very low magnetic susceptibility. Typical lacustrine species (*Candona neglecta, Limnocythere inopinata, Darwinula stevensoni*) suggest a shallow lake environment with a well-oxygenated water column. Oxygen and carbon isotope ($\delta^{18}O$ and $\delta^{13}C$) analysis of the carbonate suggests relatively steady hydrological conditions until ca. 800 cal BP when there was a significant offset to lower isotope values suggesting wetter conditions. This offset correlates with a lithological change to Late Holocene dark brown clayey silt (third zone), characterized by higher magnetic susceptibility and TOC, and lower $CaCO_3$. The absence of typical lacustrine species in the Late Holocene suggests possible lake desiccation and the onset of the modern karst environment with seasonal flooding. Such environmental change could be related to the collapse sinkhole formation in the paleolake's marginal part, as was suggested by earlier research, as well as Late Holocene climate change.

Drowned terrestrial faunal assembalges as proxies for paleoenvironmental reconstruction of a submerged paleolandscape in central Chile (32°S).

1. *Millennium Nucleus Ocean, Heritage and Culture(OHC), Chile Departamento de antropología, Universidad de Chile ARQMAR, Center for Maritime Archaeology Research of the Southeastern Pacific, Valparaíso, Chile,* ***2.*** *Millennium Nucleus Ocean, Heritage & Culture,* ***3.*** *Universidad de Chile,* ***4.*** *Pontificia Universidad Católica de Chile,* ***5.*** *ARQMAR, Center for Maritime Archaeology Research of the Southeastern Pacific, Valparaíso, Chile*

Late Pleistocene paleoenvironmental reconstructions in South America have used extinct fauna assemblages registered across vast areas of the continent. The site GNL Quintero 1 (GNLQ1) constitutes the first evidence of a drowned terrestrial site on the continental West Coast of South America, covered by sea-level rise after the Last Glacial Maximum. The site located in Central Chile´s coast (Quintero Bay, 32°S) currently lies 650 m offshore and 13 m.b.s.l. However, prior to the post-glacial rising of the sea level, the site was located several kilometers inland. A numerous well preserved terrestrial faunal bone assemblage was recovered, with a high taxonomic diversity, not only composed by extinct fauna Camelidae (cf. *Palaeolama* and cf. *Lama gracilis*), Cervidae, Equidae (*Equus* (*Amerhippus*) sp.) and Mylodontidae, but also by a large number of small mammals (mainly rodents) dated between ca. 29.000 to 21.500 cal BP. The results of taxonomic and geochemical bone analyses, together with isotopic and sedimentological data, allowed us to reconstruct a complex environmental scenario before the site was covered by the sea. The sequence started with the onset of a freshwater lagoon on a fluvial plain under relatively arid conditions which developed to into a wider and deeper freshwater lagoon under more humid climatic conditions, dominated by shrub and grassland, wetland and woody vegetation. Finally, the presence of dunes during the Late Pleistocene may supports the fact, that floodplains with fresh water lagoons and shallow wetlands developed among dunes, could represent a major coastal landscape for early postglacial Quintero Bay, where a high diversity of fauna was concentrated.

A new combination of automated detection and classification of Mediterranean pollen grains from annual pollen traps

Pollen is a valuable proxy for reconstructing current and past vegetation. Automating identification and counting of pollen grains could greatly help palynologists, by increasing sample size, and thus their spatial and temporal resolutions, and standardizing methods and results. Several recent studies have already shown the potential of deep learning for automatic pollen recognition, especially for aeropalynology. Studies on pollen traps and fossil samples remain scarce, most probably because they contain many non-pollen particles and damaged pollen grains, increasing the difficulty of the task. Here, we test a new combination of last-generation deep-learning algorithms for automatic detection and classification of pollen from annual traps containing as many as 70 Mediterranean taxa, and many debris types. A total of 16 traps were collected each of three consecutive years in six locations in France. For each trap, one slide was mounted, and photographed partially with an automatic microscope. This operation produced 1,024 images of 204x204µm per slide, which contained a few pollen grains, that could be damaged, cut, or clumped, and many debris. We first trained YOLOv5 to detect the single category of pollen on 85% of 4,096 images (256 images per slide) containing 12,344 manually detected pollen grains. On the remaining 15% of the annotated images, the model left 0.7% pollen undetected, and falsely detected 12% of debris which are meant to be excluded by the subsequent classification. We then applied the model on the remaining 12,288 images and obtained 42,156 additional pollen grains. For the classification, we have trained so far ResNet50 on 85% of 8,000 manually identified pollen grains among 26 classes, made of a single or a few pollen taxa, and one extra class of debris. On the remaining 15% of the images, we obtained a class-mean accuracy of 0.73 with per-class accuracy ranging from 0.28 to 0.96. The best classification rates were obtained for taxa we had most images for (Pistacia sp., Quercus ilex, Lycopodium sp.). We are now improving the classification, e.g. by testing other algorithms, increasing the training dataset and/or through data augmentation.

New results of decadal-scale UAC measurements from a Late Holocene peat bog in NW England

Mr. Tianyuan Wang [1], _Dr. Benjamin Bell_ [1], _Dr. William Fletcher_ [1], _Dr. Peter Ryan_ [1], _Prof. Roy Wogelius_ [2]

1. Quaternary Environments and Geoarchaeology Research Group, Department of Geography, School of Environment, Education and Development, The University of Manchester, 2. School of Earth, Atmospheric and Environmental Sciences, Interdisciplinary Centre for Ancient Life, The University of Manchester

Detection of ultraviolet absorbing compounds (UACs) in Quaternary/Holocene pollen and spores has exciting potential to evaluate past changes in UV-B radiation which remain poorly known. To date, despite advances in the methods and application of UAC detection there are still very few empirical datasets on UAC changes over Holocene timescales. Therefore, new records are needed to reveal the dominant timescales of UAC changes with a view to elucidating the drivers of past UV-B variability. In this study, we performed a high-resolution analysis of UACs in pollen and spores from a Late Holocene ombrotrophic peat bog in NW England using the fourier-transform infrared (FTIR) sprectroscopy method. We undertook FTIR measurements on isolated *Sphagnum* spores and pollen grains of *Calluna* and *Alnus* for 180 samples along the core depth (2 cm resolution for 360 cm) as well as additional measurements at 1 cm resolution for the uppermost 30 cm. The core chronology is constrained by 11 AMS radiocarbon dates on either *Sphagnum* leaves and bulk peat. The sequence spans the last 3600 cal yr BP, yielding an average sampling resolution of ~20 yr (~10 yr for the last few centuries). The study interval includes several episodes of marked change in solar output (grand solar minima). We use the FTIR data on UAC abundance, supported by multiproxy datasets (core-scanning X-Ray Fluorescence, colorimetric humification, loss-on-ignition), to evaluate plant response to past UV-B variability across different taxa, with the ultimate aim of evaluating the role of solar forcing on hydrological changes in the peat bog.

Contrasted climate patterns during the Holocene in the central Mediterranean inferred from pollen data

In the central Mediterranean region, many studies suggest that the Holocene is characterized by complex and different climatic trends on either side of latitude 40°N. This particularity in the regional climate system has been highlighted by multiple proxies showing contrasting trends of climate variations. Chironomid temperature-based reconstructions indicate the presence of a thermal optimum in Italy (10,000-7,000 cal. BP), contradicting the pollen-inferred quantification of Europe. Those discrepancies point to the need for further investigation concerning the Holocene climate of the Mediterranean region. To date, various studies have attempted to quantify the climate signal through different approaches without being able to propose a consistent climate reconstruction between proxies and sites.

In this context, and in the frame of the ANR project AUTUMNS-LAMBS, a multi-proxy method (brGDGTs and pollen) has been developed to quantify the Holocene climate in the central Mediterranean through a regional approach using multiple sites in Italy and Greece. We show here the results mainly based on pollen data, which is based on a collection of multiple sites, extracted from international pollen databases (NEOTOMA or European Pollen Database). The pollen-inferred climate is quantified by a multimethod approach, using four different methods (MAT, WAPLS, BRT and RF) and three modern databases (regional and global).

This study highlights similar climatic trends and inter-regional differences in the central Mediterranean region. Results show that not all of Europe is marked by a thermal optimum and that a longitudinal climatic gradient (40°N) in the central Mediterranean may have been present through the Holocene. In Italy, pollen and brGDGTs show a thermal optimum in the northern and central regions for the early and mid-Holocene, which is coherent with other proxies such as chironomids. This thermal optimum is less marked in southern regions of Italy, highlighting the climatic differences on either side of latitude 40°N. The late Holocene shows a climate shift between the north and the south, with a central region colder than the northern and southern ones. Moreover, the spatial heterogeneity of the Holocene climate needs to be further investigated for a better understanding of the special and temporal specificity of this climate period.

Climatic and environmental reconstruction from a primeval Fagus sylvatica forest

Ms. Amanda Mateo Beneito [1], ***Ms. Marion Lestienne*** [2], ***Ms. Imke Blacha*** [3], ***Dr. Bernd Wagner*** [4], ***Dr. Iuliana Vasilev Popa*** [5], ***Prof. Petr Kuneš*** [6]

Understanding climatic variability and how it affects long-term vegetation dynamics is essential to face the uncertainties of the current global change. For this purpose, we performed a paleoclimatic reconstruction for the last 2,600 cal. years BP in the Morské oko lake, located in the Inner Eastern Carpathian Mountains, Slovakia. This lake is surrounded by Fagus sylvatica forest, and the sediment, a total of 9 meters, has a high sedimentation rate, is highly organic, and depleted in oxygen content. The proxy used for the mean annual temperature reconstruction is branched glycerol dialkyl glycerol tetraethers (brGDGTs), which are membrane lipids of some soil bacteria. We also used the deuterium composition in the leave waxes to reconstruct the precipitation regime in the neighboring area for the studied period. Moreover, geochemistry data was used to assess changes in the catchment, pollen analysis to reconstruct the vegetation dynamics, and macro charcoal for the fire regime. There is considerable temperature stability in the lake and the range of the temperatures oscillates only about 2°C. The lake, which originated from a landslide, presents the greatest changes in erosion rates, climatic oscillations, and fire activity during its onset. There was a fast increase in the temperatures followed by several cooling episodes. During the last millennia, there is relatively climatic stability in contrast with the increase in fire activity. This study helps us to understand the forest dynamics and how they relate to temperature changes in this primeval beech forest in Vihorlat Mountains, proclaimed by UNESCO as a World Heritage Site.

Heinrich Stadial 4 as an emblematic arid event for the future forecasts of Mediterranean vegetation changes: inputs from a key high-resolution pollen record in the Alboran Sea

Ms. Liz Charton [1], ***Dr. Nathalie Combourieu-Nebout*** [1], ***Prof. Adele Bertini*** [2], ***Dr. Dael Sassoon*** [1], ***Dr. Odile Peyron*** [3], ***Dr. Vincent Lebreton*** [1]

1. Muséum National d'Histoire Naturelle, 2. Dipartimento di Scienze della Terra, Università degli Studi di Firenze, Via La Pira 4, I-50121 Firenze, Italy, 3. Institut des Sciences de l'Évolution de Montpellier

The last glacial period (MIS5-MIS2) displayed a high climatic variability at millennial scale through the Dansgaard-Oeschger (DO) cycles and the Heinrich Stadials. Heinrich Stadials (HS) represented the most severe expression of these climate oscillations, associated to a fast spread of semi-desertic vegetation characteristic of extremely dry and cold climatic conditions in the Mediterranean area. Here, we report a high-resolution palynological record for HS 4 (~39—38.5 ka BP) from Leg 161 Site ODP 976 sequence in the Alboran sea. The results of the pollen data show a clear succession from Heinrich Stadial conditions associated with steppe taxa (*Artemisia*, *Ephedra*, Chenopodiaceae), to interstadial conditions associated with temperate Mediterranean forest (deciduous *Quercus*, Ericaceae, *Quercus ilex*). Humidity and temperature are well-evidenced as the main parameters driving vegetation changes through multivariant statistics (PCA, DCA, correlation analysis), which also clearly describe the temporal succession of samples from stadial to interstadial conditions and mimics a long-term glacial/interglacial transition. Transfer functions applied to the pollen record through a multimethod approach (MAT, WAPLS and machine-learning methods as BRT) allowed to reconstruct annual and seasonal climate parameters associated to vegetation associations through time. The results show a dramatic fall in winter precipitations and annual temperatures during the HS4. The perturbation of the typical Mediterranean regime of precipitations caused a major decrease of hydric input in the region, disfavoring water-demanding forest taxa of the temperate and Mediterranean vegetation. The return to the original regime of precipitations after the arid event allowed the recovery of the temperate and Mediterranean taxa during the DO8. These results are in line with previous studies on the last deglaciation from the same core sequence, showing the high sensitivity of Mediterranean ecosystems to climate variability and especially hydric stress during the last 40 ky BP. In conclusion, future high-resolution studies of paleoenvironmental changes at millennial scale such as Heinrich Stadials, associated to climate modelling methods, might bring new data of high precision to assess human societies resilience to climate variability along the last glacial period.

Central Italy through the Early Pleistocene: Floristic dynamics in a chronostratigraphic framework

Palynological records are a powerful tool for reconstructing past distribution dynamics of plant groups, and a supplement to the regional chronostratigraphic framework documented by other datasets (e.g., δ^{18}O and magnetostratigraphic data). There have been numbers of palynological studies carried out in the Lower Pleistocene of central Italy; however, most of them are without age constraints. Here we aim at setting a framework of the distribution patterns of major taxa in the Early Pleistocene of central Italy, by comparing previously investigated, but chronologically poorly constrained, pollen records (i.e., at Gubbio, Leonessa, Madonna della Strada, and Pagliare di Sassa) with a relatively well-dated, recently acquired record from the Castelnuovo 1 borehole, in the L'Aquila Basin, central Italy, spanning the 2.1-1.5 Ma interval. The Castelnuovo palynoflora contains more than 100 sporomorphs, belonging to vegetation types of subtropical humid forest (including sporadic *Taxodium* and *Cathaya*), mixed temperate forest (including *Acer*, *Alnus*, *Quercus*, *Carya*, and *Liquidambar*), Mediterranean sclerophyllous forest (including *Quercus ilex*, *Olea*, *Phillyrea*, and *Pistacia*), steppes (including Amaranthaceae, *Artemisia*, and *Ephedra*) and other open vegetation (including Asteraceae, Cyperaceae, and Poaceae). The comparison between Castelnuovo and the other four above-mentioned palynofloras suggests that temperate and high-altitudinal taxa (including *Tsuga*, *Carya*, *Pterocarya*, *Cedrus*, *Picea*, *Abies*, *Quercus*, *Carpinus* and *Fagus*) were common in the Early Pleistocene of central Italy, while some taxa (including *Liquidambar*, *Cathaya* and *Taxodium*) occurred occasionally, and *Engelhardia* and *Sciadopitys* disappeared. As within a chronostratigraphic framework, the Castelnuovo succession will provide an excellent example for future palynological correlations (e.g., the ongoing Avezzano project with multi-proxies) in central Italy. Furthermore, this study will shed further lights on how the Early Pleistocene climatic oscillations (glacial-interglacial cycles) determined the distribution and extirpation of plants and thus vegetation patterns in central Italy.

Mid-Holocene human-environment dynamics in Italy inferred from the Botanical Records of Archaeobotany Italian Network (BRAIN)

Prof. Anna Maria Mercuri [1]***, Prof. Assunta Florenzano*** [1]***, Dr. Jessica Zappa*** [2]***, Dr. Elisa Furia*** [3]***, Dr. Eleonora Clò*** [2]

The current biodiversity loss involves complex scenarios with impacts on climate and economy and challenging health and social implications. The study of environmental transformations in a long-term perspective is the high road to biodiversity protection and understanding the risks and resilience of ecosystems. The diachronic study of global changes and the rapid development of big data in this field ensure a rapid increase in knowledge to guide nature conservation policies.

This paper focuses on the study of human-environment dynamics in Italy over the past 6,000 years based on data on plant biodiversity of natural (off-site: lake basins or peat bogs) and anthropogenic (on-site: archaeological sites) origin provided by Botanical Records of Archaeobotany Italian Network and database. The BRAIN web site (https://brainplants.successoterra.net/index.html) hosts the inventory of the archaeological researches including pollen, palynomorphs, seeds/fruits, wood, charcoals and other plant remains analyses from hundreds of sites in Italy and the Mediterranean. Case studies of pollen records providing information on environment dynamics in different Italian regions have been selected to put on evidence local features of land use and transformation.

The BRAIN datasets processing highlights the composition and changes in vegetation cover, recorded at regional and local scale, under climate and human impacts. Since ancient times, the Italian landscape has always been subject to continuous transformations in response to climate-environmental changes, tuned by cultural forcings such as agriculture and other anthropogenic impacts.

The phytolith record of Lake Ngami, Botswana, during the past 16 ka and correlation with other paleoclimatic and palaeoecological proxies

Dr. Carlos Cordova [1], **Prof. Louis Scott** [2]

1. Oklahoma State University, 2. Natural and Agricultural Sciences Faculty, University of the Free State

Lake Ngami occupies the southwestern part of the rift that forms the southern overflow catchment of the Okavango Delta. Past studies on paleo-landforms around the lake and paleoecological proxies from the lake suggest extreme changes in prehistoric and historic times. The previously published pollen record provides the pattern of regional and local vegetation change in relation to climatic and hydrological fluctuations, suggesting changes in precipitation patterns related to regional circulation patterns. The more recent phytolith record provides additional information that although concurrent with the pollen record provides additional information regarding responses of grasses to regional and local climatic and hydrological changes. Based on phytolith assemblages in modern depositional analogs across a broader area suggest that the well-defined round saddle, produced by the arid-adapted *Stipagrostis* spp (bushman grass) is a good indicator of aridity. The role of short cells produced by the Chloridoideae and Panicoideae suggests different moisture regimes. This contrasts with the idea that Chloridoideae are indicative of dryness. Likewise, the presence of woody-plant phytoliths relates more to the reduction of lake level and spreading of deep-rooted thorn trees on the lake floor. The study is a contribution to interpreting phytolith assemblages in shallow lakes in the tropics of southern Africa.

Underwater Old-growthTrees and the Past Millennia of Climate and Forest Dynamics in Eastern Canada

Mr. Alex Pace [1], *Dr. Dominique Areseneault* [2], *Dr. Jeannine-Marie St-Jacques* [1]

1. Concordia University, 2. Université du Québec à Rimouski

Old-growth forests are important natural archives of past environmental conditions. In the forests of eastern North America, eastern white cedar (*Thuja occidentalis*) is late-successional species known in the region for its record-breaking lifespan. Before the industrial period, old-growth cedar forests dominated lakeside ecosystems, but extensive commercial logging has profoundly altered the role of this species in the landscape. The few old cedar forests that remain are important relics of prehistoric information. Lakeshore cedar trees that have fallen into the water are preserved for centuries after their death in the low-oxygen environment of lakebeds, creating an opportunity to infer a millennia of environmental history. Dating the ring widths of lakeshore cedars, above and below the shoreline and studying the patterns of growth, death and deposition among them reveals important insights into the dynamics of these relic forests and their connection to past climate. The cedar trees of this region show a significant relationship to seasonal river flow records, allowing for a reconstruction of moisture conditions over the past millennia. Insights from relic old-growth cedar forests improve our understanding of climate variability and long-term forest dynamics in eastern Canada.

Middle to Late Pleistocene alluvial paleosols in eastern Sudan as indicators of palaeoclimate

Mr. MOSAB MOHAMMEDNOOR [1], ***Dr. Robert Bussert*** [1], ***Dr. Sumiko Tsukamoto*** [2], ***Prof. Omer El Badri*** [3], ***Ms. Aisha Hessen*** [4], ***Dr. Brian Kraatz*** [5], ***Prof. Johannes Müller*** [6], ***Dr. Khalafallah Salih*** [7], ***Prof. Ulrich Struck*** [6], ***Dr. Ali Eisawi*** [7], ***Dr. Faysal Bibi*** [6]

1. Technische Universität Berlin, 2. LIAG, 3. International University of Africa, 4. University of Khartoum, 5. Western University of Health Sciences, 6. Museum für Naturkunde, 7. Al Neelain University

The Atbara River in eastern Sudan is the last major tributary of the Nile before it flows through the Sahara. Along its middle reach, Pleistocene alluvial sediments, dated to about ~ 250 to ~ 15 ka, are exposed for about 200 km with a maximum thickness of 50 m. The Pleistocene sediments are rich in vertebrates and stone tools. Previous work identified two sedimentary units separated by a major unconformity, the Butana Bridge Synthem (BBS) and the Khashm El Girba Synthem (KGS), each subdivided into three intervals BBS 1-3 and KGS 1-3, from bottom to top. The BBS 2-3 and KGS 1-3 contain paleosols characterized by pedogenic features. Additionally, the BBS 2-3, KGS 1 and KGS 3 paleosols formed during MIS7, MIS6 and MIS2, whereas the KGS2 paleosols formed during MIS5 and MIS4. We used the paleosols to reconstruct the paleoclimate in the study area by performing mineralogical, petrographic, geochemical and isotopic analyses.

The field studies and the laboratory results indicate that paleo-Aridisols and paleo-Vertisols are most common, which are soils typical of arid to semi-arid and seasonally moist to subhumid climates, respectively. The Aridisols are common in BBS 2-3, KGS 1 and KGS 3. They are characterized by calcretes and contain carbonate, sulfate and halide minerals. Clay minerals are dominantly smectite and chlorite; easily weatherable silicate minerals (e.g. feldspar) and mica are also common. Vertisols that exhibit blocky peds and pedogenic slickensides are dominant in KGS 2 paleosols. Chemical index of alteration (CIA) values suggest that both paleosol types underwent moderately intense weathering during their formation. Mean annual precipitation (MAP) proxies show no significant variation between paleosol types, with an average of 818 ± 182 mm yr^{-1}, which is higher than the present-day precipitation. Minerals such as zeolite, hornblende and chlorite in both paleosol types point partially to mafic source rocks such as basalt, which are widespread in the modern Atbara drainage basin. The $\delta^{13}C$ isotope values of calcretes indicate that the vegetation varied between grassland, wooded grassland and woodland / bushland / thicket / shrubland.

Keywords: Middle Atbara, calcrete, paleosols, Aridisols, Vertisols

Tephrochronology of marine sequences in a cold seep area of the SE Tyrrhenian Sea (Paola Basin) as a tool to reconstruct main episodes of methane release

Ms. Sara Meschiari [1], ***Dr. Marzia Rovere*** [1], ***Dr. Donatella Insinga*** [2], ***Dr. Lucilla Capotondi*** [3], ***Dr. Paul Albert*** [4], ***Prof. Victoria Smith*** [5]

1. CNR-ISMAR Bologna, 2. CNR-ISMAR, Napoli., 3. Istituto di Scienze Polari, Consiglio Nazionale delle Ricerche, ISP-CNR, 4. School of Geography, Swansea University, UK, 5. School of Archaeology, University Oxford

The occurrence of hydrocarbons seeping in the marine environment is frequently overlooked due to the paucity of ocean exploration data. Reconstructing past and present hydrocarbon dynamics is not only crucial in polar regions, where bottom water warming may lead to gas hydrate destabilization, but also in other areas of the world where free gas in the sediment might be released to the seafloor, the water column and potentially to the atmosphere.

Understanding the timing of methane release is not always straightforward but can be achieved using specific and combined proxies left in the geological record.

In this study, we present the first attempt to correlate tephra deposits among marine sediment cores collected in cold seeps of the southeastern Tyrrhenian margin (Paola Basin). Sediment cores contain methane-derived authigenic carbonates that precipitated due to Anaerobic Oxidation of Methane in the Sulfate Reduction Zone with associated chemoautotrophic symbiontic shelly mega fauna. The down-core trend of abundance and isotopic characteristics of clam beds, benthic and planktonic foraminifera showed that these seep sites have remained geochemically optimal habitats over a period of more than 40,000 years. Episodes of enhanced methane flux were tentatively dated using radiocarbon on macro fauna shells and foraminifera.

In the sediment cores, tephras occur as both primary and secondary deposits and were recognized and correlated through visual inspection, magnetic susceptibility, core-scanner X-Ray Fluorescence using diagnostic elements and element ratios. Electron microprobe and LA-ICP-MS analyses were carried out on single glasses of selected primary tephra in order to characterize their composition in terms of both major- and trace-element content.

The composition of the tephras indicate provenance from the volcanic provinces of Aeolian Islands, Campi Flegrei-Vesuvius, Pantelleria. In particular, correspondence was found for basaltic trachy-andesite to trachy-andesites samples with the Intermediate Brown Tuffs units (Aeolian Islands), for the almost trachytic samples with the Campanian Ignimbrite (Campi Flegrei) and for rhyolitic to trachytic samples with the Pantelleria Green Tuff.

This multi-proxy approach provided a valid tool to constrain the chronology of the main episodes of methane release and at the same time allowed to augment previous tephra studies of the region.

Windblown diatoms in the Roosevelt Island ice core: a proxy for local paleo-environmental changes

Dr. Serena Lagorio [1], _Prof. Barbara Delmonte_ [2], _Prof. Valter Maggi_ [2], _Prof. Elisa Malinverno_ [2], _Prof. Barbara Stenni_ [1], _Dr. Dieter Tetzner_ [3], _Dr. Nancy Bertler_ [4]

Both marine and freshwater diatoms are commonly found in polar ice as a result of aeolian transport, and the identification of their species is essential to shed light on their source environment and transport pathways. In Antarctica, while pioneering studies on windblown diatoms were principally devoted to the resolution of the "Sirius debate", many studies recently aimed at using diatoms as tracers for air mass paleo-circulation. As an example, glacial ice from central East Antarctica (Dome B) revealed enhanced transport from the exposed continental shelf of Argentina and glacial-outwash sediments of Patagonia at the time when sea level reached its minimum. For recent climate, the potential of diatoms as proxy for wind strength over the Amundsen and Bellingshausen Seas has been demonstrated from annually-resolved firn cores from the Antarctic Peninsula.

In this work we investigate windblown eolian diatom valves archived in the RICE ice core, drilled onto the Roosevelt Island ice rise in West Antarctica, and use this proxy as indicator for local paleo-environmental changes at the site.

The record covers the last 12 kyr and the diatom assemblage is clearly dominated by *Fragilariopsis* spp., a marine diatom genus that includes planktonic, a few benthic and some ice-associated species. Optical microscope imaging and sizing of microfossils extracted from the RICE ice samples allows attributing about 75% of the diatom valves assemblage to *F. nana* and about 25% to *F. cylindrus* and/or *F. curta* according to morphometric data of *Fragilariopsis* spp. reported for the Antarctic seas. All these species have been mostly documented in the Southern Ocean cold water region, both in plankton and sea ice.

Over the last ca. 2700 years, the diatom concentration shows a sudden increase during the "Little Ice Age" and in particular in the 16th and 18th centuries, at the time when snow accumulation and dust influx decrease, while the stable isotope composition of the ice shows a small increase. One possible explanation for this sharp diatom concentration rise could be the development of a Roosevelt Island polynya, although additional, complementary data are needed to validate this scenario.

Deciphering eastern African environmental extremes and hydrological threshold conditions during the last 620,000 years: authigenic minerals in the Chew Bahir record

Dr. Verena Foerster **[1]*, Dr. Daniel Gebregiorgis*** **[2]*, Dr. Jonathan R. Dean*** **[3]*, Prof. Melanie J. Leng*** **[4]*, Dr. Christina Günter*** **[5]*, Prof. Henry F. The ~620,000-year-long climate record from Chew Bahir in southern Ethiopia documents the potential influence of different episodes of climatic variability on hominin biological and cultural transformation and presents therewith an unparalleled opportunity to better understand the environmental context of human-climate interactions during the Pleistocene. The coring locality of the 280-m long cores of sedimentary strata is situated near key archaeological and paleoanthropological sites, such as the Omo-Kibish where the Omo 1 and 2 *Homo sapiens* fossils were recovered. The effect, timing and especially the extent of environmental extremes and hydrological threshold conditions in one of the habitats of hominin populations is however not well understood yet. The key question in this context is: how dry was dry?

The Chew Bahir mineralogical record that provides the opportunity to decipher environmental extremes and hydrological threshold conditions. The degree of authigenic mineral alteration is indicative of wet, dry and especially hyper-arid climate intervals. Our results show that the most extreme evaporative phases are represented by authigenic mineral assemblages including Mg-enriched clays, low-temperature authigenic illite and euhedral analcime. Linking the mineralogical profile (XRD) with geochemistry (µXRF) and isotope geochemistry ($\delta^{18}O_{calcite}$) enables us to more finely differentiate levels of aridity, define depositional conditions and environmental thresholds through time. The oscillations between pronounced hydroclimatic conditions have important implications for transforming the habitats of human populations The time interval described by the core data encompasses several key hominin evolutionary benchmarks, including the transition to the Middle Stone Age, and the origin and dispersal of modern *Homo sapiens*.

A Bayesian Hierarchical Time Series Model for Reconstructing Hydroclimate from Multiple Proxies

Dr. Niamh Cahill [1]***, Prof. Jacky Croke*** [2]***, Dr. Micheline Campbell*** [3]***, Dr. Kate Hughes*** [4]***, Dr. John Vitkovsky*** [5]***, Mr. Jack Eaton Kilgallen*** [1]***, Prof. Andrew Parnell*** [1]

The Australian continent experiences hydroclimatic variability that is regarded as extreme compared to the rest of the world. Hydroclimatic risk in Australia is typically assessed using instrumental records of rain, evaporation, and streamflow that have existed for about the last 100 years, at best. Palaeoclimate proxy records provide indirect estimates of past local or regional hydroclimate and, with the use of appropriate statistical techniques, offer the scientific community an opportunity to extend instrumental records back in time and better elucidate natural climate variability. To that end, we present a Bayesian model which produces probabilistic reconstructions of hydroclimatic variability in Queensland Australia, using instrumental records of hydroclimate indices such as rain and evaporation, as well as palaeoclimate proxy records derived from natural archives such as sediment cores, speleothems, ice cores and tree rings. The method provides a standardised approach to using multiple palaeoclimate proxy records for hydroclimate reconstruction. The approach combines time-series modelling with inverse prediction to quantify the relationships between the hydroclimate and proxies over the instrumental period and subsequently reconstruct the hydroclimate back through time. We present model-based reconstructions of the Rainfall Index (RFI) and Standardised Precipitation-Evapotranspiration Index (SPEI) for two case study catchment areas, namely Brisbane and Fitzroy. In Brisbane, we found that the RFI is unlikely (probability between 0 and 20%) to have exhibited extremes beyond the minimum/maximum of what has been observed in the instrumental time period between 1889 and 2017. However, in Fitzroy there are several years during the reconstruction period where the RFI is likely (>50% probability) to have exhibited behaviour beyond the minimum/maximum of what has been observed. For SPEI, the probability of observing such extremes prior to the end of the instrumental period in 1889 doesn't exceed 50% in any reconstruction year in the Brisbane or Fitzroy catchments. Such information from catchment-scale hydroclimate reconstructions helps us to improve our understanding of the longer-term context within which known historical (i.e., instrumental) hydroclimate exists and can provide a point of comparison for future projections.

Using sedimentary ancient DNA of aquatic macrophytes to reconstruct postglacial freshwater environments

Mr. Aloïs Revéret [1], ***Dr. Dilli Prasad Rijal*** [2], ***Dr. Peter Heintzman*** [3], ***Prof. Antony Brown*** [4], ***Dr. Kathleen Stoof-Leichsenring*** [5], ***Prof. Inger Alsos*** [2]

Polar Terrestrial Environmental Systems Research Group, Alfred Wegener Institute Helmholtz Centre for Polar and MarineResearch, Potsdam, Germany*

Environmental DNA is increasingly used to reconstruct past and present biodiversity including from freshwater systems. Here, we investigate the extent to which sedimentary ancient DNA records can be leveraged for reconstructing local environmental conditions, using a case study based on aquatic macrophyte ecological niches. We used a metabarcoding dataset from ten lakes in northern Fennoscandia, mapped to a near-exhaustive reference barcode library (PhyloNorway); which we combined with a database of biotic and environmental traits of the Swedish flora. We reconstructed thermal range, continentality, water pH, trophic status, and light conditions in northern Fennoscandia freshwater ecosystems throughout the Holocene. The earliest record, comprising only 3 lakes for the Late Pleistocene, is characterised by mild conditions and habitat complexity. Individual lakes showed differing trends, with locally high variability of climatic and physico-chemical conditions. However, most lakes did not exhibit much fluctuation in trait composition during the last 9,000 years, resulting in an overall stability on the regional scale. Combined with the availability of near-complete barcode and traits databases, metabarcoding data can support wider ecological reconstructions that are not limited to aquatic plant taxonomic inventories but are also used to infer past environmental changes ranging from water-quality to climate. Sedimentary ancient DNA is shown to be a powerful tool to infer past environmental conditions from ecologically and climatically indicative taxa.

Does hydroclimate drive mercury fluxes in Lake Bosumtwi, Ghana?

Ms. Alice Paine [1]***, Prof. William Gosling*** [2]***, Dr. Isabel Fendley*** [1]***, Dr. Joost Frieling*** [1]***, Prof. Tamsin Mather*** [1]***, Dr. Timothy Shanahan*** [3]***, Dr. Nicholas McKay*** [4]***, Prof. Stuart Robinson*** [1]***, Prof. David Pyle*** [1]***, Ms. Ruth Kiely*** [2]

1. *University of Oxford,* ***2.*** *University of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics, Amsterdam, The Netherlands,* ***3.*** *The University of Texas at Austin,* ***4.*** *Northern Arizona University*

Mercury (Hg) is a volatile metal released into the atmosphere by both natural processes and human activity. The rate of transport, deposition and revolatilization of Hg in the terrestrial environment is driven by processes intimately coupled to climate, and which operate on pre-industrial timescales. Research has shown substantial Hg accumulation in tropical ocean sediments. Observed signals have been linked to changes in trans-continental precipitation patterns, tropical rain belt migration, and/or rates of sediment delivery to the ocean by run off – all as a function of climate-driven shifts in moisture availability on both short ($<10^1$-year) and long ($>10^1$-year) timescales. However, it is unclear whether these processes also impact lacustrine Hg fluxes. Previous studies have attributed the magnitude and expression of lacustrine Hg fluxes both to lake-specific processes such as sediment diagenesis and water balance, and also to catchment characteristics including ecosystem structure, surface hydrology, dust flux, and human activity. High-resolution, continuous sediment records of Hg cycling in the tropics are required to resolve the relative importance of these processes over decadal-to-millennial timescales. We present a record of Hg accumulation and deposition in Lake Bosumtwi (Ghana) between ~100–0 ka. Lake Bosumtwi is a closed, meromictic lake occupying a 1.08 ± 0.04 Ma meteorite impact crater and provides a continuous record of climate and environmental change in West Africa since ~100 ka. New Hg measurements reveal a coupled response between Hg flux and shifts in sediment lithology and composition indicative of changing lake level. We find that the amplitude and frequency of peaks in Hg increases as lake level rises, and decreases as the lake level falls. Together, these observations allude to a link between Hg flux, lake water balance, and regional moisture availability. By synthesizing our results with evidence obtained from the Bosumtwi system and the wider West African region, we can better understand the drivers of the changes in Hg deposition, and assess how these signals relate to centennial-to-millennial-scale changes in tropical vegetation, hydrology, and land use.

Session 102: West African Quaternary: understanding past climate oscillations and human responses to anticipate future adaptations

Environment, culture and African Thought

Prof. Adisa Ogunfolakan [1]

1. AG LEVENTIS MUSEUM OF NATURAL HISTORY MUSEUM, OBAFEMI AWOLOWO UNIVERSITY

The emergence of man in Africa as well as in the whole world revolutionized the environment in which they lived and still living. Conscious of the dictate of their environment, African man adjusted, related and adapted to the dictate of the environment.

The survival dictate led them to the manipulation of the environment and subsequently changed and continuing changing the environment and leading to climatic changes.

In this paper, the thoughts of the African man were examined on their traditional ways of protecting the environment and how these thoughts are being denigrated as a result of the influence of other people's culture, tradition and religion.

It concludes that serious action should be taken to protect these thoughts, adapt and modify according to the dictate of the present situation.

Sedimentologic and palynological appraisal of lithostratigraphic sequences of the eastern fringe of Dahomey Basin, Nigeria. West Africa

Prof. Olugbenga Boboye [1]

1. University of Ibadan

Integrative studies were carried out on fifty (50) ditch samples retrieved from drilled wells within the sedimentary sequences within Lagos. Lithologic study was carried out on the ditch samples which were logged at five (5) meter intervals and their litho-profiles were generated. Thin section petrography was done to determine diverse lithofacies constituting the sediment. The heavy mineral analysis is to evaluate the constituted mineral assemblages as well as the provenance of the sequences. The palynological study was carried out to evaluate the palaeoclimate, ages, palaeoenvironment and biozonation of the recovered palynomorphs. The lithologies of the studied wells (Ikorodu (IK) and Lekki (LK) wells) comprised of clayey sands, silt, clay, peat, granules and detrital fragments. The petrography revealed that the lithofacies were reworked sediment sourced from igneous and metamorphic sources hence suggested to have been transported by river. The wells have sandstone of > 90% quartz with the inclusion of other minerals constituting 10%. This suggests supermature sediments that have experienced medium transportation history in both wet and dry climates. This is corroborated by the heavy mineral assemblages that revealed the presence of zircon (Z), tourmaline (T), rutile (R), garnet (G), apatite (A), hornblende (H) and sillimanite (S), all indicating mature sediment. The palynology revealed a total of one hundred and thirty-two (132) palynomorphs. Three palynozones identified are characterized by the occurrence of *Avicennia africana, Drepanocarpus lunatus, Leiosphaeridia* sp., *Alchornea* sp., *Elaeis guineensis, Cassia* sp., *Psychotria* sp.; *Elaeis guineensis,* and *Protea* sp. The palaeoenvironment of deposition varies from marine to freshwater, while the presence of *Zonocostite ramonae* form suggests mangrove swamp forest (IK well). Based on the recovered palynomorphs, the lithofacies are dated Oligocene to Recent.

Keywords: Palynology, biozones, lithofacies, palaeoenvironment, assemblages.

Reconstitution of the paleoenvironments of the Venvé swamp in northwestern Benin : a palynological study.

Prof. Monique Tossou [1], ***Dr. Salomè Adeline Rodica ZANOU*** [2], ***Mr. Aurice TOSSA*** [1]

1. *University of Abomey-Calavi*, ***2.*** *University of Aboney-Calavi*

Detailed analysis of a core sample (2 m long) taken from a marsh located in Copargo (Djougou) allowed us to reconstruct the environment from the beginning of its formation to the present day. Field sampling was carried out using a Martin vibratory corer (Martin and Flexor, 1989), which allows an aluminum tube to be driven into the ground on a tripod. Sediment samples from the core were processed using the method of Faegri and Iversen (1989). Lithologic diagram construction was performed using the Munsell Soil Color Charts (2009). Pollen enumeration and identification was used to construct pollen diagrams and reconstruct the vegetation history around the site. The sporopollen study is complemented by the stratigraphic analysis of organic sequences and the floristic inventory. However, the chronostratigraphic framework remains undetermined. The results obtained allow 1) to understand the sedimentary dynamics of the marsh and its gradual transformation into a peat bog, 2) to verify the correspondence between the fossil pollens and the current vegetation of the marsh. It was found that the ancient vegetation did not undergo a profound change compared to the one found on the site today. Indeed, pollens of forest species such as Trichilia type, Diospyros type, Entada type, Terminalia type, Bombax sp, Newbouldia laevis were observed during the pollen analysis. Their presence gives an indication of the type of climate that would have existed at that time as well as the type of plant formation. The pollen data showed that site was occupied by a dense semi-deciduous forest type of plant formation and that the climate would be warmer and wetter in this area, which normally has a drier Sudanian climate. Indeed, semi-deciduous dense forests are found further south with a Guinean or Sudano-Guinean climate. The Venvé swamp belongs to a gallery forest where conditions were more humid. This has favored the maintenance of the dense semi-deciduous forest in this part of the Sudanian zone. Vegetation dynamics existed during the Quaternary on the banks of the Venvé Marsh. Further climate and dating studies would provide more information on the establishment of this vegetation type in the Sudanian zone.

Variable correlation between the West African Monsoon and global indices during the Last Millennium

Ms. Ellen Berntell [1] ***, Prof. Qiong Zhang*** [1]

1. *Dept. of Physical Geography and Bolin Centre for Climate Research, Stockholm University, Stockholm, Sweden*

West Africa has experienced pronounced interannual to multidecadal rainfall variability during the 20th century, resulting in devastating periods of drought and famine in the region. This is generally thought to be associated with global climate SST variability indices such as the Atlantic Multidecadal Variability, the Atlantic Niño and the El Niño Southern Oscillation. However, while these variability patterns are not stationary, and some studies have indicated a shifting relationship between the monsoon rainfall and the SST indices during the 20th century, how these relationships change on a multidecadal to centennial scale is not well understood due in part to the limited availability of long observational datasets and low paleoclimate proxy coverage in the region. Climate model simulations of the 'last millennium' (850-1850 CE) may provide opportunities to examine such temporal and spatial variability in the relationships. Increasing our knowledge on how these relationships have varied in the past will also help inform on the impact on the West African Monsoon by future spatial and temporal changes to different SST variability patterns. Here, we analyse model output from a 'last millennium' simulation produced using the fully coupled ocean-atmosphere-land model EC-Earth 3. The model results show a clear centennial variability in the correlation between the West African Monsoon and the Atlantic Multidecadal Variability, the Atlantic Niño and the El Niño Southern Oscillation through the last millennium. The varying correlation is linked to changes in the spatial pattern of the SST indices, which modifies how they impact the West African Monsoon and its regional rainfall.

Past climate reconstruction: Inherited month's names as a cultural model in the Kingdom of Dahomey in Benin (West Africa)

Prof. Henri Sourou TOTIN VODOUNON [1]***, Prof. Ernest AMOUSSOU*** [1]***, Prof. Ibouraïma Yabi*** [2]***, Prof. Constant HOUNDENOU*** [2]***, Prof. Michel BOKO*** [3]

1. Department of Geography, University of Parakou, 2. Department of Geography and Regional Planning, University of Abomey-Calavi, 3. Laboratory of Climatology, University of Abomey-Calavi

The lack of statistical or instrumental data lead to use historical archives and cultural models' heritage to understand paleo-climatic mutations and reconstruct past climates. This study aims to characterize the climate evolution using historical archives and the months referred to climatic and agroclimatic events in the Kingdom of Dahomey (southern Benin), established around the year 1600 by the Fon people.

The study is based on analysis of historical archives, decryption of the inherited months names and recorded climate data. Compiled data help to reconstruct the paleoclimate and its recent evolution focusing on criteria as average monthly rains (Rm) and temperature (Tm) and seasonal (Rs and Ts), recorded at the station of Bohicon over 1940-2021.

The inherited month names and change of some agroclimatic events show an evolution of the ancient to recent climate. Thus, January (*alunsun*), drought month (Rm = 6.9 mm; Tm = 28.7 °C); March (*xwejisun*), month of the yearly first rain (Rm = 82.8 mm; Tm = 29.9 °C); August (*avuvosun*), cold month (Rm = 96.3 mm; Tm = 25.6 °C); December (*woosun*), harmattan month (Rm = 12.7 mm; Tm = 28.6 °C) still observable testify to the recent stationarity of the subequatorial paleoclimate. But, the cultivation of pearl millet (*Pennisetum typhoides*), a crop in the Sahelian and Sudanian climates (Rs between 200 to 700 mm and Ts = 28 °C) was done by its planting in April (*lidosun*) and its harvesting in July (*liyasun*). The current seasonal rain for the growth stages of pearl millet (60 to 90 days), no longer significantly cultivated (replaced by maize), varies from 282.1 to 1110.00 mm (Ts = 27.5 °C) with 13 % of unfavorable years. The disappearance of pearl millet cultivation reveals that the tropical paleoclimate (semi-arid) would have evolved into an unfavorable subequatorial climate (humid) on the Kingdom of Dahomey.

The climate effects on people and their innovative adaptation capacity helps to preserve the memory of paleoclimate and its variation in the absence of instrumental data.

Keywords: Kingdom of Dahomey, inherited month name, recorded data, paleoclimate memory, Benin.

Reconstructing paleoclimate and paleoenvironment using lipid biomarkers in Western Central Africa: the NGaoundaba peat deposit (Cameroon)

Ms. Valentine Schaaff [1]***, Dr. Vincent Grossi*** [1]***, Dr. Matthew Makou*** [1]***, Dr. Salomé Ansanay-Alex*** [1]***, Dr. Ingrid Antheaume*** [1]***, Dr. Pierre Deschamps*** [2]***, Prof. Bruno Hamelin*** [2]***, Dr. Yannick Garcin*** [2]***, Dr. David Sebag*** [3]***, Dr. Benjamin NGounou Ngatcha*** [4]***, Prof. Guillemette Ménot*** [1]

Since the beginning of Holocene (last 11ka), African climate has encountered large paleoclimatic and paleoenvironmental changes from a globally wet climate at the beginning of the Holocene also known as the African Humid Period to a drier period from 5/6 ka to present days. Recent dry climate is not favorable for sediment deposition and preservation leading to rare and often uncontinuous records complicating paleoclimatic and paleoenvironmental interpretations based on sedimentary archives. In this study, we investigate a continuous and homogeneous 6-meter peat core from the NGaoundaba peatland (Northeastern Cameroon) over the last 10ka using a large panel of lipid biomarkers of various biological origins [microbial isoprenoid and branched glycerol-dialkyl-glycerol-tetraethers (isoGDGT and brGDGT respectively), higher plants *n*-alkanes, bacterial hopanoids and degradation products of plants]. Using variations in abundance, concentration, isotopic composition of lipids or recently developed peat-specific organic proxies, we reconstruct past changes in vegetation, precipitation, temperature or methane cycle to better understand the timing and pattern of the African Humid Period both locally and at a regional scale by comparing with other records.

A diverse assemblage of lipid biomarkers was detected: C_{17} to C_{37} *n*-alkanes, C_{27} to C_{31} hopanes and hopenes, both regular and H-shaped brGDGTs and isoGDGTs, among others. From 10 to 6ka, brGDGT-based reconstructed temperature and $\delta D_{C31\ n\text{-alk}}$ indicate warmer and wetter climate compared to present conditions, coinciding with the African Humid Period. From 7.9 to 8.9ka, depleted values of $\delta D_{C23\ n\text{-alk}}$ and high abundance of biomarkers usually associated with freshwater lake and microbial organic matter suggest a period of development of the peatland with an increase in-situ production. Abundance of *n*-alkanes and degradation products of plants and $\delta^{13}C_{n\text{-alk}}$ indicate a higher proportion of C3 plants from 8 to 6ka during the African Humid Period compared to present day where C4 plants are more frequent.

Study of the Recent Quaternary of the Southwest Coast Benin, from archaeological and archaeobotanical Data: results and perspective research

Prof. Monique Tossou [1], ***Dr. Didier N´DAH*** [2], ***Dr. Salomè Adeline Rodica ZANOU*** [3], ***Dr. BARPOUGOUNI MARDJOUA*** [2]

1. University of Abomey-Calavi, 2. University of Abomey Calavi, 3. University of Aboney-Calavi

The Quaternary is marked by alternating cold, long glacial phases and warm, shorter interglacial phases according to climate reconstruction models. These different phases led to changes at different levels on the globe as in West Africa. Indeed, it has been noted that these changes do not cover the same importance. Thus, a phytogeographic break called Dahomey-Gap observed between Nigeria and Ghana while the rest of the coast is covered with dense semipivirous forests has been noted. Could this phytogeographic anomaly be due to climatic causes or anthropic actions? Indeed, this break in the two forest blocks raises many questions about the relationship between vegetation and human activities over the past millennia. Research projects have already been conducted to study this phenomenon in Benin, but they do not cover all areas of this phytogeographic anomaly. It is therefore in search of explanations to this phenomenon that the QuaReB research project was born and proposes to collect data on the fishing route in southern Benin. The paper entitled ¨Etude du Quaternaire Récent de la Côte Sud du Bénin, à partir de données archéologiques et botaniques¨ (Study of the Recent Quaternary of the South Coast of Benin, based on archaeological and botanical data) will present the results obtained and the research perspectives by the QuaReB project team at the XXIst Congress of the International Union of Quaternary Sciences.

Session 103: Terrestrial hydroclimates: towards quantification and climate model comparisons

Exploring the causes of a multicentury pluvial event in the Altiplano with an idealised modelling experiment

Prof. Ignacio Jara [1], ***Dr. Orlando Astudillo*** [2], ***Mr. Pablo Salinas*** [2], ***Mr. Limbert Torrez Rodriguez*** [3], ***Dr. Antonio Maldonado*** [2]

Rainfall in the Altiplano is scarce and largely limited to the austral summer months (DJF), representing a critical hydrological resource for several million of people in South America. From interannual to decadal timescales, summertime rainfall variability in the Altiplano results from a complex interplay between upper and lower-tropospheric features, which is ultimately modulated by equatorial Pacific SSTs (i.e., El Niño Southern Oscillation, ENSO) and Atlantic cross-equatorial thermal gradients. However, drivers of long-term changes (100+ yr) are still largely unknown, which limits our understanding of natural and anthropogenic-caused anomalies and the capability of models to project future trends.

The combination of detailed paleoclimate series and climate simulations capable of capturing regional and local scale features is a novel approach to explore long-term hydroclimatic trends and drivers. Recent paleoclimate reconstructions from Altiplano showed what seems to be a ~400 yr pluvial event that occurred ~2000 yr ago. Yet, this event is hardly observed in records from tropical South America further north, which led to propose an intrusion of extra-tropical moisture as a potential cause. To decipher the mechanisms of multicentury pluvial events in the Altiplano we performed an idealised modelling experiment using the Weather Research and Forecast Model (WRF), a regional climate model. We simulate long-term rainfall responses forced by two different configurations that enhanced summertime precipitation in recent historical times. Preliminary results from our experiment shows that neither cold equatorial Pacific SSTs nor warmer south tropical Atlantic temperatures are capable of sustaining long-term positive summer precipitation anomalies.

Our simulations further suggest that Warm SSTs over the coast of southern Brazil and Argentina may have not driven the occurrence of multicentury pluvial events as observed in paleoclimate records. Similarly, persistent cold conditions in the Pacific are unable to simulate century-long humid anomalies, although we did not force our simulations with strong La-Niña conditions. Our experiment provides a novel approach to explore the causes and mechanisms of long-term hydroclimatic change in the Altiplano.

Water cycle and vegetation influences on leaf-wax δD variations: a modelling approach

Dr. Thomas Extier [1] ***, Dr. Thibaut Caley*** [1] ***, Dr. Didier Roche*** [2] ***, Prof. Louis François*** [3]

1. University of Bordeaux, 2. LSCE-IPSL, Laboratoire des Sciences du Climat et de l'Environnement (CEA-CNRS-UVSQ), Paris-Saclay, 3. University of Liege

The hydrogen isotopic composition of leaf wax, i.e. δD_{wax}, is derived from long-chain n-alkane that are abundant in the leaf of higher plants and well preserved in the sediments over millions of years. This proxy is usually used to infer indirect changes in the local water cycle, even if its quantitative interpretation is still an open question. The δD_{wax} signal is complex to interpret since it depends on the climate (precipitation, relative humidity, temperature), the vegetation and several isotopic fractionation processes. Additional constraints are then needed to decipher the influence of the drivers on the δD_{wax}.

We present here the first modelling approach of the δD_{wax} in a coupled climate model. The intermediate complexity model iLOVECLIM is used to develop a new module to simulate the hydrogen isotopic composition of the leaf wax, including the variation of the water isotopes, the distribution of the vegetation with 26 plant types and the isotopic fractionation processes associated with the evapotranspiration and the biosynthesis of the leaf wax. The results obtained for the Preindustrial show that the δD_{wax} presents similar spatial variations than the hydrogen isotopic composition of precipitation. The isotopic fractionation associated with the biosynthesis of leaf wax also appears to be a major driver of the δD_{wax} variations. To obtain a good model-data agreement, it is necessary to account for the role of the vegetation and of the plant types diversity on the isotopic fractionation values. This modelling approach highlights the key role of the vegetation, in addition to the water cycle, on the δD_{wax} variations.

Quantitative paleo-humidity reconstructions during the Iberian Roman period from stable isotopes of gypsum hydration water

Dr. Fernando Gázquez-Sánchez [1]***, Ms. Aurora Castillo-Baquera*** [2]***, Ms. Lucia Martegani*** [1]***, Dr. Antonio Garcia-Alix*** [2]***, Dr. Gonzalo Jiménez-Moreno*** [3]***, Dr. Francisco J. Jiménez-Espejo*** [4]***, Dr. Miguel Rodríguez-Rodríguez*** [5]

University Pablo de Olavide*

Quantitative paleoclimate records are scarce, yet important for validation of climate change models. Here we quantify changes in atmospheric relative humidity (RH) in the southern Iberian Peninsula from 3.3 to 1.4 cal ky BP, spanning the time of the Roman domain of Iberia. We reconstruct the triple oxygen (δ17O and δ18O) and hydrogen (δ2H) isotope composition of paleo-lake water in Laguna Grande de Archidona (Málaga Province) from the stable isotopes of the structurally-bonded gypsum hydration water. An evaporation isotope-mass-balance model is used to determine the range of hydro-climatic conditions that satisfy the isotopic composition of the paleo-lake water. We validate our approach by analyzing sub-actual gypsum (1997 to 2018 CE) and found that the results are consistent with lake water evaporation under RH of 54±1%, similar to the modern RH during the dry season. The sedimentary record shows that a shift from drier to wetter conditions occurred from 2.59 to 2.37 cal ky BP, when RH increases by ~8% (from 53±3% to 61±3%). Subsequently, a gradual decrease in RH extended from 2.31 to 1.43 cal ky BP and RH was 56±3‰ at 1.43 cal ky BP. The driest episodes occurred at 2.58, 2.22 and 1.52 cal ky BP, when RH fell below 54%. These arid stages match with positive phases of the North Atlantic Oscillation. Our results suggest that the hydro-climate in the southern Iberian Peninsula during Roman times was controlled by changes in regional atmospheric patterns.

CNRS, Laboratoire de Géographie Physique: Environnements Quaternaires et Actuels, Universite Paris1, 10. University of Tübingen, Department of Earth Sciences, Tübingen, Germany

Over the last glacial period, the climate of the Northern Hemisphere experienced numerous abrupt variations on millennial to centennial timescales known as Dansgaard-Oeschger events. Their understanding is underpinned by the Greenland ice core and North Atlantic marine records; terrestrial responses and potential feedbacks are less well documented. Loess-palaeosol sequences in central Europe often record these climatic changes in the form of brown soils and tundra gley horizons - indicating milder interstadial conditions - intercalated with primary loess deposits reflecting cold stadial conditions.

Here we make use of a singular material for quantitative, high resolution palaeoclimate reconstruction from loess sediments: fossil earthworm calcite granules (ECG). ECG are secreted daily at the soil surface mostly by *Lumbricus* species and experience limited vertical mixing within the loess sedimentary column. Our terrestrial data derive from stable isotopic geochemistry and radiocarbon dating of ECG, collected from two temporally overlapping loess-palaeosol sequences: Schwalbenberg and Nussloch. These sequences are located c. 180 km from one another along a NNW-SSE transect in the Rhine River valley of western Germany, archiving regional terrestrial responses to the oscillating climate of the period ~ 45-22 cal kBP (late MIS 3 - MIS 2). We present warm-season land-surface temperature and precipitation estimates at millennial timescales.

Over the time interval studied, we demonstrate that MIS 3-2 climate in the Rhine Valley was significantly cooler during the warm season and overall drier with annual precipitation reduced by up to 70%, compared to the present day. Interstadial conditions were only slightly warmer (1-4°C) than stadial ones - a difference which appears strongly attenuated compared to Greenland records. We combine quantitative estimates with mesoscale wind and moisture transport modelling, demonstrating that this region was dominated by westerlies and thereby inextricably linked to North Atlantic climate forcing.

Our approach represents a useful combination of high-resolution age-depth modelling and geochemical proxy-based climate reconstruction which can be readily adopted at other loess palaeosol sequences. A widespread application of this approach would provide an improved understanding of the regional variability over the European continent in response to North Atlantic climate changes over millennial to centennial timescales.

The effects of the temperature increase on the rainfall regime in north-central Italy

Mr. Marco Luppichini [1], ***Prof. Monica Bini*** [2], ***Prof. Roberto Giannecchini*** [3], ***Prof. Giovanni Zanchetta*** [4]

1. Department of Earth Sciences, University of Florence, 2. DST, Department for Earth Sciences, University of Pisa (Italy)., 3. Department of Earth Science, University of Pisa, Italy, 4. University of Pisa

In the last years, several works analyzed climate databases and applied physical models to study rainfall regime changes in Europe and in the Mediterranean, specifically identifying a different behavior in the rainfall regimes between northern Europe and the Mediterranean regions over the last years. This seems to indicate the presence of climatic transitional zones, like north-central Italy, where there is the passage from the wet areas of central Europe to the dry areas of the Mediterranean.

In general, the weather databases with an adequate resolution for the study of fast extreme precipitation events (EPEs) do not have an appropriate sample period length to apply mathematical methods that can help to directly understand the trends of these events. Knowing with greater accuracy the future scenarios of temperature in relationship with the current global warming, some works studied the relationship between temperature and rainfall to define also future scenarios of rainfall regimes.

In this study, we analyzed a database with more than 1,000 meteorological stations, most of them equipped with both rain gauges and thermometers located in north and central Italy. The selected database has a low rainfall accumulation period (RAP) that made it possible to analyze the relationship between temperature and rainfall in unprecedented detail the relationship between temperature and rainfall, distinguishing between fast and long events related to rainfall intensity.

The results show different relationships between rainfall and temperature according to seasons, RAPs, rainfall intensity, and geographical factors. With an increase in the temperature, the wet season shows a general increase in rainfall and a higher surge for intense and fast events, while the dry season is characterized by a general rainfall decrease of the loss of intense and longer-lasting events, experiencing fast and more intense rainfall events increase. This behavior has repercussions on the water resource, inducing a future decrease in the water available, an increase of the EPEs, and thus an extremization of the climate during the dry season in northern and central Italy.

Into the mega-monsoon: yearly flood dynamics of the Nile River during the last African Humid Period

Dr. Cécile Blanchet [1], ***Dr. Arne Ramisch*** [2], ***Dr. Monica Ionita-Scholz*** [3], ***Prof. Achim Brauer*** [1]

1. Helmholtz Centre Potsdam, German Research Centre for Geosciences GFZ, 2. Institute of Geology, Innsbruck University, Austria, 3. Helmholtz Centre Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany

Seasonal floods are life-supporting events in the Nile Valley and have been crucial to the development of complex societies. Past and present populations depend on their occurrence but the alteration of fluvial dynamics under climate change remains elusive. In this presentation, we will explore the changes in flood dynamics of the Nile River during a period of high monsoon activity known as the African Humid Period (during the early Holocene). Using a unique sediment core from the Nile deep-sea fan that contain well-preserved marine varves (i.e., annual layers), we were able to track the changes in flood dynamics at annual resolution between 9.5 and 7.5 ka BP. This remarkable 1500 yr-long annual flood record from the Nile River allows us to investigate fluvial regimes under high rainfall intensity and determine the main climatic forcing driving flood dynamics.
Varve thicknesses vary drastically through time between 0.3 and 13 mm with significant changes at 8.2, 8.9 and 8.7 ka BP occurring within a few decades. These variations suggest large modifications in the erosional regime of the Nile, leading to the deposition of variable amounts of sediments on the margin. In particular, a large variability is observed in intervals with overall thicker flood layers between 9.5 and 8.7 ka BP, which leads credence to the hypothesis of a more variable Nile flow under warmer climates. In addition, time-series analyses demonstrate a persistent El Niño-Southern Oscillation (ENSO) fingerprint throughout the record. Climatic simulations at 9 ka BP show that the Pacific state was probably shifted towards La Niña conditions, driving larger rainfall on the Nile watershed. In the presentation, we will discuss the potentiality that the large variability observed was related to a more variable ENSO or to amplification processes during a mega-monsoon interval.

The limitations of uniformitarianism: the glacial aridity paradigm

Dr. Kale Sniderman [1], Dr. John Hellstrom [2], Dr. Rieneke Weij [3], Dr. Josephine Brown [4], Prof. Jon Woodhead [2]

__1.__ School of Geography, Earth and Atmospheric Sciences, The University of Melbourne, Australia, __2.__ School of Geography, Earth and Atmospheric Sciences, The University of Melbourne, __3.__ Department of Geological Sciences, University of Cape Town, __4.__ School of Geography, Earth and Atmospheric Sciences, University of Melbourne, Victoria, Australia

The climate of the last glacial maximum (LGM, ~23-18 ka) is routinely interpreted as substantially drier than today, in most subtropical regions. This perception is largely the result of interpreting fossil pollen evidence of widespread LGM treelessness and/or reduced vegetation biomass, and evidence for increased dust deposition, within a uniformitarian framework. However, it is increasingly clear that the 'arid' appearance of LGM vegetation – treelessness, or lower inferred biomass – can at least partly be explained as an expression of C3 plants' physiological responses to, and reduced water-use efficiency under, low atmospheric CO_2.

An alternative proxy for past moisture balance which is largely independent of vegetation structure or biomass is the simple growth of speleothems, which demonstrates a positive moisture balance, at least on ~seasonal timescales. In several seasonally-dry Southern Hemisphere subtropical regions, speleothems grew through the LGM. This growth seems to contradict interpretations of arid climates that have often been based on interpreting changes in vegetation structure from fossil pollen records.

Here we present LGM-aged fossil pollen records recovered from U-Th-dated speleothems from Naracoorte (South Australia), and Weelawadji and Mammoth caves (Western Australia), regions which today experience moderately dry, mediterranean-type climates. These records show substantial changes in vegetation structure, including substantially reduced tree-cover, consistent with 'conventional' LGM wetland pollen records in the region. However, our records include a number of shrub and herb taxa that indicate moisture availability equal to or higher than today, despite striking reductions in LGM plant biomass. Higher-than-modern moisture availability at these sites is consistent with published climate model simulations. These simulations indicate that, in many regions, even where LGM precipitation was lower than today, globally widespread reductions in evaporation contributed to a more positive LGM moisture balance.

Session 104: Novel molecular tools (biomarkers and DNA) in climatic and environmental archives – challenges, advances, and prospects

Testing the limits of lacustrine faecal lipid biomarkers as tools to document human presence in the Alaskan landscape

Dr. Helen Mackay [1]***, Prof. Andrew Henderson*** [2]***, Dr. Helen Whelton*** [3]***, Dr. Ian Bull*** [3]***, Dr. Nancy Bigelow*** [4]***, Prof. Mary Edwards*** [5]***, Dr. Joshua Reuther*** [4]***, Dr. Ben Potter*** [4]

1. *Department of Geography, Durham University, Durham, DH1 3LE, UK.,* ***2.*** *Newcastle University,* ***3.*** *Organic Geochemistry Unit, University of Bristol,* ***4.*** *University of Alaska Fairbanks,* ***5.*** *School of Geography and Environmental Science, University of Southampton, Southampton, SO17 1BJ, UK*

In recent years there has been an expansion of the use of faecal sterol biomarkers to generate records of human occupation in the landscape from lake-sediment profiles. Faecal steroid biomarkers (5β-stanols, bile acids) were initially used in archaeological settings in the late 1980s and have since been successfully developed and applied to characterise the presence of humans and animals from archives of concentrated faecal waste e.g., coprolites and archaeological soils. Faecal steroids are well-preserved within lake sediments, indicating they have the potential to be direct archives of anthropogenic activity. The application of faecal biomarkers within diffuse depositional environments of lake basins, however, presents new methodological challenges, which are currently being overlooked.

We investigate the efficacy of lacustrine faecal biomarkers to trace human presence within the landscape using steroid records generated from a lake in central Alaska, with independent records of human activities over the past 2000 years. Comparisons of steroid data obtained from modern dung, catchment soils and lake sediments show that the use of sterol concentrations alone is insufficient to conclusively characterise faecal input within lake sediments. Whilst diagnostic stanol ratios can identify faecal matter, the standard archaeological threshold values require systematic testing for robust application in aquatic sediments, to account for processes such as dilution and *in-situ* primary productivity. Findings from the modern environment demonstrate that stanols alone are insufficient for characterising faecal inputs to lake cores, but that the incorporation of both stanols and bile acids, the latter of which are solely produced from digestive processes, is reliable. Overall, we demonstrate that lacustrine faecal biomarkers are effective tools to trace human presence when corroborated with additional proxies of anthropogenic impact, historical records and/or archaeological evidence. However, we highlight uncertainties relating to lake-taphonomic processes that must be addressed to optimise applications of this proxy within aquatic sedimentary archives.

Reconstructing Holocene human-climate-landscape interactions in semi-arid Mongolia using multi biomarker analyses

Dr. Marcel Bliedtner [1], ***Mr. Paul Strobel*** [1], ***Dr. Julian Struck*** [1], ***Prof. Enkhtuya Bazarradnaa*** [2], ***Prof. Roland Zech*** [1]

1. Physical Geography, Institute of Geography, Friedrich Schiller University Jena, 2. Institute of Plant and Agricultural Sciences, Mongolian University of Life Sciences

Semi-arid regions are highly sensitive to global warming and human activity, and a better understanding of past climatic changes and anthropogenic influences in such regions is therefore essential. In this context, biomarker analyses have great potential to strongly enhance our knowledge about human-climate-landscape interactions since they are source-specific and direct indicators for hydrological and temperature dynamics as well as anthropogenic landscape changes.

Here we present potentials and pitfalls of biomarker analyses in two high-altitude lakes from the Mongolian Altai (Khar Nuur) and Khangai Mountains (Shireet Naiman Nuur). At both sites, robust chronologies have been established, spanning the last 4.2 and 7.4 cal. ka, respectively. We aim at i) reconstructing hydrological conditions using compound-specific hydrogen isotopes (δ^2H) of *n*-alkanes, ii) reconstructing temperature changes with long-chain alkenones and iii) tracing anthropogenic impact in the lake catchments with polycyclic aromatic hydrocarbons (PAHs) and fecal sterols/stanols.

While the lacustrine sediments of our investigated lakes comprise a mixture of terrestrial and aquatic components, our results show that terrestrial *n*alkanes (i.e., C_{31}) from leaf waxes of terrestrial plants incorporate the δ^2H signal of the local growing season precipitation. Aquatic *n*alkanes (i.e., C_{23}) produced by algae and aquatic macrophytes incorporate the δ^2H signal of the lake's water, which can be strongly modulated by evaporative enrichment. The isotopic offset ($\Delta_{aq\text{-}terr}$) between δ^2HC_{23} and δ^2HC_{31} is a valuable indicator for evaporation changes in the lake catchments and shows distinct hydrological changes at our investigated sites. Long-chain alkenones, which are produced by the so-called Group I phylotype haptophyte algae, are abundant and seem to record changes in growing season temperatures and the timing of alkenone production rather than changes in mean annual temperatures at our high-altitude sites. The PAH perylene, which is thought to be produced by fungal species in soils, is also abundant in our lake sediments likely record phases of enhanced runoff and erosion. Fecal sterols/stanols are currently being analyzed and will finally complement the overall picture of human-climate-landscape interactions at our investigated sites.

Investigating the potential of amino acid analysis and peptide mass spectrometry in identifying burning in Quaternary fauna

Abstract

The excellent protein preservation recently discovered in Pleistocene tooth enamel has opened up exciting avenues for building chronologies (amino acid dating), evolutionary phylogenies and determining sex (palaeoproteomics) of mammalian fauna in archaeology and palaeontology. However, if samples have been heated, this will speed up protein degradation and therefore lead to loss of information. Heating events can either be anthropogenic, or through natural processes such as volcanism and wildfires.

To study this in detail, artificial high temperature heating experiments on tooth enamel from three Pleistocene subfossil fauna (Mammuthus primigenius, Coelodonta antiquitatis and Hippopotamus amphibius) and three modern taxa (Equus caballus, Bos taurus, Capra hircus) were conducted. To study the effect of high temperature heating, two techniques were used: reversed-phase high performance liquid chromatography (RP-HPLC) which provides information on amino acid concentration, composition, racemisation and peptide bond hydrolysis; and liquid chromatography with tandem mass spectrometry (LC-MS/MS), which yields peptide sequence and diagenetic post translational modifications (PTMs). Upon heating, significant changes in protein composition were observed for all samples, which were characteristic of heating rather than low temperature burial diagenesis. These patterns of degradation therefore enable us to develop a tool to identify burnt samples, as well as help us understand the potential for individual heated samples to yield useful proteomic or geochronological data.

Insight into the Holocene phytoplanktonic community of the Baltic Sea: a multi-method approach

Ms. Juliane Romahn [1], ***Dr. Jerome Kaiser*** [2], ***Ms. Alexandra Schmidt*** [3], ***Prof. Laura Epp*** [3], ***Dr. Anke Kremp*** [4], ***Prof. Miklos Balint*** [1]

1. Senckenberg Research Institute Frankfurt, 2. Leibniz Institute for Baltic Sea Research Warnemünde, 3. University of Konstanz, 4. Leibniz Insitute for Baltic Sea Research Warnemünde

The reconstruction of past environments is a challenging and rapidly developing research field. As environmental conditions determine the occurrence of organisms, remains of these organisms can be used as proxies of past environmental conditions. However, most organisms rapidly decompose after death either before or after deposition into sediments, and this process leaves only molecular remains behind, such as lipids and DNA. Further, both decaying organisms or molecular remains might be passively transported before deposition into sediments. This source-transport-sink process complicates the application of molecular remnants as proxies of past environments.

As a semi-enclosed, shallow, geologically young sea located close to the centers of the Industrial Revolution, the Baltic Sea faced anthropogenic pressures earlier than most other marine ecosystems. As human pressures caused ecological degradation in the Baltic Sea, biomonitoring started decades ago, leading to good monitoring data especially for phytoplankton communities. The latter are well-established indicators for ecological changes since they are sensitive to diverse environmental stressors. The existence of long-term observational data makes the Baltic Sea an excellent model to investigate the potential of DNA and lipids derived from phytoplankton as proxies of paleoenvironments.

Here, we compare sedimentary ancient DNA (seda DNA) and lipid biomarker data from Baltic sediments with phytoplankton monitoring data from the last 50 years. We aimed to 1.) detect possible lipid sources 2.) calibrate seda DNA and lipid biomarkers on monitoring data 3.) apply the gained knowledge for paleoenvironmental reconstructions of the Baltic Sea. We extracted seda DNA as well as lipids from several horizons, amplified DNA with primers targeting representatives of major taxonomic groups - diatoms, cyanobacteria and dinoflagellates, and sequenced amplicons on an Illumina platform. We measured lipid biomarkers for phytoplankton using gas chromatography coupled to mass spectrometry. The results allow us evaluating how precisely seda DNA marker genes and lipid biomarkers reflect observational data of phytoplankton, reconstructing Baltic Sea past environments and understanding how phytoplankton communities responded to the changing environments.

eDNA analyses from river sediments to investigate its potential to trace erosion hot spots

Dr. Charline Giguet-Covex [1], *Dr. William Rapuc* [1], *Dr. Fabien Arnaud* [1], *Dr. Pierre Sabatier* [1], *Prof. Jérôme Poulenard* [1]

1. Laboratoire EDYTEM UMR CNRS 5204 Université Savoie Mont Blanc

In recent years, the number of studies using sedimentary ancient DNA (sedaDNA) analyses for palaeoenvironmental/climatic reconstructions or for understanding human-environment interactions has increased dramatically. Technical progresses, promotion of the great potential of the tool to push the boundaries of our knowledge on the past composition of life and strengthening of the scientific community, notably through the sedaDNA society, explain this success.

However, there are still many unknowns about the ability of the tool to reflect past environments, taxonomic composition and diversity. When looking at terrestrial organisms from extracellular DNA (exDNA), one crucial question concerns the processes that are governing the DNA transfer and thus the origin of the sub-fossil sedDNA. The now-preferred hypothesis states that most exDNA is bound to mineral/organic or organo-mineral particles and thus transferred through erosion processes, making the community composition a potential signature of the sediment origin. One consequence of this statement is that, in a sediment cascade system, covering several biomes with contrasted vegetation, the sedaDNA could theoretically be used as a tracer of the sediment origin. In this study we aimed at investigating this potential.

In this aim, we applied a DNA metabarcoding approach targeting plants to exDNA extracts from modern sediments of the Arve and Rhône Rivers (six samples) and their tributaries (eight samples) upstream of Lake Bourget (a hard-water peri-alpine lake). We performed a Non-metric multidimensional scaling analysis to assess the differences/similarities in the floristic composition of the different tributaries and of the Arves and Rhône Rivers. Because the tributaries drain different vegetation belts characterized by specific taxa, they show distinct signatures. Interestingly, the signature of most tributaries was also detected downstream in the main rivers (Arve or Rhône). However, other tributaries, at the time of sample collection, did not appear to contribute to the DNA signal of the main river, raising the question of their sedimentary contribution. However, despite this remaining complexity which still needs to be addressed, these results strongly support the potential of sedimentary DNA as a new proxy to track erosion hot spots.

Ancient DNA from sediments identifies past ecosystem engineering species

Dr. Benjamin Vernot [1], ***Mr. Robin Warner*** [1], ***Prof. Christoph Sperisen*** [2], ***Dr. Vincent Robin*** [3], ***Prof. Annegret Larsen*** [4]

1. *Department of Evolutionary Genetics, Max Planck Institute for Evolutionary Anthropology, Deutscher Platz 6, 04103 Leipzig, Germany,* ***2.*** *Swiss Federal Institute for Forest, Snow and Landscape Research,* ***3.*** *Laboratoire Interdisciplinaire des Environnements Continentaux, UMR 7360 CNRS - Université de Lorraine, France,* ***4.*** *Environmental Sciences, Wageningen University & Research, Droevendaalsesteeg 3, 6708 PB Wageningen, The Netherlands*

Before humans assumed the dominant role in engineering streams and floodplains, native taxa controlled ecosystem engineering and surface change within river-floodplain systems. However, little is known about this pre-human, natural condition of European rivers and their floodplains. Furthermore, for periods where human activity was a major driver of river floodplain evolution, it is often challenging to distinguish between sites affected by human vs faunal behavior in the absence of physical evidence. In this pilot study, we aim to reconstruct the pre-human environmental condition of central European, low order streams and their floodplains. Further, we develop a methodology to identify the major drivers of ecosystem engineering at specific riparian sites. We selected three research sites in central Europe, and reconstructed the pre- and post-human palaeo-environmental conditions at these sites.

We analyzed ancient DNA from sediments (sedaDNA) and tested for the presence of specific wetland vegetation. These abundances are then compared with an analysis of botanical macroremains from the same sediments. We also test for animal ecosystem engineers, such as the beaver, water vole and aurochs, as well as domestic species. Overall, aDNA was able to identify the presence of many ecosystem engineers, with clear signatures separating the pre- and post-human ecosystems. While in the more human modified floodplain mammalian engineers dominate, vegetation dominates the record of the more natural side. In combination with a detailed chrono-stratigraphy this study shows how animal husbandry dominates land-use over a riparian forest at the more natural setting.

We additionally compare three methods for enriching and analyzing ancient sediment DNA, including novel methods for identifying the less abundant natural mammalian taxa that are missed using standard approaches. Locating where and when these species were present will not only give us an understanding of the natural and most sustainable environmental conditions of riparian areas, but will also create a baseline for a better understanding of subsequent human-environment interaction

Towards a new fossil proxy for UV-B radiation: Reconstructions of UV-B absorbing compounds from Quaternary sediment sequences

Dr. Alistair Seddon [1]***, Mr. Eirik Ballo*** [2]***, Prof. Richard Bindler*** [3]***, Dr. Monica Jordheim*** [4]***, Prof. Kirstin Krüger*** [2]***, Dr. Florian Muthreich*** [5]***, Prof. Matthew Robson*** [6]***, Dr. Boris Zimmermann*** [7]

***1.** Department of Biological Sciences, University of Bergen and Bjerknes Centre for Climate Research, Bergen, Norway,* ***2.** Department of Geosciences, University of Oslo, Oslo,* ***3.** Department of Ecology and Environmental Sciences, Umeå University, Umeå, Sweden,* ***4.** Department of Chemistry, University of Bergen,* ***5.** Department of Biological Sciences and Bjerknes Center for Climate Research, University of Bergen,* ***6.** Viiki Plant Science Centre, University of Helsinki,* ***7.** Norwegian University of Life Sciences*

Large variations in ozone and UV-B radiation at ground level are thought to have occurred in the past, with potentially major implications for climate, human societies and ecosystems. Although UV-B radiation is an important variable for understanding those processes influencing life on Earth, at present it remains challenging to reconstruct changes in UV-B radiation at the Earth's surface beyond the period covered byinstrumental measurements of the 20th century.

Since the 2000s, researchers have suggested that chemical sunscreens produced by plants, and which are also found in the walls of pollen grains and subsequently buried in lakes and bogs over thousands of years, may be used to reconstruct UV-B radiation that was received by these plants during their lifetime. However, although the evidence base for a chemical response of UV-B absorbing compounds spans a variety of species under a range of experimental settings, there remains uncertainty about whether pollen-chemical variations reconstructed from sediments respond to changing ratios of UV-B radiation: Total Solar Irradiance (e.g. as a result of changing atmospheric chemistry) or whether fossil reconstructions are more likely to reflect changes in total solar irradiance. This makes it difficult to generate precise reconstructions that can be be used in Earth system models and studies of the effects of UV-B radiation on the biosphere in the past.

Here, we assess the potential for reconstructing UV-B radiation through fossil sequences in the Holocene. Specifically, we investigate the utility of the proxy for a range of applications, including (i) whether variations in the UV-B-absorbing compound *para*-coumaric acid can reflect long-term solar forcing linked to changes in total solar irradiance; (ii) whether short-term variations in atmospheric chemistry resulting from large volcanic eruptions can be detected in the signature of UV-B absorbing compounds from annually laminated sequences.

Session 105: Quaternary mapping across the world and the IQUAME European experience

The Quaternary of Austria: Stratigraphy, processes and mapping approach

Dr. Jürgen Reitner [1], Mrs. Gerit E. U. Griesmeier [1], Mr. Christoph Kettler [1], Dr. Daniela Festi [1], Mr. Mathias Steinbichler [1]

***1.** Geosphere Austria*

Austria's diverse landscape results of the interplay of tectonic processes and climate change. The final shaping occurred during the Quaternary (the last 2.58 Ma) and is characterized by strong global climatic variations between glacial and interglacial conditions affecting the heterogeneous landscape and its archives depending on the magnitude and duration of the climatic signal.

The oldest deposits are loess-palaeosol sequences (LPSs) documenting the onset of loess accumulation at the beginning of the Quaternary. The Early Pleistocene record consist of LPSs and gravel deposits with no indication of a glacier advance and is followed by deposits of four known major glaciations, namely Günz, Mindel, Riss and Würm (from oldest to youngest). These Ice Ages were characterized by a large complex of transection glaciers, i.e. an interconnected system of valley glaciers covering large sections of the Eastern Alps with glacier tongues terminating in the Alpine foreland. All four glaciations left Glacial Sequences genetically linking tongue basins with (subglacial) till, terminal moraines and terraces with different degrees of weathering and characteristics of cover beds (e.g. LPSs).

Based on geochronological data, relations between type and magnitude of the global climate signal and the amount of reconstructed sediment production, the following correlation with major phases of global glaciations is used: Günz (MIS 16), Mindel (MIS 12), Riss (MIS 6) and (Late) Würm (MIS 2). Detailed knowledge of the Last Interglacial-Glacial cycle (130-12 ka) allows establishing models for climatically controlled sedimentary processes and glacier expansion in the longitudinal valleys of the Eastern Alps. Overdeepened valleys and increased relief leading to different types of mass movements are also a legacy of glaciations.

From the formal stratigraphic point of view, the Austrian record of Quaternary sedimentary units (van Husen & Reitner, 2011, 2022) resembles a compound stratigraphy including aspects of lithostratigraphy (lithic characteristics) as well as morphostratigraphy and allostratigraphy (discontinuities/unconformities) for the definition of different units. The youngest phase of the Quaternary (Würm Lateglacial to Holocene) is documented on geological maps not by stratigraphic units but mostly by lithogenetic units according to the "Terminology for geological mapping of Quaternary and mass movements in Austria" (Steinbichler et al. 2019).

METIQ: The Quaternary Map of Italy (1:500.000 scale) and the dynamic evolutionary model of Italian landscapes

Ahead of the INQUA 2023 in Rome, the Italian Community of Quaternary scientists gathered to produce the first Quaternary Map of Italy at 1:500.000 scale.
Italy lies on one of the most geodynamically active sectors of the Mediterranean and most of its landscape has been modelled by Quaternary geological processes. For this reason, the Italian Quaternary geological, palaeoenvironmental, geomorphological and neotectonic records are the most important proxy for evolution of Italian landscapes and ecosystems, as well as for applicative purposes as most of the population and economic activities take places on Quaternary deposits.
The existing mapping archives of Quaternary deposits in Italy are discontinuous and inherently nonhomogeneous due to different national and regional mapping projects developed during the last 2 centuries with different aims and scale of representation. Stratigraphical correlations developed through time using complex litho-, chrono-, and bio-stratigraphical criteria made correlations in terrestrial Quaternary systems somehow problematic. This was due to the fragmentary nature of the record and to lack of reliable dating techniques covering the full range of Quaternary time. Terminology defining the chrono-stratigraphical setting was often based on local or old-fashioned schemes and the need for a common language/terminology/methodology is strongly necessary to harmonize and share among Quaternary scientists the basic geoscientific information. To set the regional names and subdivisions avoiding as much as possible the problems due to local terminology, the Quaternary Map of Italy will focus on the main Quaternary series and stages as assessed by IGSC. This approach should give a summary and overview of the main characters of the subseries/stages across Italy.
A spatial database in geodatabase and geopackage formats has been prepared for data storage and management. Code lists have been prepared to facilitate data entry of new information relating to the coding provided by the Project.
The outputs will be a printed map (7 sheets at 1:500k scale) and an open GIS-based Web platform allowing the retrieval of all the attributes and related values, and the interoperability with existing Quaternary-related thematic databases such as landslides, earthquakes, Quaternary key-sites (i.e. GSSPs) etc.

The International Quaternary Map of Europe and Adjacent Areas: an European project with many facets

Dr. Kristine Asch [1]

1. Bundesanstalt für Geowissenschaften und Rohstoffe

The project of the International Quaternary Map of Europe project (IQUAME 2500) is a major international initiative coordinated by the Federal Institute for Geosciences and Natural Resources (BGR) under the auspices of the CGMW (Commission of the Geological Map of the Word, Sub-Commission Europe) and with support of INQUA. The first edition of the map (BGR and UNESCO, 1967 – 1995), a paper map, was also compiled in international cooperation and within a specific INQUA Commission for the Quaternary Map of Europe. The new map is being compiled as a Geographic Information System and will be available on-line. It will show the distribution of Quaternary deposits across the entire European continent and Quaternary off-shore geology.

The IQUAME is collecting information on numerous aspects of the European Quaternary:

- lithology and geochronology of Quaternary depositional units,
- genetic descriptions of the units,
- maximum extent of the ice sheets (Weichselian, Saalian, if possible Elsterian),
- directions of ice movement,
- extent of Arctic sea ice,
- postglacial rebound,

- off-shore Quaternary information (in cooperation with the EU EMODnet Geology project),
- active faults,
- extent of permafrost,
- key localities (e.g. geologically and anthropologically interesting sites).

IQUAME 2500 is a multinational cross-boundary project and international collaboration with research organisations and national geological surveys throughout Europe is essential. Scientists from over 40 countries are participating and a scientific board of Quaternary researchers ensures the scientific quality of the resulting map layers. BGR is developing the map mainly using the participants' contributions, but also current publications and maps and other project' results.

The participation of numerous international partners is a challenge and requires data harmonisation regarding semantics, structure and geometry. To achieve this aim, common standards and guidelines needed to be set up and applied by all participants: structured vocabularies to describe the IQUAME's contents, a common topographic base, technical procedures to include the map data and guidelines to aid the partners to submit their data to the project.

Finally, the IQUAME map will show a synthesis of the current status of European Quaternary geological mapping and research, together with numerous related scientific facets of the Quaternary history of the continent.

General Quaternary Geological Map of the Slovak Republic (1 : 200 000), Geological Map of the Danube Lowland – Danube Flat (1 : 50 000) and Geological Map of the Danube Lowland – southeastern part 1:50 000

Dr. Martina Moravcova [1]***, Dr. Juraj Maglay*** [1]***, Dr. Klement Fordinal*** [1]***, Dr. Peter Sefcik*** [1]***, Dr. Alexander Nagy*** [1]***, Dr. Ladislav Vitovic*** [1]

1. *State Geological Institute of Dionyz Stur*

Geological maps are an essential underlying layer that are used in analyzes and applications in the environmental sector, economic and administrative activities of the state administration. The creation of a geological map of a region is a multi-year process of basic and regional mapping and research. The coverage of the territory of the Slovak Republic with geological map works has lasted for more than 50 years.

General Geological Quaternary Map of the Slovak Republic 1:200 000 offers a qualitative assessment of individual genetic types of the Quaternary deposits of the Western Carpathians and Pannonian Basin on the territory of Slovakia. It shows the resulting stratigraphically assessed arrangement of the Quaternary cycle of a geodynamic development of this territory and its impact upon the nature, landscape, and mode of distribution of the relevant genetic types.

Geological Map of the Danube Lowland – Danube Flat 1:50 000 and **Geological Map of the Danube Lowland – southeastern part 1:50 000** represents the latest and most extensive mapped region in the history of geological research and mapping, with an area of 3 010 km^2 and 1 407 km^2. Maps provide a very detailed picture of the surface geological structure through more than 20 500 allocated polygons. The maps show mostly Holocene to Pleistocene/Holocene development, give an image of the geological structure, geological and structural-tectonic development of the whole Cenozoic sedimentary infill, including approximate reconstruction of the tectonic units of its pre-Cenozoic basement of the basin. The second map represents an important region with loess cover and well-developed fossil soils. The work included geophysical, hydrogeological, pedological, bearing, and environmental research; using airborne LiDAR datasets, laboratory - chemical, grain and isotopic analyzes; AMS ^{14}C, OSL, and cosmogenic ^{26}Al/^{10}Be burial dating.

These maps are compounded on the genetic-stratigraphical principle, lithological fill, and the composition of sedimentary fill rocks. And contain other annexes: text explanatory notes, map legend, scheme of the map sheet layout, lithostratigraphic table of Quaternary and geological cross-section through the Quaternary fill.

Revision of the Mid-Pleistocene ice sheet limits stimulated by geological mapping in the Polish-Belarusian-Ukrainian border region

***Prof. Leszek Marks* [1], *Dr. Aleksandra Majecka* [2], *Dr. Anna Orłowska* [3], *Dr. Katarzyna Pochocka-Szwarc* [4], *Dr. Marcin Żarski* [4], *Prof. Andriy Bogucki* [5], *Prof. Anna Hrynowiecka* [6], *Dr. Tomasz Krzywicki* [4], *Mr. Łukasz Nowacki* [4], *Dr. Joanna Rychel* [4], *Prof. Marcin Szymanek* [7], *Prof. Barbara Woronko* [2], *Prof. Ivan Zalessky* [8], *Dr. Łukasz Zbucki* [9], *Mrs. Galina Brovkina* [8], *Prof. Jerzy Nitychoruk* [9], *Mrs. Monika Pielach* [6], *Mrs. Anna Tekielska* [6], *Dr. Olena Tomeniuk* [5]**

***1.** Polish Geological Institute - National Research Institute, **2.** Faculty of Geology, University of Warsaw, Warsaw, **3.** Maria Curie Skłodowska University, Institute of Earth and Environmental Sciences, Lublin, **4.** Polish Geological Institute – National Research Institute, Warsaw, **5.** Ivan Franko National University of Lviv, Faculty of Geography, Lviv, **6.** Polish Geological Institute – National Research Institute, **7.** Warsaw University, Faculty of Geology, Warsaw, **8.** National University of Water and Environmental Engineering, Institute of Water Management and Environmental Engineering, Rivne, **9.** John Paul 2nd University of Applied Sciences in Biała Podlaska*

A reduced sequence of the Quaternary deposits in the Polish-Belarusian-Ukrainian border region and a restricted access to the border area have been both a serious problem in the past to attain a stratigraphic correlation of the Quaternary deposits and ice sheet limits in this area. Results of previous research of geological deposits and landforms, supplemented with numerous research archival boreholes permitted us to focus field works in several key sites (exposures and drillings). Sites with the Mid-Pleistocene glacial deposits were crucial for stratigraphy of the study area, the same as deposits of the Mazovian Interglacial (Holsteinian). Samples collected at key sections were subjected to lithological, geochemical, pollen and malacological analyses, and OSL and ^{14}C dating. Based on examination of several key sites and revised geology, 2 geological maps were prepared within the frames of the research project no. 2017/27/B/ST10/00165, funded by the National Science Centre in Poland. Sheets of the Detailed Geological Map of Poland (1:50 000) and the geological maps of Quaternary deposits published earlier for each of the countries (1:200 000), were used and after the selected field verification the final geological map (1:250 000) was prepared. Results enabled to verify origin and stratigraphy of deposits in the studied area. A reliable cross-border correlation of stratigraphic subdivisions enabled a considerable reduction of the Mid-Pleistocene stratigraphical units in this area, including glacial sequences of the Odranian (Saalian) and Sanian 2 (Elsterian) glaciations, as well as lake and fluvial deposits of the Mazovian and Ferdynandovian (Cromerian III-IV) interglacials. Therefore, recent investigations in the Polish-Belarusian-Ukrainian border region fundamentally revised the regional stratigraphy and palaeogeography, and proved univocally that the subordinate Warta Stadial was the most extensive during the Odranian Glaciation in this area. The study area seems to be a key one for Quaternary stratigraphy and for regional stratotypes in Central Europe.

Georgia (SW Caucasus) in Quaternary

Dr. Nino Sadradze [1], *Prof. Shota Adamia* [1]

1. Iv. Javakhishvili Tbilisi State University

The lithosphere of Georgia and the Black Sea–Caspian Sea region represents a collage of Tethyan, Eurasian, and Gondwanan terranes. During the Late Proterozoic–Early Cenozoic within the convergence zone, there existed a system of island arcs and back-arc basins characteristic of the precollisional evolution of the region.

The marine basins of the Tethys in Late Cenozoic were replaced by Transcaucasian basins of euxinic type (the Paratethys) and, later, by continental basins with subaerial condition of sedimentation.

Starting from the Late Miocene, volcanic eruptions in the central part of the region occurred under subaerial conditions.

The geochronological and stratigraphic schemes and correlations of the Mediterranean province are based on the combined interpretation of data from various fields of geological sciences.

The Cenozoic collision between the Eurasian and Arabian continental masses was coeval with the Cenozoic magmatic activity.

The Pleistocene volcanic rocks related to the transverse Van– Transcaucasian uplift. belong to the calc-alkaline basalt–andesite–dacite–rhyolitic series.

Near the town of Dmanisi the Paleolithic objects were found. The complex of fossils identifies the age of enclosing rocks as the Eo-Pleistocene corresponding to the Apsheron regiostage. In the same sediments the remains of hominides were found identified as the representative of *Homo Erectus Ergaster* . The age of the basaltic lavas directly underlying the bone-bearing horizon was determined by $^{40}Ar/^{39}Ar$ ranging from 1.95 Ma to 2.04 Ma.

The Holocene deposits with the Late Pleistocene ones are developed almost everywhere and are represented by different facies. Holocene-Upper Pleistocene deposits are plotted on the 1:200 000-scale geological map of Georgia according to the guideline “Review of the 1:2.5 Million International Quaternary Map of Europe 2014, and actualized in 2016 (Asch, K., Gdanic, A., Muller A. IQUAME2500)”. This document contains the general legend of the IQUAME-project and shows all the map symbols applied to GIS program.

Mud volcanoes, with several-meter-high cones having a wide area of mud seepage, are met only in outer Kakheti.

The Earthquake indicate active tectonics in Georgia Some of the major earthquakes have proven to be devastating.

METIQ: the last interglacial transgression (Tirreniano) for the Quaternary Map of Italy (1:500.000 scale). Five hundred points that indicate the breath of the Italian coasts

For the Congress INQUA 2023 in Rome, the Italian Community of Quaternary scientists produced a Quaternary Map of Italy at 1:500,000 scale. In particular, for the whole Italian coastal areas, a database was compiled using the outcrops of the MIS 5.5t marine transgression. For the compilation of this important time-slice, we used many outcrops represented by numerous fossil forms and deposits in the Italian coasts. We used three important databases: Walis (World Atlas of Last Interglacial Shorelines), Ferranti and Lambeck. Data resulting from these databases, (those from numerous recently published works have been added) but above all we re-evaluated (in order to fit METIQ required database), the elevation, the age, the measurement error, the relationship with original sea level, and calculated uplift rate at each site. The time slices 119 ka BP was used as maximum MIS 5,5 highstand for the central Mediterranean and corrected with the local GIA (isostasy). For each of the 500 listed sites, the accurate elevation is defined through well-known markers (the best are considered fossil tidal notches and lagoons sediments containing fossil *Cerastoderma*), coupled with a refined age assessment locally supported by radiometric dating, (OSL, ESR, Ur\Th, Aminoacid, ecc.). The chronological attribution in the Mediterranean is greatly facilitated by the presence in numerous fossil deposits of the Senegalese fauna also containing *Strombus bubonius* (whose name has been changed to *Persistrombus latus* and again *Tetystrombus latus*) this gastropod appears to have entered the Mediterranean only during the MIS 5.5 and then extinct. (except for a small area around the Strait of Gibraltar). All these sites provide robust constraints on deformation. Significant alongshore differences in site elevation between +175 and -125m a.s.l. resulted from the interplay of regional and local tectonic processes, including faulting and volcanic deformation.

Session 106: Evolution of coastal environments under natural and anthropogenic processes: the role of geoscience

Data-driven shoreline modeling - historical remote sensing and forecast analyses

Mr. Mark Lundine [1], ***Prof. Art Trembanis*** [1], ***Dr. Duccio Bertoni*** [2], ***Prof. Giovanni Sarti*** [2], ***Prof. Monica Bini*** [2], ***Mr. Marco Luppichini*** [2]

***1.** School of Marine Science & Policy, University of Delaware, **2.** Dipartimento di Scienze della Terra, Università di Pisa*

In this presentation, we describe a novel, data-driven approach for extracting satellite-derived shorelines, for constructing shoreline change timeseries, and for projecting future shoreline positions. First, to build satellite-derived shoreline datasets, we developed an image-to-image translation generative adversarial network to map RGB satellite imagery into segmented land/water images, after which shorelines are extracted via a contour tracing algorithm (marching squares). This model incorporates over 25,000 LANDSAT 5, 7, 8 and Sentinel-2 images from the Delmarva coast (USA), the New Jersey Shore (USA), Long Island (USA), and the North Tuscany Littoral Cell (Italy), spanning from 1984 to 2022. Next, we generate shore-normal transects at 15-m alongshore intervals, which we use to compute intersection points with the extracted shorelines to construct timeseries of cross-shore position along a given transect. With these timeseries, yearly linear shoreline change trends are computed through ordinary least squares, with maps illustrating the average retreat/accretion trends across broad (several km to tens of km) coastal regions. Last, we incorporate long short-term memory networks on individual cross-shore position timeseries datasets to learn the behavior of each timeseries and then project future cross-shore positions (with bootstrapped uncertainties) several decades into the future. For select regions, the projected cross-shore positions at each transect are then merged together into full two-dimensional shorelines (with uncertainty polygons), for each projected time period. All software components developed for this project are open-source and freely available, as are the trained models and labelled satellite imagery. In the future, we hope to expand this methodology to other coasts worldwide, as well as integrate higher spatial and temporal resolution imagery into this framework.

Chronologically constrained Holocene reef growth, modern reef disturbance regimes and geomorphological controls on future reef potential; Southern Great Barrier Reef, Australia

***Dr. Nicole Leonard* [1], *Dr. Mauro Lepore* [2], *Prof. Jian-xin Zhao* [2], *Dr. Alberto Rodriguez Ramirez* [2], *Dr. Tara Clark* [3], *Dr. George Roff* [2], *Dr. Ai Nguyen* [2], *Dr. Yuexing Feng* [2], *Prof. John Pandolfi* [2]**

***1.** Radiogenic Isotope Facility, School of Earth and Environmental Sciences, The University of Queensland, Brisbane, QLD 4072, Australia, **2.** The University of Queensland, **3.** School of Earth, Atmospheric and Life Sciences, The University of Wollongong, Wollongong, NSW 2522, Australia*

In the face of future challenges to coral reefs it is important to understand responses to climatic and environmental changes at multiple spatial and temporal scales. Yet, there is currently a disconnect between understanding past reef histories, modern disturbance regimes, and the potential of future reef growth. To bridge the gap between biological and geological timescales we present the results of ~500 U-Th dated corals obtained from reef flat and slope matrix cores, fossil microatolls and death assemblages from eleven continental island fringing reefs in the Keppel Islands, southern Great Barrier Reef (GBR).

Reef flat cores show that coral initiation occurred prior to 7500 years before present (yr.BP-1950), although not contemporaneously among sites. Following initiation accretion rates were comparable to reefs elsewhere on the GBR, but rapidly outpaced average rates reported for the inshore GBR in the subsequent 1500 years when sea levels were higher, and sea surface temperatures were ~1°C warmer. After 5500 yr.BP a reduction in net accretion rates was likely driven by a combination of climatic and environmental changes, as well as geomorphological constraints. Reef slope cores show limited accretion from ~500 yr.BP to present at two reef sites suggesting these reefs had reached their geomorphological limits, with coral growth now restricted to a thin veneer that is more prone to disturbance.

Death assembles ages ranged from ~6300 yr.BP to modern, with 88% of total ages occurring post-1945AD. Temporal kernel density estimates (kde's) derived from coral death assemblages were variable among sites until a multi-site peak centered around the 2006AD bleaching event, supporting observations of unprecedented modern regional scale mortality. However, when spatial kde mapping of death assemblage data (11 sites) is compared with observed monitoring of bleached coral (7 sites) our data suggests coral mortality was far more widespread than captured by observations.

This study provides a unique insight into the history of a high latitude reef region and suggests whilst future sea level rise may increase reef accretion potential in the future, a deterioration in ambient water quality, repeated SST extreme events and site-specific geomorphological constraints may impede reef growth potential in the region.

Seascape-landscape morpho-sedimentological variations at a tourist beach along the Northern Tuscany littoral cell (Italy)

Dr. Duccio Bertoni [1], *Prof. Giovanni Sarti* [1], *Prof. Monica Bini* [1], *Mr. Marco Luppichini* [1], *Prof. Art Trembanis* [2], *Mr. Mark Lundine* [2], *Mr. Grant Otto* [2]

1. Dipartimento di Scienze della Terra, Università di Pisa, 2. School of Marine Science & Policy, University of Delaware

We present data from a bathymetric survey performed along the Northern Tuscany littoral cell (Italy). This area has been marred by serious erosion for the last 100 years, especially north of Forte dei Marmi. The survey was performed with a Norbit iWBMSe multibeam echosounder, which is a compact and portable multibeam operating at 400 kHz with an integrated PosMV SurfMaster IMU and dual GNSS-aided inertial navigation system. An area of more than 130 hectares was mapped in very shallow waters ranging from -2 to -8 m. These surveys generated extremely high detail of the seafloor with less than 25 cm/pixel gridded resolution and even finer ungridded soundings. The subaerial portion of the beach was also surveyed. The topography was obtained by Structure from Motion using a DJI Mini 2 drone equipped with a camera (12MP 1/2,3" CMOS sensor and 24mm focal length) combined with ground control points, which provided a high-resolution reconstruction of the beach morphological elements. Additionally, sediment textural analyses were carried out to define the grain-size variation along backshore-offshore transects. The survey data revealed a dramatic seascape of crescentic sand bars with wavelengths of approximately 300 m and heights of 3 about m. Both the sandbar wavelength and amplitude are variable along the survey domain. These sandbars are indicative of an intermediate state beach morphology and play a tremendous role in governing the transformation of wave energy from offshore to the beach. Additionally, these sandbars influence patterns of increased or decreased erosion/wave energy on the beach. This morphology contrasts to that which was reported by previous authors who described an overlapping portion of this area as having a dissipative profile "with non-rhythmic parallel/meandering bars". The full dynamics of these sandbars are not presently known but they may likely shift in response to changes in longshore drift and energetic storm events, thereby potentially having widespread impact on the wave conditions that govern the nearshore and shoreline. These datasets underscore the importance of monitoring the seascape adjacent to the coastline as well as shoreline trends to help coastal managers make the right decisions on the management of this touristic area.

Estuarine salt marsh evolution during the Late Holocene driven by complex natural and anthropic forcing

Estuaries are very complex transitional environments, being often difficult to disentangle the different forcing factors responsible for their evolution when we analyze these systems at a millennial time scale. Similar sedimentologic responses to different types of processes, mixing of sediments by bioturbation, erosional gaps, distinction of time and space sedimentation rates, and sediment dating, are among the difficulties faced when studying recent evolution of the intertidal depositional areas.

In this study, the Late Holocene evolution of salt marshes formed in the estuarine margin of the Tróia sand spit (Sado estuary) will be presented. This area has been chosen given: (1) the different geomorphologic situations present; (2) the well-known time constrain derived from the already identified Tróia sand spit growing phases in the last 6500 years and (3) its Roman archeologic occupation.

Several cores have been retrieved from different sub-environments high and low marshes and tidal flats in three locations (subareas), allowing comparison between subareas and across the altitudinal transects (subenvironments). ^{14}C dating of the base of the cores show that the sedimentary columns deposited since mid-12th century in the northern (and more recent) tip of the spit and ca. 2000 cal BP in the southern (older) area. The analyses of ^{210}Pb and ^{137}Cs allowed deriving accretion rates of about 3.0 mm/year in the last 70 years, independently of the marsh location and height.

Several sedimentologic and geochemical proxies have been used to characterise the marsh paleoenvironmental evolution. Sediments are essentially organic mud, with some sand intercalations in low and high marsh and are sandier in the tidal flats. Organic carbon is essentially POC marine water in the tidal flats and low marsh (which may also include DOC marine water) and a mixture of DOC marine water and terrestrial plants C3 in the high marsh. Besides similar general tendencies of sedimentation in the different sub-environments, differences between subareas have been found, related to natural events and/or anthropic activities and will be discussed. This work was funded by the Portuguese Fundação para a Ciência e a Tecnologia (FCT) I.P./MCTES through national funds (PIDDAC)–UIDB/50019/2020-IDL, PTDC/CTA-GEO/28412/2017 (CLIMARES) and Ph.D. Grants PD/BD/142781/2018 and PD/BD/106074/2015.

Late Holocene evolution of Western Mediterranean Lagoons: La Albufera de València (Iberian peninsula), s'Estany des Peix and s'Estany Pudent (Formentera, Balearic Islands)
