Mediterranean coastal lagoons are dynamic ecosystems and their Holocene depositional evolution has been controlled by climatic fluctuations, sea level changes and anthropogenic pressures. In this work, we present the results of a multidisciplinary study of new sediment cores from three sites, one in the Iberian Peninsula coast (la Albufera de València, 39.333189, -0.355318), and two in Formentera a Balearic Island (s'Estany des Peix, 38.726050, 1.410906 and s'Estany Pudent, 38.724978, 1.436870). La Albufera de València has been exploited for its hunting and fishing resources since the Neolithic, and it has been heavily altered during the last century due to rice cultivation and industrial activities. We aim to reconstruct the environmental and climate conditions during the late settlement of Formentera (the oldest megalithic construction dates from 4000 BP) and the depositional evolution of the coastal sites.

According to our ^{14}C age models, the recovered sequence of s'Estany Pudent spans the last 7.5 ka, s'Estany des Peix sequence covers the last 5.7 ka and La Albufera de València record encompasses the last 4 ka. The sedimentary sequences have been studied following a multiproxy strategy including sedimentary facies, elemental geochemistry and isotopic analyses in carbonates and organic components.

S'Estany Pudent was transformed from a marsh to a coastal lagoon due to a marine transgression around 7 ka ago. The sequences illustrate depositional changes due to varied marine influence and intercalated extreme events (floods, storms). In the three lagoons, the most notable changes occurred in recent centuries and are attributable to anthropogenic pressures.

Lagoon hydrodynamics under climate change and increasing human pressure: insights from the Venice Lagoon, Italy

Dr. Alessandro Michielotto [1], ***Dr. Davide Tognin*** [1], ***Prof. Luca Carniello*** [2], ***Prof. Andrea D'Alpaos*** [1]

1. *University of Padova - Department of Geosciences,* ***2.*** *University of Padova - Department of Civil, Environmental and Architectural Engineering*

Coastal zones are transition areas, where erosion and sedimentation processes act simultaneously to reach a dynamic equilibrium. Coastal zones have been the focus of human civilization for centuries, thanks to the ecosystems services they provide. Coastal ecosystems (CEs) such as mangrove forests, salt marshes and seagrass meadows play a fundamental role in protecting coasts from storm surges and flooding and in the mitigation of climate changes, by stocking organic carbon within their sediments. Such capabilities are nowadays fundamental, since the increasing rates of sea level rise (SLR) and the intensification of extreme events (e.g., storm surges), as a consequence of climate changes, threaten the stability of coastal environments. To cope with the effects of changing climate, a number of countries have proposed to build defensive structures which might threaten the already fragile equilibrium of coastal ecosystems. As a matter of fact, the areas covered by CEs have drastically reduced during time, together with the services they provide.

For centuries, the evolution of the Venice Lagoon, the largest brackish water basin in the Mediterranean Sea, has been strongly affected by human interventions, such as the diversion of major rivers in the Renaissance period, the excavation of navigable channels and the construction of jetties at the inlets. More recently, the activation of the Mo.S.E. system, designed to protect the city of Venice and the surrounding urban settlements from flooding, has led to the regulation of tidal fluxes between the sea and the lagoon.

In this study, we propose a mathematical approach to investigate the potential effects of climate changes and increasing anthropogenic pressures on Venice CEs. The two-dimensional hydrodynamic model (WWTM) allowed us to evaluate the possible hydro- and morphodynamic effects of the increasing water levels according to the IPCC projections and, therefore, of the more frequent and prolonged activations of the Mo.S.E. system, comparing open and closed lagoonal configurations for present and future scenarios.

The southern extension of the Tiber delta with the Ostia palaeo lagoon: a record of the Mid and Late Holocene coastal development and human exploitation in the Central Mediterranean

Dr. Francesca Bulian [1], ***Dr. Ilaria Mazzini*** [2], ***Dr. Luca Alessandri*** [1], ***Dr. Michael Dee*** [3], ***Ms. John du Plessis*** [3], ***Prof. Jan Sevink*** [4]

1. Groningen Instiitute of Archaeology, University of Groningen, 2. Consiglio Nazionale delle Ricerche, Istituto di Geologia Ambientale e Geoingegneria (IGAG), 3. Centre for Isotope Research, Groningen, 4. University of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics, Amsterdam, The Netherlands

During the last decades, the northern area of the ancient lagoon of Ostia, and the Tiber delta, have been studied both in a paleoenvironmental and archaeological context. While geologists and micropalaeontologists focused on studying the sea level changes and sedimentary sequences in this highly dynamic deltaic region since the last glacial maximum, archeologists focused primarily on the late Holocene. In particular, great effort has been put in researching the foundation of the Roman city of Ostia Antica in the 7th century BC and its possible relation with salt exploitation in the area, occupied once by the palaeo-lagoon of Ostia. While the northern area of the latter has been investigated, little attention has been put into its southern part, represented by a relatively shallow and only 500-600 m wide water body. Because of its location further from the fast-prograding delta, this area is an excellent location for Holocene paleoenvironmental and sea-level reconstruction studies in the central Tyrrhenian region.

An intensive coring campaign in the southernmost extension of palaeo-lagoon of Ostia enabled the identification of three different stages during the Mid- to Late Holocene (Northgrippian to Megalayan) development of the lagoon: 1) an early lagoon connected to the sea; 2) a closed lagoon with peat deposition; 3) new opening of the lagoon and deposition of shallow marine and lagoonal sediments. Additionally, an inlet connecting the lagoon with the sea has been identified, which functioned alongside with the nearby Archeological Site of Piscina Torta. At the site, thousands of red potsherds have been found, possibly related to the salt production technique known as *briquetage*.

To obtain a clearer idea regarding the nature, age, and anthropogenic use of the three paleoenvironmental stages, the continuous section PT27-2 has been analyzed in detail using geochemical and micropaleontological methods, and the more evident changes in facies have been dated with ^{14}C. This approach allowed us to reconstruct the southern extension of the palaeo-Ostia lagoon before, during and after human occupation of the area.

Land subsidence in the Po Delta: Comacchio case study (Emilia-Romagna region, Northern Italy)

Ms. Laura Pedretti [1], ***Prof. Claudia Meisina*** [1], ***Ms. Michelle Rygus*** [1], ***Prof. Pietro Teatini*** [2], ***Dr. Claudia Zoccarato*** [2], ***Ms. Yueting Li*** [2], ***Dr. Carolina Guardiola-Albert*** [3], ***Dr. Pablo Ezquerro*** [3], ***Dr. Guadalupe Bru*** [3], ***Prof. Roberto Tomás*** [4], ***Dr. Javier Valdes-Abellan*** [4], ***Dr. Concepción Pla*** [4], ***Ms. María Inés Navarro-Hernández*** [4], ***Dr. Tommaso Letterio*** [5], ***Dr. Roberto Genovesi*** [5], ***Dr. Paolo Severi*** [6], ***Dr. Luisa Perini*** [6], ***Dr. Marco Marcaccio*** [7]

1. University of Pavia, 2. University of Padova, 3. Instituto Geológico y Minero de España IGME-CSIC, 4. University of Alicante, 5. Consorzio di Bonifica di Secondo Grado per il Canale Emiliano Romagnolo, 6. Regione Emilia-Romagna, 7. Arpa Emilia-Romagna

In the Po Delta area (Northern Italy), rapid subsidence and a large amount of sediments input fostered a complete record of the late transgressive-regressive evolution of the Quaternary when the Po River floodplain reached its maximum extent. Later, slow subsidence processes, progressive sea level rise due to icecap melting and hydrological variations of the Po River have conditioned the development of the territory. Subsidence strongly accelerated with rates up to 8 cm/year due to methane and water pumping carried out in the period 1938-1961, resulting in lowering up to 3-4 meters, with dramatic effects on the rivers and channels outflow to the sea and on the entire ecosystem. Located in the floodplain of the Po river, the phreatic coastal aquifer of Comacchio case study (Emilia-Romagna region) studied in the framework of the PRIMA project RESERVOIR (Sustainable groundwater RESources managEment by integrating eaRth observation deriVed monitoring and flOw modelIng Results) is presented. Brackish lagoon, reclaimed lands with flat topography below the mean sea level and intensive agriculture inland characterize the area. Comacchio area has a complex sediment deposition history and a 700–800 m thick sequence of marine and continental sediments of Early to Middle Pleistocene and Middle Pleistocene-Holocene age that led to a complex hydrogeological setting. The whole coastal area has been affected by land subsidence since the last World War with values that changed significantly over time and space, posing a serious issue to local structures and infrastructures. The loss of land elevation is caused by the superposition of various processes: natural consolidation, peat oxidation, surface loading due to new structures and infrastructures, groundwater withdrawals and hydrocarbon production from deep reservoirs. Disentangling the contribution of each factor to land subsidence is a difficult task due to the lack of specific extensometer stations. In this work, the spatial and temporal evolution of land subsidence is analyzed using historical measurements provided by levelling and interferometric data from ERS-1/2 (1992-2000), RADARSAT (2006-2016) and Sentinel-1 (2016-2021, RESERVOIR project). Finally, land subsidence evolution in space and time is post-processed by several methodologies (PCA, GMA, fastICA) to detect possible relationship with hydrogeological and meteorological data.

Coastal Barriers stratigraphy from the North-West Black Sea document the Black Sea connections to the World Ocean during the Upper Pleistocene

A 50-m drill (MID) from the Midia coastal barrier (Casimcea Valley, NW Black Sea) was investigated for sediment characteristics (texture, LOI, MS), geochemistry (XRF), ^{18}O isotopes, lipid biomarkers (brGDGT) and paleoecology (meiofauna, pollen) to identify and describe the facies associations. The new data are compared with another regional deep drill (MAM drill, 52 m, on the Mamaia barrier; Caraivan et al., 2012) positioned 8 km south of the Midia barrier. The combined stratigraphies reveal a longshore sequence that captured most of the significant paleoenvironmental changes that affected the western Black Sea coast during the Upper Pleistocene – Holocene; MID core stratigraphy shows a deep-inciding valley cut under the force of major sea-level oscillations.

Here, we present new data on the Black Sea level evolution during the MIS 5 – Holocene (with a focus on MIS5 and MIS3 highstands) and discuss in detail the MIS 3 interval (60-29 ka), which was characterized by fast and intense climatic and eustatic changes that affected the environment and the human living conditions. In the context of the still debated issue of the sea-level reconstruction during MIS3, where part of the direct (sedimentary) evidence of the paleo-coastline does not fit the sea-level reconstructions based on ^{18}O data from deep-sea cores, our results document two marine (transgressive) horizons at depths of 20-25 m and 40-46 m b.s.l. The upper one presents a high salinity and Mediterranean meiofauna corresponding to the last Pleistocene reconnection with the World Ocean. It is still uncertain whether this layer formed during the MIS5a or MIS3 heights, and new numerical ages (OSL) are in progress to compare with preliminary AMS measurements. Considering the two barriers formed on the tectonically stable old Casimcea Plateau (as proved by the morphometric analysis of the river terraces), the present results might elucidate the maximum global sea level recorded globally during the MIS 3 and MIS5a highstands.

Natural and anthropogenic processes in the evolution of low-lying coastal areas at Lipari (Aeolian Islands, Italy) and related vulnerability

Lipari is the largest and most populated island in the Aeolian Archipelago, a UNESCO site, and a highly frequented touristic destination. However, the waterfront of the Lipari village and other sites in the eastern and northeastern coast of the island are exposed to coastal erosion and flooding, locally enhanced by subsidence effects leading to local sea level rise. Most beaches in this coastal area appear critical, being narrow and sediment-starved. Their possible future disappearance under the impact of climate change and anthropogenic stress should have important near-future implications. Moreover, some of the studied coastal stretches are increasingly threatened by the presence of active canyons offshore, with their heads very close to the coastline, also representing a major geohazard for the local communities due to possible retrogressive erosion and coastal failure occurrence.

In the present study, this setting has been placed in the wider context of the multidecadal evolution of the main beaches, analysed through a multidisciplinary approach, which includes remote sensing techniques (aero-photogrammetry, unmanned aerial vehicle survey, and satellite data), offshore geophysical surveys (high-resolution multibeam bathymetry), and field observations. The results show a variable interaction in space and time between natural and anthropogenic factors in the long- and mid-term shoreline evolution of the studied coastal areas. Among these, changes in sediment supply due to natural or anthropogenic processes, and the construction of human-made structures interfering with the longshore drift are responsible for the main observed coastal changes. An overall precarious but persistent state of equilibrium, with alternating phases of beach accretion and retreat, allowed most of these beach to survive, despite most of them are increasingly threatened by flooding and persistent erosion. As pointed out by our analyses, these processes particularly affect the most populated coastal areas of the island, with important future implications in terms of socio-economic resources and risk assessment, also in the light of future climate changes and related impacts.

Romans did it! From open bay to closed lagune, Stjuža Lagoon, Slovenia

***Prof. Matej Dolenec* [1], *Prof. Andrej Šmuc* [1], *Mr. Primož Miklavc* [1], *Dr. Tomislav Popit* [1], *Prof. Nastja Rogan Šmuc* [1]**

1. *University of Ljubljana, Faculty of Natural Sciences and Engineering, Department of Geology, Aškerčeva 12, 1000 Ljubljana, Slovenia*

Stjuža lagoon represents a peculiarity in the otherwise ria coast of Slovenia. It represents a former bay that man has transformed into a lagoon. This transition should be at least several hundred years old, but its exact origins have been lost in the archaeological record. Geologically, the Stjuža is a part of the Late Glacial and Holocene estuary formed during the last marine transgression. As such, it represents one of the most valuable archives documenting a long period of transgression, climate change and human influence in the northern Adriatic, from the last ice age until today. In 2019, four short cores, up to 1.3 m long, were taken from Stjuža Lagoon. They were dated by C14 and subjected to sedimentological, mineralogical and geochemical analysis. The results show that Stjuža was an open bay from the earliest transgression about 9000 years ago to AD 50, where mainly clastic terrigenous sediments were deposited. Around the year 50 AD the Romans built the embankment changing the Stjuža area into a closed lagoon. In the lagoon, biologicaly govern sedimentation prevails and the energy of the environment is much lower. In addition, the Stjuža sediments clearly record the Holocene, Roman and Middle Age warm episodes and interwening cold ones. The Stjuža archive also provides evidence of atmospheric lead pollution since Roman times, with a peak of pollution around 1620 AD.

Geospatial Analysis by Portable OSL of the Expansion of the Plot and Berm Groundwater-Harvesting Agroecosystem, Caesarea, Israel

***Mr. Lotem Robins* [1], Prof. JOEL ROSKIN [2], Mr. Adam. Ostrowski [3], Prof. Revital Bookman [3], Dr. Itamar Taxel [4]**

***1.** Department of Geography and Environment, Bar Ilan University, Ramat-Gan, Israel, **2.** Bar-Ilan, **3.** University of Haifa, **4.** Israel Antiquities Authority*

Sandy beaches have been prone to growing anthropogenic pressure during the last millenniums that have controlled activation and stabilization of coastal aeolian systems. Apparently only in the Early Islamic period, aeolian sand began to be significantly but intermittently used for agriculture in the form of Plot-and-Berm (P&B) agroecosystems along the Mediterranean coast of Israel.

P&B agroecosystems are agricultural utilization of a high-water table within loose, aeolian sand situated in agricultural hinterlands. Agroecosystems are comprised of a checkerboard array of agricultural plots sunken between 3-10 m high berms. The berm interiors include sand mixed with refuse, overtopped by a dark grey anthrosediment. Similar refuse is used to form a distinct 30-50 cm thick anthrosols within the plots, covering natural aeolian sand, approximately 1-3 m above the groundwater table.

This study is part of a comprehensive geoarchaeological research of the P&B agroecosystems of Israel. The studied agroecosystem, 1 km south of ancient Caesarea, stretches around 2 km along the coast, and its width between the coast to its eastern extent is around 0.5 km. Here, during three excavation seasons, anthrosol-like units were found to comprise substrates of several types of structures upon the berms that were excavated.

Geospatial analysis of the geometries of the plots revealed changes along a west-east transect suggesting an inland oriented expansion of the agroecosystem. Portable OSL (POSL) measurements of bulk sediment samples of berms, plots and excavated structures throughout the Caesarea P&B agroecosystem (Israel) were analyzed using cluster analysis to determine hypothesized spatial expansion stages of the agroecosystem and to chronologically correlate between the structural features of the agroecosystem. Initial finds show that POSL profiles of berms suggest rapid construction in one build-up stage, let alone maintenance of the upper anthrosol while the whole agroecosystem, as the structures were constructed and utilized in several episodes during the Early Islamic and beginning of Crusader period.

Coastal response to early to mid-Holocene sea-level change: a case study from Singapore

Dr. Stephen Chua [1]***, Prof. Adam Switzer*** [2]***, Dr. Chris Gouramanis*** [3]***, Prof. Yama Dixit*** [4]***, Prof. Michael Bird*** [5]***, Prof. Benjamin Horton*** [2]

***1.** Earth Observatory of Singapore, **2.** Earth Observatory of Singapore, Nanyang Technological University Singapore, **3.** Australian National University, **4.** Indian Institute of Technology, Delhi, India, **5.** James Cook University, Cairns, Australia*

The deceleration of early to mid-Holocene (10 – 7 cal. ka BP) sea-level rise (SLR) played a key role in transforming coastal systems from estuaries to deltas. Palaeoenvironmental reconstruction of coeval coastal evolution provide case studies that can help project the response of modern coastal systems to future SLR. More than 1.3 billion people today live within 100 km of tropical coasts, but few Holocene studies of equatorial delta systems exist.

Here, we investigate the early to mid-Holocene coastal response to decelerating rates of SLR through paleoenvironmental reconstruction of the Kallang River coast in Marina South, Singapore (1.27°N, 103.86°E). We produce a high-resolution, multi-proxy (i.e., sedimentology, stable carbon isotope, XRF elemental ratios) record from sediment core MSBH01B to compare with the latest Holocene sea-level record for Singapore. We identify different coastal response phases through understanding the interplay between accommodation space (A), driven predominantly by SLR and a function of water depth, and sedimentation rate (S) using the A/S theory.

Rapid SLR of up to 15 mm/yr coupled with low sedimentation rates of 2.5 mm/yr led to localised mangrove disappearance at Marina South within ~300 years (9.5 – 9.2 cal. ka BP). Estuarine sediments were deposited from 9.2 – 8.8 cal. ka BP during high but stable SLR of 12 – 15 mm/yr and highest sedimentation rates of 5 mm/yr. Prodelta sediments were deposited from 8.8 – 8.2 cal. ka BP during high but decreasing SLR of 5 – 12 mm/yr and high sedimentation rates of 3 – 5 mm/yr. Delta front sediments were deposited from 8.2 – 7.8 cal. ka BP during low and decreasing SLR of 3 – 5 mm/yr and similar sedimentation rates of ~3 mm/yr. A prograding delta started forming from 7.8 – 7.2 cal. ka BP during lowest but stable SLR of 3 mm/yr and lowest sedimentation rates of 2 – 3 mm/yr. This study may aid predictions of modern coastal response to a variety of future SLR scenarios.

Evolution of coastal environments under inundation scenarios using oceanographic model and remote sensing data

***Dr. Sergio Cappucci* [1], *Dr. Roberto Iacono* [1], *Dr. Francesco Immordino* [1], *Dr. Lorenzo Moretti* [1], *Dr. Massimiliano Palma* [1], *Dr. Gaia Righini* [1], *Dr. Gianmaria Sannino* [1]**

***1.** ENEA*

During the Quaternary period, coastal changes, induced by the variability of climate, sea level and other natural drivers, occurred. In recent times, additional changes produced by urbanization and human activities led to profound coastline modifications. On a larger scale, human activities are also responsible for the global climate change and the associated global sea level rise trend. Quaternary coastal evolution is studied worldwide due to coastal erosion's social and economic impacts at different time and spatial scales.
In the present work, we use a high-resolution projection of future Mediterranean sea level realized at ENEA to evaluate the future risk of inundation. Different study areas of the Mediterranean Sea are investigated considering the recent sea level rise ENEA model MED 16 scenarios as the sea level fluctuations are critical factors affecting the inundation of coastal plains. The modelled sea level, together with the most advanced satellite-derived products for the characterization of the coastal environment, are included in a GIS-based approach that allows to integrate different datasets in order to obtain a reliable understandings of the coastal evolution. Local geomorphological and earth surface processes result in a continuous migration of shoreline which is enhanced or mitigated by geological and anthropogenic factors (subsidence, tectonics, etc.).
Study areas are investigated by using European Ground Motion Service (EMGS) and/or other high-resolution datasets, where available, such as the regional Synthetic Aperture Radar (SAR) or proximal sensing datasets. The coasts of Follonica and Marina Di Campo (Tuscany), Fertilia (Sardinia) and Circeo National Park (Latium) were selected as representative case study areas.
Main outcomes of this study are coastal flooding areas simulated by using the "*bathtub*" approach without considering the morphological effects during the inundation process. The Inundation zone is represented by the water level raised on a coastal DEM, selecting all areas that are below the predicted new water level. The inundation scenarios also include land cover characteristics provided by Corine Land Cover (CLC) High Resolution Level (HRL). Time horizon of 2040, 2070 and 2100 are compared and discussed considering spatial variation of local ground motion due to different geological processes as well as land cover features.

Session 107: More than the sum: fault re-ruptures and cumulative damage during seismic sequences

Completeness magnitude and b-value of Sicily and surrounding region (Italy)

Ms. Anna Figlioli [1]***, Prof. Raffaele Martorana*** [1]***, Prof. Attilio Sulli*** [1]***, Dr. Antonino D'Alessandro*** [2]***, Dr. Giovanni Vitale*** [2]

1. *Dipartimento di Scienze della Terra e del Mare, Università degli Studi di Palermo,* ***2.*** *Istituto Nazionale di Geofisica e Vulcanologia (INGV)*

In recent decades, the scientific community has given greater importance to the Gutenberg-Richter (GR) law (Gutenberg & Richter, 1944). GR is an empirical law that relates the number of events to their magnitude. The parameters of this relationship are the *a*-value and *b*-value, together with the completeness magnitude (*Mc*). The estimating of *b*-value has important scientific fallout for seismo-tectonic characterization (Petruccelli et al., 2021), research to constrain magma storage (Murru et al., 2007) or seismic sequences precursor (Gulia et al., 2018; Gulia and Wiemer, 2019; Lombardi, 2021).

The subject of the research study is Sicily and surrounding region, which is characterized by many seismic-tectonic structures like Tindari Fault System, Gela-Catania fault, onshore fault, and Hyblean-Maltese escarpment and South thyrrenian fault in offshore zone. Furthermore, in Sicily there are various volcanic systems such as the Aeolian Islands, Pantelleria, Etna, Ustica. The seismic sequence that occurred in the last century in the area object study is the one known as the "2002 Palermo earthquake".

The work focuses on the estimation of *Mc* and *b*-value, with various techniques: MAXC (Maximum Curvature) (Wiemer et al., 2000), MBS (Mc by B-value Stability) (Cao and Gao, 2002); and new applications developed by Taroni, 2021.

For the correct estimation of the *b*-value it is necessary to use an appropriate technique and correctly determine the value of *Mc.* The analysis was conducted on the Istituto Nazionale di Geofisica e Vulcanologia seismic catalogue for the period from 2002-2022.

The *b*-value map was compared with the distribution of known seismic sources, the main past seismic sequences, and the volcanic districts present in the studied area.

New empirical relationships relating earthquake induced landslides density and seismological parameters derived from the Italian historical earthquake record

Dr. Valerio Piattelli [1]***, Dr. Caterina Zei*** [2]***, Dr. Jacopo Cinosi*** [1]***, Dr. Cecilia Ciuccarelli*** [2]***, Dr. Gabriele Tarabusi*** [2]***, Prof. Tommaso Piacentini*** [1]***, Dr. Pierfrancesco Burrato*** [3]***, Prof. Enrico Miccadei*** [1]

1. *INGEO - Dipartimento di Ingegneria e Geologia, Università degli Studi "G. d'Annunzio" Chieti-Pescara,* ***2.*** *Istituto Nazionale di Geofisica e Vulcanologia (INGV), Bologna,* ***3.*** *Istituto Nazionale di Geofisica e Vulcanologia, Rome (Italy)*

Earthquakes can trigger secondary coseismic effects related to the ground displacement/deformation and the seismic action connected to the seismic waves-induced ground shaking. These secondary effects include surface faulting, river ponding/diversion, liquefaction and, among all, landslides. They occur almost constantly, regardless of the kinematic characteristics of the seismogenic sources, affecting more or less wide areas according to the seismic energy released. Besides potentially increasing the earthquake damage to the infrastructures immediately after the mainshock, they pose long lasting secondary hazards to the earthquake affected areas, also driving the morphological evolution of the territory.

Earthquake Induced Landslides (EILs) are among the most diffused secondary hazard connected to the tectonic activity, and especially affect young mountain terranes connected to the ongoing tectonic plate dynamics, where the landslides susceptibility is high, due to morphological, geological and structural reasons.

Italy sits on the plate boundary separating the slowly converging Eurasia and Nubia plates, and its mostly mountain territory is characterized by a relatively high seismic hazard, making it highly prone to EILs occurrence.

Building on a revision of the seismic induced natural effects of the CFTI5Med historical seismic catalogue, made within the INGV-UniCH FRASI Project financed by the Ministry of the Environment, we improved the database of historical EILs, collecting new data points, checking the already existing ones and geographically locating them more accurately in a GIS environment. The CFTI improved database now includes >1000 historical EILs, associated to 159 seismic sequences occurred between 117 b.C. and 1997.

We used this database to develop new empirical relationships relating the variation of EILs density with distance from the epicenter as a function of the earthquake magnitude. Using shake maps of historical earthquakes, recently published by the INGV, we also developed a new empirical relationship relating the variation of EILs density with distance as a function of the PGA.

These empirical relationships were used then to relate each landslide belonging to national landslides inventories to segments of the known seismogenic sources (DISS database), that may trigger their activation during future earthquakes, and, using a floating hypocenter approach, to build preliminary EILs scenarios for each potential hypocenter location.

Environmental effects triggered by the 19 September 2022, Michoacan earthquake (Mw 7.6): application of the ESI-07 scale

***Dr. Magdalena Velázquez-Bucio* [1], *Dr. Francesca Ferrario* [2], *Dr. Pierre Lacan* [1], *Dr. Marco Pizza* [3], *Ms. Eliana Muccignato* [3], *Dr. Aadityan Sridharan* [4], *Dr. Sabina Porfido* [5], *Dr. Sundararaman Gopalan* [6], *Prof. Alessandro Michetti* [7]**

On 19 September 2022 a Mw 7.6 earthquake occurred along the Mexican subduction zone in the Michoacán region with an onshore epicenter at a focal depth of 15 km. We document the environmental effects triggered by the earthquake by means of field surveys and remote sensing. Observed primary effects include permanent coastal uplift, while secondary effects include landslides, rock fall, liquefaction, ground cracking, lateral spreading and tsunami waves.

We assign an ESI-07 (Environmental Seismic Intensity) value to each site where an environmental effect has been observed. ESI-07 is an intensity scale based only on effects on the natural environment; intensity values are based on the dimension of each effect: amount of tectonic uplift or subsidence; volume of mobilized material for slope movements; length and width of ground cracks; diameter and height of liquefaction sand boils. We investigate the spatial distribution of earthquake effects and we draw isoseismal lines; we analyze the intensity attenuation with distance, comparing the 2022 Michoacán earthquake to previous events in the same region. Additionally, the comparison of this case study with a dataset of over 150 earthquakes analyzed using the ESI-07 scale shows a good consistency.

One of the challenges in documenting the environmental effects by the Michoacán earthquake is rainfall. Heavy precipitation in the days following the earthquake quickly erased or altered some of the effects, in particular the smaller ones. We argue that a methodological approach complementing a rapid acquisition of data in the field, screening of local news sources and remote data analysis (e.g., satellite images) can partially overcome such limitations. EEEs analysis provide useful information that should not be neglected in seismic hazard assessment.

Surface Rupture and Fault Characteristics Associated with the 2020 Mw 6.6 Masbate Earthquake

Mr. Deo Carlo Llamas [1], Mr. Bryan Marfito [2]

1. Philippine Institute of Volcanology and Seismology, 2. Earth Observatory of Singapore, Nanyang Technological University Singapore

On 18 August 2020, a magnitude (M_W) 6.6 earthquake, whose epicenter was located in Cataingan Bay, struck the island of Masbate. Preliminary investigation and seismological data indicate fault movement consistent with the Philippine Fault. In 2003, Masbate was also struck by a magnitude (M_s) 6.2 earthquake. Separated by 17 years, Masbate was struck by two M>6 earthquakes that ruptured the same segment of the Philippine Fault. The occurrence of these two strong earthquakes with very close proximity in both space and time leads to the opportunity to understand the overall seismic and slip behavior of the Masbate segment of the Philippine Fault. This study aims to determine how the fault slip associated with the 2020 earthquake was accommodated along the Masbate segment through deformation and seismicity pattern analysis. The study also aims to determine how the 2003 and 2020 earthquakes interacted, in terms of earthquake-triggering effect and slip distribution.

The 2020 M_W 6.6 Masbate earthquake produced an approximately 23-km long surface rupture onshore. Generally straight, the surface rupture exhibits continuous surface breaks, distinct shear faults, right-stepping tensional cracks, and mole track structures, which together indicate left-lateral strike-slip movement. The left-lateral displacements reach up to ~97 cm. Secondary ruptures allude to a wider and distributed deformation near the epicenter InSAR observation, supported by field investigation, indicates that post-seismic slip occurred along the rupture zone of the 2020 M_W 6.6 earthquake. The analysis of marine geophysical data revealed the possible offshore continuation of the fault rupture. Coulomb stress model suggests that the 2003 earthquake increased stress on the location of the 2020 earthquake, however, the surface rupture of the 2020 earthquake was not confined by stress decrease but rather overlapped with the 2003 surface rupture for ~20 km. Slip distributions of both surface ruptures appear complementary to each other. Both the 2003 and the 2020 earthquakes involve foreshock activity and post-seismic slip. The results of this study can provide insights into the rupture dynamics of the fault. The fault rupture history offers useful data about its likely future behavior, allowing for earthquake hazard predictions and risk mitigation.

Not Again! Short Time Intervals Between Surface Re-rupture of a Fault or Fault Segment

Dr. David Schwartz [1], ***Dr. Francesca Ferrario*** [2]

1. dFAULTconsult, 2. Università degli Studi dell'Insubria, Como

The energy released during earthquakes results from slip on fault planes. The concept of the earthquake cycle developed by Reid following the 1906 San Francisco earthquake–the accumulation of stress, it's release as slip on a fault, it's re-accumulation and re-release as fault rupture–provides us with fault recurrence intervals. These are a basic component of seismic source characterization. Depending on fault type, location in a regional stress field, and slip rate, recurrence intervals for most crustal faults or fault sections are typically in the hundreds of years to millennia.

Some recent seismic sequences, however, (2016 Kumamoto, Japan; 2016 Central Italy) unequivocally document that the same fault section can undergo repeated surface rupture in a short time interval (hours to months). This process has not been adequately documented so far, and it may have an impact on various types of seismic hazard assessment.

Here we describe a dataset of repeated historical surface ruptures along individual faults. We have collected a total of 34 cases of historical re-rupture on 25 fault segments globally. We investigate the kinematics and spatial pattern (length, displacement) of surface faulting for each rupture and the time interval (typically a few to many tens of years) between events. We develop two numerical indicators based on surface rupture lengths and the degree of overlapping, and develop a model comprised of four classes of re-rupture: identical, partial overlap, complete overlap, and rupture along conjugate faults. Finally, we discuss the implications of repeated short-term re-ruptures on empirical scaling relations and implications for paleoseismic interpretations.

The role in hazard analysis of short re-rupture times for any of the rupture classes noted is unclear although it has not been a significant issue in modeling strong ground motion hazard at present. However, re-rupture in the short-term may be an important consideration for fault displacement hazard analysis as it affects pipelines and other critical infrastructure crossing active faults.

Session 108: Equitable and ethical knowledge production in Quaternary Science

Parachute science in palaeoecology: learning from past praxis

Dr. Tom Roland [1], ***Dr. Daniel Schillereff*** [2], ***Mr. Burhan Anis*** [3], ***Ms. Amy Bray*** [4], ***Ms. Rhionne Lee*** [5]

1. Geography, Faculty of Environment, Science and Economy, University of Exeter, 2. Department of Geography, King's College London, 3. Physics and Natural Sciences, Faculty of Environment, Science and Economy, University of Exeter, 4. Biosciences, Faculty of Health and Life Sciences, University of Exeter, 5. Department of Geography & Earth Sciences, University of Aberystwyth

Palaeoenvironmental science has gained real prominence in discourses around climate and conservation futures, but the discipline has failed to question how our global-facing science has perpetuated colonial forms of knowledge extraction and production.

Palaeoecology, in particular, has produced remarkable insights into long-term landscape evolution and human-environment interactions, as well as providing impressive datasets that have fed into valuable global climate and biodiversity assessments – but the discipline continues to overlook the ways in which its colonial legacy and biases can ignore, erase, undermine and disadvantage communities in areas where research is conducted. Frequently, these communities are 'told the story' of their own people, and their responses and contributions to environmental and climatic change, often without involving or considering their ideas, knowledges or priorities. Furthermore, such studies risk drawing conclusions from an incomplete understanding of past environmental processes and trends, lacking in local knowledge and context, and potentially resulting in biased and/or inaccurate assessments of ecological baselines.

Awareness of these issues is growing across the palaeoecological community, and efforts to promote ethical and equitable practice are increasing, but there remains a lack of formalised scholarship in the field relative to other sub-disciplines of environmental and earth science. Here, we present results of a systematic and quantitative literature review of the extractive, neocolonial practice of 'parachute science' in palaeoecology – a process that sees researchers from the Global North undertake fieldwork in post-colonial and/or indigenous nations without meaningful engagement with or benefit for local communities. We developed a Python-based scraping tool which allowed us to extract a number of metadata variables associated with publications contained in Scopus keyword search results. After manual data validation, we produced a final dataset containing 7654 papers for quantitative analysis.

In addition to revealing how trends and patterns in palaeoecological parachute science have evolved in the published literature (1963-2022), we aim to highlight where and how equitable and ethical practice of scientific knowledge (co-)production is and could be taking place. We aim for our work to contribute to an important and positive conversation about a more equitable future for palaeoecology and Quaternary science more broadly.

Developing participatory palaeoecology approaches using 3D pollen models

Dr. Oliver Wilson [1], ***Prof. Robert Marchant*** [1]

1. *University of York*

Palaeoecology plays a crucial role in ecology, providing unique insights into ecosystems' long-term histories. Palaeoecologists and our methods are not alone in being able to shed light on past environmental change, however. Indeed, bringing together a wider range of perspectives and worldviews could yield a more holistic – and, by extension, complete – understanding of an ecosystem's past. This talk introduces two approaches which are being developed to explore new ways of uncovering long histories of ecosystem change alongside a wider range of public audiences. Both use 3D pollen data and tactile models to facilitate two-way communication and engagement between user communities and researchers.

The first approach aims to develop and deliver accessible training in pollen identification techniques for citizen scientist 'para-palaeoecologists'. Resources from the 3D Pollen Project, including physical and virtual models, super-resolution cross-sections and linked light micrographs, are combined to provide an intuitive and engaging introduction to the principles of pollen identification. Integrated with the eSlide virtual microscope software, these resources provide significantly improved learning and opportunities for practice compared to traditional teaching methods. By pioneering, evaluating and refining new pedagogical approaches, this project will lay the groundwork for wider citizen science involvement in palaeoecology, with implications for other teaching and learning settings.

The second approach recognises that conventional ecological interpretations of proxy data provide only a partial (and biased) view of ecosystems' histories. Combining palaeoecology, ecology and archaeology to study past land use is not uncommon, but including traditional ecological knowledge (TEK) and Indigenous voices/worldviews is very rare – both a blind spot and a source of inequity in our research. We are therefore building dialogues with Kaingang communities in southern Brazil about the region's palaeoecology and archaeology. These conversations are not only about sharing findings with people on whose land and ancestors the research focuses, but also pave the way for further collaborative, co-designed research which links TEK and scientific knowledge of past and future environments. This more 'two-eyed seeing', 'participatory palaeoecology' approach could yield stronger insights into past environmental change through more just and equitable processes of knowledge generation.

Nun cho ga: the story of a mummified baby woolly mammoth and how it is redefining our approach to Quaternary science

Mr. Jeffrey Bond [1]***, Ms. Debbie Nagano*** [2]***, Dr. Brent Ward*** [3]***, Ms. Elizabeth Hall*** [4]***, Dr. Grant Zazula*** [4]***, Mr. Derek Cronmiller*** [1]***, Dr. Duane Froese*** [5]***, Mr. Scott Cocker*** [5]***, Dr. John Southon*** [6]***, Dr. Britta J.L. Jensen*** [5]***, Prof. Michel Lamothe*** [7]

1. *Yukon Geological Survey,* ***2.*** *Tr'ondëk Hwëch'in First Nation,* ***3.*** *Simon Fraser University,* ***4.*** *Yukon Palaeontology Program,* ***5.*** *University of Alberta,* ***6.*** *University of California, Irvine,* ***7.*** *Université du Québec à Montréal*

A nearly complete, mummified baby woolly mammoth (*Mammuthus primigenius*) was discovered in the Klondike region of Yukon, Canada in the summer of 2022. This is the best preserved North American mammoth yet discovered, owing to its rapid burial and permafrost preservation, and is of similar quality to the exceptional specimens from Siberia such as Lyuba and Dima. Placer gold miners made the discovery while mechanically stripping frozen Pleistocene loessal sediments that overlies the valley-bottom, gold-bearing gravel on Eureka Creek. The discovery and rapid recovery of Nun cho ga was made possible because of the strong relationship between Yukon government scientists and the mining industry. This collaboration has also allowed a detailed record of the stratigraphic, paleoecological and geological setting of the site.

The mammoth was appropriately named by the Tr'ondëk Hwëch'in First Nation, Nun cho ga, meaning 'Big animal baby' in the Hän language. In the days following the discovery, the Tr'ondëk Hwëch'in First Nation led a series of ceremonies to honour Nun cho ga's arrival and has subsequently assumed a guardianship role of this mammoth.

Central to our experience with Nun cho ga has been the profound manner in which it brought together a diversity of people including Indigenous leaders and elders, gold miners, scientists, and politicians. This union has broadened the meaning of the discovery, and importantly, introduced Indigenous spirituality to this palaeontological discovery. With that, Nun cho ga has the potential to contribute to reconciliation and a new inclusive approach to effective collaboration of natural history resources.

This talk will detail the discovery of Nun cho ga, our current understanding of the mammoth, the landscape it inhabited, and its significance. We will also describe the mechanism of preservation, and the additional information contained in its geological setting. The ongoing and potential research is substantial, and we will outline our plan and approach to ensure this discovery leaves a legacy of understanding. Most importantly, we will convey how a scientific discovery, when viewed through an Indigenous cultural lens, can reach beyond science and provide an opportunity for community healing.

Decolonising archaeology in Iraq

Dr. Becky Briant [1], *Dr. Jaafar Jotheri* [2]
1. *Department of Geography, Birkbeck, University of London,* **2.** *Department of Archaeology, University of Al-Qadisiyah, Diwaniyah, Iraq*

Iraq has vast quantities of well-known and world-leading heritage as well as less well-known but equally significant sites. Each year it hosts many international teams who are keen to work on these sites. In this presentation, we discuss the difficulties with the present situation and also offer some solutions. Key to this process is the proper inclusion of Iraqi researchers (including the many young researchers currently being trained) in both research and publication. Publications should also be easily available in Arabic, and time and resource should be factored into projects to build capacity and engage the public within the country. There are also real threats to the preservation and conservation of sites and artefacts that can be tackled by a partnership between local international teams of researchers.

Session 109: Animals, environments & humans: diverse perspectives from the Quaternary

After the Acheulean: the lithic-fauna nexus in the Levant and beyond

Prof. Ran Barkai [1]

1. *Tel-Aviv University*

Significant cultural and biological transformations took shape in the course of the process of changes from Acheulean to post-Acheulean human adaptations in the Levant and beyond. In this talk I will put an emphasis on the lithic-fauna nexus, in an attempt to correlate between faunal turnovers/transformations and possible related technological preferences. I will focus on the dependency of Paleolithic human groups on large game and the significant relations between hunters and their prey. I will suggest that human interactions with animals were not only practical and economic, but based on ontological and cosmological conceptions. Thus, changes in the availability of major game animals might have necessitate a significant modification in human mode of adaptation, which is not only practically oriented. Furthermore, several behavioral transformations characterizing the Acheulean and post Acheulean continuum will be viewed in light of the evidence for the decline in game size during the Pleistocene. This talk will attempt at presenting a new model for reconstructing changes in human adaptation during Middle Pleistocene times in the Levant and beyond.

Geological and paleontological insights on a new Late Pleistocene fossil-bearing locality at Olduvai Gorge (Tanzania)

Ms. Beatrice Azzarà [1], ***Prof. Marco Cherin*** [1], ***Prof. Giovanni Boschian*** [2], ***Mr. Jackson Kimambo*** [3], ***Prof. Fidelis Masao*** [4], ***Dr. Fabio Bona*** [5], ***Dr. Omar Cirilli*** [6], ***Dr. Alessio Di Roberto*** [7], ***Dr. Maximiliano Fastelli*** [1], ***Dr. Elia Pandolfi Balbi*** [1], ***Dr. Azzurra Zucchini*** [1], ***Prof. Stanley Ambrose*** [8], ***Prof. Giorgio Manzi*** [9]

__1.__ Department of Physics and Geology, University of Perugia, __2.__ University of Pisa, __3.__ University of Witwatersrand, Johannesburg, __4.__ University of Dar es Salaam, __5.__ Dipartimento di Scienze delle Terra, Università degli Studi di Milano, __6.__ Howard University, __7.__ Istituto Nazionale di Geofisica e Vulcanologia (INGV), __8.__ Department of Anthropology, University of Illinois, Urbana, USA, __9.__ Dipartimento di Biologia Ambientale, Sapienza Università di Roma, Roma (Italy)

The rocks that crop out in the world-famous Olduvai Gorge (Tanzania) span the last 2 Ma and are very rich in paleontological and archeological remains, offering a clear glimpse of human evolution in the context of East African Quaternary environmental changes. However, research in Olduvai has been focused much more on the lower part of the succession (Beds I-IV), certainly richer in paleoanthropological evidence, and less on the upper part (Masek, Ndutu, and Naisiusiu Beds).

This study reports on a new fossil-bearing locality at Geolocality 83, near the 5th Fault of the Main Gorge, discovered by the THOR (Tanzania Human Origins Research) team within deposits referable to the Ndutu-Naisiusiu Beds. The first paleontological interpretation of the assemblage and preliminary geological data to reconstruct the depositional paleoenvironment are provided.

The rich and well-preserved vertebrate assemblage from Geolocality 83 is dated to 34.6-38.8 cal ka by AMS radiocarbon analysis of three ostrich eggshells. The assemblage includes

Crocodylus sp., Agaminae indet., *Struthio* sp., *Hyaena hyaena*, *Lycaon pictus*, *Canis lupaster*, *Vulpes* sp., *Caracal caracal*, *Acinonyx jubatus*, *Panthera pardus*, *Equus quagga*, *Taurotragus oryx*, *Syncerus antiquus*, *Nanger granti*, Bovidae indet., *Phacochoerus africanus*, *Pedetes* sp., and *Gerbilliscus robustus*. Hyena coprolites are also present, as well as common hyena-made modifications on vertebrate bones. Except for a few taxa (e.g., the extinct *S. antiquus*), the assemblage is largely composed of species that can be found in the present-day Serengeti savannah. Taxa such as the crocodile and especially fox suggest that the Olduvai paleoenvironment might have been at least partially different from today. Analysis of the stratigraphy and depositional environments highlights that the assemblage is the result of different burial events of which the main one is to be attributed to a hyperconcentrated flow, which is probably among the most common sedimentary processes underlying the formation of the Ndutu and Naisiusiu Beds. Stratigraphic, lithological, and sedimentological differences between the studied outcrop and the type sections of the Ndutu and Naisiusiu Beds suggest that the definition, age, and genesis of these stratigraphic units need to be revised.

Biochronology and palaeoecology of Kromdraai Unit P, South Africa, based on the fossil Bovidae

Dr. Raphael Hanon [1] ***, Dr. Jean-Baptiste Fourvel*** [2] ***, Ms. Recognise Sambo*** [3] ***, Ms. Nompumelelo Maringa*** [3] ***, Dr. Bernhard Zipfel*** [4] ***, Dr. Christine Steininger*** [3] ***, Prof. Jose Braga*** [5]

1. *Muséum National d'Histoire Naturelle,* ***2.*** *LAMPEA (UMR 7269; CNRS-Aix Marseille Université, Ministère de la Culture et de la Communication), MMSH 5 rue du Château de l'Horloge, 13094 Aix-en-Provence, France,* ***3.*** *GENUS, Private Bag 3, WITS 2050, Johannesburg, South Africa,* ***4.*** *Evolutionary Studies Institute, University of the Witwatersrand, Johannesburg, South Africa,* ***5.*** *Centre d'Anthropobiologie et de Génomique de Toulouse, Université Paul Sabatier Toulouse III, Toulouse, France*

The Kromdraai palaeontological site, located in the Cradle of Humankind (Gauteng Province, South Africa), has produced a diverse and abundant Plio-Pleistocene faunal assemblage, including key hominin specimens like the holotype of *Paranthropus robustus*. However, despite its richness and importance, the large mammal assemblage remains understudied, especially regarding the Bovidae family. Here, we provide the first taxonomic study of the newly excavated hominin-bearing deposit of Kromdraai Unit P. The bovid assemblage is composed by old Pliocene species (*Gazella gracilior*, *Makapania broomi*), a new species of buffalo species (*Syncerus* n. sp.), as well as younger Quaternary taxa (*Tragelaphus strepsiceros*, *Oreotragus oreotragus*, *Raphicerus campestris*, *Connochaetes gnou*, *Damaliscus lunatus*). Overall, bovids indicate a grassland dominated environment for the Unit P. By comparing with other Plio-Pleistocene South African sites, it is clear that *Australopithecus* is associated with woodland and closed-wet environment adapted taxa while *Homo* is found along bovid species that are adapted to open and dry environments. In contrast, the assemblages associated with *Paranthropus* show a variability of environmental adaptation among the bovids. Based on biochronological evidence, we show that the Kromdraai Unit P accumulated between 2.9 and 1.8 Ma, with a good probability to be older than 2.3 Ma.

Pleistocene bone technology from mammoth long bone (Tocuila, MEXICO)

Dr. Luis Morett [1], **Dr. Joaquin Arroyo-Cabrales** [2]
1. Universidad Autónoma de Chapingo, 2. Instituto Nacional de Antropologia e Historia

Research on the eastern shore of the Basin of Mexico, specifically in the ancient lacustrine plain of Tocuila, Municipality of Texcoco, State of Mexico, has made it possible to document the existence of twenty locations with bone remains of *Mammuthus columbi.* This work has identified the existence of an archaeo-paleontological complex covering an area of about 60 ha. Taphonomic analysis was undertaken with more than 1,300 bone remains recovered within a paleochannel filled with mud by a succession of various mudflows. Numerous fragments were identified that presumably were modified by anthropic action. According to C14 dating, these remains that came from stratigraphic units SU1 and SU5 would have accumulated at various times over three millennia from 12 and 15 thousand years before the present. The bone remains were analyzed individually to establish the taphonomic processes and identify the agents that would have influenced their condition, providing additional detail on the characteristics of the deposit formation process.
Three modification types were identified. The first consisted of simple cut marks on bone. The second was constituted by a large set of elements that morphologically suggest their probable use as fortuitous tools, presumably associated with butchery activities at the site. Both types are still subject to microscope studies to assess confirmation of human modification and use. The third type of culturally modified bones corresponds to the process of reducing long bones that were emaciated in quarries, spaces where there was previously slaughtered and butchered. A little less than fifty fragments have been recovered from these, which when analyzed as a whole reveal the existence of a reduction sequence that qualifies as bone technology. This technology is fundamentally oriented towards deriving raw material from the thick cortical structure of the large diaphysis and its eventual transformation into functional elements by its cutting edges. Here we present the characteristics of the third assembly type and the reduction sequence of the Pleistocene bone technology specialized in long bones of *Mammuthus columbi* documented in the Tocuila site.

Homo erectus, a successful hunter, catcher, or scavenger? An agent-based model about early hominin strategies to acquire meat in grasslands

Mr. Jan-Olaf Reschke [1] ***, Dr. Christine Hertler*** [1] ***, Mrs. Susanne Krüger*** [2]

1. *ROCEEH Research Centre, Senckenberg Research Institute, Frankfurt/M,* ***2.*** *ROCEEH Research Center, Senckenberg Research Institute, Frankfurt am Main, Germany*

The reasons for turning points in the history of early hominins, for instance the first dispersal of *Homo erectus* out of Africa, are often assumed to be related to environmental changes and/or access to new resources. It has been proposed that H. *erectus* used spreading grasslands with their large herds of herbivores as a corridor to disperse into Eurasia after 2.5 million years ago. How these hominins gained access to meat obtained from large animals is still under debate.

We used an agent-based model to test the effects of different proposed strategies to acquire meat. The agents in the model represent hominin foragers exploiting plants and animals to cover their daily energy demand. The model allows simulating different subsistence strategies by granting or restricting the foragers access to certain types of resources. On the basic level all foragers have access to plants, but some can additionally use strategies to acquire meat by catching smaller animals or hunting large herbivores. Furthermore, the model permits to adjust how they interact with the resources by forcing them to target certain resources, i.e., the group needs to cover its energy demand to a certain percentage by hunting.

We tested several subsistence scenarios derived from recent hunter-gatherer societies, which correspond to subsistence strategies proposed for H. erectus. The scenarios differ in the percentage of meat in the diet and the strategies applied to obtain it. To monitor the effect on the group we observed the resulting mobility patterns, the energetic return during foraging as well as the diet composition. The model reflects that H. *erectus* had several options to cover his demand in this ecosystem depending on how they exploited meat as a food source. We will present some of our results and discuss future applications of the model.

Middle Palaeolithic Avian Remains from Tabun Cave (Israel): A Palaeoenvironmental Reconstruction

Dr. Linda Amos [1], ***Prof. Reuven Yeshurun*** [1], ***Prof. Mina Weinstein-Evron*** [2], ***Dr. Ron Shimelmitz*** [1]

1. *University of Haifa,* ***2.*** *University of Haifa, 199 Aba Khoushy Ave., Haifa, 3498838, Israel*

Mount Carmel plays an important role in the movement of Middle Palaeolithic (MP) humans. The archaeological record establishes early dispersal waves of anatomically modern humans expanding out of Africa, as well as insights into potential episodes of interaction between the different hominin populations that inhabited the region. Taxonomic and taphonomic analyses of avian remains recovered from the MP layers at Tabun Cave (Mount Carmel, Israel) have provided a window through which we can examine the environment and climate in which these interactions took place.

Forty-seven species of bird were identified in 27 stratified samples from the ca. 6-m-thick archaeological deposit that constitutes the later part of the MP at Tabun Cave. These included game birds, diurnal and nocturnal raptors, waterbirds, pigeons, and small songbirds. Rock doves (Columba livia) accounted for the greater part of the assemblage in both the middle (Layer C) and later (Layer B) MP sequence. However, while some human agency was suggested by thermal traces on some bones and a significantly higher occurrence of Rock Dove remains in Layer C, data collected from Layer B reflected a wholly natural accumulation created by natural death and raptor agency. This allows us to compare the species and habitats reflected in two different modes of accumulation. Small passerines and raptors in Layer B represent the inhabitants of a cave rarely visited by humans, giving us an unbiased snapshot of the species active directly around the site. Layer C on the other hand indicates a wider catchment area, including species purposefully introduced to the cave from further afield such as water birds from the wetlands of the Mediterranean coastal plain below.

Habitat fidelity information and temperature- and rainfall preferences of each identified species were extracted from current-day distribution data and analysed to create a reconstruction of the surrounding palaeoenvironment and climate conditions throughout the MP sequence. This information was used to place Tabun in the context of other Israeli MP sites with identified bird assemblages, including nearby Kebara Cave, and produce a portrait of the Middle Palaeolithic Carmel environment where our human ancestors met and coexisted.

Faunal and Human Evolution in the Middle to Late Pleistocene of Sudan

Dr. Faysal Bibi [1]***, Dr. Brian Kraatz*** [2]***, Prof. Omer El Badri*** [3]***, Dr. Jean-Renaud Boisserie*** [4]***, Dr. Marianne Brasil*** [5]***, Dr. Robert Bussert*** [6]***, Dr. Anne Delagnes*** [7]***, Prof. Johannes Müller*** [1]***, Dr. Sakir Önder Özkurt*** [8]***, Dr. Antoine Souron*** [7]***, Dr. Sumiko Tsukamoto*** [9]***, Dr. Khalafallah Salih*** [10]***, Dr. Ali Eisawi*** [10]

1. *Museum für Naturkunde,* **2.** *Western University of Health Sciences,* **3.** *International University of Africa,* **4.** *PALEVOPRIM,* **5.** *Human Evolution Research Center, University of California, Berkeley,* **6.** *Technische Universität Berlin,* **7.** *PACEA, Université de Bordeaux-CNRS, Pessac,* **8.** *Ahi Evran University,* **9.** *LIAG,* **10.** *Al Neelain University*

Despite the existence of the Nile River in some form since the early Oligocene, very little is known about its potential role as an ecological refugium or faunal and cultural dispersal route during this long timeframe. Sudan covers a large portion of the Nile Basin, yet its vertebrate fossil record remains little explored. Since 2018 our team has conducted yearly fieldwork in Sudan with the aim of exploring faunal, archaeological, and environmental evolution during the Middle to Late Pleistocene of the Nile Basin. Following previous work by Abbate et al. along the middle Atbara River in the early 2000s, our renewed investigations have resulted in the discovery of many new sites, the recovery of a diverse faunal assemblage that includes hominins and lithics, and a new high-density OSL and 14C geochronology spanning ~250 ka to ~15 ka.

The new fossil collections comprise over 700 specimens representing over 30 species. A large number of extant taxa provide the opportunity to examine sub-specific (morphoclinal) variations between Sahelian, northern African, and eastern African forms, and to reconcile the fossil record with extant phylogeography. Extinct forms include *Elephas jolensis*, *Kolpochoerus majus*, *Syncerus antiquus,* and a hipparionine equid. Other finds include the first record of a macaque (*Macaca*) in sub-Saharan Africa, a possible northern white rhinoceros (*Ceratotherium simum cottoni*), small *Hippopotamus* and warthogs *(Phacochoerus*). The bovids indicate standing wetland habitats in what is today a region with highly seasonal rainfall and sparse vegetation. Hominins are represented by robust cranial and postcranial remains attributable to Middle Pleistocene *Homo*, and are also represented by a well-preserved Acheulean lithic assemblage. At ~160-80 ka, the hominin and Acheulean remains could be contemporaneous with early *Homo sapiens* and Middle Stone Age assemblages in other parts of the continent, suggesting the late persistence of archaic hominins and Early Stone Age culture in the Middle Atbara area. The Middle Atbara project is opening up a new regional window onto Pleistocene biogeography and the emergence of modern African ecosystems. New paleontological surveys planned for winter 2023 will target the Blue and White Nile rivers, and the initial results will also be presented here.

Multi-aspect perspectives on the Pleistocene fauna of peninsular India including current issues and future directions

Dr. Parth Chauhan [1]***, Mr. Ramandeep Singh*** [2]***, Mr. Abhimanyu Bhardwaj*** [2]

1. *Department of Humanities and Social Sciences, IISER-Mohali, Punjab,* **2.** *Indian Institute of Science Education and Research Mohali*

This paper reviews the known and some new occurrences of fossil vertebrates in Pleistocene contexts across central and southern India. Several hundred occurrences have been reported since colonial times, all of which primarily derive from fluvial contexts. These sites include Pleistocene mammals of various sizes including hominin material in central India and possible cu-marked bones from southern India. A historical review indicates research bias in specific river valleys where vertebrate fossils are generally common and occur in diverse sedimentary contexts including layers of loose or consolidated sand, silt and gravel. The Son and Narmada river valleys have yielded the highest amount of fossil material while other lesser known areas have yielded find spots or low density occurrences. The most abundant elements preserved are represented by teeth and mandible/maxilla fragments while rich bone beds or fossil clusters are generally sparse (with some rare exceptions). Current issues in Indian palaeontology are also discussed: a) how to fill the geographic gaps; b) confronting the chronological gaps; c) possible impacts of the Toba super-eruption; d) factors of extinction of specific species and co-evolution with hominins; and e) explanations for missing evidence such as hominin fossils and butchery assemblages. Finally, the paper also touches upon broad observations in relation to elemental preservation, taphonomy and potential taxonomic connections with the Pleistocene fauna of southeastern Asia. While understanding the Pleistocene palaeontological records of India is not without its challenges, the subject holds great potential for further multidisciplinary research at various levels.

Animal exploitation at the dawn of Neolithic lifeways in the foothills of the Zagros Mountains: new evidence from Chogha Golan (Iran)

Mr. Mario Mata-Gonzalez [1], ***Dr. Britt Marie Starkovich*** [2], ***Dr. Mohsen Zeidi*** [3], ***Prof. Nicholas J. Conard*** [4]

***1.** Institute for Archaeological Sciences, University of Tübingen. Department of Anthropology, University of Connecticut.*, ***2.** Institute for Archaeological Sciences, University of Tübingen. Senckenberg Centre for Human Evolution and Paleoenvironment, Tübingen.*, ***3.** Senckenberg Centre for Human Evolution and Paleoenvironment, Tübingen. Department of Early Prehistory and Quaternary Ecology, University of Tübingen.*, ***4.** Institute for Archaeological Sciences, University of Tübingen. Senckenberg Centre for Human Evolution and Paleoenvironment, Tübingen. Department of Early Prehistory and Quaternary Ecology, University of Tübingen.*

Chogha Golan is an Aceramic Neolithic tell site, located in the foothill of the Zagros Mountains (modern Ilam Province, Iran). Archaeological excavations were carried out by the Tübingen-Iranian Stone Age Research Project team between 2009 and 2010. These excavations revealed an eight-meter stratigraphic sequence, which consists of 11 archaeological horizons, mostly defined and separated by plaster floors and architectural features. Ranging from ca. 11,700 to 9,600 cal. BP, the zooarchaeological record from Chogha Golan is key to understand human-environment interactions and the socioeconomic transformations that took place at the onset of Neolithic lifeways at the eastern part of the Fertile Crescent.

Here, we present the first comprehensive analysis of the faunal remains recovered from the oldest archaeological horizon (AH 11) of Chogha Golan, in order to provide new information about the dietary breadth and animal exploitation behavior of one of the earliest sedentary communities in the region. The ungulate assemblage is mostly dominated by gazelle and sheep/goat, followed by pig and indeterminate large- and/or very large-bodied ungulates, but to a much lesser extent. Small game taxa, including both slow-moving or easy-to-catch game (tortoises) and fast-moving or difficult-to-catch animals (predominantly birds, but also fish), were frequently exploited by humans at the site. Although the carnivore component is relatively insignificant, we also documented a few red fox, wild cat and Eurasian lynx remains in our assemblage. Overall, our results suggest that the inhabitants of Chogha Golan ca. 11,700 cal. BP had a broad diet and exploited a great variety of animal resources and ecological niches. According to the diet breadth model of optimal foraging theory, diverse diets may reflect resource intensification or depletion as a result of increased hunting pressure, population growth and/or a decrease in mobility. We propose that human population density and mobility played a crucial role in shaping human-animal relationships at the dawn of Neolithic lifeways, prior to the adoption of plant cultivation and animal husbandry in the foothills of the Zagros Mountains.

Nonmarine Ostracoda as proxies in geoarchaeology

Ms. Ella Quante [1]***, Prof. Peter Frenzel*** [2]***, Dr. Anna Pint*** [3]

1. *Department of Archaeology, Max Planck Institute for Geoanthropology,* ***2.*** *Friedrich Schiller University Jena, Institute of Earth Sciences,* ***3.*** *University of Jena*

Ostracods are small crustaceans, mostly 0.5–2 mm in length, living in almost all types of aquatic habitats, both natural and man-made. Their calcitic carapaces have a high fossilization potential and allow the identification of species and even ontogenetic stages. Due to their small size, only small volumes of sediment are needed for analyses. Species-specific tolerances and preferences allow detailed palaeoenvironmental reconstructions, and typical methods of their applications include palaeoecological analysis of associations based on ecological information, as well as taphonomy, morphometric variability, and stable isotope and chemistry analyses of their valves.

In contrast to many other microfossil groups, ostracods also occur widespread and with high species richness in fresh water, and especially the palaeoenvironmental and palaeoclimatic information from ostracods has therefore been of interest in nonmarine geoarchaeological studies. Other archaeological research questions for nonmarine ostracods are, e.g., water availability and quality, land use and other anthropogenic impacts, and the provenance of materials and commercial networks. Examples include studies of Neolithic sites, where climatic changes and changes in human living strategies can be reconstructed, or reconstructions of environmental histories of areas with human occupation, and analyses of the environmental suitability of areas for human settlements. At more recent sites, climatic changes effecting land and water use, e.g., Mayan swidden and wetland field agriculture, have been interpreted using ostracod proxies, as well as human impacts on the environment, reflected by, e.g., soil erosion or aridification. Land use may be detected by ostracod analysis through eutrophication events, but mostly indirectly seen by deforestation and connected higher erosion rates and thus discharge fluctuations in streams or into lakes. Canals, dams, and other water works can be detected through ostracod analysis, and such structures' usage could be reconstructed, potentially even with a seasonal chronological resolution.

An overview of geoarchaeological studies, which all 107 in some way used nonmarine ostracods, promotes ostracod-proxies for various (geo-)archaeological research questions. At the same time, it displays the sparsity of detailed nonmarine ostracod studies at archaeological sites, which, regarding the state of research and development of new and better ostracod proxies, may further increase in the coming years.

Mollusc assemblages from the Krapina Neandertal site, Croatia (130,000 ya)

Dr. Ankica Oros Sršen [1], ***Dr. Davorka Radovčić*** [2], ***Dr. Petar Crnčan*** [3], ***Prof. Julie Lesnik*** [4], ***Prof. David Frayer*** [5]

There is emerging evidence testifying to diversity of hominin food resources during the Middle and Late Pleistocene. Recent studies point to the previously ignored importance of other (smaller) protein resources such as various species of edible arthropods and molluscs. Although thoroughly studied at the Holocene sites, mollusc assemblages present at Pleistocene hominin sites have not yet been systematically analyzed to understand its accumulation agency, to test whether they have been intentionally procured, and whether they have been incorporated into hominin diet. Here, we explore the taphonomy and accumulation agents of the mollusc remains from the Krapina Neandertal site, excavated from 1899 to 1905, and dated to 130,000 BP. We also revise the specimens taxonomically. Two classes of invertebrates were preserved and collected in the original excavations from the Krapina site: Bivalvia (1 species) and Gastropoda (7 terrestrial and 2 freshwater species). The revised total NISP is 63. Three specimens are marked with their layer provenience: 613.1 Monacha sp. (layer 8), 615.1 Holandriana holandrii (Layer 4-5, just following the layer with the highest content of Neandertal specimens), and 616 Holandriana holandrii (Layer 1, stratigraphically the oldest). All specimens are very well preserved, with 46 specimens (73%) that are complete or more than 90% complete. Majority of the specimens show black staining (59%), following with small holes (29%), irregular surface depression (25%), limonite staining (21%), and possible small animal tooth marks (18%). Helix pomatia specimens have the most interesting surface traces, including irregular surface depressions and small black linear traces on the shell, while several Campylaea illyrica specimens have traces of small animal predation. The taphonomic analysis points to possible Neandertal collection of the Helix pomatia and at least one specimen of Holandriana holandrii.

Investigating possible links between Holocene environmental changes and cultural transitions across India

Ms. Diptimayee Behera [1] ***, Dr. Parth Chauhan*** [2]

1. *Indian Institute of Science Education & Research Mohali,* ***2.*** *Indian Institute of Science Education and Research Mohali*

From the early Holocene onwards, the Indian Subcontinent has accommodated a range of diverse human cultures and associated ecological adaptations and lifestyles. From about 10 Ka onwards, the Subcontinent has witnessed the development of later Mesolithic hunter-gatherers and their subsequent regional transitions to pastoralist (Neolithic) and agricultural (Chalcolithic) lifeways. Detailed evidence of Holocene environments indicates fluctuating environmental circumstances, with many cooling periods occurring at ~1500 ± 500-year intervals. These climatic shifts appear to be linked to surface ocean circulations in the subpolar and subtropical regions. These changing climatic patterns including the development of a geographically variable monsoon throughout the Holocene directly impacted these various cultures including the Harappans and their contemporaries as well as younger Historical and Medieval empires across India, at various levels. In some regions, environmental changes led to uneven cultural transitions, geographic migrations, and the development of regionally-distinct material cultures once sedentary life-ways became established. This paper attempts to present a review broadly correlating general monsoon patterns throughout the Holocene period of India with regional cultural dynamics. The temporal variation of human habitation and respective adaptive responses suggest broad linkages to the varying climatic and physiographic features at a regional scale. In some regions, environmental changes led to uneven cultural transitions, geographic migrations, and the development of regionally-distinct material cultures. Learning how this shaped human ecodynamics in the past can help us expand our understanding of human history and implement lessons for the present as well as the future.

New record of Late Pleistocene fossil assemblage from Bandung Basin, West Java, Indonesia: a preliminary date and biostratigraphic significance

The island of Java emerged above sea level only about two million years ago. Considering its short geological age since becoming a fully terrestrial environment, Java has one of the richest and most diverse fossil faunal sequences in the world. Paleontological records include vertebrate and hominin fossils provide evidence of at least two faunal turnovers throughout the island colonization. The first turnover was from *Sinomastodon – Merycopotamus* fauna into *Stegodon – Homo erectus* fauna in the Early Pleistocene. The second turnover into *Elephas – Homo sapiens* fauna, also known as modern fauna, occurred approximately during the Middle and Late Pleistocene boundary. While *Stegodon – Homo erectus* fauna are widely distributed and well-documented throughout the island, the evidence for Late Pleistocene *Elephas – Homo sapiens* fauna are mostly restricted in cave sediments, while open landscape localities have rarely been reported due to the scarcity of data.

Here, we report the fossil assemblage discovered in the Saguling Reservoir, first reported in late 2021. On the basis of our survey and test excavation, five mammal taxa: *Bos* cf. javanicus, *Bubalus bubalis, Axis axis, Rusa* cf. *unicolor* and *Elephas* sp. are taxonomically identified. The fossil localities comprise fluvial sediments, heavily influenced by volcanic activity. A preliminary age based on ^{14}C dating of older than 50 kya for the fauna has been determined based on Carbon dating of a charcoal fragment contained in the pyroclastic flow overlying the fossil layer. OSL dating on the fossil layer and volcanostratigraphy of the alternate pyroclastic flow and fall layer are currently underway. However, these preliminary data indicate the oldest date for an open landscape site on Java yet recorded, preceding most of the modern fauna of Java

Multiproxy analysis of endangered Yak (Bos mutus) dung from Indian Himalaya: Implications for paleoherbivory and paleoecology

Dr. Swati Tripathi [1], ***Dr. Sadhan K Basumatary*** [1], ***Dr. Hukam Singh*** [1], ***Dr. H. Gregory McDonald*** [2], ***Dr. Anil K. Pokharia*** [1]

1. *Birbal Sahni Institute of Palaeosciences, 53-University Road, Lucknow-226007, India,* **2.** *Bureau of Land Management, Colorado State Office, 2850 Youngfield Street Lakewood, Colorado 80215, USA.*

The study reports the micro- and macrobotanical remains on wild Yak dung, providing evidence for understanding the diet, habitat, and ecology of extant and extinct megaherbivores. Grasses are the primary diet of the yak as indicated by the abundance of grass pollen and phytoliths. Other associated non-arboreal and arboreal taxa namely, Cyperacaeae, Rosaceae, Amaranthaceae, *Artemisia*, *Prunus*, and *Rhododendron* are also important dietary plants for their living. The observation of plant macrobotanical remains especially the vegetative part and seeds of the grasses and Cyperaceae are also in agreement with the palynodata. The documented micro- and macrobotanical data are indicative of both Alpine meadow and steppe vegetation under cold and dry climate which exactly reflected the current vegetation composition and climate in the region. The recovery of *Botryococcus*, *Arcella*, and diatom was observed in trace amounts in the palynoassemblage which would have been incorporated in the dung through the ingestion of water and are indicative of the presence of a perennial water system in the region. Energy dispersive spectroscopy analysis marked that the elements contained in dung samples have variations in relation to the summer and winter, which might be due to the availability of the food plants and vegetation. This generated multiproxy data serves as strong supplementary data for modern pollen and vegetation relationships based on surface soil samples in the region. The recorded multiproxy data could also be useful to interpret the relationship between the coprolites of herbivorous fauna and the palaeodietary, the palaeoecology in the region, and to correlate with other megaherbivores in a global context.

Bear coprolites? Preliminary study of the coprolites from the Juan Labranz Cave (Cuenca, Spain)

The study of coprolites can provide valuable information about both the producers and the environment in which they lived. The value of coprolites as an indirect record of a species increases in the absence of associated skeletal remains. However, how reliable are the identifications of the producers based solely on this type of remains? Here we present the results after studying 34 coprolites collected *in-situ* in Quaternary sediments of Juan Labranz Cave, a karst cavity in Cuenca (Spain) developed in dolomites located at the boundary between the Iberian Mountain Range and the Tertiary Tagus Basin, in the Jucar River valley. Morphometric studies indicate that most of the coprolites were produced by spotted hyena, but there are two outliers with atypical morphologies exceeding the size of any hyena droppings. According to their width, it is observed that they fall within the typical size of the faeces of modern Iberian brown bears after they have scavenged. Comparing the internal content of the coprolites through a micro-CT scanner, it can be seen that whereas most of the bone fragments assigned to hyenas are smaller and rounded, the two atypical specimens contained numerous fragments of sharp edges, indicating carrion consumption and hardly no digestion of the bones. Although the presence of bears in the Juan Labranz cave was already known because of the bear beds, claw marks and skeletal remains, the study of these two coprolites provides valuable information that can help identify bear coprolites in sites where there is no other evidence indicating the presence of these animals. Furthermore, it broadens our knowledge of these traces, which are very common in Quaternary and older terrestrial deposits.

Carnivores of the Epivillafranchian biochron: contributions from the Sierra de Atapuerca

***Dr. Nuria Garcia* [1], Prof. Ralf-Dietrich Kahlke [2], Dr. Rosa Huguet [3], Prof. Eudald Carbonell [4]**

***1.** Grupo UCM Ecosistemas Cuaternarios, Dpt de Geodinámica, Estratigrafía y Paleontología, Fac. de CC. Geológicas, UCM, Madrid. Centro Mixto UCM-ISCIII de Evolución y Comportamiento Humanos, Madrid, Spain., **2.** Research Station of Quaternary Palaeontology Weimar, Senckenberg Research Institutes and Natural History Museums, **3.** IPHES-CERCA, Institut Català de Paleoecologia Humana i Evolució Social, Tarragona - Departament d'Història i Història de l'Art, Universitat Rovira i Virgili, Tarragona - Unit associated to CSIC, Dept Paleobiología, MNCN, Madrid, **4.** Departament d'Història i Història de l'Art, Universitat Rovira i Virgili, Tarragona, Spain - IPHES-CERCA, Institut Català de Paleoecologia Humana i Evolució Social, Tarragona, Spain*

Two deposits in the Sierra de Atapuerca include layers whose chronological contexts indicate age positions of around one million years. The first is level TE9c of the Sima del Elefante site, dated to about 1.2 Ma and representing one of the oldest sites with evidence of human occupation in Western Europe. The second deposits are the basal layers of the Trinchera Dolina (TD3-4 and TD5) site, with ages ranging between 1.1 Ma and 0,9 Ma. The 18th International Senckenberg Conference held in Weimar, Germany (2004) saw the proposal of a new Early Pleistocene biochron: the Epivillafranchian. While this term previously had been proposed by Bourdier in 1961 and some authors later considered it, the main catalyst for its establishment came with the abundant mammal fossils from the Untermassfeld site in Thuringia, Germany. The selection of the most representative European large mammal assemblages within the 1.2 - 0.9 Ma chronological interval was discussed in the frame of that meeting and subsequently published in detail [RF1]. Today, the Epivillafranchian is a widely accepted biochron and the localities dated to that time interval are primed for study and revision.
The two deposits from Atapuerca, level TE9c of Sima del Elefante and basal layers of Trinchera Dolina are rich in mammal fossils and their age covers the entire timespan represented by the Epivillafranchian. Our study focuses on the recorded carnivores, analysing taxa included in the original Untermassfeld proposal and adding new results from the Sierra de Atapuerca sites. Although the different Epivillafranchian sites have many species in common, also some differences in the faunal compositions are detected, which might be related with the respective special habitat conditions and/or taphonomic processes of the sites' formation. The study of the carnivores from the mentioned Sierra de Atapuerca localities complete our knowledge about the Epivillafranchian period as well as on the environment in which Europe's early humans lived.

Levantine overkill: 1.5 million years of hunting down the body size distribution

Mr. Jacob Dembitzer [1]***, Prof. Ran Barkai*** [2]***, Dr. Miki Ben-Dor*** [2]***, Prof. Shai Meiri*** [2]

1. *Department of Earth, Environment and Resources Sciences, University of Naples Federico II,* ***2.*** *Tel Aviv University*

Multiple large-bodied species went extinct during the Pleistocene. Many have pointed to changing climates and/or human hunting as the cause of these extinctions. We studied the causes of Pleistocene extinctions in the Southern Levant, and their subsequent effect on local hominin cultural complexes, by examining faunal remains in archaeological sites across the last 1.5 million years. We examined whether climate and climate changes, and/or human cultures, are associated with these declines. We recorded animal abundances published in the literature from 133 stratigraphic layers, across 58 Pleistocene and Early Holocene archaeological sites, in the Southern Levant. We used linear regressions and mixed models to assess the weighted mean mass of faunal assemblages through time and whether it was associated with temperature, paleorainfall, or paleoenvironment (C3 vs. C4 vegetation). We found that weighted mean body mass declined log-linearly through time. Mean hunted animal masses 10,500 years ago, were only 1.7% of those 1.5 million years ago. Neither body size at any period, nor size change from one layer to the next, were related to global temperature or to temperature changes. Throughout the Pleistocene, new human lineages hunted significantly smaller prey than the preceding ones. This suggests that continuously targeted the largest species in their environments, and when the largest species were depleted the next-largest were targeted. Technological advancements likely enabled subsequent human lineages to effectively hunt smaller prey replacing larger species that were hunted to extinction or until they became exceedingly rare.

Northeast Iberian Peninsula as a refuge ecosystem during the last Glacial Period: Insights from stable isotope and tooth wear analyses

Dr. Dorothée Drucker [1]***, Prof. Florent Rivals*** [2]***, Prof. Jordi Nadal*** [3]***, Dr. Joaquim Soler*** [4]***, Dr. Isaac Rufí*** [4]***, Prof. Julià Maroto*** [4]

1. *Senckenberg Centre for Human Evolution and Palaeoenvironment (S-HEP) at the University of Tübingen, Tübingen,* ***2.*** *ICREA, Barcelona, Spain; Institut Català de Paleoecologia Humana i Evolució Social (IPHES-CERCA), Tarragona, Spain; Departament d'Història i Història de l'Art, Universitat Rovira i Virgili, Tarragona, Spain,* ***3.*** *Seminari d'Estudis i Recerques Prehistòriques (SERP), Universitat de Barcelona, Barcelona, Catalonia,* ***4.*** *Institute of Historical Research, University of Girona, Girona, Catalonia*

The Iberian Peninsula acted as a refuge region during the last Glacial Period as illustrated by the continuous human occupation recorded in the archaeological context of the Upper Paleolithic (ca. 45,000 to 12,000 years ago). In this southern part of Europe, terrestrial ecosystems maintained a vegetation productive enough to allow animals and their predators to persist over the harsh climatic conditions of the Last Glacial Maximum. Either the ecological traits of the large herbivores were flexible enough to adjust to contrasted conditions over time, or they could maintain the same type of diet and habitat due to the local attenuation of the climatic change.

In this communication, we will explore the diet and habitat/environment of horse (*Equus* sp.) and red deer (*Cervus elaphus*) from the Upper Palaeolithic occupation at the Serinyà sites of Arbreda cave (Aurignacian Gravettian, and Solutrean; ca. 42,000-21,500 years ago) and Bora Gran (Magdalenian; ca.16,000-14,700 years ago). Horse and red deer were important animal preys of the hunter-gatherers of the northeast Iberian Peninsula albeit in different proportions over time. We have conducted intra-individual sampling of enamel along molar teeth and measured the relative isotopic abundances of ^{13}C and ^{18}O in carbonate. The results should provide information on seasonal variation in diet and environment experienced by both species. In parallel, bones were selected to extract collagen and perform ^{13}C and ^{15}N analysis. Bone collagen remodels over the life of the specimens and provides a long-term information on diet and habitat. In addition, dental wear analyses were performed on the same specimens to investigate their long-term (mesowear) and short-term (microwear) dietary habits between grazing and browsing. Confronted to the results of the isotopic analyses, the dental wear analysis can contribute to disentangle the effects of the climate from those of the diet.

We will examine potential change in the niche of the horse and red deer before, around and after the Last Glacial Maximum and evaluate how the environmental conditions may have triggered changes in the diet and habitat of these two species. The results will also be considered from the point of view of human subsistence.

Stegodon SEAcross-ing: Swim, Shrink, and Disperse

Dr. Christine Hertler [1], ***Dr. Ericson Hölzchen*** [2], ***Mr. Jan-Olaf Reschke*** [1], ***Mr. Iwan Pramesti Anwar*** [3], ***Dr. Alexandra van der Geer*** [4], ***Mr. Emmanuel Kipruto Ngetich*** [1], ***Dr. Mika Puspaningrum*** [3]

1. ROCEEH Research Centre, Senckenberg Research Institute, Frankfurt/M, 2. German Research Center for Artificial Intelligence, Trier University, 3. Bandung Institute of Technology, 4. Naturalis Natural History Museum Leiden

Elephants are known as ardent, skillful, and persevering oceanic swimmers. Smaller sea straits between the mainland and an island or between islands therefore do not represent major barriers for dispersals. *Stegodon*, phylogenetic relative of the family Elephantidae, followed a similar pattern. The fossil record of *Stegodon* in insular Southeast Asia and Wallacea illustrates a wide distribution area ranging from Java, through Flores and Sumba, to Timor, and stretching north to Sulawesi and the Philippines. Simultaneously, proboscideans underwent island dwarfing. En route to remote islands in Wallacea, dwarf stegodons in Flores for instance evolved c. 50 % body mass reduction relative to the ancestral species in mainland Southeast Asia. Reductions in body size have an impact on swimming performances and thus dispersal capabilities.

In order to examine the capabilities of *Stegodon* to disperse across insular Southeast Asia and Wallacea we applied SEAcross, an adapted version of the hominin sea crossing ABM. Because stegodons show island dwarfism, we developed a dwarfing scenario and determined crossing success rates (CSR) for a range of size categories.

We used oceanographic maps to determine critical features of sea straits: width, and current velocity and direction. The three parameters were applied to configure a standardized environment for each sea strait.

With respect to the *Stegodon* agents, we applied a physiological swimming model which allows to calculate optimum swimming speed and maximum distances by quadrupedal paddling from the relation between costs of transport and energy storage available. In this model, both variables, optimum swimming speed and energy storage, are dependent on size parameters, in particular head body length and body mass. Small-sized stegodons therefore have less energy at their disposal and swim with lower optimum speed. Consequently, they are less successful in crossing sea straits. Progressive dwarfing may render it impossible to cross a particular sea strait.

Our results identify and illustrate potential routes for *Stegodon* across the Sunda Shelf and Wallacea. We furthermore determine the maximum geographic distribution range in reach of stegodons of various size categories when moving across the focal islands.

New dietary insights for Homo spp. during the Pleistocene: evidence from the Italian peninsula over time

The study of the paleodietary inference of our ancestors is crucial for understanding the relationship between evolutionary, cultural and palaeoenvironmental change. In this work we focus on the dietary habits that enabled *Homo* to face progressive climatic deterioration started with the Early-Middle Pleistocene Transition in the Mediterranean region and culminated in the Last Glacial Maximum. To do so, we rely on the traces left by food on tooth enamel (dental microwear analysis) of teeth from three *Homo* species (*H. heidelbergensis*, *H. neanderthalensis* and *H. sapiens*) that preserved antemortem wear from two key sites of the Middle and Late Pleistocene in central Italian Peninsula (Fontana Ranuccio, in Anagni and Fossellone Cave, in San Felice Circeo). Hence, dietary data on these samples are presented and discussed here for the first time. Besides important *Homo* remains, these sites have been selected for their abundant accompanying large-mammal fauna, associated lithic and bone industry, and excellent stratigraphic control data that altogether can provide in-depth climate and habitat information of the fossil human populations which occupied this region during the Pleistocene. Teeth from the Acheulean site of Fontana Ranuccio consist of several isolated remains, while fossils from Fossellone Cave (found together with Mousterian lithic industry in the case of Fossellone 3 and Aurignacian lithic industry in Fossellone 2) are comprised of several pieces included in mandibular or maxillary fragments. Our analyses reveal microwear differences (especially in frequency of microscopic scars and dimensions) among sites and species, especially between the *H. neanderthalensis* and *H. sapiens* samples from the same site (Fossellone, M. Circeo). Results suggest that different species probably based their diets on different trophic resources, at least occasionally, and had different subsistence strategies. These findings further indicate that significant dietary diversification occurred during the evolution of the *Homo* genus in the Italian Peninsula, to cope with climate instability and progressive deterioration.

Late Pleistocene Climates and Environments in the Tapi River Valley, India, and associated palaeoanthropological significance

***Dr. Prabhin Sukumaran* [1], Prof. Stanley Ambrose [2], Dr. Lewis Owen [3], Ms. Swati Verma [4], Mr. Varun Vyas [4], Mr. Mihir Tanksale [5], Dr. Parth Chauhan [5]**

***1.** Charotar University of Science and Technology, **2.** Department of Anthropology, University of Illinois, Urbana, USA, **3.** North Carolina State University, **4.** Maharaja Sayajirao University of Baroda, **5.** Department of Humanities and Social Sciences, IISER-Mohali, Punjab*

Many unique factors contribute to the potential of multidisciplinary research in South Asia to enhance the understanding of Late Pleistocene climates, *Homo sapiens* migrations, and megafauna extinctions. South Asia has diverse and dynamic climatic zones, favorable paleoenvironments, glacial biotic refugia, a long history of human occupation, high genetic diversity in present-day populations, and was an essential corridor for biotic interchanges between western Eurasia and eastern Asia. Discovery of later Quaternary human fossils would substantially improve our understanding of the evolutionary trajectories of our species in South Asia. The present study is a step towards this goal. A Late Pleistocene sedimentary sequence has been identified from the central Tapi River Valley, Maharashtra, India, where extensive Quaternary landforms, many Paleolithic sites, and extinct ostrich eggshell fragments have been recorded. A 14m sedimentary sequence has been sampled at 2cm intervals for multi-proxy analyses, including grain size distribution, the surface texture of quartz grains, palynology, ancient DNA, OSL dating, and stable isotope geochemistry. We report significant signatures of climate changes in this sediment sequence. The present study uses carbon and oxygen stable isotope geochemistry results on 196 carbonate nodules, the carbon isotope ratio of soil organic matter of 74 samples, and the total inorganic carbon percentage of 74 samples from the sediment sequence. Samples were analyzed for optically stimulated luminescence dating. Carbonate stable isotopes show distinctive combinations of proportions of C3 and C4 plants and generally low humidity during the Upper Pleistocene. Holocene carbon isotopes span most of the range of C3 to C4 plant cover, with generally higher humidity. The stable isotopic data and OSL dates are compared with available results from archaeological research in this region to infer the possible climate window(s) for prehistoric *H. sapiens* to expand into the Indian subcontinent.

The timing and ecological consequences of Pleistocene megafaunal decline in the eastern Andes of Colombia

Mr. Felix Pym [1], ***Dr. Felipe Franco-Gaviria*** [1], ***Mr. Ismael Garcia Espinoza*** [1], ***Dr. Dunia Urrego*** [1]

1. *University of Exeter*

Examining the ecological consequences of the Late-Quaternary megafaunal extinctions within biodiversity hotspots is crucial for our understanding of the potential consequences of contemporary extinctions. We present the first multi-species record of spores of coprophilous fungi (SCF) from Monquentiva and the high Andean forests of Colombia to reconstruct Late-Pleistocene and Holocene megafaunal abundance. Fossilised pollen and charcoal are used to examine the consequences of megafaunal declines on the surrounding vegetation and fire activity. Our SCF record indicated the presence of Pleistocene megafauna at least since 30,290 BP, with two waves of megafaunal decline at ca. 22,900 and 10,990 BP. At Monquentiva, megafaunal decline in the early Holocene resulted in transitional non-analogue vegetation, a loss of some herbivore-dispersed plant taxa, an encroachment of palatable and woody flora, and a rise in fire activity. Differences with other published South American records suggest that ecological consequences of megafaunal declines were habitat-specific. Overall, we show that ecosystems in the eastern Colombian Cordillera were highly sensitive to the decline of megafaunal populations. Under the current biodiversity crisis, management and conservation efforts must account for the effect of local herbivore declines on the dispersal of certain plant species, on fire activity and the potential loss of ecosystem services.

Changes of the objective in the lithic tools production during the Uluzzian and the Aurignacian of Grotta Serra Cicora A (Nardò – Lecce, Southern Italy)

Grotta Serra Cicora A (SCA) opens in the Mesozoic limestone of the Park of Portoselvaggio (Nardò, LE) and it's part of an important cave system frequented during Paleolithic in which the researches mainly concentrated during the 60s and the 70s of the last century. The stratigraphic sequence of this cave testifies the frequentations of *Homo neanderthalensis* and the ancient diffusion of *Homo sapiens* in Italy.
The "Museo della Preistoria di Nardò" has lately started the review of the collections as part of a wider project aimed at the reconstruction of the evolution of the coastal landscape in relation to the organisational strategies of the territory developed by the human groups.
One of the main purposes of the new researches is to implement the available data on the transitional phases from Middle Paleolithic to Upper Paleolithic and, in this framework, the update of the data coming from SCA is an important opportunity to understand the existing relationship between the Uluzzian of the Neretina coast and the rise of the following Aurignacian and the implication of this substitution on a territorial and extraterritorial scale.
In this work we display the preliminary results of the study of the Upper Paleolithic lithic tools found in the external survey realized by E. Borzatti and currently preserved in the Museum. In the stratigraphic sequence, the reconstruction of the technical system of production highlighted a relevant change in the technical behaviour. This change finds confirmation both in the morphotechnical and in the dimensional characteristics of some categories of tools. From the analysis it emerges that there is a specific selection of the raw materials and the introduction of exogenous lithotypes.
The changes that we can observe open the possibility to acquire more detailed information about the group mobility and the organisation of the activities. The prosecution of the studies goes in this direction, finalised on one side to reconstruct the environmental changes and the taphonomic processes, on the other to understand the cultural aspects such as the identification of the raw materials procurement areas, the techno-functional analysis of the tools and the faunal resources management.

European-scale agent-based model to track anthropogenic and natural impacts on vegetation during the Last Interglacial and the Early Holocene

Ms. Anastasia Nikulina [1], ***Dr. Fulco Scherjon*** [1], ***Dr. Katharine MacDonald*** [1], ***Ms. Anhelina Zapolska*** [2], ***Ms. Maria-Antonia Serge*** [3], ***Mr. Marco Davoli*** [4], ***Ms. Elena Pearce*** [4], ***Mr. Dave van Wees*** [2], ***Prof. Didier Roche*** [2], ***Dr. Florence Mazier*** [3], ***Prof. Jens-Christian Svenning*** [4], ***Prof. Guido R. van der Werf*** [2], ***Prof. Wil Roebroeks*** [1]

Anthropogenic impact on the environment started long before the spread of agriculture. Available ethnographic and Last Interglacial and Early Holocene archaeological evidence show that not only climatic fluctuations, megafauna activities and natural fires impacted landscapes, but also that foraging societies altered their occupation areas via vegetation burning. Because of the complexity of landscape dynamics, it is challenging to evaluate and distinguish different types of impact in proxy-based reconstructions. Here we present an agent-based model (ABM) designed to track different types of impact on vegetation with specific focus on the role of hunter-gatherer vegetation burning during the Last Interglacial and the Early Holocene.
The European-scale ABM was implemented in Netlogo 6.2.0. The following input datasets were used: GTOPO30 digital elevation model, WISE dataset for distribution of large rivers and lakes, output of a dynamic vegetation model (CARAIB), pollen-based estimates of past land cover obtained from the REVEALS model and estimations of megafauna plant consumption. The temporal resolution of the ABM model is one year, and the spatial resolution is 10 km. This model includes four types of impact: climate, human-induced vegetation burning, natural fires from lightning and megafauna vegetation consumption. Every simulation step is compared against REVEALS estimates to define parameter values which lead to matching pollen-based estimations. To quantify the intensity of each source of impact, their modifications are tracked during simulation runs. Additionally, sensitivity analysis identifies the key parameters which determine the intensity of anthropogenic impact.
The preliminary results show that it is possible to distinguish and quantify the different types of impact if the chosen datasets are combined in a continental ABM. Such an approach allows one to clarify the role of each source of impact in interglacial landscape dynamics. The future steps include production of maps to illustrate possible scenarios of modified vegetation.
The research is financed through the European Union's Horizon 2020 research and innovation programme within the TERRANOVA project, No 813904 and supported by the Liveable Planet program of Leiden University. This work was performed using the compute resources from the Academic Leiden Interdisciplinary Cluster Environment (ALICE) provided by Leiden University.

New evidence for human-lion interactions during the Middle Palaeolithic

Mr. Gabriele Russo [1]***, Dr. Annemieke Milks*** [2]***, Dr. Dirk Leder*** [3]***, Dr. Tim Koddenberg*** [4]***, Dr. Robert Darga*** [5]***, Prof. Wilfred Rosendahl*** [6]***, Prof. Thomas Terberger*** [3]

Large carnivores have played a pivotal role in the behavioral and cultural evolution of the hominin species. By competitive pressures, niche partitioning, and ever-shifting relationships between predator and prey, the human lineage has adapted to coexist with its competitors on the landscape. The lion is one of the most formidable predators humans could encounter. Today, just as during the Pleistocene, this large gregarious felid is a specialized hyper-carnivore that often dominates the trophic chain of the environment in which it lives. It is, therefore, not surprising that lions held distinctive meanings among Paleolithic human groups. The multilevel relationship between *Homo sapiens* and lions is well exemplified by the representations of the big cat in European Upper Paleolithic art and the increasing presence of lion remains in anthropogenic assemblages up to the end of the Pleistocene. However, the evidence for human-lion interactions before the arrival of our species in Europe is comparatively scarce and scattered.

Here, we report the discovery of new evidence for Neanderthal-cave lion (*Panthera spelaea*) interactions during the Middle Paleolithic. The recovery of distal phalanges at least 190 ka old from Einhornhöhle, Germany, represents the oldest evidence of large felids' pelt usage in the archaeological record. This new evidence hints at the socio-cultural importance of lions for central European Neanderthals. In addition, we present the results of the first systematic taphonomic analysis on a cut-marked lion skeleton dated to 48 ka found at Siegsdorf. Our results suggest that the predator was intentionally killed and the carcass processed at the kill site before being abandoned. This contributes to a unique snapshot of Neanderthal hunting behavior.

This new evidence suggests that lions were not passive antagonists for the Mousterian foragers but an active part of their landscape. We conclude that Neanderthals could engage big cats economically and culturally, as *Homo sapiens* did later – and continue to do today.

Session 112: Micromorphology as a tool in Quaternary studies to reconstruct changes in natural and anthropogenic sequences

Late Quaternary paleoenvironmental changes in the Homo-bearing karst landscape of Lamalunga (Altamura, Italy): pedogenesis and geomorphic processes from field scale to micromorphology

Dipartimento di Scienze della Terra e Geoambientali, Università degli Studi di Bari Aldo Moro; Istituto di Geoscienze e Georisorse, CNR-Pisa

A multidisciplinary approach was applied to assess the major paleoenvironmental changes occurred from the middle Pleistocene to the Holocene in a karst environment of South Italy, where an entire skeleton of Homo neanderthalenis of middle Paleolithic age (known as homo of Altamura) was discovered in a cave 30 years ago. The landscape consists of a small, gentle-flanked fluviokarstic valley, where there is the opening of the Homo-bearing cave, which has captured with a regressive upslope erosion a paleo-doline formed on Creteacous limestone. On top of the bedrock, a pedostratigraphic succession includes an older, truncated reddish paleosol with carbonate accumulations unconformably overlain by a grey tephra, locally reworked, sourced from the nearby Vulture volcano and dated ($^{40}Ar/^{36}Ar$) to 320±70 ka. The whole succession is buried by a brown soil developed on slope deposits with angular clasts, which exhibits cm-thick terrestrial carbonate beds consisting of composite micritic crusts dated (U/Th) to 22 and 17 ka. The upper carbonate level is overlain by a dark brown topsoil. Physicochemical, mineralogical and micromorphological analyses allowed us to reconstruct the interplay between pedogenic and geomorphic processes in the light of major paleoclimatic changes. XRPD analysis of all soil horizons displayed peaks of calcite, quartz, feldspar and mica, pointing to an allochthonous siliciclastic input in addition to the local carbonate parent material. Oriented specimens of the clay fraction revealed the occurrence of illite/smectite mixed layers and kaolinite as pedogenic clay minerals, which depict a moderate to high degree of soil development. Soil thin sections showed clay coatings with degeneration features and pedorelicts including similar illuvial pedofeatures in the lower paleosol. These findings suggest interglacial-like, temperate or warm humid climate conditions, followed by geomorphic instability. Lenticular microstructure with banded fabric developed in the tephra, indicates ice lensing due to freeze-thaw cycles, suggesting an overprinting of periglacial conditions. Some clay coatings and Fe-Mn segregations were detected in the intermediate soil. The carbonate pedofeatures, filling pores or variously impregnating the pedogenic matrix, displayed precipitation/dissolution features in response to cyclical changes from drier to moister conditions. Similar features were observed in both the carbonate crusts, likely controlled by stadial/interstadial shifts.

Site formation and context of human occupations at the Paleolithic site of La Ferrassie (Dordogne, France)

Dr. Vera Aldeias [1], ***Dr. Dennis Sangathe*** [2], ***Dr. Shannon McPherron*** [3], ***Dr. Laurent Bruxelles*** [4], ***Dr. Alain Turq*** [5], ***Dr. Paul Goldberg*** [6]

__1.__ ICArEHB - Interdisciplinary Center for Archaeology and the Evolution of Human Behaviour, University of Algarve, __2.__ Simon Fraser University, __3.__ Max Planck Institute for Evolutionary Anthropology – Department of Human Evolution, Leipzig, Germany., __4.__ Traces laboratory, CNRS, __5.__ Musée National de Préhistoire, __6.__ Geoarchäologie Institut für Naturwissenschaftliche Archäologie (INA), Eberhard-Karls-Universität Tübingen

The Paleolithic site of the "*Grand abri*" of La Ferrassie (Dordogne, France) is one of the best-known Middle and Upper Paleolithic sequences in Europe. Excavations at the site have spanned more than a century and uncovered rich archaeological assemblages associated with the Mousterian, Châtelperronian, Aurignacian and Gravettian technocomplexes. As part of renewed excavation, here we report on the geoarchaeological results from two excavation sectors to understand both the depositional history of the sediments and their implications to understand human occupations at the site. Originally a karstic cave, the stratigraphic sequence in the Western Sector comprises first fluvial deposition (Phase I), followed by soliflucted deposits and accretion cones emanating from an upper platform (Phase II) and, finally, spatially restricted channeling (Phase III). Most archaeological assemblages are associated with Phase II and reflect an interplay between occupations directly in this area and bones and artifacts sliding down the slope from the upper platform. Unlike in the Western Sector, in the Northern Sector - situated along the limestone wall and several meters inside the footprint of the cave - cold features dominate the entirety of the sequence; we interpret these as being linked to microenvironments specific to this location of the karst rather than to general (external) climatic conditions. Relevant is the identification of patterned ground formation in this area, which can be clearly linked to the "monticule" features first reported by Capitan and Peyrony and erroneously interpreted as anthropogenic in origin. Our geoarchaeological results point to a large and complex karst system, with distinct depositional sources and often locally independent sedimentary histories throughout its extent. These formation pathways have differently impacted the main occupation areas and resulted in distinct degrees of preservation of the archaeological assemblages throughout the different areas of the site.

The Châtelperronian in context: Micromorphology studies of the Middle to Upper Paleolithic transition at Quinçay (France)

Mr. William Murphree [1]***, Mr. Igor Djakovic*** [2]***, Prof. Marie Soressi*** [2]***, Dr. Vera Aldeias*** [3]

1. *Interdisciplinary Center for Archaeology and the Evolution of Human Behavior (ICArEHB), University of Algarve, Faro,* ***2.*** *Department of Human Origins, University of Leiden,* ***3.*** *ICArEHB - Interdisciplinary Center for Archaeology and the Evolution of Human Behaviour, University of Algarve*

The French cave site of Quinçay – also known as Grand Roche de la Plématrie - represents one of the few multi-layered Châtelperronian sites in Europe. The site was initially excavated by Leveque (1968-1990) and has been the target of renewed multidisciplinary excavations since 2020. Ongoing geoarchaeological research at Quinçay has re-examined the stratigraphic framework and provided key insights into site formation processes. The site is a karstic cavity with a complex set of depositional environments and distinct degrees of organic preservation throughout the sequence. The basal deposits are affected by intense phosphatization associated with guano inputs that both predate and are synchronous with the Mousterian and first Châtelperronian occupations. Successive events of roof fall are hypothesized to have widened the cave's entrance and contributed to a marked change in the geochemical environment inside the site. Subsequent Châtelperronian occupations have good bone preservation and sedimentary inputs related to contributions from allochthonous sources. The uppermost levels are less rich archaeologically and capped by spatially patchy aeolian deposits. These are overlain by massive limestone boulders associated with a subsequent collapse of the cave roof. Interestingly, the entirety of the sequence is affected by cryoturbation with cold features clearly discernible in all studied thin sections. In all, our high-resolution micromorphological studies demonstrate a complex and dynamic system of biogenic, geogenic and anthropogenic processes and provide new insights into the nature of the Middle to Upper Paleolithic transition at the site.

Reconstructing site formation processes and archaeological preservation at the open-air Aurignacian site of Breitenbach, Germany

Dr. Aroa Garcia-Suarez [1]

1. *Spanish National Research Council*

Upper Palaeolithic open-air sites are poorly known. This is partly due to a long-lasting research bias towards cave and rockshelter sites, more easily recognisable in the archaeological record. By contrast, the interpretation of intra-site data from open-air Late Pleistocene sites is limited by a number of challenges that might include the excavation techniques, the occurrence of post-depositional disturbances, the applicability of the interpretative models developed (especially those deriving from a particular ethnographic context), and the unequal balance between the quantitative analysis of the record and its interpretation. Addressing these issues entails the high-resolution characterisation of lithological boundaries and site formation processes to document changes in the depositional contexts. This goal is better achieved with a microstratigraphic approach, which allows the study of deposits to a great detail, further contributing to the identification of the physical and chemical postdepositional processes that may have affected the site since its abandonment.

This contribution focuses on the micro-contextual study of the occupation horizon and immediately adjoining layers at the open-air Aurignacian site of Breitenbach, Sachsen-Anhalt, Germany, through the integration of micromorphological and FTIR analyses. Results shed light onto the depositional and post-depositional histories of the site, contributing to elucidate the integrity of the find-bearing sediments and the geoarchaeological impact of the processes of disturbance. Particular attention has been paid to exploring individual components of spatial behaviour and pyrotechnology to explore the habitation patterns of Aurignacian hunter-gatherers.

Interpreting multi-scale data from Late Pleistocene hunter-gatherer landscapes: examples from open-air sites in northern Malawi

The Karonga area in northern Malawi has a rich record of Middle Stone Age (MSA) hunter-gatherer activity, evidenced by lithic artefacts found in remnants of an alluvial fan system. Excavations revealed several intact assemblages including among others at Chaminade II, with occupations dating between 47-30 ka, the site complex of Bruce, with multiple occupations between 51-31 ka, and Mwanganda´s Village, which had a terminal MSA occurrence dated between 26-15 ka. Geoarchaeological and environmental efforts have focused on reconstructing the types of physical environments that attracted MSA foragers. Challenges were posed by poor organic preservation, limited possibilities for dating, and high complexity of site formation histories. Post-depositional processes included bioturbation by termites, mineral weathering, groundwater fluctuations, as well as the formation of iron-manganese nodules, calcrete paleosols, and laterites. The overall redness and homogenized macroscopic appearance of the sediments may raise the impression that each site followed a similar formation pattern. However, through careful field analysis and micromorphology, we reconstructed unique site formation histories for each site. Through coupled thin section and stable carbon and oxygen analysis of pedogenic carbonates we were able to obtain on-site environmental data, supplemented by radiocarbon dates, providing an additional control for the chronology of the sites besides the extensive dating of sediments with Optically Stimulated Luminescence.
Combining data from on-site microarchaeological analyses with semi-local and regional proxies (e.g., palynology and phytoliths), we discovered that late MSA activity and tool production occurred in locally more open riparian environments within evergreen gallery forest, surrounded by a regional vegetation dominated by miombo woodlands and savannah. Additionally, MSA hunter-gatherers exploited the confluence of river and wetland areas along the shores of Lake Malawi, which likely served as important corridors for the dispersal of biota. The results of our work show that by integrating ecological and chronometric data within a framework of site formation histories, it is possible to obtain more dimensional interpretations of late Pleistocene forager environments than typically expected in tropical environments with poor organic preservation.

Stepping Back in Time: A multi-proxy study of micromorphological samples from human footprints and associated wetlands at the Pleistocene-Holocene transition in the Great Salt Lake Desert, Utah

Dr. Alison Damick [1]***, Dr. Tammy Buonasera*** [2]***, Dr. Natalia Égüez-Gordon*** [3]***, Dr. Carolina Mallol*** [3]***, Dr. Daron Duke*** [4]***, Dr. D Craig Young*** [5]

Reconstruction of paleoenvironments at the Pleistocene-Holocene transition in North America has attracted significant research attention, and the basin of pluvial Lake Bonneville has served as a critical laboratory in the Desert West. Changes in terrestrial and stratigraphic records deposited during the late Pleistocene regressive phase of Lake Bonneville provide information on regional climatic drivers. Locally, these changes influenced the wetland habitats that were key to early occupation of the Great Basin by humans, ca. 13,000–9500 cal yr BP. Several sites with significant preservation of early human activity in Lake Bonneville have been recorded within U.S. Air Force-managed lands of the Great Salt Lake Desert in western Utah, USA, including the Wishbone Site, a hearth-side Haskett campsite preserving the earliest documented evidence for human use of tobacco. Previous paleoenvironmental studies in this area demonstrate that between ~13,000–12,400 cal yr BP, a shallow lake formed fed by overflow from neighboring Lake Gunnison. Multiple lines of paleoenvironmental evidence show a transition to warmer conditions by the early Holocene, leading to desiccation by, or intermittently within, the middle Holocene. As the lake dried up over time, a lush freshwater marshland associated with river flow and groundwater discharge formed a shallow deltaic system across the basin landscape.

The recent discovery of 88 human footprints in the sediments associated with this shallow deltaic system and in proximity to the Wishbone site has motivated a closer look at the micro-scale development of the wetlands and associated vegetation communities, with two primary goals: 1) to better constrain the dates of the geomorphological units and eventually the footprints themselves, and 2) to better understand precise changes in vegetation communities in relation to human presence in the basin and early human exploitation of those resources. To that end, this paper presents a multi-proxy study of micromorphological samples taken from the geological sections exposed near the archaeological sites and from the footprints themselves. Phytoliths, lipid biomarkers, compound specific δ^{13}C and δ^{2}H isotope analysis of long chain alkanes, and micromorphological sediment data are analyzed to address these research goals.

Geoarchaeological evidence of Late Holocene land use transitions in Northern Mesopotamia from the infilling od Assyrian canals

Dr. Luca Forti [1], ***Dr. Stefano Costanzo*** [2], ***Prof. Daniele Morandi Bonacossi*** [3], ***Prof. Andrea Zerboni*** [1]

1. *Department of Earth Sciences, University of Milan,* ***2.*** *Università degli Studi di Napoli "L'Orientale",* ***3.*** *Dipartimento di Studi Umanistici e del Patrimonio Culturale, Università di Udine*

In Northern Mesopotamia (present-day northern Iraq), during the Neo-Assyrian Empire, a complex system of canals was built to increase the surface of cultivable land and improve the efficiency of the irrigated waterscape of the hinterland of Nineveh and other major urban centres. The main aims of these facilities for water harvesting were to grant socio-economic prosperity to the entire Neo-Assyrian Empire. In the late 7th century, political instability led to the Assyrian state's rapid downfall, triggering the defunctionalisation of the canal systems and the formation of a sedimentary infilling. We investigated the natural and anthropogenic processes in charge of the formation of the infilling at three different portions of King Sennacherib's Khinis canal system. Along the stratigraphic sequences, we identified water-lain sediments, desiccation features, gravel-bearing colluvial deposits, and pastoral occupation layers, anchoring the deposit to radiometric dating and contextualising it against the known regional climatic history. Phases of use, abandonment and repurposing of the canals derived from pedostratigraphic analysis evidenced a significant shift in land use from agriculture to pastoralism after the collapse of the Neo-Assyrian Empire, thus suggesting a dynamic adaptation and resilience of the local communities in response to the joint effects of climatic transition towards aridity in the Meghalayan and geopolitical instability.

Dismantling urban Dark Earths. The combination of micromorphology and phytoliths analyses to understand past activities in the early medieval layers of DIVA (Antwerp, Belgium)

***Dr. Mónica Alonso-Eguiluz* [1], *Ms. Sarah Lo Russo* [1], *Prof. Yannick Devos* [1], *Dr. Luc Vrydaghs* [2], *Mr. Daan Celis* [3], *Prof. Karin Nys* [1]**

1. Multidisciplinary Archaeological Research Institute (MARI), Vrije Universiteit Brussel, Belgium, 2. Multidisciplinary Archaeological Research Institute-Vrije Universiteit Brussels, 3. Dienst Archeologie, stad Antwerpen, België/ Urban Archaeolgy Department, city of Antwerp, Belgium

Dark Earths are a ubiquitous phenomenon in urban contexts. They are typically thick, dark coloured, humic, and homogeneous layers embedding high amounts of information concerning past human activities. Their study and interpretation are not easy, since there are no clear boundaries in their stratification (Nicosia et al., 2017). Recent excavations on the site of DIVA (Antwerp, Belgium) have uncovered between 1 and 2 meters thick Dark Earth, chronologically bracketed between the end of the Gallo-Roman empire and the 11th century, corresponding to the period when the city begins to emerge. The site was located just next to the 10th century fortified nucleus or 'burcht' of Antwerp. As written information for this period is not abundant, and given the difficulty of understanding Dark Earth based on field data alone, multi proxy approaches are key to come to a better understanding of early city formation.

In our contribution we will present the results of the micromorphological study and the phytolith analysis on thin sections. This integrated study has been realized to better understand the economic activities carried out during the mentioned period, and consequently the formation processes that generated the Dark Earths. Micromorphological results allowed us to distinguish different strata derived from different activities sequenced as follows: 1) agricultural activities in a dry environment, 2) activities close to a settlement, 3) and walked surfaces within a settlement and stabling with more water saturated conditions. The phytolith record described in agricultural layers is dominated by grasses from the C_3 *Pooideae* subfamily, commonly found in humid and temperate environments. Distribution patterns are dominated by isolated and clustered phytoliths, suggesting postdepositional processes (anthropogenic, biogenic or a combination of both) that transported them from their original position. This study sheds new light on the origins of Antwerp and is in agreement with previous results obtained in other sites of the city, where ground rising and agricultural activities were also documented.

Session 115: Palaeoenvironmental research in SW Asia: Recent advances & future opportunities

Important findings from the TephroMed project I: Synchronising two important ICDP records of the eastern Mediterranean region using tephra

***Dr. Rebecca Kearney* [1], *Dr. Markus Schwab* [1], *Dr. Ina Neugebauer* [1], *Dr. Christina Günter* [2], *Ms. Oona Appelt* [3], *Dr. Nadine Pickarski* [4], *Mr. Daniel Redant* [1], *Dr. Rik Tjallingii* [1], *Prof. Achim Brauer* [1]**

The eastern Mediterranean region is crucially located between two contrasting climatic zones and precipitation regimes, the humid Mediterranean climate to the north and the hyper-arid Saharo-Arabian desert belt to the south. Lake sedimentary archives provide important insight into past hydroclimatic variability through multiple environmental proxies. However, chronological uncertainty prevents detailed insight into regional climatic (a)synchronies. The application of tephra (volcanic ash), both visible and non-visible (cryptotephra), can be a powerful chronologic tool in correlating palaeoclimatic records, particularly over vast distances.
The TephroMed project aimed to precisely synchronise two important ICDP palaeoclimatic records from eastern Mediterranean through the use of tephrostratigraphic investigations: Lake Van, Turkey (PALEOVAN) and The Dead Sea, Israel (DSDDP). Both records have undergone palaeoenvironmental and climatic reconstructions which have indicated contrasting past regional responses to large-scale climatic events. Though both records are dated through absolute and relative methods (radiocarbon, U-Th, varve counting, wiggle-matching), inherited large chronological uncertainties do not allow detailed insight into the potential climatic time-transgressive nature between the two sites. Yet, both records have tephra deposits within their lacustrine sediments, highlighting the potential to facilitate the alignment of both records using tephra.
Here, we present new volcanic glass chemical data from key tephra layers in both Lake Van and The Dead Sea ICDP cores. The use of major, minor and trace element volcanic glass chemistry (EPMA and LA-ICP-MS) allows correlation of tephra layers between the two cores, providing an important chronological alignment. Additional correlations to other important climatic archives in the Mediterranean have been made with the Dead Sea and Lake Van, improving the chronology for these records. As a result of finding these isochronous markers, we can now start to answer questions associated with regional expression of past climatic events and their temporal transgression.

Exploring the challenges of linking local and inter-regional archaeological and environmental records of Southwest Asia: the example of Ararat-1 cave (Armenia)

One of the major challenges in archaeological research is to create a cause-and-effect relationship between environmental oscillations and changes in material culture. Yet, still, the construction of detailed arguments about causality in such interactions remains a persistent pursuit. Establishing a finer chronological resolution that enables us to move beyond correlation to causation, remains as much a theoretical task as a methodological one. Climatic fluctuations during Marine Oxygen Isotope Stage 3 (MIS 3, c. 60 – 27 ka) have been suggested to be one of the possible triggers of the Middle to Upper Palaeolithic (MP to UP) transition in Eurasia.

In this lecture, we will present the recent results of the excavations in Ararat 1, a cave located in the Ararat Depression, Armenia. Based on a combination of sedimentological and geochronological (luminescence, radiocarbon, and tephrostratigraphy) techniques, together with analysis of the faunal remains and lithic assemblage, the site can be dated within the 50-35 ka interval. Our preliminary understanding of the available proxies at the site suggests a stable ecological niche of a semi-desert with no major changes occurring throughout this time interval. The multiscale chrono-environmental framework at Ararat 1 provides evidence for the long-term co-existence of Middle and Upper industries in the Armenian Highlands and the neighbouring regions. Similar to the varied local ecological manifestations of climatic oscillations during MIS 3 in Southwestern Asia, such major "events" like the Middle to Upper Paleolithic are asynchronous societal processes displayed differently geographically, and of myriad societal mechanisms. The ongoing excavations and research at the site would aim to refine and clarify the possible connections between nuanced ecological fluctuations with the intensity of occupation at the cave.

Changes in minerals during accumulation of the loess-paleosol sequence at Baluchabad, Northern Iran

Phyllosilicates (clay minerals) are formed through the weathering of silicate minerals over time which is strongly dependent on environmental conditions, i.e. climate, and can thus provide information on paleoenvironmental conditions during their formation. Clay minerals in loess deposits are mainly inherited from the source sediment, however, post-depositional weathering can also alter clay minerals by neoformation, transformation, and illuviation. The Baluchabad loess-paleosol sequence is characterized by twelve paleosols grouped in four pedocomplexes. The sequence is 54 m thick and accumulated on the northern foothills of the Alborz Mountains near Kalale city. For mineralogical analysis, 22 samples of the clay fraction in paleosols and underlying loess horizon were selected and saturated with K, and Mg. The K-saturated samples were heated at 550 C furthermore Mg-saturated samples were treated with Ethylene Glycol solvation. Treated samples were examined by an X-ray diffractogram machine. X-ray diffraction pattern of oriented samples showed the main clay minerals include smectite, chlorite, illite, and kaolinite. Previous studies showed that their presence in north Iranian loess-paleosol sequences had been inherited from the sediment source, nonetheless, pedogenetic processes under different environmental conditions in paleosols can change their abundance. Comparing the amount of smectite in paleosols with the loess below them shows that the amount of smectite in paleosols has increased, which indicates warmer and more humid environmental conditions with poor drainage. Also, by comparing the paleosols with each other, the amount of smectite increases by moving from the top to the bottom of the section revealing increases in pedogenic processes intensities at the bottom of the Baluchabad profile is more than the paleosols near the surface. In addition, the concluded result of mineralogy corroborates and is in accord with the micromorphology and magnetic susceptibility results. Therefore, the mineral abundance changes in paleosols demonstrate weathering and transformation of clay minerals during their formation, which indicates changes in pedogenesis processes.

5,000 years of environmental change and anthropogenic impact deduced from gravity sediment cores from Lake Sevan, Armenia

Prof. Torsten Haberzettl [1]***, Ms. Marie-Luise Adolph*** [1]***, Ms. Ulrike Amelung*** [1]***, Dr. Ara Avagyan*** [2]***, Dr. Kurt Friese*** [3]***, Mr. Hayk Hovakimyan*** [2]***, Dr. Sébastien Joannin*** [4]***, Dr. Norbert Nowaczyk*** [5]***, Ms. Kristina Sahakyan*** [2]***, Dr. Martin Schultze*** [3]***, Dr. Lilit Sahakyan*** [2]

Lake Sevan is located in eastern Armenia close to the border to Azerbaijan. With a length of ~70 km, a width of ~50 km at an altitude of 1900 m a.s.l. it is one of the largest freshwater high-mountain lakes. The lake itself is structured in two parts: the larger southern part called Big Sevan has a maximum water depth of 34 m whereas the northern smaller part called Small Sevan has a water depth of 65 m in the centre and a maximum water depth of 83 m close to the northern shore as a result of active tectonics.

Up to now, only limited information exists about more distal profundal sediments from Lake Sevan. Studies, which have been carried out so far, focused on micropaleontological investigations such as ostracods or pollen. Chemical investigations let alone multi-proxy approaches have rarely been done. In order to explore the further potential of sediments from Lake Sevan we recovered 16 gravity cores (51-141 cm length) from both parts of the lake in October 2021. All cores are clearly characterised by a more homogenous sedimentation in the lower part of the core and a more diverse succession in the upper part, which can likely be attributed to intense water level regulations since Soviet times, and anthropogenic impact in the subrecent past. In addition to that, the longest recovered sediment sequence (SEV21-6; 141 cm length) is finely laminated in the bottom part.

Radiocarbon ages on two cores from the centres of each lake part indicate a rather constant sedimentation rate since 5,000 cal BP in Big (SEV21-6) and 3,000 cal BP in Small Sevan. These chronologies are currently checked using paleomagnetic secular variation stratigraphy. Subsequently, they will be used in combination with a multi-proxy approach consisting of grain sizes, CNS, XRF-scanning and visible-spectrum scanning reflectance spectroscopy (VIS-RS) analyses as well as micropaleontological parameters (pollen, diatoms) for paleoenvironmental reconstructions.

Middle to late Pleistocene human-environment dynamics at the arid margin of the Levant: integrating archaeological and paleoclimatic records from the Greater Azraq Oasis Area, Jordan.

Dr. April Nowell [1], ***Dr. Christopher Ames*** [1], ***Dr. Carlos Cordova*** [2], ***Dr. James T. Pokines*** [3], ***Ms. Kelsey C. Boyd*** [4], ***Dr. Jeremy Beller*** [5], ***Dr. Kurt Heinrich Wogau Chong*** [6], ***Mr. Daniel Stueber*** [1]

The Azraq Basin is an approximately 12,000 km^2 endorheic drainage system in the Syro-Arabian Desert at the eastern margin of the Levant. The centre of the basin, which we refer to as the Greater Azraq Oasis Area (GAOA), is characterized by a saline mudflat with until recent times two wetlands on its northern end. Desiccation of these wetlands in the early 1990s and subsequent construction activities have exposed middle and late Pleistocene wetland deposits containing abundant Lower, Middle, and Upper Palaeolithic stone tools and faunal remains. Landscape-focused geoarchaeological research has since demonstrated that the past c. 350 ka in the GAOA are characterized by paleoenvironmental fluctuations that shifted the quantity and distribution of freshwater resources, ranging from expansive waterbodies and wetland landscapes to desert refugia characterized by isolated spring pools and wet meadows. Such dramatic shifts in the ecosystem would have influenced seasonal faunal and floral resource availability and thus hominin mobility decisions and settlement patterns during the Paleolithic. Results also indicate that the steep climatic gradient from northwest to southeast across the southern Levant likely extends back into the Middle Pleistocene. In this paper, we present results of our ongoing efforts to integrate the middle to late Pleistocene archaeological, paleoenvironmental, and paleoclimatic records of the GAOA, including new data concerning lithic technology and faunal remains, as well as from microbotanical, isotopic, geochronological, and protein residue analyses. As the available data sequences are fragmentary, something commonplace in arid contexts, elucidating long-term human-environmental dynamics requires a multi-scalar approach that draws on a variety of paleoenvironmental archives that must be combined with a well-developed understanding of landscape evolution. Despite this challenge, developing a more detailed understanding of the environmental and archaeological history of this period is essential to evaluating the eastern arid margin of the Levant played as a corridor for dispersals of Pleistocene hominins throughout Southwest Asia.

The Paleoclimate Implications of the Vedi Travertine (Ararat Valley, Armenia)

The analysis of paleoenvironmental records coupled with records of human behavior provides valuable insight to archaeologists wishing to understand how and why hominin behavior changed throughout the Pleistocene. Though the archaeological record of the Armenian Highlands and the Southern Caucasus is rich, the region lacks long term continuous records of paleoclimate change to compliment these records of human behavior. To address this gap in paleoclimate research in the region, here we present initial results of a coring project together with geomorphological mapping on the Vedi travertine, a large (~30 m) sequence of Quaternary spring deposits in the Ararat Valley, Armenia. Uranium series dating will provide chronological constraints on this core, and stable isotope ($\delta^{18}O$ and $\delta^{13}C$) and trace metal analysis will be used for paleoenvironmental information. Along with these traditional analyses, novel analyses of matrix-bound biomarkers, such as *n*-alkanes, will provide complimentary paleoenvironmental data. Together, the data from this travertine core will provide an important record of hydrological change in the region.

Tracing cryptotephra to Levantine archaeological and environmental records: successes, challenges, and future steps.

Studies of marine, lake and archaeological sites in the wider Mediterranean region have demonstrated the value and utility of non-visible volcanic ash layers (cryptotephra) in the correlation and dating of climate and archaeological records. In recent years, significant advances in this avenue of research have been made, most notably with the results of the RESET project. However, to date, only minimal investigations have been made to expand the framework eastwards into the Levant, despite the rich and globally significant archaeological records present.

Here we describe the results of a renewed investigation, funded by the Leverhulme Trust, which aims to expand the application of cryptotephra to a number of Levantine Palaeolithic records. These records are crucial for understanding the timing of early Modern Human dispersals ‘out of Africa’, their interaction with Neanderthal populations during the Pleistocene and the role that climate may have played in these encounters. Seventeen sites were examined as part of the project with results focused here on those which have given the most notable ‘successes’ and ‘challenges’.

Cryptotephra concentrations in the Levantine sites, are in the majority of cases, exceptionally low and are frequently complicated by a mixed chemical signature. The potential volcanic source regions for these are numerous, with Italian, Aegean and Anatolian Volcanic Provinces all suspected as contributing to the deposits identified. To tease the maximum amount of information from these complex tephra records has required a forensic-style approach as well as advances in analytical techniques. These efforts have in part proven successful with at least one robust tephra being identified as originating from the Kos volcano and serving as a regional marker horizon during MIS5e.

Session 118: Cave deposits for in deep understanding Quaternary climate and environment

Innovative and interdisciplinary karst cave excavation of rare pre-LGM sediments in northern Norway

Caves are extraordinary time capsules of past ecosystems and environments and their sediment deposits have great potential to answer questions regarding palaeoclimate, sea level change and landscape development. In high latitudes these deposits are crucial for better understanding the extent of the ice sheet cover and periods of retreat during the Quaternary glaciations. There are over 1100 known karst caves in Norway and around half of these have been mapped and investigated. Yet, deposits predating the last glacial maximum (LGM) are incredibly rare due to erosion and removal of sediments by flushing meltwater from the glaciers.
We capitalise on the excellent preservation conditions in a high-latitude (68°50'N) karst cave in northern Norway with an extra-ordinary rich pre-LGM faunal record, estimated to range in age between 70 000 and 120 000 BP. Sediments in the Storsteinhola cave system were excavated using optimised and innovative methods for comparative, interdisciplinary analyses from the fields of archaeology, geology, sedimentology, palaeozoology and ancient DNA. Chronology is established combining radiocarbon analyses of bone, cosmogenic nuclide burial dating of quartz-rich clasts, ^{230}Th/^{234}U dating of calcite speleothem and calcareous concretions, and optical stimulated luminescence and paleomagnetic dating of sediments. The upper part of the deposit consists of shallow marine sand and beach gravel from the Late Glacial, reflecting a high relative sea-level following the last deglaciation. Below are glaciolacustrine fines and glaciofluvial sandy gravel from period(s) with ice-cover, followed by a boulder-rich, crudely stratified diamicton. Within these layers we have identified a diverse number of Arctic related faunal taxa through a novel combination of bulk-bone metabarcoding and morphological identification. We combine sediment analyses with the detected faunal diversity for the reconstruction of the local palaeoenvironment and Scandinavian ice sheet history. Through our interdisciplinary research we obtain new knowledge for the glacial period in northern latitudes and highlight the importance of cave sites to research.

Stable isotopic signatures of fossilised rodent teeth from Naracoorte Caves: Insights into late Quaternary climate change in South-eastern Australia.

Understanding impacts of past climate and environmental change on mammal communities is important for understanding dynamics of future ecosystem change. Stable isotope analysis of bioapatite from fossilised mammal teeth is a well-established technique for reconstructing past climate and vegetation; however, is underutilised at Australian vertebrate fossil sites. The Naracoorte Caves World Heritage Area (NCWHA) in South Australia, preserves abundant, owl-pellet derived late Quaternary small mammal fossil assemblages, providing ideal sample sizes to reconstruct temporally resolved climate and vegetation records using stable isotopes. In this study, we use isotope ratio mass spectrometry to analyse stable carbon and oxygen isotopic composition of bioapatite in fossil teeth from three Australian rodent species as a proxy for reconstructing palaeoclimate and palaeovegetation of the Naracoorte region. Lower incisor teeth from three species of the genus *Pseudomys (P. auritus, P. australis and P. shortridgei)* were sampled across 43 sedimentary layers from a palaeontological excavation in Blanche Cave (NCWHA) spanning from around 65 to 14 thousand years ago. This time period is significant as it covers human arrival on the Australian continent and the mass extinction of around 68 species of birds, reptiles, and mammals with body masses greater than 40 kg. The Blanche Cave deposit therefore captures environment prior to, during and following these important palaeoecological changes across the region. Our reconstructions of palaeoclimate and palaeovegetation from carbonate- and phosphate-bound components of bioapatite reveals change in the dominant vegetation type from open woodland to grassland at the time of the Last Glacial Maximum (LGM). Changes in the water regime also reveal a shift from cool and wet to warm and dry conditions in and out of the LGM. The results of this study demonstrate the potential for using rodents, which are commonly abundant in Naracoorte fossil deposits, to establish directly associated climatic and vegetation records, and provide an improved contextual framework for evaluating extinction events, such as Late Pleistocene megafauna extinction, in Australia. Our approach has the potential to be extended to megafauna, enabling better understanding of how large mammal communities responded to changes in climate and vegetation during the last glacial cycle and beyond.

Producing high-resolution 20th Century speleothem records: Milling, Laser-Ablation, and mixed methods dating on stalagmites from Madagascar and Australia

High resolution analysis of recently growing speleothems and comparison with independent climate records can help determine which components of the hydroclimate system are recorded in speleothem $d^{18}O$ and trace element ratios. This includes local and regional rainfall amount, seasonality, evaporation, in-cave kinetic effects and more. However, at such young ages, low ^{230}Th accumulation reduces the precision of U-Th ages that make speleothems such powerful paleoclimate records at other timescales.
In this study we adopt a mixed methods approach to dating 20th and 21st century stalagmites that allows for absolute chronologies with sub-decadal accuracy. Our approach combines annual geochemical cycles, radiocarbon bomb-pulse modelling, collection dates, and conventional U-Th ages. We test our method on recently growing stalagmites from Careys Cave in Australia and Anjohibe in Madagascar, both of which contain short 20th century hiatuses. Using the new mixed methods age models, we compared high-resolution micro-milled $d^{18}O$ records with local rainfall station, satellite and reanalysis estimates of past rainfall. In Madagascar we show a tight coupling of stalagmite $d^{18}O$ and satellite rainfall estimates with less than 2 years age offset. This potentially opens the door to a paleotempestology record identifying tropical cyclone activity. With this we can examine whether past tropical cyclones have an outsized $d^{18}O$ impact relative to the already extreme rainfall amount. In Australia we show good coherence of stalagmite $d^{18}O$ and trace element ratios with historical droughts recorded at local meteorological stations. Seasonal correlations allow us to begin estimating potential biases in the stalagmite proxies. Overall, coupling stalagmite $d^{18}O$ records with recent independent rainfall indicators, which we term paleo-monitoring, allows us to build more robust and nuanced proxy interpretations, giving confidence in paleoclimate reconstructions of the more distant past.

Stalagmite-based paleofire reconstruction using organic biomarkers: a case study from cave KNI-51, tropical Western Australia

Contemporary human activity is altering rates and intensities of wildfire, but the nature of fire activity prior to the modern era is poorly understood. Here we investigate the utility of a novel paleofire proxy: trace pyrogenic organic compounds in stalagmites. Polycyclic aromatic hydrocarbons (PAHs) are linked to burning of biomass and are transported downward through soil and bedrock by infiltrating rainwater and incorporated into stalagmites in underlying caves. We couple PAHs with *n*-alkanes, which may be used to infer past vegetation conditions, to provide complementary evidence of fire. In this pilot study, we have so far analyzed three fast-growing and precisely-dated aragonite stalagmites from KNI-51, a shallow cave in the fire-prone tropical savanna of Western Australia. The thin layer of fractured bedrock above the stalagmite chamber, coupled with a minimal soil layer allows quick transfer of combustion products to the cave system.

To test the stalagmite-paleofire link, we performed several experiments. First, we assessed the possibility of surface contamination on the stalagmites by measuring PAH and *n*-alkane abundances and distributions in sequential digestions. Second, because KNI-51 often floods and flood sediment is incorporated into the stalagmites, target compounds were measured in soils above the cave, sediments lining the stalagmite chamber floor, and flood-derived sediment incorporated within stalagmites as possible sources of these organic compounds. Third, we considered as additional sources other possible biological and geological influences, such as regional oil and gas fields or microbial activity. And fourth, satellite-mapped fires occurring proximal to the cave were correlated to PAH abundances in a recently active portion of one stalagmite.

The results support the contention that PAHs and *n*-alkanes in KNI-51 stalagmite carbonate likely reflect paleofire activity. While flood sediment contains PAHs, no significant correlation was found between target compounds and the presence of flood layers. We argue that biomass burning and the consequent fire-induced breakdown and particle deposition are the main sources of target organic compounds in these stalagmites. Given that karst is present in many fire-prone environments, and that stalagmites can be precisely dated and grow continuously for millennia, the potential utility of a stalagmite-based paleofire proxy is high.

High precision 230Th/U dating of tropical speleothems reveals decadal- to centennial-scale variability in soil carbon cycling and hydroclimate over the past 40 ka

In recent decades, tremendous progress has been achieved in ^{230}Th/U dating of speleothems and other secondary carbonates, which allows for a wealth of continental hydroclimate reconstructions on absolute time scales. Here we demonstrate the feasibility of absolute decadal to sub-centennial age precision for speleothems from Larga Cave in Puerto Rico, which have U contents of 400–800 ng/g, and reveal a high, but well reconstructed initial ^{230}Th content. Age uncertainties achieve a median of <4‰, providing an excellent time control over the past 40 ka at multi-decadal to sub-centennial scale resolution.

Trace element records (including e.g., Mg/Ca, Cu/Ca, or Zn/Ca) and stable oxygen and carbon isotopes (δ^{18}O and δ^{13}C) indicate significant changes in hydroclimate, which are, however, decoupled to soil carbon cycling indicated through a high-resolution dataset of ^{14}C, i.e., the dead carbon fraction (DCF). While stable isotope and trace element time series track changes of the amount of rainfall, associated with prominent northern hemispheric millennial scale climate events such as the Dansgaard-Oeschger (D/O) events or Heinrich Stadials, the DCF pattern exhibits extreme centennial-scale variations with a large range from 20% up to more than 50%, reflecting three main soil carbon cycling states across the termination. During the Last Glacial Maximum (18–25 ka), DCF variability vanishes indicating minor soil carbon changes above the cave. In contrast, preliminary DCF results from the Holocene suggest a possible second stable soil carbon cycling mode and better ventilated soil.

Thanks to the combined study of high precision ^{230}Th/U and ^{14}C dating, the Larga Cave speleothem record will allow to detect abrupt changes in soil carbon cycling and host rock dissolution over large parts of the past 40 ka. Together with analyses of hydroclimate-sensitive proxies the relation to local and regional (hydro)climate on multi-decadal to millennial timescales can be investigated.

Temperature thresholds on Central America hydroclimate during the last glacial cycle

Mr. Giuseppe Lucia [1], ***Dr. Matthew Lachniet*** [1], ***Prof. Amos Winter*** [2], ***Dr. Juan Pablo Bernal*** [3], ***Prof. Hai Cheng*** [4]

1. *University of Nevada Las Vegas,* ***2.*** *Earth and Environmental Systems Department, Indiana State University, Terre Haute,* ***3.*** *Universidad Nacional Autonoma de Mexico, Juriquilla,* ***4.*** *Xi'an Jiaotong University*

Speleothem oxygen-isotope ($\delta^{18}O$) records from tropical and sub-tropical regions have been widely applied as proxy of regionally-integrated rainfall and monsoon strength variations, providing key insights on the processes controlling low-latitude paleoclimate dynamics . For instance, speleothem $\delta^{18}O$ paleo-monsoon records from East and Southeast Asia, as well as North and South America indicate a strong link between changes in orbital insolation and regional hydroclimate, suggesting that moisture availability and rainfall regimes are highly sensitive to insolation associated with Earth's precession cycles. However, some tropical monsoon regions, such as Central America document hydroclimate records that differ from the canonical orbital paradigm, implying that complex dynamics linked to ocean-atmosphere interactions and sea surface temperatures exert a more dominant control. Here, we present a replicated new, 130 kyr-long U/Th-dated speleothem $\delta^{18}O$ record from Guatemala, and discuss the relationship between orbital forcing, ocean-atmosphere thermodynamics, and hydroclimate response of the Central American Monsoon (CAM) during the last glacial cycle. Our data differ substantially from the gradual orbital summer insolation curve at 15°N and instead show abrupt wet-to-dry transitions partially coincident with autumn insolation minima, including monsoon weakening during MIS 5b and 5d, coeval to periods of autumn insolation minima, lower greenhouse gases concentrations, and tropical Atlantic surface temperatures (SSTs) below 27.5 °C. These dry intervals coincide with some of the Northern Hemisphere cold events known as Heinrich and Greenland Stadials. Contrarily, negative $\delta^{18}O$ excursions (stronger monsoon regimes) are documented during interglacial insolation maxima, and are synchronous to intervals where greenhouse gases were higher and tropical SSTs above 27.5 °C. In addition, no clear Dansgaard-Oeschger cycles are identified in our new record during the MIS 3 and 2, suggesting that regional hydroclimate in our study area is not strictly linked to the millennial-scale variations of the Intertropical Convergence Zone position, despite our close vicinity to the tropical North Atlantic. We conclude that CAM convective systems respond to temperature thresholds modulated by atmospheric heating and ocean-atmosphere-land interactions that can cause abrupt monsoon collapses independently of the background climate state.

Subglacial speleothems: a promising emerging archive in paleoclimate science

Prof. Christoph Spotl [1]

1. Department of Geology, University of Innsbruck, Austria

Speleothems from cold high-latitude or high-elevation caves are very sensitive paleoenvironmental archives because they form close to the freezing point of water, and Arctic or Alpine soils – the source of carbon dioxide for karstification – are thin and vulnerable. Therefore, it is widely assumed that cooling of the climate will cause an interruption in the growth of these speleothems. However, this ignores the fact that atmospheric cooling leads to a lowering of the equilibrium-line altitude and expansion of glaciers. A temperate glacier overflowing a karst system prevents the latter from freezing. Although glacials were generally less humid than interglacials, caves in mountain regions, for example, had a much higher chance of being covered by glaciers (and thus kept "warm") during cold climatic periods than caves at lower elevations, which were often in the permafrost zone. These periods without frost in caves that were covered by temperate glacier ice can be recorded by speleothems if the host rock contains disseminated pyrite, a microscopic sulfide mineral that is widely distributed in impure limestones, dolostones and marbles. Recent and ongoing research in caves of the Eastern and Western Alps in Europe has shown that speleothems from such subglacial environments are widespread and provide unprecedented opportunities to obtain records of environmental change covering the long glacial periods. When combined with the study of conventional warm-climate speleothems controlled by soil dynamics and locally present cryogenic cave carbonates (as robust indicators of the presence of paleo-cave ice accumulations), the possibility opens up to exploit the full paleoclimate potential of Arctic and Alpine caves on glacial-interglacial time scales.

Session 120: Volcanic impacts on climate and society

High resolution sulfur isotopes from ice cores: improved estimates of the volcanic forcing of climate

Dr. Andrea Burke [1]***, Ms. Helen Innes*** [1]***, Ms. Laura Crick*** [2]***, Prof. Kevin Anchukaitis*** [3]***, Dr. William Hutchison*** [2]***, Prof. Joe McConnell*** [4]***, Prof. Michael Sigl*** [5]***, Prof. Rob Wilson*** [2]

The record of the volcanic forcing of climate over the past 2500 years is reconstructed primarily from sulfate concentrations in ice cores. Of particular interest are stratospheric eruptions, as these afford sulfate aerosols the longest residence time and largest dispersion in the atmosphere, and thus the greatest impact on radiative forcing. Sulfur isotopes can be used to distinguish between stratospheric and tropospheric volcanic sulfate in ice cores since stratospheric sulfur aerosols are exposed to UV radiation which imparts a mass independent fractionation. Thus, sulfur isotopes in ice cores provide a means to identify stratospheric eruptions and calculate the proportion of sulfate deposited from a volcanic event that came the stratosphere, allowing us to refine the historic record of explosive volcanism and its forcing of climate. Here we present high-resolution (sub-annual) sulfur isotope data from both Greenland and Antarctica across a suite of unidentified eruptions from the anomalously cold decades of the 530s, 1450s and 1600s, as well as the newly identified eruption of Okmok in 43 BC, to investigate the climate forcing potential of these eruptions.

The Youngest Toba Tuff (YTT) supereruption (74,000 years ago) and its effects on the Indian Monsoon

The global environmental impact of the YTT supereruption ~74 ka remains unclear, ranging from having negligible climatic effects to shaping the evolution of modern humans. Climate models and terrestrial proxy records suggest a significant cooling of the Asian landmass after the YTT supereruption that might have affected regional climate such as the Indian monsoon system. However, the immediate effect of the eruption on the Indian monsoon system has not been indisputably demonstrated in proxy records such as marine sediments. Here, we present a nearly annually resolved phytoplankton-based primary productivity (PP) record from laminated sediments in the northeastern Arabian Sea that shows a ~65% increase in PP for about 10–20 years directly after the eruption. This PP increase is best explained by elevated nutrients in surface waters caused by a deepening of the ocean mixed layer due to strengthened northeasterly Indian winter monsoon winds. Stronger Indian winter monsoon winds might have been the result of an increased north-south air pressure gradient caused by cooling of the Asian landmass right after the YTT supereruption. This interpretation is independently supported by previous modeling studies and demonstrates strong evidence for an Indian monsoon response to the YTT supereruption, potentially impacting also the northwestern Indian Ocean. Intensified northeasterly winds must have decreased the PP in the upwelling region off Somalia, similar to modern observations during winter. Consequently, the marine food supply of early humans in that region might have been significantly reduced after the YTT—a factor that potentially contributed to the timing of the postulated early human migration window during this time.

Regional monsoon sensitivity to Pinatubo-like volcanic eruptions of different sulfur emission strengths

Dr. Roberta D'Agostino [1] ***, Prof. Claudia Timmreck*** [2]

1. *National Council of Research, Institute of Atmospheric Sciences and Climate,* ***2.*** *Max Planck Institut für Meteorologie, Hamburg*

The impact of volcanic forcing on tropical precipitation is investigated in a new set of sensitivity experiments within the Max Planck Institute Grand Ensemble framework. Five ensembles are created, each containing 100 realizations for an idealized 'Pinatubo-like' equatorial volcanic eruption with emissions covering a range of 2.5-40 Tg sulfur (S). The ensembles provide an excellent database to disentangle the influence of volcanic forcing on monsoons and tropical hydroclimate over the wide spectrum of the climate's internal variability. Monsoons are generally weaker for two years after volcanic eruption and their weakening is a function of emissions. However, only a stronger than Pinatubo-like eruption (~10 Tg S) leads to significant and substantial monsoon changes, and some regions (such as North and South Africa, South America and South Asia) are much more sensitive to this kind of forcing than the others. The decreased monsoon precipitation is strongly tied to the weakening of the regional tropical overturning. The reduced atmospheric net energy input and increased gross moist stability at the Hadley circulation updraft due to the equatorial volcanic eruption, require a slowdown of the circulation as a consequence of less moist static energy exported away from the intertropical convergence zone.

Constraining the climatic impacts and season of occurence of the Mazama Ash: insights from laminated marine sediments from the NE Pacific

Prof. Helen Roe [1]***, Dr. Karen Logan*** [2]***, Prof. Tim Patterson*** [3]

1. *Geography, School of Natural and Built Environment, Queen's University Belfast, Belfast, UK,* ***2.*** *Queen's University Belfast,* ***3.*** *Department of Earth Sciences, Carleton University*

Tephra deposits from the cataclysmic eruption of Mt Mazama, Oregon at ca. 6,730 ^{14}C yr BP have been widely reported in sediment records from the western United States and southwestern Canada, and the ash layer represents one of the most important stratigraphic markers for the mid-Holocene in western North America. In spite of a substantial literature on the ash, there remain uncertainties about the character and distribution of the tephra fall-out and the climatic impacts of the ash. In this paper we present the results of a very high-resolution study of a diatomaceous marine sediment core (MD02-2494) from Effingham Inlet, SW Vancouver Island, British Columbia, spanning the interval of the ash. The sediments were deposited under anoxic conditions, are well laminated and preserve a seasonal to sub-seasonal record of primary productivity change, permitting clear delineation of the season of tephra deposition. Scanning Electron Micrographs reveal that the lower boundary of the ash is sharp, suggesting sudden inundation and highlighting a lack of bioturbation and sediment reworking. The ash was deposited as a discrete unit, with little interspersed within it except for some *Chaetoceros affinis* resting spores and *Chaetoceros* vegetative cells. This indicates that the ash was deposited en masse rather than gradually or in stages. The volume of ash in the core suggests that the ash likely restricted light availability in the water column and temporarily suppressed primary productivity until it descended through the photic zone. Thin section analysis of diatomaceous sediments spanning a ca. 30 year interval around the ash further confirm that prior to the ash-fall, climate was characterized by warm, dry conditions with significant autumn productivity. However, increased precipitation and enhanced pelagic intrusion into the inlet are inferred around the time of the ash fall, possibly as a result of storm activity associated with high volumes of ash in the atmosphere. These conditions were sustained beyond the impact of the eruption. The presence of the Mazama ash in Effingham Inlet has redefined the known boundaries of the ash-fall in the NE Pacific region, which has not previously been documented this far northwest of the source.

Volcanic glass from the 1.8 ka Taupō eruption, New Zealand, in Antarctic ice: implications for eruption timing, impact assessments and ice core chronologies

Mr. Stephen Piva [1], *Dr. Simon Barker* [1], *Dr. Nels Iverson* [2], *Dr. V Holly L Winton* [3], *Prof. Colin Wilson* [1], *Prof. Rewi Newnham* [1], *Prof. Lionel Carter* [3], *Dr. Bruce Charlier* [1], *Dr. Nancy Bertler* [3], *Prof. Nelia Dunbar* [2], *Dr. Michael Sigl* [4]

1. School of Geography, Environment and Earth Sciences, Victoria University of Wellington, 2. New Mexico Bureau of Geology & Mineral Resources, 3. Antarctic Research Centre, Victoria University of Wellington, 4. Climate and Environmental Physics, Physics Institute and Oeschger Centre for Climate Change Research, University of Bern, Switzerland

Geochemical analyses of microscopic volcanic glass shards (5–30 µm long) extracted between 278.822 to 278.866 m depth from an interval of the Roosevelt Island ice core (RICE), eastern Ross Sea, Antarctica, associated with increased non‐sea‐salt conductivity and insoluble particle count measurements at 230 ± 32 CE indicate that two chemically distinct populations of trachytic and rhyolitic glass are present and derived from explosive eruptions of Mt. Melbourne, Northern Victoria Land, Antarctica and Taupō volcano, New Zealand, respectively. Unpolished scanning electron microscopy analysis using energy dispersive spectrometry (SEM‐EDS) and polished electron microprobe analysis using wavelength dispersive spectrometry (EMPA‐WDS) were conducted due to the low number and small size of analysable particles. Recognition of tephric material from the independently‐dated 232 ± 10 CE Taupō eruption for the first time in Antarctica provides valuable links to mid‐latitude terrestrial and marine palaeoenvironmental and palaeoclimatic records in widely different geographic areas and depositional environments. These links can aid reconstructions of volcanic impacts on climate, offer insights into the ash cloud extent, dispersal and long‐distance transport of tephra in the Southern Hemisphere, and will help to correlate between and constrain the age of existing ice core and blue ice chronologies in Antarctica.

The Possible Climatic and Societal Impacts of Volcanic Eruptions in the Former Han Dynasty (202 BC- 8 AD)

Dr. Zhen Yang [1]

1. Trinity College Dublin

The climate history of China is well-documented, and the sufficient written records allow scholars from multiple disciplines to reconstruct the climatic characteristics of different times. The Former Han dynasty (202 BC- 8 AD) experienced several periods of climatic anomalies, and the society was profoundly influenced by the perceptions of environmental changes, especially philosopher Dong Zhongshu's "ominous politics". This presentation selects two historical periods, 180-150 BC and 60-30 BC, in order to explore the climatic stresses and atmospheric optical anomalies that were possibly related to volcanic activities, as well as how society was impacted and responded to such consecutive natural disasters in these periods. It examines the possible association between these climatic anomalies and volcanic eruptions by comparing evidence from historical sources to natural archives. For example, in 43 BC, when the Okmok volcano in Alaska erupted, the pale sun and cold summer were recorded in China, and the Empire suffered continuous floods, famines and plagues since the 40BCs. Similar climatic phenomena also happened in the 160BCs, in which, three large volcanic eruptions were documented by evidence from natural proxies, such as ice-cores. Furthermore, while most scholars employ quantitative methods to portray climatic and societal changes over a long span of time, the selection of the decade before, during and after climatic anomalies allows detailed assessments of the reliability of each written historical record. This research aims to evaluate the climatic and societal stresses by categorizing and quantifying relevant historical data. It will reconstruct how the Former Han society was impacted and gradually restored societal, economic and political stability. Building on this, a comparative analysis of the two historical periods will be conducted. The period 60-30BC inherited the political legacy from the period 180- 150 BC, but significant changes took place in various aspects, such as state governing and the understanding of natural disasters. Thus, by comparing the societal responses to calamities of these two periods, we can examine whether such changes were effective in terms of disaster prevention and mitigation, thereby identifying factors that may contribute to better resilience to drastic environmental changes.

Reconsidering the Egyptian ‘Famine Stela’ in light of volcanically-induced climate forcing in the 160s BCE

Dr. Selga Medenieks [1]

1. *Trinity College Dublin*

The inscription of the so-called ‘Famine Stela’, carved into rock on Sehel Island in Egypt, describes a time when the Nile River failed to flood for seven years, leaving its banks unfertilised and barren, and afflicting the people with a catastrophic famine. Although presented as a monument left by an ancient king, the text was carved in the Ptolemaic period and is usually attributed to the reign of Ptolemy V Epiphanes (r. 205-180 BCE). However, an alternative possibility is that the stela dates to his successor Ptolemy VI Philometor (r. 180-145 BCE) and should be reconsidered in the light of an entirely different set of circumstances. Recent refinements to the dating of volcanic eruptions in antiquity and new research on their climate forcing effects, particularly on Nile flood suppression and disruption to rainfall patterns, identifies an extended period of environmental instability in the 160s BCE. It is argued that the circumstances of this decade, in which a trio of significant volcanic events precipitated low temperatures, unseasonal rainfall, poor Nile flooding and repeated crop failures, catalysed a prolonged food crisis – and that this time provides a more likely context than earlier, demonstrably less volatile periods, for the preoccupations of the authors of the Famine Stela. That text may now be reassessed as a response to the famine that afflicted the First Cataract of the Nile in the mid-second century BCE.

Climatic and societal impacts in Scandinavia following the 536/540 CE volcanic double event

Prof. Kirstin Krueger [1], ***Ms. Evelien van Dijk*** [2], ***Dr. Ingar Mørkestøl Gundersen*** [3], ***Ms. Anna deBode*** [4], ***Mr. Helge Høeg*** [5], ***Prof. Kjetil Loftsgarden*** [3], ***Dr. Johann Jungclaus*** [6], ***Prof. Claudia Timmreck*** [7], ***Dr. Manon Bajard*** [2], ***Prof. Jostein Bakke*** [4], ***Mr. Eirik Ballo*** [2], ***Dr. Sanne Boessenkool*** [8], ***Prof. Anne Hope Jahren*** [9], ***Prof. Henrik Svensen*** [9], ***Dr. Annike ter Schure*** [8], ***Prof. Frode Iversen*** [3]

1. *Department of Geosciences, University of Oslo,* ***2.*** *Department of Geosciences, University of Oslo, Oslo,* ***3.*** *Museum of Cultural History, University of Oslo, Oslo,* ***4.*** *Department of Geography, University of Bergen, Bergen,* ***5.*** *Cultural Historical Museum, University of Oslo, Oslo,* ***6.*** *Max-Planck-Institut für Meteorologie, Hamburg,* ***7.*** *Max‐Planck-Institut für Meteorologie, Hamburg,* ***8.*** *Centre for Ecological and Evolutionary Synthesis (CEES), Department of Biosciences, University of Oslo, Oslo,* ***9.*** *Center of Earth Evolution and Dynamics (CEED), Department of Geosciences, University of Oslo, Oslo*

In the Northern Hemisphere, the mid-6th century was one of the coldest periods of the last 2000 years, which was initiated by volcanic eruptions in 536 CE and 540 CE. Here, we study the effect of this volcanic double event on the climate and society in Scandinavia with a special focus on Southern Norway. Running an ensemble of Max Planck Institute ESM transient simulations for 521-680 CE based on the PMIP4 past2k set-up, temperature, precipitation and atmospheric circulation patterns are analysed. The simulated cooling magnitude is used as input for a growing degree-day (GDD) model for different study areas in Southern Norway, representative of typical meteorological and landscape conditions. Pollen from lake sediments and peat bogs inside these study areas are analysed at high resolution (1-3 cm sample intervals) to give insights into the validity of the GDD model set-up with regard to the volcanic climate impact on the regional scale, and to link the different data sets with the archaeology records. We find that after the 536/540 CE double event, a maximum surface air cooling of up to 3.5 °C during the mean growing season is simulated locally for Southern Norway. With a worst-case regionally averaged scenario cooling of 3 °C, the GDD model indicates crop failures in our northernmost and western study areas, while crops were more likely to mature in the southeastern study area. These results are in agreement with the pollen records from the respective areas. Archaeological excavations show, however, a more complex pattern for these areas with abandonment of farms, severe social impact but also a continuation of occupation or a mix of those. Finally, we discuss the likely climatic and societal impacts of the 536/540 CE volcanic double event by synthesising our new and available data sets for whole Scandinavia.

Session 121: The anthropology of climate change

Modelling human responses to past climate change

Prof. Axel Timmermann [1], *Dr. Jiaoyang Ruan* [1], *Dr. Ali R. Vahdati* [2]

1. IBS Center for Climate Physics, Pusan National University, 2. University of Zurich

In this presentation I will provide an overview of the main numerical modelling methods used to simulate human responses to past climate change. These include:

1) eco-geographic species distribution models, which link archaeological and anthropological data of human remains with paleo-climatic information to derive patio-temporal estimates of habitat suitability.

2) density-based models to describe human dispersal and multi-species interactions. Such models are usually based on reaction-diffusion partial differential equations equations, with empirically constrained demographic and dispersal parameters and are used to study human migration and competition with other groups.

3) Agent-based models, which capture the dynamics of individuals in a time-varying climatic environment through specific rules. These models have the advantage that cultural and genetic factors can be explicitly included and simulated.

For each of these methods, I will introduce one realistic example to highlight their capability in informing us on species interactions, origins and speciation events and to demonstrate their overall advantages and disadvantages. The presentation concludes with a discussion on how these methods can be combined to obtain more realistic estimates of predator-prey relationships and of carrying capacity.

Effects of glacial climate on hominin habitat overlap and gene flow

Dr. Jiaoyang Ruan [1], *Prof. Axel Timmerman* [1], *Prof. Pasquale Raia* [2], *Dr. Kyung-Sook Yun* [1], *Ms. Elke Zeller* [1], *Prof. Alessandro Mondanaro* [3], *Dr. Mirko Di Febbraro* [2], *Dr. Danielle Lemmon* [1], *Dr. Silvia Castiglione* [2], *Dr. Marina Melchionna* [2]

Archaic human admixture has played a critical role in shaping the genomic ancestry of modern humans, leaving a legacy even in our present-day population. When, where, and how often hominin interbreeding happened, nevertheless, is largely unknown. In this study, we combined extensive fossil, archaeological, and genetic data with transient Pleistocene climate and biome simulations to determine how orbital-scale climate shifts affected the level of introgression between Denisovans and Neanderthals. Specifically, we developed and applied two species distribution models to predict the habitat suitability for Denisovans and Neanderthals at every location and time during the past 400,000 years, as well as the level of habitat encroachment - a proxy for population/genetic introgression. Our analyses revealed that glacial/interglacial changes in atmospheric CO2 concentrations caused large-scale shifts in temperature and vegetation across Eurasia, which controlled where and when these two hominin groups lived, overlapped, and interbred. Finally, we will show our most recent findings from a density-based dispersal/interaction model, which can quantitively simulate the spatiotemporal change of the two-hominin admixture during last 2 glacial cycles.

And yet, they had to start somewhere. A new method to find the area of origin of past Homo species

1. *DISTAR, Universita di Napoli Federico II,* ***2.*** *Depeartment of Earth Sciences, University of Florence,* ***3.*** *IBS Center for Climate Physics, Pusan National University*

The area of origin (AOO) of past *Homo* species is a hotly debated, yet poorly resolved issue in paleoanthropology. Aside from naming issues, sister species relationships between pairs of lineages are well-established (e.g. *Homo heidelbergensis* and *Homo sapiens* in Africa, *Homo neanderthalensis* and Denisovans in Eurasia). Yet, the AOO of these species pairs is obscure, and the environmental conditions that set apart the two species in the pair are little investigated (but see Raia *et al.* 2020; Timmermann *et al.* 2022). We developed a new method, named *RRphylogeography*, that takes advantage of species distribution modeling, and from phylogenetic reconstructions of trait evolution to estimate the best-suited, most probable AOO for any species pairs. Applied to the record of *Homo*, *RRphylogeography* suggests a Central European origin for the split between Denisovans and Neanderthals. Although surprising, this AOO is consistent with the extra-African distribution of *Homo heidelbergensis*, which should have been ancestral to the pair. The split between *H. heidelbergensis* and us is not unambiguous. Three areas, East Africa, South Africa and the Western Maghreb are suitable AOOs for *H. sapiens,* supporting the idea of a geographically structured archaic metapopulation (Scerri et al. 2019). How much each region contributed to the speciation process into *Homo sapiens* and whether the transition from archaic to modern traits emerged in one or in different regions, sequentially or in parallel (Meneganzin *et al.* 2022) remains elusive.

A comparative study of climate resilience in Neanderthals and H. sapiens

Prof. Ariane Burke [1]***, Prof. Julien Riel-Salvatore*** [1]***, Mr. Simon Paquin*** [1]***, Mr. Benjamin Albouy*** [1]

1. *Université de Montréal*

The permanent settlement of Western Eurasia by *Homo sapiens* during the Late Pleistocene coincides with the gradual decline and eventual disappearance of the Neanderthals. Whether the Neanderthals were driven to extinction by unstable climate conditions, competitive exclusion, or a combination of the two has been hotly debated since the last century. Our understanding of the process of population replacement in Europe has been revolutionized by new archaeological discoveries, improved chronology, advances in paleogenetics, climate reconstruction and climate modelling. It is now generally accepted that Neanderthals and *H. sapiens* co-existed in Eurasia for several thousand years, interbred successfully, possessed similar cognitive abilities, demonstrated complex social skills and adapted to climate change through technological and social innovation. Why then did Neanderthals become extinct? The co-existence of Neanderthals and *H. sapiens* in Europe during MIS 3 provides a unique opportunity to compare the resilience of two recent hominin species in a context of rapid climate change in an attempt to answer this question.

Winter driven seasonality changes during Dansgaard-Oeschger cycles: potential impact on human populations in Western Europe during MIS 3

Marine isotope stage 3 (MIS 3) (~60-30 ka) exhibited large-amplitude millennial climatic oscillations that were particularly pronounced in the North Atlantic region. Referred to as the Dansgaard-Oeschger (D-O) cycles, these alternations of warm (GI – Greenland Interstadials) and cold phases (GS – Greenland Stadials) likely impacted human populations of Western Europe by modifying the distribution of resources upon which they depended. To understand this impact, we explored the nature of the D-O cycle climate signal in Western Europe using 18 pollen records that enabled the reconstruction of the vegetation and key climatic parameters such as seasonal temperatures and precipitation. Our results show a clear response of the vegetation to the climate changes associated with D-O cycles, with arboreal vegetation during warm phases and non-arboreal vegetation during cold phases. More importantly, our results demonstrate that the vegetation changes were mainly driven by shifts in winter temperatures and precipitation, with lower temperatures and precipitation during GS and vice versa, whereas summer conditions remained relatively stable throughout MIS 3. It has been demonstrated that during the LGM seasonal variability influenced long-term patterns of human habitat suitability. Our results suggest that the D-O cycles over Western Europe were mostly a winter phenomenon, likely related to the atmospheric circulation over the North Atlantic. Here we test the hypothesis that stronger seasonality during GSs altered the seasonal distribution of suitable habitat, forcing human populations to modify their spatial distribution, which ultimately influenced demographic patterns.

Changes in Climate extremes in Zambia during Green and Dry Sahara periods and their potential impacts on hominid dispersal

Mr. Roberto Ingrosso [1]***, Prof. Francesco SR Pausata*** [1]***, Mr. Dominic Alain*** [1]***, Dr. Katja Winger*** [2]***, Prof. Michelle Drapeau*** [3]***, Prof. Ariane Burke*** [3]

1. *Geotop-Université du Québec à Montréal, Montréal, Canada,* ***2.*** *Université du Québec à Montréal, Montréal, Canada,* ***3.*** *Université de Montréal*

Africa experienced orbitally forced climate cycles throughout the Pleistocene, when the African humid periods, or "Green Sahara" periods, alternated with dry periods. These climate cycles are thought to have influenced patterns of human dispersal on a continental scale. In this study, we use a regional climate model to simulate archetypal Green and Dry Sahara periods under high and low boreal summer insolation to investigate changes in climate variability and extremes with a focus on Central Africa. Our results suggest that Zambia provided better environmental conditions for hominin populations during the Dry Sahara periods than the Central African Plateau (CAP). On the other hand, the Green Sahara periods were relatively drier and hotter than the Dry Sahara periods over the Zambian region with an increase in the length of droughts and an intensification of temperature extremes. At this time, river valleys would have provided a refuge from arid conditions, channelling hominin dispersals into the CAP and northward into the Sahel and the Sahara.

Synthesizing climate model and proxy data with a spatio-temporal Gaussian Process

Dr. Christian Sommer [1], Dr. Seth D. Axen [2], Dr. Alexandra Gessner [2], Dr. Nils Weitzel [3], Dr. Álvaro Tejero-Cantero [2]

__1.__ The Role of Culture in Early Expansions of Humans (ROCEEH), Heidelberg Academy of Sciences and Humanities, University of Tübingen, Germany, __2.__ Cluster of Excellence Machine Learning, University of Tübingen, Germany, __3.__ University of Tübingen

A growing number of spatial and temporal high-resolution climate modelling products with regional and global coverage have fuelled the use of paleoclimatic data in all disciplines studying the Quaternary. Anthropologists examine hominin dispersal, demography or extinction with Species Distribution Models, archaeologists study cultural change in the light of climate, and geomorphologists feed Landscape Evolution Models with climate data. However, the choice of an appropriate product is not always made based on an objective assessment of different candidates, but rather based on availability through data portals, compatibility with research software, publication bias and researchers' subjective preferences. We present a method that combines a large number of published paleoclimate simulations, existing gridded reconstructions and proxy data to infer a consensus model and make the uncertainty of different data sources transparent.

Our setup for the timeframe between 21 ka and 6 ka BP in Europe reuses published data from 12 climate simulation snapshots of the Last Glacial Maximum (LGM) and the Mid-Holocene (MH), two continuous datasets with 1,000 year resolution that statistically combine simulations and non-European proxies, and a large compilation of pollen-based climate reconstructions for Europe. Climate-field reconstructions (CFRs) combine these datasets into a statistical spatial or spatiotemporal model. To date, there exists no consensus paleoclimate model that is continuous in space and time, produces predictions with uncertainty, and can include data from various sources. Our Gaussian process (GP) model has these desired properties; however, GPs scale unfavorably with data of the magnitude typical for building CFRs. We build on recent advances in sparse spatiotemporal GPs that reduce the computational burden by combining variational methods based on inducing variables with the state-space formulation of GPs. We successfully employ such a doubly sparse GP to construct a probabilistic model of European paleoclimate from the LGM to the MH that synthesizes paleoclimate simulations and pollen data.

In the future, we aim to extend this method to global coverage and longer time-periods. Our product is targeted at researchers from diverse fields, who (a) request consensus paleoclimate estimates for certain points in space and time that (b) make the degree of agreement between various sources transparent.

Session 123: Advances in tectonic geomorphology, paleoseismology, and multi-disciplinary active fault studies

Timescales of intraplate surface rupture preservation from modeling and the landscape record

Dr. Jessica Thompson Jobe [1], ***Dr. Nadine Reitman*** [1]

1. *Geological Hazards Science Center, U.S. Geological Survey, Golden, Colorado 80401, USA.*

Large surface-rupturing continental intraplate earthquakes are uncommon globally and are thought to have recurrence intervals of thousands to hundreds of thousands of years based on the paleoseismic and geomorphic record. However, the preservation of surface ruptures is impacted by several variables, such as climate, depth and/or magnitude of the earthquake, frequency of surface-rupturing events, anthropogenic modification, and pre-existing topography or geomorphology, resulting in biased or inaccurate estimates of recurrence intervals and hazard from the landscape record alone. In this study, we take a two-pronged approach to better understand how surface ruptures of primarily dip-slip events may be preserved in intraplate settings. First, we use a two-dimensional (2D) scarp diffusion model for typical intraplate settings and explore different parameters influencing the creation and erosion of surface-rupturing features. These parameters include the initial magnitude of surface rupture vertical offset (likely related to the depth and magnitude of faulting), climate (using diffusion rate as a proxy for precipitation), and recurrence interval of similar magnitude events. Second, we compile and evaluate historical and paleoseismic evidence of surface ruptures in intraplate settings in a variety of climates, such as the Central and Eastern United States, Australia, Europe, Central Asia (Mongolia, China), India, and West Africa, to compare with the diffusion modeling results. The historical and prehistoric earthquakes in these regions have different fault kinematics and earthquake depths and magnitudes, allowing for a spread of examples to compare the influence of different parameters in the diffusion modeling. This study highlights the variable degrees of preservation in different intraplate settings and the implications for interpreting the seismic hazard of a region based on the limited geomorphic record.

Long- and short-term surface deformation and seismotectonic framework of the Mw 7.7 2001 Bhuj earthquake epicentral area (Gujarat, NW India)

Dr. Pierfrancesco Burrato [1], *Dr. Nicolò Parrino* [2], *Mr. Eshaan Srivastava* [3], *Dr. Antonino Maltese* [4], *Prof. Javed Malik* [3], *Prof. Luigi Ferranti* [5], *Dr. Maurizio Gasparo Morticelli* [6], *Prof. Attilio Sulli* [6]

1. Istituto Nazionale di Geofisica e Vulcanologia, Rome (Italy), 2. Dipartimento di Scienze della Terra e del Mare, Università di Palermo, Italy, 3. Department of Earth Sciences, Indian Institute of Technology Kanpur, 4. Dipartimento di Ingegneria, Università degli Studi di Palermo, 5. Dipartimento di Scienze della Terra, dell'Ambiente e delle Risorse, Università di Napoli "Federico II", 6. Dipartimento di Scienze della Terra e del Mare, Università degli Studi di Palermo

The Mw 7.7 (source USGS), 26 January 2001 Bhuj earthquake (23.4 ° N, 70.3 ° E) was the largest intraplate earthquake occurred in the current century and, in spite of its magnitude, was characterized by the lack of clear evidence of primary surface faulting. Based on the seismological record, the event occurred along a roughly east-west reverse fault in the Kachchh region of NW India, a low strain rate pericratonic rift basin hit by large earthquakes having long recurrence time (e.g., the Mw 7.8, 1818 Allah Bund and the Mw 6.1, 1956 Anjar earthquakes), where the climatic and tectonic forcings rival in controlling the landscape evolution. However, the long-term prevalence of the tectonic forcing is testified by occurrence of fault-bounded high topography areas, such as the Kachchh, Wagad and Island Belt uplands, surrounded by the near flat topography of the Banni plain salt marsh, part of the Great Rann of Kutch.

The 2001 seismic event was widely studied in the past two decades using SAR, remote sensing, post-seismic field surveys and paleoseismological investigations, however the seismogenic sources and the seismotectonic framework of the area are not firmly established. Indeed, due to their poor morphological signature and the few subsurface geophysical data available, the geometrical and kinematic parameters of many of the active structures recognized in the field are still controversial.

To provide new constraints to the seismotectonic characterization of the area, following a critical review of the literature, we propose a multidisciplinary approach to investigate both the long-term and the short-term surface deformation induced by the active faults, including the 2001 seismogenic source, that force the evolution of the landscape.

We studied the long-term deformation (from Kyr to a few Ma) through morphometric analysis of the main drainage patterns and relief distribution. In addition, we investigated the short-term deformation (from years to two decades) through InSar analyses.

We present a proposal of location and geometrical and kinematic characterization of the active faults driving the recent geological evolution, thus improving the understanding of the seismotectonic framework of an area that hosted one of the deadliest intraplate earthquakes ever recorded.

The Børglum fault, Sorgenfrei-Tornquist Zone, northern Denmark: a multi-method approach reveals fault kinematics, timing of fault activity and paleo-earthquake magnitude

Faults in low-strain intraplate areas can be the source of unexpected and fatal earthquakes, because of the long intervals between individual seismic events and the fact that such faults are often covered by young sediment, which makes fault detection difficult. We present a multi-method approach based on outcrop analyses, shear-wave seismic reflection surveys, DEM analyses and numerical simulations that focuses on the Børglum fault in northern Denmark, which represents one of the northern boundary faults of the Sorgenfrei-Tornquist Zone. Previous studies showed evidence that the Børglum fault is seismically active and with a length of at least 250 km, it is capable to produce significant seismic events. This fuelled the demand for further analyses of the fault structure and its seismic hazard potential. Two shear-wave reflection seismic surveys were acquired to image the near-surface structure in the vicinity of the Børglum fault. The seismic surveys indicate that the Børglum fault is not an isolated fault, but most likely represents a complex fault system with a strike-slip component. Positive flower structures on the seismic surveys, the presence of elongated mini-basins and the geometry of the drainage pattern in the study area support a strike-slip interpretation. The seismic surveys indicate that faults in the study area were probably active at the end of the Saalian glaciation (MIS 6). Furthermore, soft-sediment deformation structures and disaggregation bands developed in Late Pleniglacial to Lateglacial sediments point to repeated phases of fault activity with earthquakes magnitudes of up to M=7. The reflector pattern on one of the seismic surveys indicates that a major fault of the Børglum fault system in the study area nearly reaches the Earth's surface. A step in the topography above the fault probably represents a fault-scarp. Together with the geometry of the drainage pattern, this implies a close relationship between fault activity and topography in this region. The timing of fault activity and numerical simulations of deglaciation-related lithospheric stress build-up indicate that the Børglum fault is a glacially triggered fault and that this part of the Sorgenfrei-Tornquist Zone can be interpreted as susceptible to glacially triggered fault reactivation.

Neotectonics and fault segmentation of the Ulsan fault and Yeonil tectonic line, SE Korea

Mr. Kiwoong Park [1]***, Dr. Sambit Prasanajit Naik*** [2]***, Mr. Ohsang Gwon*** [1]***, Mr. Hyeon-Cho Shin*** [1]***, Prof. Young-Seog Kim*** [1]

The Korean Peninsula which is located far from the plate boundary has been regarded as a relatively stable region compared with the plate boundary in terms of earthquakes. However, the recent two moderate earthquakes (the 2016 M_w 5.5 Gyeongju earthquake, and the 2017 M_w 5.4 Pohang earthquake) that occurred on the Korean Peninsula have triggered a change in the national perception of earthquakes. Since these earthquakes occurred adjacent Yangsan and Ulsan faults located in the southeastern part of the Korean Peninsula, the demand for paleoseismological research on these faults has increased.

The Ulsan fault zone is NNW-SSE trending reverse dominant fault with a length of approximately 60 km from Ulsan to Gyeongju city in the southeast Korean Peninsula. The Ulsan fault zone was presumed based on the clearly recognized fault valley on the map, geomorphological characteristics related to the uplift of the eastern mountain range, and geophysical survey. However, direct evidence of the Quaternary reactivation of the Ulsan fault through surface geological surveys is insufficient due to the thick sediment layers which covered the urbanized area. Meanwhile, several active faults have been reported along the Yeonil Tectonic line which is located approximately 4-5 km east of the Ulsan fault. It is necessary to understand uniform faults through fault segmentation as well as geometric-kinematic correlations to interpret the spatio-temporal history of a series of fault systems. In this study, we consider not only the geometric segmentation but also the paleoseismic parameters (slip rate, recurrence interval, etc.) along the Ulsan fault zone. Furthermore, a more systematic fault segmentation is attempted through the quantification of each component by reflecting all of the kinematic fault behavior, structural characteristics, and especially geomorphological characteristics of the mountain front range.

An automatic approach to estimate earthquake chronologies from paleoseismic fault records

Dr. Octavi Gómez-Novell [1], ***Prof. Bruno Pace*** [1], ***Dr. Francesco Visini*** [2]

Earthquake occurrence estimates along active faults are crucial for fault-based seismic hazard assessments. Hence the use of paleoseismic datasets has become increasingly relevant for fault characterization, especially in regions where the catalogues are too short to capture their longer seismic cycles. One of the main challenges in paleoseismic research though is to objectively correlate data from multiple sites along a fault and thus, to establish reliable paleoearthquake chronologies. Several issues including large dating uncertainties, poor stratigraphic resolution/preservation and fault offset variability along strike can cause this. Subsequently, these eventually hinder the detection of paleoearthquakes and increase the uncertainties in their time constraints.

We present a new approach to derive paleoearthquake chronologies in faults by means of multi-site correlation of paleoseismic trench data and statistical modelling for a proper treatment of the uncertainties. The approach seeks to maximize objectivity in the whole procedure and for this reason, it strictly relies on the numerical dates limiting event horizons in trenches as inputs. From these data and using an automatic algorithm, all event occurrences in each site are modelled as probability density functions (PDFs) and then correlated by computing a product curve that represents the overall fault occurrence probability. The peaks in this product curve are extracted as final PDFs and interpreted as the earthquake chronology of the whole fault. In contrast with other approaches, the correlation process is not restricted to individual events. Instead, an event in one site can participate to the correlation with more than one event in another site if their time ranges overlap. This allows to accommodate into the approach the inherent event underdetection problem of paleoseismology, especially when uncertainties in event timing are large. The outputs of the workflow are simple and can be further used as inputs to calculate critical fault parameters (e.g., recurrence times).

The approach we present allows modelling the paleoearthquake history of faults from paleoseismic information, while constraining the uncertainties in event dating. Specifically, the approach can be useful in settings where the large event date uncertainties or number of sites prevent straightforward interpretations.

Geochemical (XRF) evidence of land-level change during the 1700 CE Earthquake at Cascadia using an ITRAX Core Scanner

Dr. Isabel Hong [1], ***Mr. Anthony Giang*** [2], ***Dr. Jessica Pilarczyk*** [2]

Along the Cascadia subduction zone, relative sea-level (RSL) reconstruction studies are critical for understanding coastal flooding risk because Cascadia has not experienced rupture during the instrumental period. Beneath tidal wetlands along Cascadia, coastal subsidence during successive, prehistoric earthquakes is commonly recorded by stratigraphic sequences of sharp (< 1 mm) mud-over-peat contacts. At Cascadia, the application of sedimentological and paleontological proxies to sediment cores with repeated mud-over-peat contacts have permitted the reconstruction of past land-level change during megathrust earthquakes. In this study, we explore how elemental analysis of sediment from tidal wetlands can be used to better understand coastal subsidence during successive, prehistoric Cascadia subduction zone earthquakes.

We apply X-ray fluorescence (XRF) analysis on two sediment cores, located ~ 1 km apart, from the lower and middle Niawiakum River, Willapa Bay, USA. Both cores contain a sharp, mud-over-peat contact which has been inferred to record subsidence during the 1700 CE Earthquake. The sediment cores were analyzed using an ITRAX Core Scanner at 100-μm resolution (30 kV; 55mA) using a molybdenum x-ray tube. Elements were measured in counts per second and normalized to the ratio of Compton to Rayleigh (incoherent/coherent) scattering. XRF measurements show differences in elemental concentrations between the underlying peat and overlying mud concurrent with land-level subsidence and the subsequent deposition of allochthonous marine sediments. In the lower and middle Niawiakum River sediment cores, the underlying peat show lower concentrations of silicon and titanium and higher concentrations of bromine. Across the mud-over-peat contact is a sudden shift to higher concentrations of silicon and titanium and lower concentrations of bromine in the overlying intertidal mud. Our results suggest that RSL reconstruction studies of land-level change caused by prehistoric megathrust earthquakes may be aided by XRF analysis, a rapid analytical technique that allows for higher resolution data points compared to other micropaleonotogical and sedimentological methods (100-μm vs. <1-cm).

High-Resolution seafloor quantitative morphologic analysis to characterise the growth of a transtensional system (North-South fault system, Alboran Sea)

Ms. Ariadna Canari [1], ***Dr. Hector Perea*** [2], ***Dr. Sara Martínez-Loriente*** [1], ***Dr. José Vicente Pérez-Peña*** [3], ***Dr. Léa Pousse-Beltran*** [4], ***Dr. Jaume Llopart*** [1]

A better understanding of fault segment growth and interaction in seismically active regions improves our knowledge to asses the associated hazards. These may be more critical in areas that accommodate relatively slow tectonic deformation since they may enclose active faults capable of producing moderate to large earthquakes, despite the long recurrence intervals between events (10^3 to 10^4 years). An example is the Alboran Sea, a Neogene basin located in the Westernmost Mediterranean Sea that absorbs part of the convergence between the Eurasian and Nubian plates (3 - 5 mm/year). Currently, it is characterised by slow tectonic deformation and low to moderate-magnitude earthquakes. However, large historical and instrumental events have also occurred (i.e., the Almeria 1522 IEMS98 VIII-IX or the Al-Idrissi 2016 Mw 6.4 earthquakes). Our objective is to characterize the seafloor geomorphology produced by the Plio-Quaternary activity of the North-South faults, in order to discuss the system growth and evolution, and the regional kinematics. To this aim, we have analysed the area using different morphologic approaches and an ultra-high-resolution bathymetry dataset (1 meter resolution). Firstly, we have performed different relief visualisation techniques to map the faults' trace. Secondly, we have applied quantitative morphometric methods to estimate the scarp morphological parameters for each fault, with special emphasis on their height. Parallel and perpendicular swath profiles have provided the information to classify the fault scarps in different groups according to their magnitude and to analyse the distribution and relations between the different fault segments. Then, bathymetric profiles across the fault scarps have been used to accurately evaluate the variations on the height of the scarps along the different fault segments. In addition, we plan to improve our faults trace segments analysis by using semi-automated algorithms and neural network models on our dataset. Initial findings reveal several fault scarps striking N-S, resulting in horst and graben systems, as well as large fault segmentation and small accumulated fault displacements. Our results, suggest that the area is in an initial stage of evolution and related to the development of a transtensive left-lateral shear zone.

Construction of a multi-lake palaeosismometer for the Xianshuihe Fault (SE Tibet)

Mountain lakes have been recognized as remarkable archives of seismic events globally. However, quantitative estimates of both palaeointensities and locations have not yet been obtained. Earthquake records in lake sediment depend on external (i.e., earthquake characteristics) and internal (e.g., sedimentation rate, basin geometry) factors. To evaluate paleo-earthquake characteristics, precise calibration of lake sensitivity with documented earthquakes is necessary to disentangle earthquake versus site-related parameters.
We tested this methodology on six small mountain lakes located along the active Xianshuihe fault system, SE Tibetan Plateau. Sediment cores collected in 2021 were dated with short-lived radionuclides and radiocarbon ages. We performed a multiproxy approach, including granulometry, loss-on-ignition, magnetic parameters, continuous XRF core scanning, and discrete quantitative measurements, XRD, and SEM for microfacies analyses. These observations allowed us to identify event deposits and validate their co-seismic origin, thanks to the Chinese seismic catalogs covering the last three centuries. We discuss how magnitude, rupture extent, and epicenter-lake distance control the trigger of event deposits at each site. Considering the calibrated site sensitivity, triangulating between several lakes where events are recorded provides a regional palaeosismometer yielding event's intensity and location.

Using lacustrine paleoshaking evidence to quantitatively determine earthquake source parameters

Dr. Katleen Wils [1]***, Dr. Kris Vanneste*** [2]***, Ms. Morgan Vervoort*** [3]***, Prof. Jasper Moernaut*** [4]***, Prof. Marc DeBatist*** [3]***, Prof. Maarten Van Daele*** [3]

Lacustrine paleoseismology has proven an invaluable tool to adequately reconstruct the seismic shaking history of a particular region, especially along subduction zones where the seismic hazard is multifold. One of the main strengths in such studies lies in the application of a multi-lake approach, in which spatio-temporal correlation of sedimentary shaking evidence allows distinguishing imprints related to large-scale megathrust earthquakes from those caused by locally intense intraplate shaking. Unfortunately, the relationship between local ground motions and earthquake source parameters such as magnitude and rupture location—both of which are crucial for adequate seismic hazard assessments—is usually inferred by considering qualitative rather than quantitative constraints. To overcome this drawback, we developed a methodology based on the principles of probabilistic seismic hazard assessment and ground motion modelling. To explain an observed spatial distribution of sedimentary shaking imprints (or the lack thereof) for a particular paleoearthquake, we infer the minimum and/or maximum shaking intensity that must have been achieved at each location. The probability that an earthquake with a specific magnitude in a certain location produces ground motion levels that fall within the range defined by these minimum and maximum thresholds is then calculated by application of a suitable intensity prediction equation (IPE) or ground motion prediction equation (GMPE). To illustrate these concepts, we present a case study from a ~4400 year old earthquake, identified in the Chilean Andes in the sediments of Lago Castor and Pollux as well as in Aysén Fjord. The methodology has thus been successfully applied to crustal earthquakes, for which fault geometry, morphology and length are well-constrained and rupture variability is limited. In the near future, we aim to apply the same principles to megathrust earthquakes by also taking into account variability in, for example, rupture depth, length, directivity and slip distribution.

Multi-disciplinary approaches in Lake Iznik (NW Turkey): new insights into past large earthquakes.

In Turkey, the North Anatolian Fault (NAF), accommodating the westward movement of Anatolia with respect to Eurasia, is one of the most active faults in the world. A series of earthquakes (M>6.8) have propagated from east to west during the last century. The next rupture seems to be expected in the Marmara region, south of Istanbul. However, the geometry of this fault becomes more complex in this region. It splits into three branches, one of which borders the southern Marmara Sea and Lake Iznik. This median segment of the NAF (MNAF) has very low seismicity today, and low displacements are recorded by GPS, which leads to considering it inactive. However, the city of Iznik, the cradle of Christianity, has preserved valuable historical evidence in contrast to its observations. To better understand the seismic hazard in this area, it is necessary to catalogue the seismic activity and locate past ruptures.

Our work led to identified two active faults after different geophysical and coring campaigns in Lake Iznik. The study of short (<4m) sediment cores sampled on both sides of the E-W fault passing near Iznik city shows that the last rupture, dating from 1065 CE, corresponds to a devastating historical earthquake documented in the archaeological buildings of the city. In addition to this localised rupture, numerous other event deposits are present in the sediments (laterally and temporally). We showed that different types of deposits are sometimes recorded for the same earthquake and that one type of deposition is only observed for the 1065 CE earthquake, which takes place in the lake, unlike the others, suggesting that this type of deposition may depend on ground motion parameters besides the source-core distance.

We also compiled marine and lacustrine palaeoseismological studies carried out at the scale of the western part of the NAF. We show that the relationship between sedimentation rate and the onset of earthquake-induced slope destabilization does not work in the marine environment, unlike in the lacustrine environment. We also show that Lake Iznik records earthquakes from the NNAF and the MNAF, whereas the Sea of Marmara records only NNAF earthquakes.

The paleoseimological potential of large tectonic lakes on Sulawesi, Indonesia

The Island of Sulawesi, in eastern Indonesia, is located at the triple junction of the Australian, Pacific and Eurasian tectonic plates. The stress between these plates is released through earthquakes, especially along the Palu-Koro Fault, crossing the island from northwest to southeast, as documented with the 2018 Mag. 7.5 Palu earthquake. Past major earthquakes are poorly documented on the island. A recent study on Lake Towuti shows more abundant turbidite deposits during the Last Glacial Maximum. But this single study site does not provide evidence of necessarily more intense tectonic activity as climate also appears to control the occurrence of event-driven deposits. We suggest climate strongly influences the sensitivity of slopes to fail during seismic shaking in this tropical setting as a consequence of lowstand-forced sediment redeposition Climate-controlled lake-level fluctuations substantially alter the sensitivity of Lake Towuti to be impacted by mass wasting. To better understand how climate and earthquakes interact in generating mass wasting, we compare two different study sites and their record of event deposits. Lake Poso, in central Sulawesi, is located ~50 km to the east of the Palu-Koro Fault and potentially an ideal site to document seismic activity related to this major fault system. Poso's sensitivity is underlined by documented nearby recent earthquakes, some of them occurring even along its longitudinal axis. Further factors strengthening the paleoseismic potential of the lake include assumed steep subaquatic slopes, sufficient sediment input from major inflowing rivers, and shoreline features favouring sediment destabilization to generate mass movements. A complete geophysical survey, combined with sediment coring, will allow to unravel the Late Quaternary evolution of Lake Poso and will help to understand the climatic and tectonic forces that control sedimentation in this understudied setting.

Lake paleoseismology in the Eastern Alps: from historical earthquake calibration to testing seismic hazard curves and analyzing rockslide triggers

In intraplate regions, long-term reconstruction of earthquake occurrence provides important data for informing and testing hazard assessments. We have studied lakes in Carinthia and Tyrol (Austria) combining multibeam bathymetry, reflection seismics, sedimentology and geochemical techniques to establish 14-16 ka long records of past seismic shaking by analyzing subaqueous landslides, turbidites and in-situ sediment deformations. Age-depth models incorporate annual lamination counting and radio-isotopes (^{14}C, ^{210}Pb, ^{137}Cs). Based on the sedimentary imprint of historically-documented earthquakes (EMS-98 Intensity of V to IX at the lakes) we derived (i) seismic intensity thresholds for sedimentary imprints in different lake basins and (ii) scaling relationships between sedimentary parameters and seismic intensity. These ground motion indicators have then been applied to the prehistoric lacustrine sediment records.

In Carinthia, the sedimentary archive of Wörthersee recorded 44 earthquakes of intensity ≥V (max. IX). Recurrence statistics reveals the following: (1) Poissonian earthquake recurrence, as used in the probabilistic seismic hazard assessment, is confirmed for the last 2,800 years; (2) the current seismic hazard curves of the study area agree with the lacustrine paleoseismic record; (3) episodes of enhanced earthquake frequency can occur and need to be considered in seismic hazard analysis; (4) the last ~800 years show relatively many high-intensity events, with the 1348 CE earthquake producing the largest imprint of all Holocene events.

In Tyrol, 25 severe earthquakes are recorded in lakes Plansee, Piburgersee, and Achensee, from which four left imprints in two or more lakes. Earthquake recurrence intervals range from ca. 1,000 to 2,000 years. Plausible epicenters and magnitude estimates were derived by a reverse application of an empirical intensity prediction equation showing that paleo-earthquakes with a minimum M_W 5.8-6.1 might have occurred that were larger than known historical events. Temporal and spatial coincidence of paleoseismic evidence with multiple large rockslides at ~4.1 and ~3.0 ka BP reveals that such severe earthquakes are a key mechanism for major rock slope instability in the Eastern Alps. At Achensee, seismic profiles show coseismic surface rupture of a lake-crossing thrust at □8.3 ka BP and twice during late Glacial times.

Earthquake, gravity, or glacier? Deciphering deformation mechanism in Quaternary deposits along Idrija Fault in formerly glaciated Soča Valley, southeastern Alps

Dr. Petra Jamšek Rupnik [1]***, Dr. Manja Žebre*** [1]***, Dr. Jernej Jež*** [1]***, Dr. Marjana Zajc*** [1]***, Prof. Frank Preusser*** [2]***, Dr. Giovanni Monegato*** [3]

In a highly dynamic environment such as the Alps, the study of active faults is often challenging because of the interaction between different processes that shape the surface. Different processes can deform Quaternary sediments in similar ways, but because of the associated geohazards, interpretation of deformation mechanisms can have a major impact on society. In such environments, it is even more important to use a variety of methods to study active faults and distinguish between different deformation mechanisms in Quaternary sediments.

We studied deformation structures in Late Quaternary sedimentary succession located on the slopes of the formerly glaciated Soča Valley in an ice-marginal area of Most na Soči and within the deformation zone of the Idrija Fault, a large, active, dextral strike-slip fault, one of the most important seismic sources in the area. Landforms, sediments, and deformation structures were studied through integrated geomorphological, sedimentological, and structural geological mapping using photogrammetric and leveling surveys, paleoseismological techniques, optically stimulated luminescence dating, and ground penetrating radar surveys. The succession consists of glaciofluvial, glaciolacustrine, glacial, and slope deposits from the Penultimate Glaciation and the Last Glacial Maximum. The older glaciofluvial succession is tilted and cut by a series of faults and joints, and the glaciolacustrine strata also show soft-sediment deformation.

Because of the local geologic setting, several possible deformation mechanisms had to be considered: glaciotectonics, gravitational faulting due to ice-decay or slope instability, and paleoseismic activity. After a detailed structural analysis, we interpreted some deformations as secondary structures resulting from repeated paleoseismic activity of the Idrija Fault during the deposition of the succession dated to the Penultimate Glaciation, as well as some structures resulting from glaciotectonics and gravitational faulting. The transtensional nature of the deformations at the studied site indicates the local character of the Idrija Fault, which can be explained by a local releasing bend. The complexity of the fault and the first paleoseismic evidence from the Penultimate Glaciation provide valuable new data for understanding the seismic hazard of this regional fault.

New insights into the active tectonics of the Eastern Southern Alps

The northward motion and counterclockwise rotation of the Adriatic Plate leads to crustal deformation in the Southern Alps. Many aspects of this deformation, especially in the hinterland of the Southern Alpine orogenic front, are still not well-understood, mainly owing to the very low convergence rates. Here we present new results from the Italy-Slovenia-Austria border region that help to better understand the localization (or the lack thereof) of tectonic deformation, the postglacial activity of large faults, and the patterns of seismicity. We combine tectonic geomorphology studies on high-resolution digital elevation models with the analysis of satellite imagery, field mapping, near-surface geophysics, geodesy, paleoseismology, and Quaternary dating techniques to understand the pattern of Late Quaternary tectonics. In Slovenia, deformation is taken up by a system of NW-SE striking right-lateral strike slip faults in a more than 60 km-wide shear zone. Some of these faults are long enough to produce earthquakes exceeding magnitude 7, however, there is neither historical nor geological evidence for this. Additionally, many smaller, <15 km long faults show postglacial activity and in general, the deformation is widely distributed. In Italy, most of the deformation is accommodated by thrusting at the South Alpine orogenic front and in the Friulian Plain. Historical reports prove that strong earthquakes (M>6) occurred in the interior of the mountain chain, but seismicity is comparably low. Geological evidence of fault activity is poor because sedimentation/erosion, including landslides and rockfalls, and anthropogenic imprint dominate the present-day landscape and outpace any tectonic signal. We found a similar picture in Austria, where geological evidence of active faulting is sparse, despite a record of strong historical earthquakes. New dating results from both deformed and undisturbed geomorphic markers allow us to place constraints on the maximum amount of deformation that is accommodated in southern Austria and on fault activity in Slovenia.

The discovery of a forgotten earthquake: paleoseismological and archeoseismological evidence of a Late Antiquity event in Como, Northern Italy.

Dr. Franz Livio [1]***, Dr. Francesca Ferrario*** [1]***, Dr. Elisa Martinelli*** [1]***, Prof. Sahra Talamo*** [2]***, Prof. Alessandro Michetti*** [3]***, Dr. Paul Blockley*** [4]

Italy has one of the most complete and accurate historical seismic catalogues in the world, which can be considered as complete for the last ca. 1000 years for Mw ≥ 6.5. Nonetheless, it is well known that ancient events (i.e., older than medieval times) can hardly be accurately recorded by historical sources and that the probability of incompleteness grows with age. In regions characterized by low deformation rates, such as the Po Plain, an exceedingly long earthquake recurrence interval could possibly imply a significant underestimation of the seismic hazard.

Natural records, conversely, can be effective in filling the apparent gap in seismicity for ancient times. Some of the best examples are reported in studies on lake sediments, potentially able to image lake floor faulting or, more frequently, record large earthquakes as eq-triggered landslides/turbidites. From previous studies, geological offshore evidence of a Late Antiquity event hitting Northern Italy has been reported in the Alpine Lakes, possibly indicating a source area in the Central or Southern Alps. A definitive consensus of this hypothesis was lacking and the supposed earthquake-triggering together its age remains questionable if age-depth models are flawed or if we consider that mass wasting events can also be triggered by climatic causes as well.

Additional constraints for a possible seismic triggering would ideally be furnished by onshore evidence that is less prone to concurrent triggering by other causes, and the consistency of both the evidence would provide an ideal integrated set of evidence for seismic triggering.

In this work, we present a suite of onshore evidence of an ancient earthquake that hit the city of Como during the Late-Antiquity. By means of an archeoseismological and paleoseismological approach, we discuss secondary earthquake-induced effects that provide tight chronological constraints to the event occurrence. A comparison with previously published but less-constrained evidence for the same event provides a new hypothesis on the possible location of the seismogenic source.

Quaternary landscape evolution as a proxy for characterizing the active tectonics in a low strain rate region (Northern Sicilian margin, Italy)

The areas undergoing a tectonic deformation at 1 mm/yr or less are considered tectonically Low Strain Rate regions (LSRr) and are characterized by infrequent, but nonetheless potentially damaging sesimicity. The Landscape Evolution (LE) of these regions is principally driven by climate controlled surface processes, inducing erosion and sedimentation rates overwhelming the active faults morphological signature, thus causing their hidden geometry and hampering their identification and mapping. Such framework, that drives to the underestimation of the seismic hazard, induces the society to host valuable anthropogenic assets in these regions considering them relatively safe, increasing the exposition, or not urge to the earthquake preparedness, increasing vulnerability. For these reasons, the infrequent seismicity may cause significant losses in LSRr, and identifying active structures is one of the primary challenges for both the scientific community and modern societies.

This work proposes a multidisciplinary approach to detect active geological structures and their related deformation in such areas. We designed our approach to quantitatively study the offshore and onshore landscape and LE through a multidisciplinary morphotectonic, tectonostratigraphic and GNSS joint analysis. To test this approach, we selected as LSRr natural laboratory the partially offshore northern Sicilian margin (southern Italy), in the coastal sector located between the two major cities of Palermo and Termini Imerese. This area includes the compressional structures of the northern sector of the Apennine-Maghrebian fold and thrust belt, presently accommodating the slow Africa-Europe plate convergence.

The main results we achieved are:

1. new evidence of active tectonic deformation in this region;
2. the 3D modelling of two NNW-trending active faults;
3. the slip rate of a segment of the westernmost of the two detected faults;
4. the redefinition of the coastal uplift rates;
5. a newly recorded relative GNSS velocity field for the study area;
6. a new morphotectonic map;
7. a new inland and coastal LE model of the study area.

Our multidisciplinary approach allowed us to shed new light on the active tectonic framework and created new opportunities for further studies on the long-term deformation of a slowly deforming area that crosses the physical limit of the coastline.

Glacially triggered faulting in a formerly glaciated intra-plate area: Consequences for Quaternary erosional patterns and the near-surface geological architecture

Mr. Peter Sandersen [1], ***Mr. Flemming Jørgensen*** [2]

1. GEUS - Geological Survey of Denmark and Greenland, Department of Groundwater and Quaternary Geology Mapping, C. F. Møllers Allé 8, Building 1110, 8000 Århus C, Denmark, 2. Region of Central Denmark

Hypotheses about connections between deep-seated faults and the formation of erosional valleys in former glaciated areas have been suggested for more than a century. These hypotheses were typically based on large-scale topographic observations combined with sporadic subsurface data, but combinations of multiple datasets were generally not possible.

Around 25 years of buried tunnel-valley mapping in Denmark has resulted in three independent, nation-wide vector datasets: 1) Buried tunnel valleys, 2) Deep-seated faults (mapped in connection with oil and gas exploration surveys), and 3) Present-day topographic valleys. In order to systematically investigate to which extent faults may have impacted on the erosional patterns during the Quaternary, we have compared the three separate vector datasets with respect to orientations.

Several correlations in the datasets were observed. Correlations between the orientations of tunnel valleys and deep-seated faults suggested that structural weaknesses along faults have altered the hydraulic properties of the sedimentary strata and thereby created biased subglacial erosion patterns. However, correlations between deep-seated faults and erosional valleys in the present-day landscape, pointed to active tectonics allowing the erosion to reflect the tectonic framework in the topography. We thus propose a model that invokes the mechanism of glacially triggered faulting acting in all of the Danish area, causing an impact on the erosion patterns throughout the Quaternary. The erosion seems biased towards old, well-established patterns over active faults as these zones appear more susceptible to erosion. Our findings suggest that recurrent impact on erosion patterns from glacially triggered faulting can be expected in other areas in and around former glaciated areas.

Applying glacially triggered faulting to all of Denmark implies that deep faults may reach all the way to the terrain surface, and thereby guide and enhance erosion, but at the same time they impose disturbances on the sedimentary succession and the topography. The suggested model for the relationship between the tectonic framework and the erosion in former glaciated areas is therefore important for interpretations of geomorphology and the geological architecture. Several near-surface geological phenomena that have been difficult to explain using the traditional tool-box of glacial geology will now likely find alternative explanations.

What can uplifted, deformed Pleistocene palaeoshorelines tell us about long-term faulting offshore southwestern Crete?

Dr. Jenni Robertson [1], ***Prof. Gerald P. Roberts*** [1], ***Dr. Athanassios Ganas*** [2], ***Dr. Marco Meschis*** [3], ***Dr. Delia M. Gheorghiu*** [4], ***Dr. Richard Shanks*** [4]

1. Department of Earth and Planetary Sciences, Birkbeck, University of London, London, UK, 2. National Observatory of Athens, 3. Istituto Nazionale di Geofisica e Vulcanologia (INGV), 4. Scottish Universities Environmental Research Centre, East Kilbride, UK

Coastal landforms such as palaeoshorelines provide a record of uplift associated with offshore faulting. However, in the forearcs of subduction zones where complex tectonic regimes dominate, compressional and extensional faults may be contemporaneously active. As such, the cause of palaeoshoreline uplift and deformation in subduction settings may not be clear, which confounds attempts to undertake effective seismic hazard assessment.

We undertake spatio-temporal analysis on sequences of Pleistocene palaeoshorelines in southwestern Crete where deformed Holocene marine notches are associated with coseismic uplift of up to 9 m from the 365 CE Mw >8 earthquake. Previous investigations into the Holocene notches have been used to infer that the dominant mechanism of uplift may be slip either on a reverse crustal fault or on the subduction interface. However, seismic reflection studies south of Crete infer the presence of numerous active offshore extensional faults whose role in long term deformation is unclear.

New ^{36}Cl exposure dating on Pleistocene wave-cut platforms and palaeoshoreline mapping in combination with existing age controls facilitates detailed interrogation of spatial uplift rate changes along a ~30 km E-W section of the coastline encompassing the uplifted 365 CE notch sites. We observe that the Late Quaternary uplift rates increase from west to east, a spatial uplift pattern that is inconsistent with published vertical deformation models of reverse faulting. These findings imply that other mechanisms of uplift may contribute to Late Quaternary palaeoshoreline deformation.

Elastic half-space dislocation modelling is used to interrogate the coseismic spatial uplift patterns expected to occur from slip on extensional offshore faults that are suggested to run parallel to the coastline of southwestern Crete. We use these coseismic uplift patterns as a proxy to examine the possible long-term (~400 ka) cumulative spatial uplift patterns that may occur due to extensional faulting. Our findings demonstrate at least one offshore extensional fault, with a minimum length of 28 km capable of producing Mw >6.5 earthquakes, may also contribute to uplift along southwestern Crete. Over Late Quaternary timescales, it may be that a combination of active extensional and compressional faults is responsible for uplift across the wider area of western Crete.

Active Fault Segments from Middle Strand of the North Anatolian Fault system, characterization and paleoseismicity, NW Turkey

***Prof. Julia de Sigoyer* [1], *Dr. Renaldo Gastineau* [2], *Dr. Yacine Benjelloun* [3], *Dr. Edward Duarte-Martinez* [4], *Dr. Pierre Sabatier* [5], *Dr. Stefano Fabbri* [6], *Prof. Flavio Anselmetti* [7], *Prof. Stéphane Garambois* [2], *Prof. Mustafa Şahin* [8], *Dr. Serkan Gündüz* [8]**

***1.** Univ. Grenoble Alpes, Univ. Savoie Mont Blanc, CNRS, IRD, Univ. The Middle branch of the North Anatolian Fault (MNAF) forms part of the western termination of the dextral strike slip NAF system (Turkey). No recent earthquake was recorded on the MNAF in the last centuries contrary to the others active segments. 148 km of the MNAF were mapped using high resolution satellite imagery and field data. Offsets of landforms were systematically measured along 8 sub-segments of fault. Their statistical analysis shows coseismic lateral displacement of 3-6.5 m, that correspond to Mw~6.8-7.4 historical earthquakes able to propagate along several fault segments. Three segments bounded the Iznik Lake. Geophysical (bathymetric, seismic, Ground Penetration Radar) and paleolimnological studies (30 cores) were carried out in and around the Iznik Lake, to follow the structure of the MNAF in the lake and retrieved past earthquakes catalogue recorded by the lake sediments.

Two active fault segments were identified for the first time into the lake. The Iznik fault and the South Boyalica fault. The EW Iznik fault, is linear, parallel to the main dextral segment of the MNAF. It cross cut part of the lake and is connected on-land to the main fault segment. Several cores sampled from both part of the Iznik fault, associated to seismic data indicate that the fault has ruptured for the last time in 1065 CE with a vertical offset of 48 cm, we are still looking for markers horizontally offset.

The 1065 CE earthquake is recorded in all the cores of the lake. No earthquake was recorded after the 1065 in the Iznik sediments suggesting that it has totally purged the slopes of the lake. This earthquake has strongly damaged the Iznik city and destroy a famous basilica located on the shore. According to preliminary result, the penultimate earthquake on the Iznik Fault could be associated to the 368 CE historical earthquake; 7 centuries could have separated the two last earthquakes. The current seismic gap of 10 centuries on the Iznik Fault segment of the MNAF greatly increases the seismic hazard in this region showing that the MNAF must be considered in the seismic risk assessment of the NAF system.

Active shortening and prehistoric ruptures in basins of the central Tien Shan: insight from high-resolution DEMs and GPS velocity data

Dr. John Dianala [1], ***Prof. Richard Walker*** [2], ***Dr. Kanatbek Abdrakhmatov*** [3], ***Dr. Christoph Grützner*** [4], ***Mx. Magda Patyniak*** [5], ***Mx. Alana Williams*** [6], ***Mr. Aidyn Mukambayev*** [7], ***Prof. Edward Rhodes*** [8], ***Mr. Erkin Rahimdinov*** [3]

1. *National Institute of Geological Sciences, University of the Philippines, Diliman,* ***2.*** *Department of Earth Sciences, University of Oxford,* ***3.*** *Kyrgyz Institute of Seismology,* ***4.*** *Institute of Geological Sciences, Friedrich-Schiller University Jena,* ***5.*** *Institute of Geosciences, University of Potsdam,* ***6.*** *School of Earth and Space Exploration, Arizona State University,* ***7.*** *Data Center of the Institute of Geophysical Research NNC RK, Almaty; Satbayev University, Almaty,* ***8.*** *Landscape Dynamics, Department of Geography, University of Sheffield, Sheffield S10 2TN, UK*

Hundreds of kilometers north of the India and Eurasia collision front, the central Tien Shan accommodates around 20 mm/year of shortening across its ~400-km width. Late 19th to 20th century earthquakes with magnitudes of 7 to 8+ have been documented in the northern and southern sections of the mountain belt. In contrast, knowledge of such earthquakes occurring in interior basins did not exist until the recent advent of high-resolution remote sensing and better accessibility. In this study, we investigate the evidence of fault deformation along a transect following a known steep gradient in the GPS velocity, which has been suggested to indicate creep or shallow fault locking. By generating digital elevation models (DEMs) from Pléiades stereo-satellite imagery and drone photogrammetry, complemented with available High Mountain Asia DEMs, we document distributed east-west trending thrust faulting along a 3-5 mm/yr north-south GPS velocity gradient. In a paleoseismic trench at the eastern end of the transect, less than 10 km north of the Karkara Rangefront Fault (near the Kazakh-Kyrgyz border), faults with at least 0.5-m of displacement overthrust deposits of Holocene age. Westward, in the Issyk Kul basin, sub-parallel young folds that appear to be underlain by shallow thrust faults accommodate shortening. Further southwestward, fresh-looking scarps and vertical offsets no larger than 3 meters along E-W thrust faults in the Karakudzhur and Naryn basins may indicate single-event offsets, with the lateral extent of continuous fault scarps empirically equivalent to the rupture lengths of M ~7 earthquakes. Infrared stimulated luminescence dating in a paleoseismic section in Naryn suggests that slip on the fault, of at least one meter, happened after 4.2 ka. Constraining the aseismic and seismic partitioning with existing data remains elusive; nevertheless, the semblance of scarps with known earthquake ruptures in the region and the present-day shortening inferred from GPS data highlight the importance of studying the potential seismic hazard of faults in the interior basins.

Earthquakes of the Silk Road – an overview of results from the EROICA program

We present an overview of outputs from the Leverhulme Trust EROICA program (Earthquake ruptures of Iran and Central Asia). The program aims to explore the variability of earthquake rupture styles and fault behaviours within the interior of Asia using a range of techniques, that make use of the extremely well preserved landscape, the abundant and rich cultural heritage, and the often long and detailed historical record. We combine field observations (geomorphology, paleo-rupture mapping, and paleoseismology), optical satellite image and digital elevation model analysis, earthquake seismology and epicentral location using heritage datasets, and combined historical-archeological-geological analysis. Our results have helped us at local scale to understand the sources of individual historical earthquakes, and to better appreciate the vulnerability of specific cities and infrastructure sites. More generally we are slowly building an appreciation of plate interior earthquake rupture styles and variabilities that stretches over an appropriately long time span (>1000 years), and over a sufficiently wide region, that we are able to explore the processes in rare but very large events.

Slip variability and temporal clustering along the Imperial fault at Mesquite Basin, Imperial Valley, California

Prof. Aron J. Meltzner [1], ***Prof. Thomas Rockwell*** [2], ***Ms. Rebecca Tsang*** [2], ***Dr. Paula Figueiredo*** [3]

1. *Earth Observatory of Singapore, Nanyang Technological University,* ***2.*** *Department of Geological Sciences, San Diego State University,* ***3.*** *Marine, Earth and Atmospheric Sciences, North Carolina State University*

Paleoseismic trenches across the Mesquite Basin section of the Imperial fault revealed channels that cross the fault at high angle and that are displaced in the subsurface. These channels incised into and are embedded within lacustrine strata associated with Lake Cahuilla fillings. Three-dimensional excavation of these channels yielded information on slip in the past six surface ruptures. Displacement is well documented for the 1940 and 1979 events, with 15–20 cm of coseismic lateral slip in each event at the site. A small rill is deflected by ~60 cm, which we attribute to the 1940 and 1979 events plus creep and afterslip.

In contrast to the modern deflected channel, two subsurface channels, each ~50 cm wide, are beheaded with no rounding of the channels or flow along the fault. This relationship argues that displacement in each of the corresponding events—the sixth and fifth events back (E6 and E5)—exceeded 50 cm; the channel spacing suggests slip of 1.4–1.5 m in each event. A younger channel complex contains a sequence of nested channels that suggest two additional surface ruptures—the fourth and third events back (E4 and E3)—with smaller displacements than in E6 and E5.

The ages of these past surface ruptures are constrained by local ^{14}C dating, by the stratigraphic relationship of each event horizon to lacustrine intervals, and by the regional late Holocene lake history. The youngest pre-1940 event (E3) occurred when the site was underwater, around the time of the most recent Lake Cahuilla highstand, ca. 1732 CE. Events E4–E6 all occurred between then and ca. 1520 CE. The oldest channel, beheaded by E6, is offset a total of ~5.0 m. Hence, the northern Imperial fault has sustained ~5.0 m of slip in the past ~500 years, with the majority (~4.4 m) occurring in the four earlier events between ~1520 and ~1732 CE. These results imply that slip per event at the site ranges from ~0.15 to ~1.5 m, and the slip rate for the Imperial fault in the Mesquite Basin averages ~1 cm/yr for the past five centuries but varies over time.

Rupture History of the Himalayan Frontal Thrust in east and in west of Bagmati River, Central Nepal

Prof. Koji Okumura [1]***, Mr. Tomoru Yamanaka*** [1]***, Dr. Hisao Kondo*** [2]***, Mr. Prakash Pokhrel*** [3]***, Dr. Soma Nath Sapkota*** [3]

1. *Hiroshima University,* ***2.*** *Geological Survey of Japan,* ***3.*** *Department of Mines and Geology, Nepal*

The 2015 Golkha earthquake raised concern about the future large earthquake in south of the 2015 source area. The Golkha earthquake ruptured 10 to 20 km deep portion of the plate boundary interface ~50 km away from the surface trace of the Himalayan Frontal Thrust (HFT). Therefore it is necessary to evaluate the earthquake potential of the shallowest part of the thrust in central Nepal. After 2018 and 2019 paleoseismology works in Butwal area, in 2020 we excavated two trenches on the Himalayan front in east and in west of Bagmati river to examine the terminations of past events and to know the rupture history. At the Dumachaur Khola site 4 km east of Bagmati river, 3 or 4 events in 3500 years are excavated. The penultimate event here is dated around 3000 year B.P.. At the Gopalkoti-Dandatol site, 0.7 km west of Bagmati river, 3 events between 7th and 14th century C.E. are recognized. 1934 ruptures do not appear and 1255 (or 12th century) event is the last event in both trenches. The exposures were excellent with the master thrust fault through layered fine sedements containing many charcoal pieces, but the interpretation of the even time-series is difficult. Findings from three trenches around Butwal and these two across Bamati River are as follows. (1) 1934 rupture did not reach Bagmati River in west. (2) In west of Butwal, the timing of the last surface rupture coincides with 1344 earthquake without any evidence of 1255 (or 13 century) and 1505 ruptures around Butwal. (3) The last event around Bagmati River crossing occured in 1255 or in 12th centrury. (4) The timing of the penultimate event in west of Bagmati River is about 1000 year B.P. while it is about 3000 year B.P. in east of Bagmati River. Though a lot of paleoseismological works has been carried out along the HFT in central Nepal and Central Seismic Gap, we still know little about penultimates event on most segments.

Session 125: African Quaternary Anthro-environments: Palaeoecology and cultural responses to environmental variance

Hominins and Environmental Change: A Tale of Two Taxa

Prof. Matt Sponheimer [1]

1. *University of Colorado Boulder*

It is generally understood that gauging the impact of climate/environmental change on hominin speciation, extinction, and distribution requires well-resolved paleoenvironmental data. To date, however, there has been less focus on how hominin ecological diversity and competitive mammalian interactions modify hominin interactions with the environment. In this paper, I discuss this lacuna through the lens of two hominin genera that are believed to be ecologically disparate: *Paranthropus* and *Homo*. I argue that even though these taxa are in many ways well understood, arguments about the impacts of climate/environmental change for each are seriously underdetermined. One of several reasons for this is our lack of knowledge about how these Pleistocene primates, and their chief competitors, used resources within their habitats.

The norm not the exception: MSA open air sites in the Kalahari reflect early human behaviour and adaptation to dryness

Prof. David Thomas [1], ***Dr. Sallie Burrough*** [1], ***Prof. Sheila Coulson*** [2], ***Prof. David Nash*** [3], ***Dr. Sarah Mothulatshipi*** [4], ***Dr. Sigrid Staurset*** [1]

1. *School of Geography and the Environment, University of Oxford,* ***2.*** *University of Oslo,* ***3.*** *University of Brighton,* ***4.*** *University of Botswana*

An assumption of early human absence, avoidance or departure has influenced the reading of interior southern African dryland anthro-landscapes for many decades. Whether by design or accident, this has shaped theories of evolution, adaption and dispersal during the Middle Stone Age. The vast interior dryland of southern Africa (the Kalahari, from the Orange River north to the Okavango) has not figured large in direct investigations of MSA adaptations and has widely been assumed to have been relatively empty or avoided due to dryness post- 130 k yr. Interest in the region's archaeology has recently re-emerged, with intensive investigations of key sites on the southern margin (Wilkins, 2020) renewing interest in the subcontinent's interior as a place of early human innovation and adaptation.

New assessments show that the heart of the Kalahari too is replete in unexplored open air sites (Coulson et al., 2022), that when intensively investigated reveal an outstanding richness of records of early human response and adaptation to environmental change and dryness (Thomas et al., 2022). We show how interdisciplinary investigations can reveal a detailed picture of direct, positive and not isolated responses by MSA human to environmental conditions more generally regarded as challenging and inhospitable.

New insights into the late Pleistocene paleoecology using δ13C and δ18O enamel isotope evidence from Gotera, Southern Ethiopia

Mr. Seminew Mogesie [1]***, Ms. Caterina Aureli*** [1]***, Ms. Marianna Fusco*** [2]***, Prof. Mary Anne Tafuri*** [3]***, Prof. Enza Elena Spinapolice*** [1]

1. *Dipartimento di Scienze dell'Antichità, Sapienza Università di Roma, Italia.,* ***2.*** *Dipartimento di Scienze dell'Antichità, Sapienza Università di Roma, Italia; Department of History and Art History, Universitat Rovira I Virigili, Tarragona, Spain.,* ***3.*** *Dipartimento di Biologia Ambientale, Sapienza Università di Roma, Roma (Italy)*

The origin of behavioral modernity, geographic dispersal, and technological development of Anatomically Modern Humans (AMH) coincided with the profound late Pleistocene stadial, and interstadial climatic episodes might have impacted human adaptation and resilience. It has been argued that tropical eastern African highlands with locally available resources such as water, landscape setting, precipitation, and highland forests were potential refugia during the Late Pleistocene environmental and climatic stresses. Nonetheless, this aspect becomes obscure in Ethiopia where site-specific environmental and climatic records of MSA sites remain poorly studied. Here, we present the result of $\delta^{13}C_{enamel}$ and $\delta^{18}O_{enamel}$ stable isotopic analysis of bulk and sequential samples (n=62) of mammalian teeth enamel from Gotera. The newly discovered MSA site of Gotera in southern Ethiopia dated to the Marine Isotope Stage 3 (MIS 3) provides fresh data about the ecological context of AMH. We discuss the new insights into the environmental and climatic contexts as well as the subsistence strategies of AMH in southern Ethiopia.

Assessing past human-vegetation relationships in the SW Ethiopian highlands using wood charcoal identification

***Dr. Stéphanie Bodin* [1], *Dr. Elena Hensel* [2], *Dr. Ralf Vogelsang* [3], *Ms. Jennifer Markwirth* [1], *Dr. Manuel Casas-Gallego* [4], *Dr. Karen Hahn* [4], *Dr. Katharina Neumann* [1]**

***1.** Department of Paleoanthropology, Senckenberg Research Institute, **2.** Institute of Geography, University of Cologne, **3.** Institute of Prehistoric Archaeology, University of Cologne, **4.** Institute for Ecology, Evolution and Diversity, Goethe University, Frankfurt/M*

The highlands of South West Ethiopia are part of the Eastern Afromontane biodiversity hotspot. They host more than 5200 vascular plant species of which about 10% are endemic. Nowadays, the vegetation of the highlands is highly impacted by human pressure and in particular agropastoralist activities which have led to a dramatic deforestation. The remaining patches of Afromontane forests grow between 1800 and 3000 m asl, where the rainfall and temperature ranges are suitable to allow their persistence. As the highlands capture higher rainfall than the lowlands, it has been hypothesized that they may have acted as refugium areas during dry periods, for example after the African Humid Period, while the lowlands were undergoing aridification and resource depletion.

So far, no palaeoecological data are available in the SW highlands to test this hypothesis. Yet, archaeological excavations led in rock shelters in the last decade have provided abundant and well-preserved palaeobotanical remains, including macroscopic wood charcoals and phytoliths dating back to the end of the African Humid Period.

Here, we present the results of the wood charcoal analysis from the Sodicho and Mochena Borago rock shelters, located in the SW highlands at 1900 and 2200 m asl, respectively. Charcoal assemblages from Sodicho indicate an opening of the dry Afromontane forest linked to human activities (fires) after the African Humid Period. This is evidenced, for example, by the dominance of a fire-tolerant Proteaceae and *Acacia* sp. in the assemblage as well as burnt phytoliths. Charcoal analysis from Mochena Borago is still ongoing, but so far, the forest around this rock shelter seems to have been less impacted, as indicated by the presence of typical forest taxa (*eg.* the gymnosperm *Podocarpus falcatus*). Our results suggest that even if the highlands may have kept a forest cover during dry periods, human activities were also shaping the landscape in some areas, showing that people were not necessarily seeking refuge in dense forest cover but were also actively modifying it, likely to improve resource availability.

Benthic foraminifera from the nearshore area of the Mediterranean coast of Central and NW Libya: A preliminary survey

Mr. Salah El-Ekhfifi [1]***, Dr. Ahmed Muftah*** [2]***, Mr. Mohammed F. El Hassi*** [3]

1. *NOC, lIBYA,* ***2.*** *Faculty of Science, Department of Earth Sciences, University of Benghazi P.O. Box 9480, Benghazi, Libya,* ***3.*** *Department of Geological Engineering, Bright Star University, City Road 11, P.O.B. 21864, Al Brega*

The Mediterranean Sea is among the hotspot's areas severely affected by biological invasion, particularly benthic foraminifera. This survey is an attempt to record and identify the benthic foraminifera in the Mediterranean coastal area of Libya. A total of seven samples were collected along 500 km of the Libyan coastal area, from Sabratah in the NW to Sirte in the central, for studying the sediments physical characteristics and foraminiferal assemblages' composition. Sediment textures were mainly fine to very coarse sand dominated by calcareous bioclastic debris of mollusks, echinoids, and foraminifers, with minor quantities of ostracods and bryozoans. The total number of species recorded in all samples is (25) species were identified, and one Indo-Pacific species, "*Amphistegina lobifera*," was recorded. The average value of the population density (number of specimens individuals per gram of dry sediment) was low to moderate, averaging about 154, with the lowest count at Tajurah Coast. The foraminiferal assemblages of the northwestern area, extending from Sabratah to Misratah, were low-diversified and abundant (D) only with *Amphistegina lobifera* and *Textularia agglutinans*. The central coastal area extended from Bu'ayrat al Hasun to Sirte has a high species diversity (S) and is dominated mostly by milliolids. *Amphistegina lobifera* is currently rapidly broadening its biogeographic range in the Mediterranean Sea with increasing temperatures brought on by climatic change, especially in the oligotrophic waters dominating the Libyan coastal area. However, this study recommends that a detailed investigation be accomplished to study the invasive species in the Libyan coastal area and the associated environmental consequences.

Paleoclimate models and vertebrate archaeofaunal assemblages in Pleistocene Africa

Dr. Emily Hallett [1]***, Dr. Jacopo Niccolo Cerasoni*** [2]***, Dr. Michela Leonardi*** [3]***, Prof. Andrea Manica*** [4]

1. *Department of Anthropology, Loyola University Chicago,* ***2.*** *Loyola,* ***3.*** *Department of Zoology, University of Cambridge,* ***4.*** *University of Cambridge*

This research presents vertebrate faunal taxonomic identifications from two Late Pleistocene archaeological sites in Africa: 1) Contrebandiers Cave, Morocco, and 2) Iho Eleru, Nigeria. Contrebandiers Cave is located on the Atlantic coast of Morocco and contains Middle Stone Age and Later Stone Age deposits with 11,000+ point-provenienced vertebrate faunal remains. Iho Eleru is a rock shelter in southwest Nigeria with approximately 200 vertebrate faunal remains. Both archaeological sites have been chronometrically dated and the ages have been published elsewhere. The habitat preferences of the identified taxa from both sites were used to reconstruct the past habitats surrounding each archaeological site. Paleoclimate from global circulation models was used to reconstruct the past climates surrounding each archaeological site. Climate data was accessed using pastclim (an R package for paleoclimatic reconstructions), and archaeofaunal data was collected by the primary author and has been published elsewhere. For both archaeological sites, the modelled paleoclimate matches the habitat reconstructions based solely on archaeofaunal remains. This suggests that paleoclimate from global circulation models–such as those used in pastclim–and Late Pleistocene African animal distributions agree with each other.

Session 126: Sub-annual to decadal records of environmental change

High-resolution reconstructions of Holocene ENSO from the Great Barrier Reef using short-lived marine gastropod shells

Ms. Mahsa Alidoostsalimi [1]***, Dr. Amy Prendergast*** [1]***, Prof. Russell Drysdale*** [1]***, Dr. Josephine Brown*** [1]***, Prof. Ian J. McNiven*** [2]***, Prof. Sean Ulm*** [3]

1. School of Geography, Earth and Atmospheric Sciences, University of Melbourne, Victoria, Australia, 2. ARC Center of Excellence for Australian Biodiversity and Heritage, Monash Indigenous Studies Center, Monash University, Clayton, Victoria, Australia, 3. ARC Center of Excellence for Australian Biodiversity and Heritage, College of Arts, Society and Education, James Cook University, Cairns, Queensland, Australia

In recent years, there has been a growing interest in using short-lived marine mollusc shells as a paleoclimate archive by virtue of their ability to preserve high-resolution paleoclimatic and paleoenvironmental information in multiple biogeochemical proxies. Moreover, valuable information about past environments, human-environmental interactions, and seasonal foraging practices can be obtained via the analysis of marine gastropods from archaeological sites. *Rochia nilotica* and *Conomurex luhuanus* are two of the most common archaeological shells excavated from shell middens spanning the Mid-to-Late Holocene, in the northern Great Barrier Reef (GBR); however, their use as archives to reconstruct the Mid-to-Late Holocene ENSO (El Niño-Southern Oscillation) has not yet been tested. In this study, we compare temporally successive oxygen isotope and trace element records (d18O, Mg/Ca, Sr/Ca, and Ba/Ca) in modern *R. nilotica* and *C. luhuanus* shells with instrumental environmental records to test whether we can quantitively reconstruct past environmental parameters. Preliminary results show that modern *R. nilotica* and *C. luhuanus* reliably record environmental factors (e.g. sea surface temperature and salinity) in equilibrium with the surrounding environment at monthly to daily resolutions. These proxies will ultimately be applied to reconstruct localised Mid-to-Late Holocene ENSO records at sub-seasonal scales in the Great Barrier Reef. Results obtained from this ongoing research can be used to compare with climate model simulations to provide more robust reconstruction of paleo ENSO behaviour and offers an opportunity to decipher the long-term shellfish management strategies of Indigenous peoples in the GBR environment to provide a baseline for future marine resource management in the GBR.

Toward a novel multi-century archive of tree mast using pollen from varved lake sediments

Dr. Valerie van-den-Bos [1], *Dr. Joe Prebble* [1], *Dr. Gavin Dunbar* [2], *Dr. Xun Li* [1], *Dr. Marcus Vandergoes* [1], *Dr. Sarah Richardson* [3], *Prof. Huw Horgan* [4], *Dr. Katherine Holt* [5], *Dr. Jamie Howarth* [2], *Prof. Richard Levy* [1]

Mast seeding – the pronounced inter-annual variability and synchrony in seed production – can have profound local ecological impacts. In New Zealand forests, mast years lead to rapid increases of non-native mouse populations, followed by increases in non-native mustelids, which in turn predate highly vulnerable native bird and reptile fauna.

We explore the potential for generating long (centuries to millennia) proxy records of tree mast seeding, from pollen deposited in lake sediments. This proxy record uses pollen recovered from varved sediments from a core collected from Lake Ohau, South Island, New Zealand to reconstruct masting events for two genera of Southern Beech, *Fuscospora* spp. and *Lophozonia* spp. We find average mast frequencies inferred from *Fuscospora* pollen from a 43-year sediment core collected from Lake Ohau comparable to seed fall expected for the catchment using a differential-temperature (ΔT) statistical model for the period 1974–2016. In contrast, *Lophozonia* pollen mast frequency in the 1974–2016 timeseries was consistently lower than that predicted by the ΔT model, although the patterns of variability were broadly similar.

We explore this approach in a second 32-year pollen timeseries from Lake Ohau, spanning the pre-instrumental period 1833–1864. During this interval, average air temperature was ~1°C cooler than the late 20th century, and interannual variability of air temperature was subdued, such that mast frequency predicted by the ΔT model is the lowest in 200 years. We find mast frequency in our pollen records reflects this pattern for *Fuscospora*, with a minima of mast frequency from 1850, compared to the 1974–2016 record, but not for *Lophozonia*.

This paper demonstrates that a centuries-long pollen record from the varved Lake Ohau sedimentary sequence has the potential to form a valuable proxy for *Fuscospora* masting that would supplement existing seedfall records. Long records of this type could significantly enhance our understanding of the environmental drivers of mast seeding.

From source to sink: paleoenvironmental reconstruction along the MIS 3 Rhine River with mammoth teeth

Mr. Zuorui Liu [1]***, Dr. Amy Prendergast*** [2]***, Prof. Russell Drysdale*** [3]***, Dr. Jan-Hendrik May*** [4]

1. *School of Geography, Earth and Atmospheric Sciences, University of Melbourne, Melbourne, VIC, Australia,* ***2.*** *School of Geography, Earth and Atmospheric Sciences, University of Melbourne, Victoria, Australia,* ***3.*** *University of Melbourne,* ***4.*** *School of Geography, Earth and Atmospheric Sciences, The University of Melbourne*

Mammoth teeth are increasingly studied with stable isotopes for paleoenvironmental reconstructions during the past decades due to their frequent discoveries and capacity of recording sub-annual scale paleoclimatic variations. In this study, eleven molar teeth of woolly mammoth (*Mammuthus primigenius*) coming from different locations within or near the Rhine River catchment were studied for oxygen ($\delta^{18}O$) and carbon ($\delta^{13}C$) isotopic compositions in their enamel carbonate. The samples were radiocarbon dated to several time windows during approximately 33-40 ka cal BP, and they were discovered in the fluvial sediments of multiple locations in Swiss Alps and Upper Rhine Graben, as well as dredged from the southern North Sea, covering from the approximate origin to the downstream delta of the Rhine Catchment during Marine Isotope Stage 3 (MIS 3).

We sequentially drilled the enamel of all specimens following the growth direction at millimetre resolution, and the obtained enamel powder was analyzed for $\delta^{18}O$ and $\delta^{13}C$ values using IRMS mass spectrometry. We then plotted time-series of $\delta^{18}O$ and $\delta^{13}C$ variations from all sample locations, and the high-resolution records were interpreted to reconstruct a variety of paleoenvironmental properties, including river hydrology, precipitation, air temperature, vegetation composition and sub-seasonal scale climatic changes. These paleoenvironmental properties were compared between different sample locations to investigate the spatial gradients in paleoclimatic and paleoecological conditions, as well as river hydrological balance, from south to north along the Rhine River. These high-resolution isotopic data were further combined with regional sediment and pollen records to provide a high-resolution framework for reconstructing the complex and variable paleoenvironmental conditions of MIS 3 in Central Europe.

A proxy calibration study for a freshwater archive in south-east Australia and its implications for understanding past human-animal-environment relationships

Ms. Chloe Stringer [1]***, Dr. Amy Prendergast*** [2]***, Dr. Jillian Garvey*** [3]***, Dr. Jan-Hendrik May*** [1]***, Mx. First People of the Millewa-Mallee Aboriginal Corporation .*** [4]***, Mr. Henri Wong*** [5]***, Dr. Patricia Gadd*** [6]***, Dr. Vladimir Levchenko*** [5]

1. *School of Geography, Earth and Atmospheric Sciences, The University of Melbourne,* ***2.*** *School of Geography, Earth and Atmospheric Sciences, University of Melbourne, Victoria, Australia,* ***3.*** *La Trobe Univesity,* ***4.*** *First People of the Millewa-Mallee Aboriginal Corporation, Mildura, Victoria,* ***5.*** *Australian Nuclear Science and Technology Organisation, Lucas Heights, Australia,* ***6.*** *ANSTO*

Sub-annual proxy archives are lacking from the Central Murray River Basin (CMRB) in south-east Australia, which lies on Ngintait and First People of the Millewa Mallee Country. As people have been living in this region for at least 15,000 years, the development of sub-annual paleoenvironmental proxy archives could provide valuable insights into human-environment interactions during the diverse climatic and environmental changes of the Last Glacial Maximum – Holocene transition. The large number of shell midden sites found along the Murray River provide the potential for archaeological freshwater bivalve specimens to act as sub-annual, local archives, with the approach known as sclerochronology, unlocking details of the relationship between shell growth patterns, associated geochemistry, and the ambient environment. However, before archaeological material can be interpreted, a modern calibration study must be completed to understand the robustness and reliability of the proxy archive.

This paper presents the results of a modern calibration study of the freshwater bivalve species *Alathyria jacksoni*, collected live from the CMRB in 2017 and 2021-2023. The study also included the collection and analysis of water samples, and water and climate data. The mollusc specimens were analysed using various techniques, including SEM, SIMS (SHRIMP), IRMS and LA-ICP-MS, to understand how the growth and geochemistry of modern *A. jacksoni* shell specimens relates to the surrounding environment and hydrochemistry of the current Murray-Darling Basin system. Apart from the relevance of this analysis for archaeological and paleoenvironmental research, this investigation also provides valuable insight into the life history and behaviour of the *A. jacksoni* population, which may aid current efforts to better understand and conserve this freshwater mollusc species. Given the species range of *A. jacksoni*, the results of this study are applicable to paleoclimate research throughout the Murray-Darling Basin.

Marine shell isotope records of Holocene temperature and upwelling shifts on the west coast, South Africa

Dr. Emma Loftus [1], **Prof. Julia Lee-Thorp** [2], **Prof. Judith Sealy** [3]

1. Ludwig Maximilian University of Munich, 2. School of Archaeology, University of Oxford, 3. Stable Light Isotope Laboratory, Department of Archaeology, University of Cape Town

The arid west coast of South Africa features substantial Holocene and late Pleistocene archaeological deposits of shellfish remains in both open-air coastal middens and rockshelters. These deposits, testament to millennia of coastal forager subsistence behaviours, also preserve rare regional archives of seasonal climate information in the shell geochemistry. We present a modern study of serial stable carbon and oxygen measurements for the limpet Cymbula granatina, from locations upstream and downstream of a large, summer upwelling cell, demonstrating the utility of this species for palaeoclimate and seasonality studies. We reconstruct shifts in sea surface temperatures and upwelling activity from the well-dated archaeological sequence at Elands Bay Cave and nearby sites. We also examine marked shifts in the annual scheduling of hunter-gatherer shellfishing in the region across the period. We discuss these patterns with respect to the broader archaeological record, particularly changes in settlement patterning and the arrival of pastoralists to the region.

Demonstrating the relationship of Araucariaceae tree-ring width and Carbon-13 measurements to climate in subtropical Eastern Australia

In the past decade, high-resolution tree-ring records from the tropics and subtropics of Australia have been developed, enabling climate reconstructions in a region that generally lacks both historical and instrumental climate data. Most tree-ring work in tropical and subtropical Australia focuses on ring-width measurements, while tree-ring stable isotope studies are relatively few. Stable isotopes in tree rings often provide complimentary climate information to tree-ring width analysis relating to different environmental variables. Rigorous studies of tree-ring stable isotopes have not been widely undertaken in the Australian tropics. Here we present a comparison study between ring-width measurements and isotopic data for a subtropical Australian site in Lamington National park, Southeast Queensland. Annual tree-ring chronologies from *Araucaria cunninghamii* trees have been developed spanning 1805-2014 CE using ring-width measurements from 18 trees, and for 1950-2013 CE based on Carbon-13 from 5 trees. The dating of these chronologies was confirmed using radiocarbon measurements and densitometry. Climate correlations demonstrate that while both chronologies capture moisture variability, their signals are not identical. Preliminary analysis suggests the isotopic signal provides a regional representation of conditions that the more localized ring-width signal. Extending on this analysis, the ring-width chronology was used to develop a drought reconstruction which clearly indicates a recent step shift in drought conditions in Southeast Queensland, potentially demonstrating an anthropogenic influence on this region's climate. This study illustrates the importance of investigating multiple forms of environmental evidence when undertaking dendrochronological studies in the tropics and subtropics where we are limited to relatively short historical climate records.

Palaeoenvironmental context for Middle to Upper Palaeolithic hominins in the Levant from multi-proxy analyses of marine and terrestrial gastropod shells

Dr. Amy Prendergast [1]

1. *School of Geography, Earth and Atmospheric Sciences, University of Melbourne, Victoria, Australia*

The Levant was a key corridor for dispersals and interactions between hominin species during Marine isotope stage 3 (MIS 3). This project investigates whether seasonal environmental changes associated with rapid climate events played a role in the expansion of our own species, *Homo sapiens* (modern humans), and the demise of Neanderthals during this time in the Levant. Humans respond to changes in their local environment on daily to seasonal timescales. Therefore, robust assessments of the impact of environmental change on human behaviour requires an understanding of local environmental change at seasonal to sub-seasonal resolution. Applying sclerochronology (the analysis of incremental growth structures) and geochemistry to mollusc shells can provide some of the few sub-seasonal resolution palaeoenvironmental proxies in the mid to high latitudes. Obtaining these records from food-refuse archaeological specimens enables the reconstruction of paired records of how humans responded to environmental changes in the past.

Here we present high-resolution environmental reconstructions from stable isotope analyses of marine gastropods (*Phorcus turbinatus, Patella caerulea*), and land snails (*Helix spp.*) from several key Middle to Upper Palaeolithic archaeological assemblages in the Levant. Serially sampled δ^{18}O, Mg/Ca, and Sr/Ca analyses of marine gastropod shells provide sub-monthly snapshots of sea surface temperature, whilst δ^{18}Oand δ^{13}C analyses of terrestrial gastropod shells provide sub-seasonally-resolved records of rainfall variability and vegetation change. This evidence for fluctuating temperature, rainfall and seasonality regimes throughout MIS 3 appears to be linked with northern hemisphere millennial-scale climate oscillations These highly resolved environmental records, coupled with well-dated archaeological sequences provide a framework for assessing the complex interplay between early modern humans, Neanderthals and their local environments. The archaeological records show *Homo sapiens* occupation occurred during both warmer and cooler phases and during both high and low seasonality regimes, indicating that modern human populations showed resilience in the face of environmental fluctuations and resource uncertainty. We are examining whether this changing seasonality played a role in the demise of Neanderthal populations in the region. These paired cultural-environmental records demonstrate the importance of generating local, high-resolution palaeoenvironmental records to enable nuanced examinations of human-environment interactions during critical periods of the late Pleistocene.

1000-years of reconstructed summertime extreme jet stream behavior driven by a wavenumber-5 Rossby wave pattern

Dr. Ellie Broadman [1]***, Dr. Kai Kornhuber*** [2]***, Dr. Valerie Trouet*** [1]

1. The University of Arizona, 2. Lamont-Doherty Earth Observatory, Columbia University

In the Northern Hemisphere, the jet stream is an important driver of terrestrial climate, including extreme events such as heat waves. As such, there is interest in understanding the jet stream's response to anthropogenic greenhouse gas forcing. One hypothesis posits that under anthropogenic global warming, the jet stream is becoming more meandering, or wavier, which can be described by the "wavenumbers" of planetary Rossby waves that influence jet stream position. Wavenumbers have been described in studies focused on the instrumental period, which demonstrate that some summertime wavenumber patterns, such as wavenumbers 5 and 7, are associated with a meandering jet stream that drives hot, dry conditions in regions of North America, Europe, and Asia, impacting important food production regions. Despite interest in current and future jet stream behavior, little is known about its past and natural variability, making it difficult to determine whether these wavenumbers have become more frequent in recent decades.

In this first attempt to reconstruct Northern Hemisphere Rossby waves and associated jet stream behavior using paleoclimate data, we present a 1000-year reconstruction of summer extreme wavenumber 5 (wave-5) events based on tree-ring-inferred Palmer Drought Severity Index (PDSI) data compiled in the North American Drought Atlas (NADA) and the Old World Drought Atlas (OWDA). We developed a wave-5 index as our reconstruction target based on the number of weeks during May, June, and July that wave-5 is in its preferred Rossby wave phase to induce simultaneous droughts. Our reconstruction targets PDSI anomalies associated with extreme wave-5 events in three regions across the Northern Hemisphere (two in NADA and one in OWDA) using a stepwise linear regression, and explains ~40% of wave-5 variability over the instrumental period (1948-2005). Our results suggest that the recent occurrence of extreme wave-5 jet stream positions is not increasing, and that this aspect of jet stream behavior has remained stable under global warming. We also show that these wave-5 positions are related to the El Niño Southern Oscillation, where wave-5 is more likely to be in these extreme phase positions during La Niña events, consistent with analyses focused on the instrumental period.

Interface of tree-ring δ18O spectrum across moisture regime of southeastern Tibetan Plateau

Dr. Santosh Shah [1] ***, Dr. Nivedita Mehrotra*** [2] ***, Mr. Lamginsang Thomte*** [2] ***, Dr. Uttam Pandey*** [3] ***, Dr. Narayan Gaire*** [4]

1. *Birbal Sahni Institute of Palaeosciences, 53-University Road, Lucknow-226007, India,* ***2.*** *Birbal Sahni Institute of Palaeosciences,* ***3.*** *Indian Institute of tropical Meteorology,* ***4.*** *Patan Multiple Campus*

The present study area encompasses the "Third Pole of the earth" which is considered as "Water tower of Asia" strongly influencing the hydroclimate for a large population in East and South Asia. The varied topography of the region results in its complex hydrological regimes, resulting in its high sensitivity to climate change. The inadequate long-term climate observation is however, not sufficient to understand the climate dynamics and to model and predict the climate scenario. The strengthening of long-term quantification of hydrological changes under changing climate is significant for water managers and policy-makers to develop sustainable water resources strategies. With view to this, we reconstructed gridded summer (June-August) precipitation totals for southeastern Tibetan Plateau encompassing eastern Himalaya region using network of tree-ring $\delta^{18}O$ records. This precipitation reconstruction characterized the hydroclimatic variability in terms of drought and pluvial since 489 CE. The reconstruction was assessed for its variability and strengths with special emphasis for major global climatic events i.e., medieval climate anomaly (MCA) and little ice age (LIA). The declining trends of moisture variability during mid 19th century to recent is observed which might be the serious concern for future sustainable hydroclimatic scenario of the region. The gridded precipitation reconstruction shows affinity with sea surface temperature (SST) of the Indian and Pacific Oceans.

Session 127: Uncovering the environmental legacies of colonialism

Palaeoecological insights on ecosystem management in Cape Pillar, lutruwita/Tasmania, to promote biocultural heritage and enhance tourist experience

Dr. Matthew Adeleye [1]***, Prof. Simon Haberle*** [1]***, Dr. Stefania Ondei*** [2]***, Prof. David Bowman*** [2]

1. *Australian National University,* ***2.*** *University of Tasmania*

Cape Pillar is part of the Tasman National Park in lutruwita/Tasmania, SE Australia, and home to some of Australia's endemic species, as well as a major tourist destination in the Southern Hemisphere. However, projected frequent drought and fire weather in SE Australia over coming decades has triggered growing concerns about the future of the dense sclerophyllous vegetation that currently dominate the Cape. Given that the Cape has been occupied by the Palawa Indigenous people of lutruwita for millennia before their removal by European colonists, understanding the nature of vegetation and fire regimes before and after European invasion will provide a solid knowledge base for management actions in the Cape Pillar area. Using a multi-proxy palaeoecological method combined with historical aerial photography and oral accounts of early Europeans voyages to Cape Pillar, we show that major bushfires only became common in the Cape after the removal of Palawa people in the early 1800s. Open diverse vegetation with low fire activity was maintained by Palawa people in the Cape for over two millennia and was subsequently replaced by dense scrubby vegetation after colonisation, with major bushfires at least every 3–4 decades, exacerbated by climate change over the last century. Long-term management programmes targeted at restoring pre-colonial open heathland will not only promote biocultural heritage in Cape Pillar but will also protect tourists and the multi-million dollar infrastructure in the region.

Land-use change in Hispaniola before and after Columbus' arrival

Prof. Henry Hooghiemstra [1], *Dr. Alvaro Castilla-Beltrán* [2], *Prof. Menno Hoogland* [3], *Prof. Corinne Hofman* [4]

1. Institute for Biodiversity and Ecosystem Dynamics, 2. University of Southampton, 3. Leiden University, 4. Faculty of Archaeology, Leiden University, Einsteinweg 2, 2333, CC, the Netherlands

We reconstructed human impact and environmental change from 2 sediment cores in the Cibao Valley. We studied 2 cores from sediment-filled meanders of the Yaque River and 1 core from the coastal mangrove forest. From 195 CE meander infill is documented by changing grain size distributions, organic matter concentration, and pollen from wetland plants. Indigenous populations must have increased since 1050 CE. Between 1250 and 1450 CE pre-colonial modifications of the landscape were primarily the result of fire-use and small-scale clearings for crop cultivation and slash-and-burn agricultural practice. After Columbus' arrival in Hispaniola (1492 CE) European diseases caused indigenous sites became abandoned. Increasing coprophilous fungal spores evidence Europeans had introduced cattle rapidly leading to more open forest. Intensive land-clearing and large-scale agriculture on the moist and nutrient rich soils along the Yaque River expanded from 1650 CE onwards. Colonists and introduced enslaved labour force increased causing deforestation and erosion. Two centuries after European colonizatio(18thC) land-use in the Cibao Valley had become a balance between substantial livestock and crop cultivation. Pollen grains have evidenced cereals, maize, and potentially also sugar cane, amaranthaceous crops and tobacco. After 1950 CE, swamp vegetation of *Typha* and Cyperaceae decreased, pointing to an almost fully terrestrialized meander with little standing water, reflecting the present-day setting. This multiproxy reconstruction of anthropogenic environmental change shows a clear differentiation between an immediate introduction of livestock and after some 150 years the development of a European style agriculture, providing a context for archaeological investigations. Mangroves near the first permanent European colonial outpost in the Americas underwent no significant impacts. During the last 200 years all natural ecosystems suffered from severe deforestation, degradationand implementing an irrigation system leading to the present cultural landscape.

Pre-European Ecology on the Northern Plains

Dr. Tom Shay [1]

1. *University of Manitoba*

The Great Plains grassland has been called the "American Serengeti." Before their near-demise or extinction, in the 19th Century, bison (*Bison bison*), pronghorn (*Antilocapra americana*), deer (*Odocoileus* spp.), elk (*Cervus canadensis*), and their predators, grizzly bears (*Ursus arctos horribilis*), and wolves (*Canis lupus nubilus*), the grassland year must have resembled the so-called "grazing succession" of East Africa. In this sequence, smaller herbivores, then larger ones, take advantage of available forage in a predictable sequence as the season progresses. Notably, grass protein is highest in spring but declines later in the year. A major difference between the African and American grazing year is Africa's lean time is the dry season while northern plains animals must contend with winter's cold and snow. With climate as the driver, I hope to unravel the various animal ecologies during the late 18th Century.

Adding fuel to the fire: have fires in Southeast Australia always burned so hot?

Mr. Anthony Romano **[1]***, Prof. Michael Fletcher* **[2]***, Dr. Shira Maezumi* **[3]***, Dr. Michela Mariani* **[4]***, Dr. Simon Connor* **[5]**

1. *School of Geography, Earth and Atmospheric Sciences, The University of Melbourne,* ***2.*** *University of Melbourne,* ***3.*** *Max Planck Institute for Geoanthropology,* ***4.*** *University of Nottingham,* ***5.*** *School of Culture, History and Language, College of Asia and the Pacific, Fellows Rd., The Australian National University, Acton*

Prior to colonisation by Europeans, many landscapes around the world had been deliberately shaped, maintained and cared for by Indigenous peoples using skilful land-management practices. These land management practices were suppressed and eradicated via colonisation; subsequently replaced with the imposition of European landscape ideals. This shift in management has led to a broad set of environmental consequences that pose contemporary challenges, many of which are now being compounded by the impacts of climate change. Recent catastrophic wildfires have kindled discussion about the return and expansion of Indigenous cultural burning practices to mitigate against climate-driven catastrophic wildfires across these landscapes.

Causes for catastrophic wildfires across Southeast Australia are framed around four themes: 1. Climate change; 2. Ignitions; 3. Fuels; and 4. Risk-adverse policy frameworks. Compounded with these are wilderness ideologies, which have allowed for policy and research to ignore past ecological conditions and ignore and suppress a wealth of Indigenous knowledge of healthy landscape management. Here, a synthesis of our palaeoecological research from across Southeast Australia is discussed to highlight coherent trends of landscape change pre- and post-British Invasion. By doing so, we aim to understand the influence of Aboriginal management, namely fire, and the consequences of the removal of strategic and managed burning across Southeast Australia. Through this research, we can develop datasets of environmental change spanning the pre- to post-British Invasion period to create appropriate baselines and management approaches that can guide future landscape management of the Southeast Australian landscape.

Ngā wā taio Māori o mua: Past cultural ecosystems in Aotearoa

Dr. Matiu Prebble [1], ***Prof. Atholl Anderson*** [2], ***Prof. Simon Holdaway*** [3], ***Prof. Thegn Ladefoged*** [3]

1. *University of Canterbury,* ***2.*** *Australian National University,* ***3.*** *University of Auckland*

The prevailing depictions of the environmental past of Aotearoa New Zealand are heavily focused on 'pristine pre-human' ecosystems. These come at the expense of our understanding of the dynamic cultural ecosystems that Māori constructed prior to European colonisation. Furthermore, Māori continued to dominate the economy of Aotearoa well-into the colonial period up until the 1870s, producing most of the food supply. Yet, our understanding of how Māori adapted their cultural landscapes to the colonial economy is limited and poorly explored using palaeoecological tools. Indeed, most restoration, conservation and Quaternary scientists in Aotearoa appear to remain intent on bypassing the pre- or post-colonial past.

Vast kūmara (*Ipomoea batatas*, sweet potato) cultivations, for example, once connected hundreds of pā (fortified villages) and kainga (villages) across the extensive flood plains of Waikato Awa (Waikato River) revealed by archaeological excavations. These cultural landscapes are monumental, but continue to be destroyed with ongoing land development. Kūmara cultivations formed on mounds (puke) and borrow pits (rua) have been well described, but little is known of the cultural wetland ecosystems that buffered the margins of forests, lakes and rivers, that are now target areas for continued drainage, or ecological restoration for emission trading schemes. Here, insights into pre- and post-colonial cultural ecosystems are drawn from fossil records from wetlands, capturing the last 1000 years of ecological change. Early 14th century archaeological and palaeoecological evidence for irrigated taro (*Colocasia esculenta*) cultivations are presented, reflecting the ancestral cultural ecosystems of the tropical Pacific Islands. Evidence for later adaptation and expansion of kūmara cultivation in the 16th century, as well as the production of potatoes (*Solanum tuberosum*) for the growing colonial market in the early 19th century, is explored. Together with Mātauranga Māori (traditional Māori knowledge), the palaeoecological data captured from lake and swamp sediments could provide baseline ecological data for cultural restoration projects, further reawakening indigenous pride in the achievements of Ngā Tīpuna (the ancestors).

What was the impact of British invasion on vegetation and fire-regime in southeast Australia?

Dr. William Henriquez [1]***, Prof. Michael Fletcher*** [2]

1. *School of Geography, Earth and Atmospheric Sciences, The University of Melbourne,* ***2.*** *University of Melbourne*

Extensive areas of Victoria, a relatively fertile region of southeast Australia, are the homelands of a number of Aboriginal groups who have managed them for millennia using construction, aquiculture and burning methods. Post British invasion, the value of this region was rapidly recognized for Europeans and the land was quickly stolen by settlers for agriculture and livestock. To what extent this shift from an Aboriginal management of country to European-style land management affected the landscape remains an open question. Here we present detailed fossil pollen and charcoal records from sediment cores obtained from Lagoon Landsdale located in Victoria, southeast Australia, to examine vegetation and fire-regime changes since the British invasion. Our data shows a considerable change in vegetation composition and fire activity following invasion and dispossession of lands, and provides a quantitative benchmark for future management of this area and further afield.

A Tale of Two Lakes: Cultural Landscapes, climate change and the environmental legacies of colonialism on the tropical islands of New Guinea and Timor-Leste.

Prof. Simon Haberle [1], ***Dr. Simon Connor*** [1], ***Dr. Larissa Schneider*** [1], ***Dr. Kelsie Long*** [1], ***Dr. Susan Rule*** [1], ***Dr. Frederico Santos*** [2]

1. *Centre of Excellence for Australian Biodiversity and Heritage, School of Culture, History and Language, Australian National University, Canberra ACT, Australia,* **2.** *Instituto do Petróleo e Geologia, Dili, Timor-Leste*

The tropical rainforests of New Guinea and Timor-Leste have been inhabited by culturally and linguistically diverse peoples for more than 40,000 years, creating cultural landscapes that have endured and adapted through extremes of climatic and social change. The cultural landscapes of New Guinea and Timor-Leste have come under increasing pressure from mining, population growth, land clearing, invasive species, and novel pollutants within the last 300 years of colonial expansion and exploitation. This study details the last 4000 years of environmental change in two large lakes – Ira Lalaro (Timor-Leste) and Lake Kutubu (Papua New Guinea) – and demonstrates through multi-proxy palaeoenvironmental indicators the unprecedented transformations in aquatic and terrestrial biota that have occurred in the last 300 years of colonialism. We argue that the incorporation of an adequate historical perspective into models for wetland management and conservation combined with traditional ecological knowledge is critical to mitigate the impacts of ecological catastrophes such as biodiversity loss into the future.

Session 128: African Acheuleans in the Early/early Middle Pleistocene: triggers, techno-subsistences, time-lines

From East to North-West: magnetochronological contribution in dating the oldest African Acheulean archeological sites

Ms. Serena Perini [1] ***, Prof. Giovanni Muttoni*** [1]

1. *Department of Earth Sciences, University of Milan*

Magnetostratigraphy is a key tool for the temporal interpretation of archeological stratigraphies of Quaternary age. Magnetostratigraphy provides age constraints of archeological levels as well as correlations between distant series using chronostratigraphic (time-equivalent) surfaces represented by magnetic polarity reversals, offering the opportunity to place in a common temporal framework critical archeological site for a better understanding of human evolution.

We present the magnetostratigraphic results from the Melka Kunture (Upper Awash Valley, Ethiopia) and Thomas Quarry I (Casablanca, Morocco) archeological areas providing a new temporal framework for human presence and for the first local occurrence of the Acheulean lithic technology in two sites located at the opposite edges of the African continent during the Pleistocene. Each site is associated whit a peculiar litostratigraphic context since at Melka Kunture the archeological levels are enclose within a volcano sedimentary succession characterized by reworked volcaniclastic material variably intercalated with cinerites and tuffs in primary position, some of which have been dated with radiometric techniques, while at Casablanca the sedimentary formation hosting the archeological layers is characterized by coarse-grained biocalcarenites, calcirudites and cave continental infill deposits.

Our data combined with numerical age data from the literature, allowed to reconstruct age models of sedimentation and thus the ages of the archeological levels therein contained.

According to our age-depth depositional models, main archeological levels at Melka Kunture resulted ranging from ~0.6 Ma to ~2.1 Ma, with the notable first emergence of Acheulean technology in Ethiopia estimated at 1.95 (-0.025; +0.1) Ma. At Casablanca, our data indicate the occurrence of early Acheulean technology at ~1.3 Ma**.**

What zooarchaeological evidence for animal consumption during the emergence and development of the Acheulean in Africa?

Dr. Camille Daujeard [1]***, Dr. Raphael Hanon*** [2]***, Dr. Juan Marín*** [3]

1. *UMR 7194 CNRS, Muséum National d'Histoire Naturelle, Université de Perpignan Via Domitia, Sorbonne Universités, Institut de Paléontologie Humaine, Paris,* ***2.*** *1) Evolutionary Studies Institute, University of Witwatersrand, Johannesburg 2) UMR 7194, MNHN/CNRS/UPVD, Paris, France,* ***3.*** *Universidad Nacional de Educación a Distancia (UNED)*

The discovery of cut-marked bones (3.39 Ma, Dikika, Ethiopia) and lithic artefacts (3.3 Ma, Lomekwi 3, Kenya) prior to 3 M years in Eastern Africa challenged current views of human evolution by extending the antiquity of animal consumption using stone tools. However, evidence of meat consumption through the identification of butchery marks before 2.6 Ma is still under debate. The current paradigm postulates that diversification of dietary behaviours, with an increasing part of large game hunting and primary access to carcasses, took place shortly after 2 Ma in Africa. From this date onwards the direct evidence of meat consumption becomes more numerous, as well as the first persistent and structured dwellings. At the same time, between 1.9 and 1.7 Ma, we observe the onset of the Acheulean and the emergence of *Homo erectus sensu lato* populations. However, all these changes cannot be causally related, and rather than the result of behavioural evolution, they could be primarily the result of sampling bias. Moreover, most of the cut-marked remains account for only 1% of the faunal assemblages, and some cut mark identification remains questionable or still needs more evidence. Our knowledge probably also suffers from a lack in the development of taphonomic methodology, and contextual and/or historiological biases. Anyway, although meat consumption occurred quite early in human evolution, common meat consumption, complex forms of cooperative hunting, entire butchery sequences and stone and carcass transport, seem to have developed later, after 1 Ma, throughout the African continent and the Levant in conjunction with early Middle Pleistocene environmental and technical changes. Here, we undertake a literature review in order to provide an exhaustive list of faunal collections bearing tangible cut-marked bones from African sites dated to the period of the emergence and development of the Acheulean, between 1.8 and 0.5 Ma.

The earliest appearance of the Kombewa technique within the Acheulian techno-complex: A technological leap or continuous change?

Dr. Tegenu Gossa [1]***, Prof. Erella Hovers*** [2]

1. 2- Department of Prehistory, Institute of Archaeology, Hebrew University of Jerusalem, 2. Department of Prehistory, Institute of Archaeology, Hebrew University of Jerusalem

The Kombewa technique is often regarded as representing a high degree of sophistication in Large Cutting Tool (LCT) blank predetermination strategies in the Early Stone Age Africa. This technique results in a blank with thinner and biconvex faces that requires relatively minor investment at the shaping stage of LCT production. Thus, the technique is innovative in terms of management of the volumetric configuration of LCTs at *debitage* stage. Despite its techno-morphological advantages, use of the Kombewa technique does not appear to have increased throughout the time span of the African Acheulian, for reasons that have yet to be explored.

To date, the earliest appearance of Kombewa technique is reported from the early Acheulian site-complex of Konso at localities KGA7-A2 and KGA8-A1, both dated to between 1.4 to 1.3 Ma. LCTs made on Kombewa flake blanks were also identified in the younger Konso locality KGA12-A1 (ca. 1.2 Ma). The use of Kombewa production has also been recorded in numerous other Acheulian sites across the wider geographic range stretching from eastern Africa to the Levant and Arabian Peninsula, all of them younger than the earliest Konso record.

Recently, utilization of the Kombewa technique has been recorded at locality MW5 (dated to 1.37 – 1.34 Ma) of the Melka Wakena early Acheulian site-complex, on the southeastern Ethiopian highlands, broadly coeval with the earliest record at the Konso site-complex. The two sites are situated within different paleogeographic, paleoecological, and paleoenvironmental contexts and are over 300 kms apart from one another. The co-occurrence of the Kombewa technique at both sites lends itself to explanation as a case of convergent evolution or as a proxy for pace of technological transfer across the eastern African landscape over a narrow temporal span. The current paper discusses the trends in the use of Kombewa technique and its implications for our understanding of trajectories of technological transfer as well as potential models of Homo *erectus* mobility patterns across the diverse landscape of eastern Africa.

Kanyimangin: a new 1 million years old site in West-Turkana, Kenya

The Early to Middle Pleistocene Transition (EMPT 1250-750 ka) is a period characterised by major environmental changes. These changes are reflected in the archaeological and faunal records which are marked by behavioural, cognitive (Acheulean specialisation/expansion) and morphological (encephalisation) innovations within the genus*Homo*. Unfortunately, the EMPT African hominin fossil record is scarce and poorly correlated with the archaeological record. Here we present faunal and chronometric data of a newly discovered EMPT site in West Turkana: Kanyimangin.

In August 2017, the Trans-Evol Project started fieldwork in the floodplain of the Kerio River (Turkana Basin, Kenya), identifying a new palaeontological and archaeological locality. Kanyimangin is located within the Kalabata river (a tributary of the Kerio river) circular anomaly, where *ca.* 15-meter-deep sediments are preserved from erosion by a series of five sandstones. Although there has been almost no focussed local palaeontological and geochronological study, sediments in that area were believed to be older than 3.7 Ma. However, using combined palaeomagnetism and bio-chronological approaches, we obtain an age estimate between 0.90 and 1.19 Ma.

Kanyimangin has yielded substantial lithic (n=344) and faunal (n=2155) assemblages originating partly from buried contexts. The latter comprises 212 individual specimens (NISP) distributed across 20 taxa. The faunal spectrum is composed of both aquatic and terrestrial taxa, including: *Palaeoloxodon (Elephas) recki* cf. *recki*, *Panthera* sp., *Hyaena hyaena*, *Equus grevyi*, Rhinocerotidae, *Kolpochoerus (limnetes) heseloni*, *Phacocoerus* sp., *Hippopotamus amphibius*, *Syncerus caffer*, *Aepyceros melampus*, *Alcephalus buselaphus*, cf. *Nanger granti* and a Renducini as well as the narrow-snouted *Euthecodon brumpti,* a broad-snouted crocodile, turtles/tortoises, snakes, fish and amphibians.

Palaeomagnetic results reveal a normal polarity for the archaeology-bearing sandstone and evidence for a subsequent period of reverse polarity. Together with the presence of *Palaeoloxodon recki* cf. *recki* recovered from the same sandstone, this suggests a Matuyama age for the site after the Olduvai subchron. To date, most faunal remains were recovered from survey, which limits their biostratigraphic potential; however, the presence of well-fossilised *Phacochoerus sp.* and *Alcephalus buselaphus* specimens recovered on the surface of the archaeology-bearing sandstone equally suggests a Jaramillo (1.06–0.90 Ma) or Cobb Mountain (1.19 Ma) age for the site.

The roots of Acheulian Large Cutting Tools duality: A morpho-technological view from 'Ubeidiya, Israel

Dr. Gadi Herzlinger [1]***, Prof. Naama Goren-Inbar*** [1]

1. The Institute of Archaeology, The Hebrew University of Jerusalem, Jerusalem

The site of 'Ubeidiya, situated in the Upper Jorden Valley, Israel, and dated to roughly 1.5 MaBP, is one of the earliest Acheulian sites outside Africa. Rich lithic assemblages recovered from multiple stratigraphic units, alongside faunal remains and environmental evidence provide the basis for reconstructing numerous aspects of the subsistence, technological and cultural behaviors of Early Pleistocene hominins. The lithic assemblages of 'Ubeidiya show a significant morphological and technological difference from all later known Levantine Acheulian assemblages, being reminiscent mostly of Early Acheulian assemblages from East Africa. Recently, a renewed morpho-technological study combining high-resolution, objective 3D geometric morphometric with traditional technological analyses has been conducted on a sample of Large Cutting Tools (LCTs) from the site. The results corroborate the morpho-technological difference between the 'Ubeidiya LCTs and those recovered from later Acheulian assemblages in the region, while providing a quantitative characterization of the nature and magnitude of these differences. Furthermore, an in-depth analysis of the 'Ubeidiya material demonstrates a clear separation between two classes within the wider LCT category – one with two bifacially worked faces (i.e., handaxes) and the other with more than two, but not all necessarily worked faces (i.e., trihedrals, multihedrals, picks). This separation can be seen on both the morphological and the technological aspects. The results show that the technological paths leading to each of these classes were separated at a very early stage of the *chaîne opératoire*, namely a decision made when the raw material was selected. Several lines of evidence support the notion that this selection was a result of a deliberate decision rather than random chance. The behavioral pattern of intentionally producing two (or more) morpho-technological classes of LCTs is well known from later Acheulian assemblages and was shown to be supported by complex and well-developed cognitive capacities. The results obtained in the current study show that these capacities were already well established in the minds of hominins by the time of 'Ubeidiya.

Differentiated technical behavior in the late Acheulean site of Jaljulia, area D (Israel).

***Dr. Cyrielle Mathias* [1], Dr. Sol Sánchez-Dehesa Galán [2], Mrs. Maayan Shemer [3], Prof. Ran Barkai [4]**

***1.** Tel Aviv University ; UMR 7194 HNHP, **2.** Institute of Archaeology, Tel Aviv University, Tel Aviv 69978, Israel; TEMPS UMR8068, CNRS, Nanterre; Centre de Recherches Français à Jérusalem., **3.** Israel Antiquities Authority; Ben Gurion University of the Negev, **4.** Tel-Aviv University*

The archaeological record of the Levant reveals important changes in the techno-economic organization of late Acheulean groups. Well-dated and large-scale excavations are though rare.
In this paper, we present the results of a global technological analysis of both debitage and shaping *chaînes opératoires* from the area D of Jaljulia, dated to ca. 500 ka. The site, located in the central coastal plain, has yielded several areas rich in lithic material excavated in 2016-2017 by the IAA and Tel-Aviv University. Area D, the oldest one, yielded 24,146 flint artifacts including many bifaces and a rich flake production.
The study of the bifacial pieces shows a priority focused on the distal part of the pieces that indicates a higher technical investment that decreases as it reaches the bottom. This result in higher morphological variability of the pieces that do not reflect lower technical skill of the knappers, but is related to the goals of the knapping activity. A limited range of morphologies of the distal part and the use of blanks of different sizes indicate the search for specific goals in the production and illustrate the diversity of tools produced.
On the other hand, the flaking *chaines opératoires* are diverse, including Levallois (*Lato sensu*), Discoid, S.S.D.A. and Cores-on-Flakes. While hierarchized systems (mainly referred to as part of “Prepared Core Technologies”) are present in small proportions in the late Acheulean Levant, in area D of Jaljulia they represent around 30% of the global flake production.
Flint types used are exclusively local, however, specific blanks and flint types were selected for different production goals. Shaping was preferentially made on brecciated Mishash flint, when more fine-grained varieties were used for flaking, together with Turonian flint. Even within flake production, the hierarchized concepts are applied to higher quality cobbles/pebbles.
Finally, double-patinated items, recycled pieces (including bifaces with preferential removals) and ambiguous pieces indicate a possible continuum between the production systems.
In the broader context of the Levantine Acheulean, Jaljulia offers an original combination of technical choices that reflect important behavioral changes.

Stratigraphy, geochronology and paleoecology at the Earlier Stone Age coastal sites of Mormolo, Benguela Province, Angola

Mrs. Isis Mesfin [1], ***Dr. Maria Helena Benjamim*** [2], ***Dr. Eslem Ben Arous*** [3], ***Mr. Diego Dias Pavei*** [4], ***Dr. Raphael Hanon*** [1], ***Dr. Thibaud Saos*** [5]

__1.__ Muséum National d'Histoire Naturelle, __2.__ Museu Nacional de Arqueologia de Benguela, __3.__ Max Planck Institute for Geoanthropology, __4.__ University of Sergipe, __5.__ University of Perpignan Via Domitia

Mormolo H8-3, an open-air site discovered by L.J. Pais Pinto in the 1970s, is located on the +100m high raised beaches of the Benguela Province (Angola). The Benguela Province is famous for the good preservation of the coastal sedimentary deposits and their prehistorical bearing over a 50 km strip – especially in a massive Red Sand deposit. The base of this deposit is composed of several layers of Stone Age artefacts. However, the raised beaches prehistorical content remained poorly investigated – in the exception of Dungo IV site where excavations, geochronological and lithic analysis were conducted. In 2021, in the framework of the Mormolo Archaeological Project, the new investigations conducted in the neighboring +100m raised beach of Mormolo aimed to build an archaeological map and to work on an extended network of Earlier Stone Age sites estimated to be >500 ka. More specifically, our work aimed to provide key data to study the earliest human occupations at local scale on the on coastal territories and mobility at the onset of the Middle Pleistocene. We initiated the excavations of two localities: Mormolo H8-3 and Mormolo H8-4. The former has preserved faunal vertebrate and invertebrate (sharks, crabs and shells) whereas the latter is interesting for its high density of lithic remains.
Here, we present the first results by providing a new stratigraphic and sedimentological framework as well the taphonomy geochronological (ESR dating) and marine fauna results. We discuss 1/the sites setting in the broader context of Earlier Stone Age open-air sites in Sub-Saharan Atlantic Africa, 2/ the potential of the Benguela Province sites to provide new evidences on the antiquity of the relationship human-coastal environments and 3/ the relationship hominin groups/coastal territory.

Eastern Morocco is well known for its Late Pleistocene cave records. However, until recently, the open-air older record has been scarcely investigated. A cooperative project initiated in 2006 is aimed at investigate the entire Pleistocene open-air sites in the area to test the human settlement in a region close to the well-known Early and Middle Pleistocene archaeological and palaeontological sites of the Moroccan Atlantic seashore and of the Haut Plateaux of Algeria.
Here we present Oued Rabt, a precisely dated Middle Pleistocene Mode 2 site in the Aïn Beni Mathar – Guefaït basin (ABM-GFT). This basin corresponds to the westernmost area of the Haut Plateaux and Salt Lake region of Maghreb, a physiographic unit placed between the Mediterranean and Saharan domains and isolated from the Atlantic coast. Through different proxies we place this archaeological settlement in its ecological setting and discuss its role in the human settlement in the region and importance for the Moroccan and Maghrebian Mode 2 record.

Will the Western African Pleistocene record ever be able to contribute to the interpretation of the African Acheulean(s)?

In West Africa, the chronology, population dynamics and technical behaviour for the Early Stone Age are probably the least understood of the continent for this time period. The Oldowan seems to be virtually absent, and the oldest known industries are designated as Acheulean or Sangoan, depending on the presence of bifacial tools and cleavers or picks respectively, although the Acheulean is generally considered to be older. The earliest dates available so far do not pre-date 300 ka for either of these cultural units, and the few available dates are considered to require revision. Among the main issues is the meager amount of *in situ* sites and the environmental conditions unfavourable for Pleistocene sedimentary sequences to be well preserved, thereby also affecting dating methods' efficiency. However, in the framework of the international program "Human Populations and Palaeoenvironement in Africa- Falémé project", we are currently conducting intensive research on two well preserved *in situ* Acheulean sites located in eastern Senegal, at the Malian border. These two sites, located some 10 km apart, show different site-functions as well as technological and typological divergences between the industries, suggesting the succession of two Acheulean occupations in the area. Efforts to date the sedimentary sequences by OSL and ESR are ongoing, involving methodological developments adapted to the West African Middle Pleistocene sedimentary context. Here, we present these sites and our combined approaches to address the persistent backlog of Early Palaeolithic studies in West Africa, particularly with respect to the Middle Pleistocene Acheulean record. The overall objective is to ensure that data on West Africa finally contribute to an integrated vision of the dynamics at work on the continental scale, at least on the basis of lithic material and a better chronology, since the Pleistocene fauna remains to this day an even greater enigma in this region.

Session 130: Advancing paleoscience in underrepresented regions: promoting records of past socio-environmental systems in the Global South and beyond

Long-term stability and change in Mozambique's savanna woodlands

Mozambique's highly diverse savanna woodlands have developed hand-in-hand with human activity over millennia. Despite the long history of human interaction with these ecosystems, currently they are under threat from human-induced climate change, fire regime change, unsustainable logging and agricultural demand from rapid population growth. Governments and non-government organisations are responding to these threats by implementing policies and practical measures to restore Mozambique's ecosystems. However, these efforts could be misguided in the absence of ecological baselines. We studied the Holocene history of vegetation in Inhambane Province to provide a long-term context for restoration and conservation. Our data contradict the view that this region was a coastal forest prior to recent deforestation, showing instead that species-rich savanna woodland has been a persistent feature. The dominant tree species in today's vegetation are not the same species that prevailed in the past. Fire has been a key disturbance in savanna woodland dynamics for at least 7000 years. These data indicate a dynamic system that evolved and continues to evolve in response to climate and humans. Efforts to restore dense coastal forest in these areas of ancient savanna woodland could lead to biodiversity loss and the erosion of the irreplaceable cultural values and sustainable livelihoods that these ecosystems have supported for millennia.

Climate changes inferred from sedimentary biomarkers during the Pleistocene-Holocene transition in central Chile (~34ºS)

The ancient Tagua Tagua Lake (ATTL) is one of the few places in South America where evidence for a direct megafauna kill site is linked to a sedimentary record of environmental change. The ATTL record is thus ideal for assessing Coupled Human and Natural Systems during the Pleistocene-Holocene transition (PHT). In this work, we carried out a climatic and environmental reconstruction based on sedimentary biomarkers of the archaeological site Taguatagua 3 that indicates more arid and cooler conditions during the late Pleistocene than previously described. Our multi-proxy record spans the last ~20 ka cal BP in a 2.8 m deep sedimentary sequence (14 AMS 14C dates) and was sampled for bulk geochemical indicators, grainsize, n-alkyl leaf waxes (n-alkanes, n-alkanols, fatty acids), sterols, branched glycerol dialkyl glycerol tetraethers (brGDGTs) and calcite isotopic composition (δ18O and δ13C) from carbonate-rich sections. Lipid biomarkers show higher abundance of n-alkanes and n-alkanols compared to fatty acids. Mean annual air temperature (MAAT) estimated using brGDGTs show average values of 16.5ºC, similar to temperatures of sedimentary pigment-based reconstructions in other Late Holocene records from central Chile. n-Alkane, n-alkanol and sterol time series showed that the greatest increase coincided with wet events (i.e. estimated by δ18O carbonate and δD in n-alkane) during the PHT and the Early Holocene. Major shifts occurred at ~12.5-12, ~11.5-11, and ~10.5-10 ka cal BP characterized by the onset of wetter conditions. Additionally, we detected a statistically significant cold pulse between ~11.7 and 10.5 ka cal BP that corroborates previous results. The ATTL record suggest important changes in the strength of the South Pacific anticyclone, synchronous with large-scale atmospheric changes during Younger Dryas, but persisting 500 years after the onset of the Holocene.

Holocene hydrological changes in southeastern Mozambique

Climate changes are one of the drivers responsible for lake hydrological changes. Thus, the InMoz project aimed to understand southeastern Mozambique's hydrological changes through the Holocene. This is particularly relevant because there are few paleoclimate studies in this region of the globe. The study of paleohydrological changes in Mozambique is essential to better understand regional and global patterns of climate change and the impact of their dynamic on human populations (i.e., settlement pattern and dispersal). To do so, we collected a ca. 6 m long sediment core on a Mozambican coastal lake, and we analyzed it using a multi-proxy approach (e.g., sediment texture, geochemistry, diatoms, ostracods, mollusks and foraminifera). The analyzed proxies showed that from 7200 to ca. 4100 cal BP the lake water varied between salt and freshwater, because of marked seasonality during a warmer and wetter climatic phase than today. Between ca. 4100 and 1200 cal BP, the lake water became mostly brackish. From ca. 1200 cal BP to the present, it was mostly freshwater. Throughout the record, the proxies indicate that the lake water was alkaline and there was an increasing trend towards eutrophic conditions. Thus, the lake's hydrological shifts were likely driven by an increasingly moist climate in the catchment area and the introduction of agricultural activities in the region, reflecting long-term interactions between humans and the surrounding environment. This work was financed by the Portuguese Science Foundation through project PTDC/HAR-ARQ/28148/2017 and contract CEECINST/00146/2018/CP1493/CT0002.

Vanuatu cultural landscapes across time and space

Islands are emblematic cases of anthropogenic impacts on ecosystems. First human settlements in Remote Oceanic Islands came along with major landscape modifications. Which factors led to the failure or the establishment of a sustainable human-ecosystem interaction remains an open question. Reconstructing past human activities can help to retrieve information on the environmental responses to different degrees of change. The archipelago of Vanuatu is a key area for the recent human colonization of the Pacific (~3000 years ago), which came along with major landscape modifications and is vulnerable to extreme events and climatic changes, past, present, and future. Through the multi-proxy analysis of lakes sediment cores from the archipelago of Vanuatu, we provide paleoclimatic and paleoenvironmental reconstructions, combining geochemical tools based on biomarkers with sedimentological and palaeoecological analyses in sites with different degrees of archeological knowledge. High-resolution radiocarbon dated sedimentological records from the islands of Efate, Espiritu Santo, and Ravenga are presented and confronted against different times and modes of human occupation. Environmental reconstructions are validated with local knowledge and memories to understand indigenous communities' resilience to environmental changes observed in the cores such as extreme events (volcanic eruptions, droughts, cyclones). Tracing past land-use and climate change, on remote Pacific islands, and the response of local inhabitants to these changes highlights the links between cultural activities, such as agricultural practices, and the environment and contribute to identifying key factors related to the ecological resilience and the adaptive capacity of socio-ecological systems in changing environments.

Understanding flood histories and anthropogenic impacts on lakes in South Asian mega deltas

Climate change and anthropogenic impacts on freshwater ecosystems in South Asia exacerbate issues caused by dynamic, and densely-populated river mega deltas. These ecosystems face impacts from changes to their hydrology, alteration of seasonal monsoon patterns, urbanisation, industrialisation and land-use change. Floods derived from seasonal rains or extreme weather events have historically brought benefits as well as hazards. South Asia is highly vulnerable to projected climate changes and its associated impacts, but the uncertainty in changes to severity and frequency of floods, as a result of a paucity data of flood data, makes it difficult for policy makers to plan for management of and development of adaptation strategies for vulnerable freshwater ecosystems. Moreover, many societies are dependent on the services provided by lakes and other waterways in these systems and a need to understand the impacts they are having to work toward sustainable usage. Palaeolimnology is well-placed to put flooding and anthropogenic impacts on waterways in context and provide much needed long-term data series that is lacking in this global region. In this study, we use multiple sediment cores recovered from oxbow lakes on the Ganges-Brahmaputra-Meghna Delta spanning India and Bangladesh. Chronologies have been established using ^{210}Pb radiometric dating and multi-proxy analysis including grain-size, magnetic susceptibility, XRF, and pigments was conducted to detect flood histories and anthropogenic impacts. Our results are the first to put climatic and anthropogenic impacts in context with the limnological history of these important social-ecological mega-deltas.

Understanding human-driven ecosystem change in a rare Malaysian flood pulse wetland (Tasik Chini)

Dr. Jack Lacey [1], Dr. John Boyle [2], Dr. Charlotte Briddon [3], Dr. Stefan Engels [4], Dr. Mushrifah Idris [5], Prof. Melanie Leng [1], Prof. Suzanne McGowan [6], Dr. Keely Mills [1], Dr. Virginia Panizzo [7], Prof. David Ryves [8], Dr. Christopher Vane [1]

Tropical areas are undergoing rapid environmental change as a combined result of climate change and human impact on the landscape, which significantly threatens the quality and biodiversity of freshwater ecosystems. Tasik Chini is a flood pulse wetland located in Peninsular Malaysia and is one of the few lake basins in the low-lands of this region. The site is of great ecological importance and designated a UNESCO Biosphere Reserve. In recent years, the natural vegetation of the catchment and surrounding area has become increasingly influenced by forest clearance, oil palm plantations, mining, logging, and tourism, which have resulted in pollution, soil erosion, and external nutrient loading to the lake. The main outflow river has also been dammed to help sta-bilise the water level. Together, these activities have changed the hydrological balance of the lake, influenced biodiversity causing species and habitat loss, and led to eutrophication. To understand the influence of major changes in catchment land use on the lake and to investigate the key drivers of ecosystem change, sediment cores have been recovered from across Tasik Chini. The first core is from a site adjacent to a tourist resort, the second core is from a basin situated close to mining activity, and the final core was retrieved from a site furthest from major catchment disturbance. An established chronology based on ^{210}Pb dating shows each gravity core covers back to the late 19th century and spans the transition to enhanced human impact within the catchment. Organic geochemistry (%C, C/N, carbon isotopes, Rock-Eval pyrolysis), diatom assemblage, elemental concentra-tions, and sedimentary pigments have been analysed on each core to reconstruct past environmental conditions. Combined with a longer sediment record from the lake dating back to 4.8 ka, data show how past variability compares to recent anthropogenic-induced environmental change and define how different catchment distur-bances have contributed to ecological change at this internationally important wetland site. This information is vital to assess ongoing human impacts at the site as a means to provide science-based management strategies and thereby counter the main drivers of ecosystem degradation.

Reconstructing biogeochemical cycling and primary producer community change at Hoa Binh Reservoir, Vietnam

The Hoa Binh reservoir is a major impoundment upstream of the Red River Delta (RRD), Northern Vietnam. Since its construction in 1988, downstream mean discharge has reduced in tandem with suspended sediment transport, which together with sea level rise, have contributed to an increased risk of saline water intrusion in the RRD. Palaeoecological reconstructions from Hoa Binh reservoir, dated radiometrically, document the transition and stabilisation of the lake since its creation from river impoundment in 1988. First changes in sediment composition are identified after c. 1997, when an increase in organic content (Rock Eval) and $\delta^{15}N$ compositions takes place. After c. 2004 there is evidence of increasing Fe_2O_3 deposition, concomitant with an increase in sedimentation rates. Algal pigments also show a general increasing trend after 2004, with prevalent concentrations of cryptophytes (alloxanthin), siliceous algae (diatoxanthin), chlorophytes (lutein) and cyanobacteria (canthaxanthin). Further increases of these algal groups are documented post c. 2010 with sedimentary preservation indicators (Chl *a*:*a* phorbins) also showing an increasing trend; the latter possibly reflecting the increases in sedimentation rates and organic carbon fluxes in response to cultural eutrophication. Similarly, diatom concentrations (*Aulacoseira* and *Cyclotella species*) show a sharp increase after c. 2010, pointing to a more eutrophic environment and changes in lake stratification.
%C shows a gradual increasing trend since dam implementation, with a decline in $\delta^{13}C$ signatures (from c. −24 to −29‰), with C/N values (<10) indicating that throughout the core carbon is sourced from aquatic productivity. Microcystin occurrences also indicate the presence of cyanotoxins throughout the sediment record (reaching up to c. 50 ng g^{-1} OC^{-1}) with highest fluxes being recorded in the surface sediments (>750 ng cm^{-1} yr^{-1}). This is concomitant with the appearance of *Cyclotella stelligera* after c. 2016. Together, the multi-proxy stable isotope, geochemical and algal analysis adopted in this study demonstrate the recent impact of increased aquaculture in the Hoa Binh reservoir, which has triggered the increased proliferation of harmful algal blooms, eutrophication and an increase organic carbon fluxes to the sediment record.

Fossil-CO2 have been detected in tree species in Central Amazon basin due to mining operations and increased use of rivers as trade routes

Tree rings has been widely used for atmospheric radiocarbon (^{14}C) calibration purposes, including those associated with the post-1950AD (nuclear era). However, tree ring ^{14}C records have been limited along tropical latitudes. Recently we obtained precise ^{14}C dates in tree rings (1937 to 2007) of the parenchyma-rich *Hymenolobium petraeum* tree species from the Central Brazilian Amazon (Porto Trombetas, 1°S, 56°W). Radiocarbon results showed that the *H. petraeum* atmospheric ^{14}C signals surrounding the bomb peak (1950–1971) are in agreement with the broader changes associated with reported values of the Southern Hemisphere ^{14}C curve based on a stand-alone tree ring ^{14}C record of *Tectona grandis,* Indonesia. After 1980, *H. petraeum* atmospheric ^{14}C signals reveal local fossil fuel-related contributions that are most likely from heavy-duty diesel engines used by mining operations as well as those from shipping activities by cargo ships in the Amazon River downstream and estuary areas. The local dilution of atmospheric $^{14}CO_2$ captured in wood tissue and measured by high-precision ^{14}C accelerator mass spectrometry coincided in time with the implementation and expansion of the mining activities and trade networks that uses the Trombetas and Amazon rivers to handle most of export shipments of country’s ore, soybean and corn by transnational business giants. Thus, atmospheric ^{14}C variability in the Central Amazon has a wide range of natural and anthropogenic sources, and must be monitored closely.

Session 133: Unravelling Mediterranean sensitivity to past rapid climate variability

Expressions of Holocene Rapid Climate Changes in eastern Mediterranean proxy data

Prof. Eelco Rohling [1]

1. *Research School of Earth Science, Australian National University, Canberra, Australia*

During Holocene Rapid Climate Change (RCC) cold events, reflected in Greenland non-seasalt K^+ time series, Mediterranean surface-water temperatures were reduced, and deep-water ventilation changes occurred. This indicates that the basin was affected intensely and persistently enough to overcome the considerable inertia of its deep and extensive water mass. We explored the impact of cold winter events on the eastern Mediterranean with an idealised model that uses Greenland ice-core K^+-based changes in the annual frequency of 10-day cooling events with increased wind speeds (based on modern observations), superimposed upon the winter half-year of a regular (sinusoidal) annual cycle. The model resolves evaporation, precipitation, temperature, salinity, and stable oxygen isotopes. It considers only cold anomalies relative modern conditions, and not intervening events that may be warmer than present. It also ignores long-term (orbital) changes. Reconstructed sea-surface coolings agree well with observed coolings, both in timing and in amplitude. Concomitant salinity increases are simulated, in agreement with density changes that can be inferred from deep-water ventilation during the cold anomalies. The model simulates strong increases in negative degree days at 2 km altitude in Crete, which agree with reports of persistent snow cover in high Cretan mountains during the Little Ice Age. Snow-line drops are simulated down to altitudes of 770 m for the Levant, consistent with snow events observed in Jerusalem (787 m) during modern cold outbreaks over the eastern Mediterranean. Modelled precipitation increased by similar amounts in Crete and the Levant, and $\delta^{18}O$ of precipitation decreases in both locations, albeit by different amounts. Hence, the $\delta^{18}O_p$ changes do not seem to reflect a classical "amount effect", but instead changes in the mass-balanced mixing between the amount of moisture held in incoming air (lower for colder events), and the amount of moisture added due to evaporation from the sea (greater for colder events). The modelled $\delta^{18}O_p$ changes agree well with high-frequency $\delta^{18}O$ at Jeita Cave, Lebanon. Overall, the experiments indicate that a more rigorous quantitative framework is needed for interpreting the varied expression of abrupt climate events on Mediterranean proxy records because compensating effects can lead to a variety of counter-intuitive impacts.

Opposite trends of tree cover changes in the Mediterranean Basin around the 4.2 ka BP event

Dr. Fabrizio Michelangeli [1], *Dr. Federico Di Rita* [1], *Dr. Alessandra Celant* [1], *Prof. Donatella Magri* [1]

1. Dipartimento di Biologia Ambientale, Sapienza Università di Roma, Roma (Italy)

In the Mediterranean Basin the so-called “4.2 ka BP event” is recognized as a period of overall climate instability connected to hydrological changes, although the timing, nature, and expression of climate change were not uniform. Tree cover changes in pollen records are an excellent candidate proxy for reconstructing the geographical expression of moisture changes over time.

To investigate the response of vegetation to climate variability during the 4.2 ka event, we compiled a pollen database of 486 sites from all over the Mediterranean Basin and surrounding regions. Our aim was to verify whether general trends of increases/decreases in tree cover are detectable throughout the Basin and whether they show any spatiotemporal pattern. We considered variations in Arboreal Pollen (AP) percentages before and after 4.2 ka BP as a simple, uniform, and direct proxy for past tree cover change. The comparison of AP% before (4.5 ka BP), at the onset (4.2 ka BP) and at the end (3.9 ka BP) of the 4.2 event suggests that coherent increases and decreases in tree cover occurred in different areas of the Mediterranean Basin.

Between 4.5 and 4.2 ka BP, a forest decline is observed in NW Iberia, in Sicily, and the southern Italian Peninsula, while in Mediterranean Iberia, Morocco, and the Levant, there was a moderate increase in tree cover. In a wide belt including France, N Italy, Corsica, and Sardinia, the northern Balkan Peninsula, and the Caucasus, there were minimal variations.

Between 4.2 and 3.9 ka BP, an increase in forest cover is observed in NW Iberia, in Sicily, and the southern Italian Peninsula, while in Mediterranean Iberia, Morocco, and the Levant an opening up of forests occurred. No statistically significant changes in AP% are recorded in the geographical belt stretching from France to the Caucasus.

These results allow to circumscribe regions sensitive/unsensitive to hydrological changes across the Basin and to highlight consistent spatiotemporal patterns of bioclimatic change. Tree cover variations revealed bioclimatic processes of opposite polarity in different regions of the Basin, suggesting the occurrence of a sign-switching pattern centred at 4.2 ka BP.

Deglacial and Holocene changes in Mediterranean Thermohaline Circulation: A joint perspective from Eastern and Western basins

The dominant arid climate conditions over the Mediterranean (Med) control water properties and the formation processes of intermediate and deep water masses. Deep convection cells occur in both the E- and W-Med basins and there are interconnected through the intermediate waters mostly formed in the easternmost area of the Med. During last deglaciation and Holocene periods both E- and W-Med had experienced periods of major disruptions in deep convection. The last organic layer (ORL1) formed in the W-Med during the deglacial period and later the last sapropel (S1) in the E-Med. Both enhanced productivity and enhanced stratification are regarded as the causes for the two events but responding to different drivers, the deglacial freshening in the case of the ORL1 and the African monsoon flooding for the S1.

Here we present U/Mn ratios measured in the foraminifera diagenetic coatings from sediment cores from both E- and W-Med. The nature of this proxy, sensitive to oxygen water content, allows its application in a wide range of oceanographical/oxygen conditions, a situation that compromises other proxies whose carrier is limited by the changes in oxygen content. This approach allows us, by the first time, to compare the oxygen evolution of individual basins and at different water depths by means of the same tool. The obtained results indicate the deglacial development of an intense minimum oxygen zone in the W-Med associated to the LIW which extended down to at least 950m in association with the ORL1 formation, highlighting that the E-Med could also had had an important role in the development of this ORL1. During the Younger Dryas a re-ventilation process of the W-Med interior started at around 900m and evolved upwards and downwards to fully develop at shallower and deepest depths (300 and 1840 m respectively) at the onset of the S1 in the E-Med. Changes in the thermohaline system of the E and W-Med were closely related but with opposite sign in their response during critical events such as the S1.

Variabilities in Mediterranean water circulation across the Holocene and the last interglacial humid periods

Projections of the Mediterranean thermohaline circulation generally indicate stagnant circulation by the end of the 21st century, although the amplitude of the changes is variable with models. To evaluate the sensitivity of the Mediterranean circulation to different forcing, we studied the intermediate and deep water states during Holocene and the last interglacial when excess freshwater inputs had promoted the deposition of organic-rich layers "sapropels" in the eastern basin. The deposition of sapropels S1 (6.1-10.5 ka) and S5 (centred around 125 ka) was related to strong stratification of water column and consequent reduced ventilation. We reconstructed seawater neodymium isotopic compositions ($^{143}Nd/^{144}Nd$ or ε_{Nd}) by analysing authigenic fractions from the western (ODP site 977 in the Alboran Sea and PRGL1-4 in the Gulf of Lion) and eastern (SL95 in the Gulf of Sirte) basins. To evaluate hydrological perturbation, planktonic foraminiferal oxygen and carbon isotopic compositions ($\delta^{18}O$ and $\delta^{13}C$) were analysed for eastern basin cores (SL95 and MD04-2724 in the Levantine Sea).
The new authigenic ε_{Nd} records from the western basin showed limited variation from -9.3 to -8.0 for the study periods. In contrast, the eastern basin core presented a marked ε_{Nd} increase during sapropel periods from about -8 up to -4.6 with higher values during S5. Since the western ε_{Nd} range is comparable with the present-day water value, reconstructed zonal seawater ε_{Nd} gradient was enhanced during sapropel depositions. The new planktonic foraminiferal $\delta^{18}O$ ranged from -0.9 to 4.8‰, and -2.3 to 3.3‰ over the past 140 ka for SL95 and MD04-2724, respectively. Both records showed a marked decrease in foraminiferal $\delta^{18}O$ and $\delta^{13}C$ that started prior to S1 and S5. A 6-box model calibrated for the modern seawater ε_{Nd} suggests the observed increase in zonal ε_{Nd} gradient can be produced by reduced circulation in the eastern basin and more radiogenic Nd inputs including enhanced Nile river particle loads and/or longer contact with labile detrital sediments due to stagnant circulation. The relationship between the hydrological perturbation suggested by planktonic foraminiferal stable isotopes and authigenic ε_{Nd}records will be discussed using compiled data.

Abrupt and persistent shutdown of the thermohaline forcing during MIS5e in the Adriatic Sea: insights from shallow-water sapropel sediments

The orbitally-driven anoxia that cyclically occurred in the Eastern Mediterranean Sea (EMS) is one of the strongest evidence showing how climate change and thermohaline forcing are connected to each other. Most of the focus in sapropel studies has been traditionally placed on deep sediments where the sapropel is indeed well-expressed yet far from the margins where dense water forms. To provide a shallow-water perspective, we investigated the Sapropel S5 on the Adriatic shelf (borehole PRAD1-2; 185.5 m water depth) during MIS5e. This archive is strategically located in a region where the dense cold-water interacts with the seabed before cascading off the margin. Zr/Rb (grain size) and Mg/Al (sediment provenance) ratios were used to resolve the degree of dense water export while the extent of deoxygenation was reconstructed through trace elements (U, V, Mo, Sb) and benthic foraminifera abundance. Stable isotopes of foraminifera ($\delta^{18}O$,$\delta^{13}C$) and organic geochemistry data (TOC, alkenones) provided additional information about water column and sediment properties. Finally, we synchronized our record from the margin with other deep sapropel S5 (LC21, 971A, KS205 and 967) to harmonise shallow and deep archives over a common time scale.

Collectively, our results show that the shutdown of the convection over the margin was an abrupt event (ca. 128 ka BP) that occurred in a few centuries. Pre-sapropel deoxygenation started ca. 131 ka BP without signs of weakening in the dense water formation; this puts forward the hypothesis that pre-sapropel changes were driven by trophic conditions possibly linked to sea level rise and advection of nutrient-rich Atlantic waters. Weak dense water formation lasted for about six millennia while the redox conditions changed throughout this period suggesting a scenario of steady stagnation superimposed to variable productive conditions. Overall, our results do not support the hypothesis that anoxia requires a long prelude of deep-water stagnation driven by the post-glacial inflow of relatively fresh deglacial Atlantic waters; rather our data highlight the abrupt nature of convection that responds to short-term climate variability. In our presentation, we further discuss the thermohaline shutdown in terms of freshening and general winter warming compiling evidence from the literature.

Abrupt Mediterranean storm track reorganization and cooling during the mid-last Interglacial at Peqi'in Cave (Israel)

Dr. Elan Levy [1], ***Dr. Hubert Vonhof*** [2], ***Dr. Miryam Bar-Matthews*** [3], ***Dr. Alfredo Martínez-García*** [1], ***Dr. Avner Ayalon*** [3], ***Prof. Alan Matthews*** [4], ***Dr. Vered Silverman*** [5], ***Dr. Shira Raveh-Rubin*** [5], ***Ms. Mareike Schmitt*** [1], ***Prof. Gerald Haug*** [1]

1. Max Planck Institute for Chemistry, 2. Climate Geochemistry, Max Planck Institute for Chemistry, Mainz, 3. Geological Survey of Israel, 4. Institute of Earth Sciences, The Hebrew University of Jerusalem, 5. Weizmann Institute of Science

The mid last interglacial (mid-LIG; ca. 126 ka) was punctuated by reductions of North Atlantic Deep Water (NADW) ventilation and North Atlantic Sea Surface Temperature (SST) cooling. Associated with these marine events are evidence of terrestrial cooling and climate change in speleothems from central and southern Europe. Here we reconstructed a temperature record from organic compounds (TEX_{86}) in a speleothem at Peqi'in Cave (northern Israel) and show that the mid-LIG cooling event extended to the eastern Mediterranean. The temperature record exhibits a climate optimum during the early-LIG (128 - 127 ka) followed by a significant irregular cooling of up to 3-4°C (126 - 123 ka) and then a recovery (123 - 118 ka). However, there is a lack of clarity on how mid-LIG oceanic changes in the North Atlantic are connected to the eastern Mediterranean cooling and reconstructing the atmospheric configuration is key to understanding this connection. We investigated atmospheric configuration changes during the LIG by extracting small volumes of paleo-rainfall trapped in the speleothem crystalline structure (fluid inclusions), measuring the stable isotope composition ($\delta^{18}O$ and δD), and then reconstructing a high-resolution *d-excess* ($\delta D - 8\times\delta^{18}O$) record. The Peqi'in *d-excess* record reveals shifts in the paleo- Eastern Mediterranean Meteoric Water Line (EMMWL) which argue for moisture uptake changes in the Mediterranean that are also coupled with the LIG temperature changes. The *d-excess* decreases from an early-LIG peak at 35‰ to below 20‰ at ca. 126 – 122.5 ka (minimum 16.5‰) and then increases after ca. 122 ka to 26 ‰. To explain these *d-excess* trends we determined the long-term contributing factors for modern rainfall *d-excess* in Israel (for rainfall events at Soreq Cave between 1995 and 2021). Extending these results to the LIG suggests a wintertime dominant storm track reorganization, characterized by a shift from meridional (northerly) to zonal (westerly) trajectories, occurred in the eastern Mediterranean from the early- to mid-LIG. The shift to zonal trajectories with clear North Atlantic origin during the mid-LIG underpins a mechanism for facilitating cooling in southern Europe and the eastern Mediterranean.

Changes in Atlantic Intermediate Water circulation and Mediterranean Outflow during Termination V in the Southwest Iberian Margin

***Prof. FRANCISCO SIERRO* [1], *Dr. Nils Andersen* [2], *Mr. Javier P. Tarruella* [1], *Mrs. LUCIA AZIBEIRO* [3]**

***1.** Universidad de Salamanca, **2.** Christian Albrechts University Kiel, **3.** University of Salamanca*

The size of the Northern Hemisphere Ice sheets reached one of the highest levels during Marine isotope stage 12. Their collapse during Termination V caused a deep impact on the Atlantic and Mediterranean thermohaline circulation. Large amounts of freshwater were delivered from the Eurasian and Laurentide Ice sheets to the north Atlantic and the Mediterranean, causing a rapid sea level rise and a reorganization of Atlantic and Mediterranean Meridional Circulations. To better understand the impact of these changes we studied stable isotope records in planktic and benthic foraminifers in IODP Site U1389 in the Gulf of Cadiz (SW Iberia, NE Atlantic), ODP site 977 (SE Iberian Margin, Western Mediterranean) and site PRGL1 (NW Mediterranean). Planktic foraminifer assemblages were also analyzed to estimate sea surface temperature and changes in surface seawater d18O in the Atlantic inflow and the western Mediterranean. A significant meltwater event is recorded at the onset of Termination V in the SW Iberian Margin, synchronous with the arrival of cool, subpolar low salinity surface waters. The imprint of freshwater is also recorded in the Mediterranean surface waters both in the westernmost and NW Mediterranean, as well as in the Mediterranean Outflow. In the NW Mediterranean, this event is related to a rapid sea level rise recorded by a sudden change in the sedimentation linked to the landward retreat of Rhone deltaic system in the Gulf of Lion.

Session 134: How Absolute and How Relative: Challenges and Resolutions Associated with Applying Dating Techniques in the Quaternary period

Amino acid geochronology: advances and limitations in bivalve shells

Dr. Martina Conti [1], ***Dr. Paul Butler*** [2], ***Dr. David Reynolds*** [2], ***Dr. Harry Robson*** [3], ***Prof. Nicky Milner*** [3], ***Prof. James Scourse*** [2], ***Prof. Kirsty Penkman*** [1]

The SEACHANGE project is a multidisciplinary project that aims to reconstruct marine ecosystems prior to and after significant cultural transitions. For robust geochronology, radiocarbon dating of organic material, cross-matched and cross-dated sclerochronology (dating of hard tissues of shells) are employed. Cross-matched floating sclerochronologies (not precisely calendar-dated) can provide annual resolution records spanning decades to as much as 500 years for the longest-lived shells. Developing this record requires visually and statistically comparing growth ring width patterns (cross-matching) across numerous samples. Such an endeavour can be hugely time consuming and therefore needs to be targeted appropriately, especially when dead-collected samples are of unknown antiquity. Radiocarbon dating can be a very precise technique, but it is not always economically viable, especially for a large number of samples (>2,000), and it requires correcting for the marine reservoir effects.
Here we explore the potential for range-finding age estimates of individual dead shells by amino acid (AA) geochronology. AA dating is a relatively fast and cheap technique, which can be used to constrain the time period for any floating sclerochronologies. Previous work on the intra-crystalline protein fraction from calcareous biominerals has resulted in a robust dating method for the Quaternary period. High precision can be achieved in warm environments, for example, cross-dated Porites coral skeletons provided precisions ±24 years across different colonies in samples from the last 150 years.
In addition to the already known caveats of AA geochronology, bivalve shells also present the additional complication of having different microstructures. These have shown significant but consistent variation in AA composition between the microstructural layers, meaning that targeted sampling is necessary to establish a robust and reproducible method for dating bivalve shells. In SEACHANGE, aragonitic Arctica islandica and calcitic Ostrea edulis are targeted in the first instance to constrain mediaeval and Mesolithic-Neolithic shell middens, respectively, showing the range and resolution in dating. These preliminary results indicate that the inner portion of the outer shell layers (iOSL) of A. islandica and foliated layer of O. edulis should be targeted for AA geochronology.

Advances in amino acid dating of Pleistocene mammalian tooth enamel

Directly dating mammalian remains is extremely difficult beyond the limits of radiocarbon dating (~50 ka). One possible direct dating method is to use the predictable breakdown of proteins and amino acids in biominerals that contain closed-system organics. This has been a powerful tool for age estimation in calcium carbonate biominerals (back to ~2.5 Ma). It's application to mammalian tooth enamel has been challenging but we have developed a novel method to target a proteinaceous fraction in enamel protected within the biomineral crystals (the intra-crystalline fraction), which has alleviated difficulties associated with contamination, leaching and environmental influences.

The extent of intra-crystalline protein degradation (IcPD) in elephantid enamel has been tested against known age material from the British Isles, the East European Plain and the Mediterranean, showing a strong correlation between IcPD and age. It is therefore now possible to provide direct age estimates for unknown age elephantid material from these regions. Analysis of horse and bison remains from several Middle Pleistocene sites, enables investigation into the taxonomic differences in the rates of amino acid breakdown.

We are currently extending the approach to mammalian enamel from Africa, with a focus on sites that are important for understanding human evolution. The technique is being applied to diverse taxa (e.g. equids, suids, bovids, rhino, antelope) to build complementary geochronologies that improve the robustness of age assessments.

To better understand the processes of amino acid preservation, we are investigating taphonomic alteration of fossil enamel using an array of techniques including high resolution imaging. We are also exploiting the advances in microfluidic technology to develop a "lab-on-a-chip" approach for preparation of enamel samples, with a twofold aim: firstly, to reduce sample sizes from ~30 mg to ~ 1 mg; and secondly to ultimately enable IcPD dating to be undertaken outside specialist labs.

Direct cosmogenic nuclide isochron burial dating of early Acheulian stone tools at the T69 Complex (FLK West, Olduvai Bed II, Tanzania)

Dr. Toshiyuki Fujioka [1]***, Dr. Alfonso Benito-Calvo*** [2]***, Prof. Rafael Mora*** [3]***, Prof. Lindsay McHenry*** [4]***, Prof. Jackson Njau*** [5]***, Prof. Ignacio de la Torre*** [6]

1. *Centro Nacional de Investigación sobre la Evolución Humana, Burgos, Spain,* ***2.*** *Centro Nacional de Investigación sobre la Evolución Humana (CENIEH),* ***3.*** *Universitat Autonoma de Barcelona,* ***4.*** *University of Wisconsin-Milwaukee,* ***5.*** *Indiana University,* ***6.*** *Instituto de Historia, CSIC-National Research Council*

Olduvai Gorge is one of the best-known paleoanthropological sites worldwide for the wealth of its Early Pleistocene paleontological-archeological record. This paper contributes to the ongoing effort to construct a solid geochronological framework for Olduvai archeological sequences by applying cosmogenic nuclide-isochron burial dating directly to stone artefacts. We apply the method to a new site named T69 Complex, located in the FLK West gully and positioned stratigraphically in Bed II. The chronology of Olduvai Bed II is not well constrained compared to underlying Bed I, due to fewer tephra layers suitable for K-Ar and Ar-Ar dating. This study applies a radiometric method that has never been attempted before at Olduvai Gorge. Cosmogenic nuclide-isochron burial dating is significant as it can be applied directly to stone tools, rather than indirectly estimating ages from surrounding sediments that are not always guaranteed to be the same age as the artefacts they contain. The method utilizes two cosmogenic isotopes (Be-10 and Al-26) measured in multiple samples collected from a stratigraphic horizon to determine a burial age. The approach is innovative by overcoming the uncertainty of conventional simple cosmogenic burial dating, e.g., the issue of post-depositional nuclide production. The stone tools selected for dating in this study were collected from the main archeological unit, T69L20. The dated artifacts are six cores and two hammerstones of quartzite. The resulting age in this study yields 1.48 ± 0.25 Ma for the Bed II sequence, which is consistent with previous dates from upper (~1.3 Ma) and lower bounding layers (~1.7 Ma). To our knowledge this is the first attempt to apply the cosmogenic nuclide-isochron burial dating directly to stone tools. The result is promising and opens up a new opportunity for future archeological studies. This Middle to Upper Bed II stratigraphic interval at Olduvai Gorge is a key period for our understanding of the disappearance of *Homo habilis* and the emergence of the Acheulian. This paper helps to more narrowly constrain the chronostratigraphic context to interpret assemblage variability during the onset of the Acheulian, at ~1.5 Ma in Olduvai Gorge.

Geochronology of Quaternary sediments at the Jeongokri archaeological site, South Korea

Dr. Jin Cheul Kim [1], ***Dr. Sei-sun Hong*** [1], ***Dr. Jin-Young LEE*** [2], ***Dr. Seungwon Shin*** [3], ***Prof. Daekyo Cheong*** [3], ***Dr. Tae-Ho Lee*** [1], ***Dr. Hoil Lee*** [4], ***Dr. Yire Choi*** [1], ***Dr. Hyeon-Seon Ahn*** [2], ***Dr. Han Woo Choi*** [2]

1. *Korea Institute of Geoscience and Mineral Resources (KIGAM),* **2.** *Korea Institute of Geoscience and Mineral Resoiurces,* **3.** *Kangwon National University,* **4.** *KIGAM*

The Palaeolithic site of Jeongokri, South Korea, is known for first discovering the so-called "Acheulian-like" handaxes in East Asia. The geology of this study area is composed of Precambrian gneiss, Jurassic granite, Quaternary unconsolidated gravel and sand layers, Quaternary basalt, Quaternary unconsolidated fluvial sediments and paleosols with decreasing age. The palaeolithic artefacts have been excavated from the uppermost paleosols in the Jeongokri area. In this study, direct dating of the artefact-bearing layers was attempted by applying OSL techniques, which showed great potential for use in the accurate determination of the timing of deposition. To extend the age range of OSL dating, a thermally transferred optically stimulated luminescence (TT-OSL) signal and single-grain K-feldspars using the post-Infrared Infrared stimulated luminescence (pIR IRSL) were also investigated. The Jeongok Basalts were directly analysed using the Ar-Ar method. ^{10}Be dating from the unconsolidated gravel and sand layers underlying the Jeongok Basalt were dated for burial age. These results of multiple absolute dating methods allow the development of chronologies of the Jeongokri archaeological sites and constrain the timing of the earliest hominin occupation in South Korea.

Finding and dating microlithic sites in the central Narmada Basin: a field memoir from an archaeologist's eye

Dr. Nupur Tiwari [1]

1. *Department of Humanities and Social Sciences, IIT Bombay*

It has always been a dilemma for researchers working in the field of prehistoric or palaeolithic archaeology, especially in India, to find sites in a stratigraphical context and find a suitable dating method to establish geochronology. Majorly the sites are found in surface context. These archaeological logs on the landscape speak vastly of the palaeolithic occupations in India during the Quaternary period. Microliths are one of the small tool types abundantly found on the landscape all over India (apart from the Siwaliks and north-eastern India). Due to the lack of sites in a stratigraphical context, it has become nearly impossible to understand and comprehend the antiquity of microlithic sites in India. For the author's doctoral fieldwork (2015-2019), the central Narmada Basin was chosen to locate and document these microlithic bearing sites. Out of 225 microlithic occurrences, eighteen major sites were chosen for collections and out of these eighteen sites, six were shortlisted for OSL and sedimentology sample collections. Finding large sections in this region with microliths embedded in stratigraphy was daunting, and none were found. The spread of microliths was mainly restricted to the undisturbed areas of the pediment zone of the Vindhyans and Gondwanas. To select the sites for OSL dating, a few crucial factors were considered, i.e. the area should be least disturbed, artefact distribution and density, and artefact condition. Microliths were found freshly eroding from the 50 cm- 1-meter sediment accumulation, shaping into small mounds and the sample was collected from the middle of these sections. Sediment variation was seen at all the locations. After multiple visits to these shortlisted sites, OSL collection areas were selected, sections were correctly scraped, and the sample was collected following all the protocols. Aluminium and stainless steel tubes were used to acquire the sample. This paper discusses a preliminary attempt to date and establishes the geochronology of microlithic sites in the central Narmada Basin.

Tephrochronology in Scandinavia: precise dating of abrupt climate changes during the Last Glacial–Interglacial Transition

Dr. Simon Larsson [1]

1. *Department of Physical Geography, Stockholm University*

Tephrochronology, meaning the usage of tephra deposits preserved in natural archives for dating and correlation purposes, has become a powerful and versatile chronological tool in palaeoclimate science as well as in other fields of study. Horizons of volcanic ashes (detected either as visible layers or as low-concentration "cryptotephras") can be found in sediments and ice at distal locations, far from their volcanic sources, and used as time markers that enable direct comparisons between study sites separated by vast distances. Tephra studies have been undertaken in Scandinavia for decades and recently presented results from Sweden and Norway provide insights into their application in the dating of abrupt climate changes during the Last Glacial–Interglacial Transition on various spatial scales.

Three well-known tephras have been identified at Körslättamossen in southernmost Sweden: the Icelandic Hässeldalen Tephra and Vedde Ash, and the German Laacher See Tephra (the first finding on Scandinavian mainland). This has enabled comparisons between palaeoclimatic reconstructions from this and other study sites in northern Europe, contributing to the interconnections of the European tephra framework and to the not-yet-settled debate of whether the Younger Dryas cold stage was a synchronous or a time-transgressive event in this region.

On the Fosen peninsula in central Norway, identifications of the Fosen Tephra and the Vedde Ash at a number of sites relating to the position of the Scandinavian Ice Sheet around the time of its Younger Dryas readvance have revealed errors in a previous chronology of the palaeoglacial events, acting as an example of tephrochronology's usefulness on the more local scales of landscape history and geomorphology.

Tephrochronology is not a perfect method; within the successes of the projects presented here lie also complications and issues that require further discussion and research efforts. The detection of tephra horizons can contribute significantly to age models, but only as long as the tephras can be confidently identified, and with methodological advances leading to new findings, the current state of tephrochronology is continuously becoming more complex.

Do anomalous fading limit the applicability of luminescence dating of Iron Age urns of Sivagalai, South India?

Situating a particular archaeological event in history demand not only accurate but also precise ages estimated from radiometric dating methods. In a recent excavation at Sivagalai (8.6387° N, 77.9781°E) near the southern tip of India, rice grain found in an urn (A2 layer Urn 3) was radiocarbon (AMS) dated to be ca. 3100 years (3209 – 3000 cal BP). To test the applicability of the luminescence dating method, a total of 13 sub-samples were collected from five urns (A2 Urn 1, A2 Urn 3, L13 Urn 2, L13 Urn 5, and L13 Urn 8). Infra-red stimulated luminescence (IRSL) of polymineral fine-grain (4-11 mm) was used for equivalent dose (De) estimation using SAR protocol. As IRSL fades with time, the fading correction was done using three existing procedures. The effectual dose rate was computed from the three different sources of dose rate for age calculation. The ages obtained using polymineral IRSL were corrected using three different fading correction methods but all are inconsistent among them and with ^{14}C age suggesting a conspicuous failure of the fading correction procedures. This may be because these procedures are not able to correct for unusually larger fading rates (10.6 – 14.6 %/decade; 3-5 %/decade is the typical range). The XRD analyses suggested the presence of high temperature feldspar (sanidine) in the samples and that, possibly, can be associated with large fading rate.

In addition to conventional IRSL signal, unconventional signals (post IR IRSL, post violet IRSL and multiple elevated post IR IRSL) were also used for equivalent dose estimation. The result indicates that L13 URN 8 which may be younger than A2 Urn 3 for which AMS ^{14}C age is available, could be of ca. 2200 – 2500 years old. We also luminescence dated two samples in another premier laboratory and results are comparable. So, the question arises whether large fading rate limit the applicability of luminescence dating? Yes, if IRSL signal is used, but unconventional signals are promising to overcome this limitation. Experiments are underway and the results will be presented during the conference.

Session 135: Mammals biochronology and palaeoecology of the Euro-Mediterranean Quaternary

The Final Pliocene and Early Pleistocene faunal dispersals from east to Europe and correlation of the Villafranchian biochronology between eastern and western Europe

Prof. Nikolai Spassov [1]

1. *National Museum of Natural History at the Bulgarian Academy of Sciences*

The Villafranchian stage in the mammal fauna evolution in Eurasia (~ 3.4 Ma – 1.1/1 Ma) is associated with the beginning of the formation of the modern appearance of the fauna of today's Palaearctic. The time from the Mid-Piacenzian (~ 3.4-3.2) to the end of the Early Pleistocene was a time of particularly intense dispersal of species and of faunal exchange between Eurasia and Africa. Usually the dispersal is instantaneous from a geological point of view, but in some cases reaching W. Europe happens later. Of the three taxa that have become classic examples of bioevents associated with the beginning of the Pleistocene, *Equus*, Mammuthus and *Canis*, an example of a very rapid dispersal from the east is *Equus*. Its appearance in Eurasia is possibly already at the end of the Pliocene, but the first reliable dates are of the same age (2.6 Ma). The earliest *Canis* appearance seems to be related to *C. neschersensis*, found in one of the localities of Perrier with a probable age of 2.78 - 2.6 Ma (not in Vialette, as claimed, where the remains are from *Eucyon*), but the mass dispersal, the so called " Canis event" happens later: Slivnitsa, Bulgaria – Seneze, France (~ 2.1. Ma). An example of asynchronous entering is the mammoth, which appeared with *M. rumanus* in Eastern Europe earlier, at 3.2 Ma. Earliest *Vulpes* appearance in Europe is at Musselievo, Bulgaria (Middle-Late Piacenzian); *Panthera* ~ 2.5 Ma ago (Varshets, Bulgaria) and *Pachycrocuta* (Gerakarou, Greece), shortly after Slivnitsa time. The mass dispersal of bovids is particularly intense in MNQ18a (Slivnitsa). Rich Balkan localities such as Varshets, with an age between Roca-Neyra (2.6 Ma) and Saint-Vallier (at least 2.4 Ma) and Dafnero (2.4-2.3 Ma) mark the beginning of the Middle Villafrancian in the region. Slivnitsa (Bulgaria, ca. 2.1. Ma), shows a new cooling and closing of the Bosphorus and the time of potentially the earliest possible dispersal (Taman Peninsula) of *Homo* in Europe. Apollonia (Greece) correlate with the end of Pirro Unit. The probable appearance of *Panthera fossilis* is in Kunino (Bulgaria) - beginning (?) of the Galerian.

The field vole Microtus agrestis (Linnaeus 1761) from the Middle Pleistocene site of Schöningen 13 II (Germany)

Dr. Elisa Luzi [1], ***Prof. Thijs van Kolfschoten*** [2], ***Dr. Jordi Serangeli*** [3], ***Prof. Nicholas J. Conard*** [4]

__1.__ Institut Für Naturwissenschaftliche Archäologie (INA), University of Tübingen, Hölderlinstr. 12, 72074 Tübingen, Germany, __2.__ Faculty of Archaeology, Leiden University, Einsteinweg 2, 2333, CC, the Netherlands, __3.__ University of Tübingen, Senckenberg Centre for Human Evolution and Palaeoecology, Paläon 1, 38364 Schöningen, Germany, __4.__ Department of Early Prehistory and Quaternary Ecology, University of Tübingen, Schloss Hohentübingen, 72070 Tübingen, Germany

Schöningen is an important Palaeolithic locality in Central Europe, particularly famous for the wooden throwing spears that were found at the site Schöningen 13 II-4. The locality yielded also a huge collection of well-preserved small and large mammal remains from a late Middle Pleistocene sequence of deposits that forms the base of detailed palaeontological, palaeoecological and biochronological studies.

In this study, the first lower molars (m1) of the field vole *Microtus agrestis* recovered at the Schöningen 13 II sequence have been analysed from a morphological (n=102) and morphometric (n=50) point of view, focusing on changes in size (L) and on the relative elongation of the anterior part of the tooth (a/L). Our data show no significant changes in the a/L values (p=0.36), but a significant decrease in L (p=0.009) between layers Schö 13 II-3 and Schö 13 II-4.

Based on the ecological requirements observed in living populations, the decrease in size of *M. agrestis* through the sequence indicates a general decrease in humidity in the surrounding of the site, and in particular of the ground-water resources. A conclusion that is in agreement with the paleoenvironmental reconstruction inferred from the small mammal assemblages and with data from other environmental proxies.

The recurrent morphologies displayed by the m1s, and the stable values of the a/L index suggest the presence of a steady permanent population that adapted to the environmental changes rather than migration/dispersal of populations from/to nearby regions.

A comparison with other Middle Pleistocene sites from the Mediterranean area shows that the population of Schöningen differ from those of Italy or Spain. The values of a/L at Schöningen are higher than those from Mediterranean sites related to MIS 11-10, but lower than those related to MIS 9-6. The Schöningen population resembles the MIS 9-8 assemblages from Hungary. Future research will add more data from Central Europe and our on-going studies will allow to refine the biochronological position of the site Schöningen 13 II.

Palaeoecology and palaeoneurology of an enigmatic Early Pleistocene deer from Pirro Nord (Italian Peninsula).

1. *Department of Earth Sciences, University of Zaragoza,* ***2.*** *Department of Earth Sciences, Sapienza University of Rome,* ***3.*** *Department of Physics and Geology, University of Perugia,* ***4.*** *Department of Geosciences and Geography, University of Helsinki,* ***5.*** *Department of Earth Sciences, University of Florence,* ***6.*** *ARAID Foundation, University of Zaragoza*

Medium-sized deer represent a good reference group for the Villafranchian fauna because of their abundance in Early Pleistocene deposits of Southern Europe. Their evolutionary history is still highly debated, as multiple classifications and systematic revisions have been proposed with specimens being ascribed to numerous fossil and modern genera such as *Pseudodama*, *Metacervoceros*, *Rusa*, *Axis*, *Dama*, or *Cervus*. While most studies focus on the taxonomy of the group, few have been performed on the evolution of cervids in relation to major Early Pleistocene climatic events such as the onset of the Quaternary glaciations. A remarkably rich collection of fossils belonging to this group of cervids has been unearthed from the Early Pleistocene site of Pirro Nord (Apricena, southeastern Italy). Here we analyse palaeoecological and palaeoneurological data of the Pirro Nord sample to investigate both habitat occupation and the evolutionary history of this group during the Early Pleistocene. To do so, we integrate dietary proxies (dental wear patterns and stable isotopes signal) with morphological data from a virtual endocast of a well-preserved male specimen, a largely unexplored research path in cervid palaeobiology studies. Moreover, palaeoneurological data may also provide clues to solve the systematics issue of this group. Dental mesowear results point to a long-term mixed diet for this taxon, while a leaning towards a grazing behaviour is suggested by dental microwear patterns. The range of the stable isotope $\delta^{13}C$ ratios implies that it foraged on abrasive water-stressed C3 vegetation in warm woodland and semi-open habitats, a result consistent with other palaeoenvironmental and palaeoclimatic reconstructions of Pirro Nord. Preliminary palaeoneurological data points to a closer affinity of the endocast morphology of this taxon to extant fallow deer *Dama dama* than to red deer *Cervus elaphus*. Our research represents a novel approach to the study of Early Pleistocene fossil deer palaeoecology that can be extended also to other groups to investigate their evolutionary history in relation to climate changes.

The Middle Pleistocene mammal fauna from the Megalopolis Basin (Peloponnese, Greece) and its importance for biostratigraphy and palaeoenvironment

Wiener Laboratory for Archaeological Science, American School of Classical Studies at Athens, Athens, Greece*

Megalopolis basin hosted during the late Early–Middle Pleistocene (~900–150 ka) a large and shallow lake, which resulted in a stratigraphic sequence composed mainly of lacustrine sediments intercalated by lignite seams. During the last decade (2012–2022) we conducted systematic and multidisciplinary field investigations in the basin, which led to the discovery of new sites with abundant archaeological/palaeontological material from stratified contexts, significantly enriching our knowledge of Pleistocene terrestrial ecosystems and hominin adaptations in the wider region. Here, we focus on three sites: Kyparissia-4, Marathousa-1 and Marathousa-2. We provide an updated overview of their mammalian fauna, and discuss the implications for biostratigraphy and palaeoenvironment.

The stratigraphically lowest of the three sites, Kyparissia-4, has yielded a diversified fauna rich in cervids, represented mainly by *Praemegaceros verticornis*. *Hippopotamus antiquus* is also quite abundant, including a partial skeleton. The coexistence of the voles *Microtus* (*Microtus*) and *Mimomys* spp. (medium- and large-sized species) at Kyparissia-4, indicates an early Middle Pleistocene age. Marathousa-1 (~500–400 ka, MIS 12; based on radiometric dating and magnetostratigraphy) stands out for its wealth in exceptionally well-preserved cultural, faunal and floral finds. Biostratigraphically correlated after the *Mimomys*/*Arvicola* transition, the vole assemblage is dominated by *Arvicola mosbachensis*. Alongside a diversified fauna, Marathousa-1 has yielded one *Hippopotamus* and two *Palaeoloxodon antiquus* (elephant) partial skeletons, the most complete fossil mandible of *Macaca sylvanus* (macaque), and the first record of "*Lutra*" *simplicidens* (otter) in Greece. The roughly contemporaneous Marathousa-2 has yielded mainly *Hippopotamus antiquus* fossils, some of which belong to a single individual. Anthropogenic modifications on elephant (Marathousa-1) and hippopotamus (Marathousa-2) bones provide evidence of megafauna exploitation and shed light on the subsistence behaviors of Pleistocene hominins.

Within the Early–Middle Pleistocene succession (middle Villafranchian–Galerian) of the Greek fossil record, the Galerian faunas of Kyparissia-4 and Marathousa-1, 2, mark the mammal reorganization close to the Early/Middle Pleistocene transition that took place in Europe. Finally, the presence of mammals generally indicative of temperate/milder conditions in different stratigraphic levels of the basin, including colder periods during glacial/stadial stages, points to their continuous presence in this southern region, which potentially comprised a refugium capable of retaining freshwater bodies throughout the year.

The Early Pleistocene large mammal succession of Greece: implications for pan-European biogeographic correlations

***Dr. George Konidaris* [1] *, Prof. Dimitris Kostopoulos* [2]**

***1.** Palaeoanthropology, Eberhard Karls University of Tübingen and Senckenberg Centre for Human Evolution and Palaeoenvironment, Rümelinstr. 23, 72070 Tübingen, Germany,* ***2.** School of Geology, Aristotle University of Thessaloniki, 54124 Thessaloniki, Greece*

Located at the eastern corner of Mediterranean Europe, Greece occupies a critical position for mammal dispersals to/from Europe, western Asia and Levant/Africa, and constitutes potential passageway towards western Europe. During the last decades numerous fieldwork campaigns in several sites (e.g., Dafnero, Sesklo, Vatera, Volakas, Libakos, Mygdonia Basin) by several palaeontological teams have greatly enriched the fossil record, and provided valuable taxonomic, biostratigraphic, palaeoenvironmental and taphonomic data.

Ongoing investigations by our team focus mainly in two regions: Dafnero (Western Macedonia), and Mygdonia Basin (Central Macedonia). Dafnero, dated to ~2.3 Ma, yielded a diversified middle Villafranchian fauna, rich in stenonoid horses, small- to medium-sized bovids, cervids and giraffids, and additionally includes the primate *Paradolichopithecus*. In Mygdonia Basin there are currently thirteen vertebrate sites, located in at least three stratigraphic horizons and correlated to different parts of the late Villafranchian–Epivillafranchian, broadly covering ~1 myr of faunal succession. The middle/late Villafranchian transition is well-captured at Gerakarou-1 (~2.0–1.8 Ma), the oldest Pleistocene site of the basin, where several taxa mark their last local appearance, while several others, like the hyaena *Pachycrocuta*, signify the beginning of a new biozone. Dated within the 1.8–1.5 Ma interval, Tsiotra Vryssi, the Krimni sites and Kalamoto-2, are characterized by a combination of typical late Villafranchian components, and more "archaic" elements, while they document the co-occurrence of the bovines *Leptobos* and *Bison*. The gradual faunal "modernization" terminates in the youngest site of the basin, Apollonia-1 (~1.3–1.1 Ma), close to the late Villafranchian/Epivillafranchian boundary, where the assemblage is dominated by large-sized horses and large-sized bovids and cervids, accompanied by a diversified carnivoran guild.

Based on previous studies and new data we provide the updated local Early Pleistocene mammal succession by means of Faunal Units and discuss key taxa in both regional and pan-European frame. Using available local chronological markers, and biochronological evidence, we time-calibrate the local faunal scale and correlate it with well-dated faunas of western Europe. The results form the basis for discussion of already set turnovers, dispersal and extinction/immigration events, and showcase the importance of the local record for the investigation of the European terrestrial ecosystems.

An updated review on the Plio-Pleistocene large mammal assemblages from the Iberian Peninsula

At the dawn of the new century, several new Pliocene and Pleistocene sites have been discovered, and subsequently excavated, in the Iberian Peninsula during the XXI Century. The plethora of information obtained from these new field surveys, combined with the new taphonomic and paleoecological research performed on old collections during the last two decades, improved substantially our knowledge on the Iberian Plio-Pleistocene ecosystems.
Especially noteworthy are the data obtained from the new field surveys on the Ruscinian locality of Baza-1 (Baza basin, Andalusia) and Camp dels Ninots (Catalonia). Furthermore, new discoveries were made on Late Villafranchian and Epivillafranchian localities of the Peninsula (e.g. Vallparadís Section in the Vallès basin, Catalonia and the Orce sites in the Baza basin), including a continuous pre-Jaramillo to Jaramillo succession (Quibas complex, in Murcia). Finally, new prospections and surveys conducted on central Iberia and Pyrenean sites of Middle to Late Pleistocene have shed new light into the dynamics of glacial stages in Western Europe after the Early-Middle Pleistocene transition (EMPT).
At the end of Pliocene, the onset of new climate dynamics, characterized by Glacial-Interglacial phases, reshaped the structure of the previous ecosystems and, subsequentially, the faunal associations of Western Europe. A successive climatic transition, the EMPT, furtherly extreme the delicate conditions that allowed the persistence of tropical associated taxa, triggering the transitions toward more modern faunas.
The new data emerged by the study of the above-mentioned localities provide us a new glimpse on the Iberian environments and its inhabitants before and after these transitions. Here we present the latest results and an updated review of the Iberian Plio-Pleistocene assemblages with special emphasis on the climatic changes and the related biogeographical associated consequences.

Dietary traits of Haploidoceros mediterraneus, a biochronological marker of the transition from the Middle to the Late Pleistocene in southwestern Europe

Prof. Florent Rivals [1]***, Dr. Antigone Uzunidis*** [2]

1. *ICREA, Barcelona, Spain; Institut Català de Paleoecologia Humana i Evolució Social (IPHES-CERCA), Tarragona, Spain; Departament d'Història i Història de l'Art, Universitat Rovira i Virgili, Tarragona, Spain,* ***2.*** *Institut Català de Paleoecologia Humana i Evolució Social (IPHES-CERCA), Zona Educacional 4, Campus Sescelades URV (Edifici W3) 43007 Tarragona, Spain*

Haploidoceros mediterraneus is a peculiar medium-sized deer with scarce occurrence. It is geographically limited to an area at the southwest of Europe. *H. mediterraneus* is distinguished from other similar-sized deer on the basis of the antler shape. The species has been identified in five sites in southwestern Europe. In southern France, it has been recovered in two Late Middle Pleistocene sites (MIS 9–7), Lunel-Viel (Hérault) and Igue des Rameaux (Tarn-et-Garonne). In the Iberian Peninsula it has been documented at Cova del Rinoceront (Barcelona) and PRERESA (Madrid), providing a longer time span for the genera at least until MIS 5 (early Upper Pleistocene). The absence of *H. mediterraneus* at younger sites suggests that extinction could be occurred at the beginning of the Last Glacial period, at least in the Iberian region, and make this species a biochronological marker of the late Middle to early Upper Pleistocene. The aim of this presentation is to analyse its diet which is still poorly known and to highlight the palaeoecological significance of this species. For this purpose, we performed tooth mesowear and microwear analyses to reconstruct the dietary traits and habitat of *H. mediterraneus* from Lunel-Viel, Igue des Rameaux, Cova del Rinoceront and PRERESA. All the populations of *H. mediterraneus* show browsing or browse-dominated mixed feeding dietary traits. In comparison to other cervids from the same localities, when they co-occur, the dietary traits show different patterns. At Igue des Rameaux amont it overlaps with the red deer while at Lunel Viel it has lower abrasive diets than the red deer (caves I and IV) and the megaloceros (cave I). It also fits within the dietary range of the extant red deer and fallow deer. The analysis of the dietary traits indicates that *H. mediterraneus* is a rather eurytopic species in comparison to *C. elaphus*. It that was living in mixed wooded vegetation under temperate environmental conditions. Our results indicate that besides being a good biochronological indicator, *H. mediterraneus* is also a significant palaeoecological marker for the Middle and Late Pleistocene of southwestern Europe.

An updated review of the Quaternary hippopotamus fossil record from Iberian Peninsula

Mr. Darío Fidalgo [1], ***Dr. Joan Madurell*** [2], ***Ms. Roberta Martino*** [3], ***Dr. Luca Pandolfi*** [4], ***Prof. Antonio Rosas*** [1]

1. *Museo Nacional de Ciencias Naturales (CSIC),* **2.** *Universitat Autònoma de Barcelona,* **3.** *Universidade NOVA de Lisboa,* **4.** *University of Basilicata*

Several large mammal taxa with African affinities, including Hippopotamidae, have extended their geographical range into Europe several times during the Quaternary. A first entry of *Hippopotamus* into European continent via the Levant is generally accepted, with their oldest recorded occurrences in Turkey, Greece and Italy (ca. 2.1-1.8 Ma). Less clear is the purported second migration of this group, with earliest records around 0.5 Ma. To clarify this biogeographical and dispersal pattern, a detailed revision of the fossil record of *Hippopotamus* in Europe, Africa and Levantine area is therefore necessary. In this work, we review the fossil record of *Hippopotamus* from the Iberian Peninsula, continuing with the inertia of research begun in recent years for areas such as Italy and Greece. The most widely shared hypothesis considers the presence of two species of the genus *Hippopotamus* in the Iberian record. *H. antiquus* has potential records in the Peninsula starting from 1.7 Ma, at the Mencal-9 (Granada) site, until the mid-Middle Pleistocene, when hippopotamus specimens begin to be attributed to *H. amphibius*. The attribution of the Early Pleistocene specimens to *H. antiquus* is well supported, with the discovery of partial or complete skulls at sites such as Vallparadis Section (Barcelona), Incarcal Complex (Girona), Barranc de la Boella (Tarragona), Bòvila Ordis (Girona) and Barranco León (Granada), or complete limb bones such as Algoz (Algarve). On the other hand, very few Middle Pleistocene specimens can be clear taxonomically determined to establish the precise timing of the specific turnover. Only the material from the site of Mealhada (Aveiro) have been studied paleontologically, defending the presence of *H. amphibius* at the end of the Middle Pleistocene. However, these specimens are documented by a phalanx and a cuboid, that are, objectively, difficult to identify at specific level. Accepting the presence of *H. amphibius* in this chronology, the LOD of this species in the Iberian Peninsula would be referred to MIS 4, in the Toll cave (Barcelona). It is worth mentioning the discovery of two sites, Barranco León and Bolomor Cave (Valencia), which represent one of the few confirmed European contexts with evidence of human exploitation of hippopotamuses.

The Epivillafranchian in European biochronology: marker taxa, boundaries, and localities

Dr. Leonardo Sorbelli [1]***, Prof. Marco Cherin*** [2]***, Dr. Marzia Breda*** [3]***, Dr. Marco Peter Ferretti*** [4]***, Ms. Maria Prat Vericat*** [1]***, Mr. Darío Fidalgo*** [5]***, Ms. Beatrice Azzarà*** [2]***, Ms. Elpiniki Maria Parparousi*** [2]***, Dr. Saverio Bartolini-Lucenti*** [6]***, Prof. Joan Madurell-Malapeira*** [7]

Biochronology is one of the most used and powerful approaches to relate biological events to the geological time scale in the terrestrial realm. In Europe, the period that embraces the last ca. 3.3 Ma is traditionally defined by the succession of three European Land Mammal Ages (ELMAs) based on large mammals, defined by Italian palaeontologists and today widely used on a continental scale. These ELMAs are the Villafranchian (ranging from the late Pliocene to most of the Early Pleistocene), Galerian (from the late Early Pleistocene to the mid Middle Pleistocene), and Aurelian (spanning the last ca. 0.4 Ma). These biochrons cover a crucial phase in European palaeoenvironmental and palaeoclimatic evolution, which includes the establishment of Quaternary glacial-interglacial cycles.

About 1.2 Ma, the obliquity-forced 41 ka glacial rhythm characteristic of the Villafranchian started to change, with a progressive increase in the amplitude of climatic oscillations and the establishment of strong asymmetry in global ice volume cycles. The shift towards a 100 ka cyclicity was followed by the first major build-up of global ice during MIS 24–22 (ca. 0.9 Ma). These events - grouped within the so-called Early–Middle Pleistocene Transition (EMPT) - led to major environmental changes and faunal turnovers in Europe, and ultimately triggered the extinction of Villafranchian taxa which were unable to adapt to the harshening of environmental conditions and to the dispersal of newcomers from Asia and Africa (including *Homo*). In European biochronology, this transitional period has been recognized under the name of Epivillafranchian. This biochron, spanning from ca. 1.2 to 0.8 Ma, is a pivotal period for understanding the processes that shaped European modern mammal faunas.

Here we present a comprehensive reappraisal of the Epivillafranchian concept, revising its marker taxa and chronological boundaries by means of the analysis of some of the most important localities. Given the significant amount of data collected in the last years that support the existence of “transitional” faunas in Europe between the Villafranchian and Galerian, in agreement with other authors we strongly support the use of the Epivillafranchian as a formal biochron in the ELMA system.

The Epivillafranchian carnivoran guild from the Vallparadís Section and the Early-Middle Pleistocene Transition

Ms. Maria Prat Vericat [1]***, Dr. Leonardo Sorbelli*** [1]***, Dr. Isaac Rufí*** [2]***, Ms. Claudia Tura-Poch*** [1]***, Mr. Víctor Vizcaíno-Varo*** [1]***, Dr. Saverio Bartolini-Lucenti*** [3]***, Prof. Joan Madurell-Malapeira*** [4]

1. *Institut Català de Paleontologia Miquel Crusafont,* ***2.*** *Universitat de Girona,* ***3.*** *Universitá di Firenze,* ***4.*** *Departament de Geologia, Universitat Autònoma de Barcelona*

Since the Late Pliocene, the intensification of the glacial dynamics in the Northern hemisphere induced changes in the European ecosystems. The progressive shift from wooded areas with tropical affinities to mixed forest, forested-steppes, and savanna-like environments favored the dispersion of large ambush-pursuit predators (e.g., *Homotherium*, *Megantereon*, *Xenocyon*) into Europe.

At the latest Early Pleistocene, the progressive increase in the amplitude of climatic oscillations started, which induced the onset of a strong asymmetry in the global ice volume cycles. This interval is named "Early-Middle Pleistocene Transition" (ca. 1.2-0.4 Ma) or EMPT. The time range includes the so-called "0.9 Ma event" when the first relevant build-up of global ice occurred.

The available European fossiliferous sites with multiple stratigraphic horizons spanning the entire EMPT interval are overall scarce. The Vallparadis Section (ca. 1.2-0.6 Ma) is among the few localities that recorded this period. Through the section that comprises the late Early Pleistocene period, the Carnivora guild includes long-persisting taxa such as *Homotherium crenatidens*, *Megantereon* sp., *Panthera gombaszoegensis*, *Puma pardoides*, *Lynx pardinus*, *Pachycrocuta brevirostris*, *Canis (Xenocyon) lycaonoides*, *Canis mosbachensis*, *Vulpes alopecoides*, and *Meles meles*. Most of these taxa persist in the section until MIS21 (ca. 0.85 Ma) and survive the '0.9 Ma Event'. In addition to that, other newcomers, such as *Panthera fossilis* and *Ursus deningeri,* appear in the section around MIS31 (1.05 Ma).

The progressive cooling trend of the EMPT favored the spreading of open habitats in the whole of Mediterranean Europe, and with it, the dispersal of these new carnivores, the reduction of diversity, and the interspecific competition. Here we present a review of the Vallparadís Section Carnivora guild, focusing on the co-occurrence of the remnants of Early Pleistocene guilds and the first Middle Pleistocene groups entering Europe during the Epivillafranchian.

The thorny question of the absence of suids from Europe during the Late Villafranchian

Dr. Alessio Iannucci [1]

1. *Dipartimento di Scienze della Terra (PaleoFactory lab.), Sapienza Università di Roma, P.le Aldo Moro, 5, 00185 Rome, Italy;*

According to an influential hypothesis, suids would have been absent from Europe during the post-Olduvai to pre-Jaramillo late Early Pleistocene (c. 1.8-1.2 Ma). Arguments enumerated in favor of this “suid gap” are the lack of suid remains from extensively sampled fossil localities of this age and the r-selected reproductive strategy of suids, which would translate in a high representation of their remains in the fossil record. However, while the reproductive potential of suids might explain their evolutionary success and current dynamics of increase of wild boar populations, there is apparently no direct relationship between reproductive strategy and preservation rate of a taxon in the fossil record. In fact, latest Early Pleistocene (Epivillafranchian) suids are often documented by fewer remains than many other artiodactyls of similar size. Moreover, while it is undeniable that suid fossils have not been recovered from several European localities dated between c. 1.8 and 1.2 Ma, there are some remains that could fill this apparent gap. The case of suids underlines an important caveat often neglected in inferring faunal dynamics of the late Early Pleistocene of western Europe —including the dispersal of hominins— i.e., the unequal geographic distribution of most extensively investigated paleontological sites of the c. 1.8-1.2 Ma age (mainly located in the Iberian and Italian Peninsulas), and hence the resulting probable bias for biochronological correlations. The dependency from biochronology is salient for correlating localities of the c. 1.8-1.2 Ma period, given the paucity (or low resolution) of available radiometric estimates and of paleomagnetic reversals detectable in continental deposits. In other words, it is not possible to rule out that Late Villafranchian suid populations survived at low demographic densities or in scarcely sampled areas (e.g., France and Germany), and the same might be true for other species.

Time matters: testing for ecological niche changes in Late Quaternary European ungulates

Dr. Michela Leonardi [1], ***Dr. Francesco Boschin*** [2], ***Dr. Paolo Boscato*** [2], ***Prof. Andrea Manica*** [1]

1. Department of Zoology, University of Cambridge, 2. U.R. Preistoria e Antropologia, Dipartimento di Scienze Fisiche della Terra e dell'Ambiente, Università degli Studi di Siena

The last 50 thousand years represent a very informative period for the study of paleoecology. From a climatic point of view, they are characterized by large fluctuations which greatly impacted the environment. From a methodological perspective, they are covered by the radiocarbon dating method that allows precise chronological attribution of the archaeological record, and association with palaeoclimate. Finally, the recent development of nearly-continuous palaeoclimatic data series over the last tens of thousands of years provides the appropriate context to investigate species responses to climatic change over this time scale.
We developed a novel modelling framework to reconstruct the paleoecological dynamics of large animal species, and we applied it to four generalist European ungulates that survived the Pleistocene-Holocene transition: horse, aurochs, red deer, and wild boar.
We not only reconstructed their distribution through time, but we also tested if their realized niche changed in response to the climatic changes observed in the region between the last part of the Pleistocene and the Early Holocene.
We could show that all four animals changed their niche with species-specific responses to climate fluctuations, despite being generalist and showing similar wide distributions through time. We also suggest the fact that species with long generation times can change their niche over time frames in the order thousands of years cautions against assumptions of niche stability when studying Late Pleistocene paleoecology.

The Late Pleistocene spotted hyena (Crocuta crocuta) from San Teodoro Cave (Sicily, Italy) and implications for the evolutionary history of Mediterranean Quaternary Hyaenidae.

Dr. Dawid Adam Iurino [1], ***Dr. Alessio Iannucci*** [2], ***Dr. Angharad Katherine Jones*** [3], ***Prof. Filippo Spadola*** [4], ***Dr. Gabriella Mangano*** [5], ***Prof. Nicola Iannelli*** [4], ***Prof. Danielle Schreve*** [6], ***Prof. Raffaele Sardella*** [1], ***Prof. Laura Bonfiglio*** [5]

__1.__ Department of Earth Sciences, Sapienza University of Rome, __2.__ Dipartimento di Scienze della Terra (PaleoFactory lab.), Sapienza Università di Roma, P.le Aldo Moro, 5, 00185 Rome, Italy;, __3.__ Royal Holloway University of London, __4.__ Università degli Studi di Messina, __5.__ Museo della Fauna, Messina, __6.__ Royal Holloway, University of London

In 1859, while Darwin was publishing his monumental work on the origin of species, the cave of San Teodoro was discovered at Acquedolci, a small town along the north-eastern coast of Sicily, in the province of Messina. The richness of Late Pleistocene faunal remains and Upper Palaeolithic human burials and artefacts, has made this locality a key site to explore human and animal diversity and distribution on Mediterranean islands. Taking into account the Late Pleistocene fossil record recovered from San Teodoro Cave, coprolites and bones of *Crocuta* stand out for their abundance. These remains suggest a prolonged period of occupation of the cave by hyenas, a hypothesis supported by the occurrence of adults and cubs, whose bones show, in some instances, clear evidence of bitemarks produced by other hyenas. In the last years, the San Teodoro Cave was the subject of several taphonomic studies, indicating this site as one of the best preserved hyena dens of the Late Pleistocene of Europe. Despite this, a formal systematic description of the hyena osteological remains is still missing.

In this contribution, we provide a brief summary of the first comprehensive study of cranial and postcranial bones of the Late Pleistocene *Crocuta* from San Teodoro Cave, and its implications for taxonomy and evolutionary history of Mediterranean Quaternary hyenas. The study includes biometric and morphological analyses carried out by making comparisons with extant and fossil hyenas, and a CT-based description of the virtual casts of both brain and paranasal sinuses. Due to the large number of damaged epiphyses, biometric analyses were mainly performed of craniodental material.

Attractiveness of the Denizli Basin for humans and animals during the Early Pleistocene (1.6-1.2 Ma). A pathway to Europe through Anatolia?

Mr. Nicolas Boulbes [1], Dr. Anne-Marie Moigne [2], Dr. Serdar Mayda [3], Dr. Vadim Titov [4], Dr. Christophe Falguères [2], Mr. Olivier Tombret [2], Prof. Jean-Jacques Bahain [2], Dr. Anne-Elisabeth Lebatard [5], Dr. Amélie Vialet [2], Dr. M. Cihat Alçiçek [6]

***1.** Institut de Paléontologie Humaine, Fondation Albert Ier, Paris, UMR 7194 HNHP / MNHN-CNRS-UPVD, EPCC-CERP Tautavel, **2.** Muséum National d'Histoire Naturelle, UMR 7194 HNHP, MNHN-CNRS-UPVD, Paris, **3.** Ege Univ, Faculty of Science, Dept. of Biology, Izmir, **4.** Southern Scientific Centre RAS, Rostov-on-Don, **5.** Aix Marseille University, CNRS, IRD, INRAE, College de France, CEREGE, Aix-en-Provence, France, **6.** Pamukkale University, Department of Geology, Denizli*

At the crossroads between Africa, Asia and Europe, Turkey occupies an important place to follow animal and human dispersions through time. However, Pleistocene sites with macrofauna are relatively rare in Turkey. Consequently, the upper travertine of the Denizli Basin, whose delivered bones of large mammals as well as other indicators of biodiversity (voles, crabs, leaves, ostracods…) and a fragmentary *Homo erectus* skull, constitutes a key-site to track the different migratory paths. Multidisciplinary work including biochronology, dating by cosmogenic nuclides, paleomagnetism and combined ESR/uranium-series, constrains the fossiliferous deposit between 1.6 and 1.2 Ma.
Thus far, the faunal list consists of the following taxa: *Archidiskodon meridionalis meridionalis*, *Stephanorhinus* cf. *etruscus*, *Equus* cf. *apolloniensis*, *E.* cf. *altidens*/*E.* cf. *mygdoniensis*, *Metacervoceros rhenanus*, *Arvernoceros* sp., *Cervalces* (*Libralces*) ex gr. *minor-gallicus*, *Gazella* sp., *Palaeotragus* sp., Bovinae gen. indet. This fauna is characterized by the mixture of ("archaic") Villafranchian components (cervids, *Palaeotragus*, *Gazella*) and "modern" late Villafranchian newcomers as the advanced equid *E. apolloniensis*. At the regional scale, comparisons are limited. The association is older than the central Anatolian record of Dursunlu (0,9 Ma) which includes *Mammuthus trogontherii* and a caballoid horse. The neighbor localities of Yassigüme (Burdur Basin) share Villafranchian typic taxa as *Leptobos* cf. *etruscus* and *Gazellospira* together with more primitive stenonid horse. In a larger window, the Denizli's fauna resembles those from the late Villafranchian of Southern/Eastern Europe, and, to some extent, from Western Asia. Affinities are found with eastern Mediterranean fauna from the Early Pleistocene of Mygdonia basin (Macedonia, Greece). The association from Denizli can be correlated with early Late Villafranchian Psekups Faunal Complex from Ciscaucasia. At the same time, the Kocabaş skull has been shown to be closer to African fossils (1.8-1 Ma) than to *Homo erectus* from Dmanisi and Asia and a role in the settlement of Western Europe has been suggested.

From the palaeoenvironmental perspective, the Denizli's fauna can be confronted to the exceptional pollen archive from the Acigöl Lake located a few tens of kilometers. Most of Denizli herbivores are thermophilic species occupying different biotopes around the basin, which may have represented an attractive watering place with ample vegetation.

The faunal response to EMPT in Central Europe

***Prof. Ivan Horacek* [1], *Prof. Oldrich Fejfar* [2], *Stanislav Cermak* [3], *Dr. Jan Wagner* [4], *Mrs. Tereza Hadravova* [1], *Mrs. Nikoleta Dubjelova* [5], *Dr. Lucie Juřičková* [1], *Dr. Jan Hošek* [6]**

1. *4Department of Zoology, Faculty of Sciences, Charles University, Viničná 4, 128 45 Praha 2,* ***2.*** *Faculty of Science, Charles University,* ***3.*** *Geological Institute, the Czech Academy of Sciences,* ***4.*** *5Department of Paleontology, National Museum, Václavské náměstí 68, 110 00 Praha 1,* ***5.*** *Department of Paleontology, Masaryk University Brno,* ***6.*** *Czech Geological Survey*

Faunal dynamics associated with the Early Middle Pleistocene Transition (EMPT), an essential turning point of the Late Cenozoic history, was investigated using a rich fossil record obtained from a series of complex sedimentary sequences in the Czech Republic. Cross correlation of particular sedimentary series supported by the magnetostratigraphic and morphostratigraphic references enabled to date most of the records in terms of climatostratigraphic units and reconstruct putative faunal rearrangements during the period from MIS 22(23) to MIS 14.

In total we analyzed 64 community samples of small ground mammals (MNI>15) recognizing 45 phenotypically distinct taxa. Total abundance of the set was 13995 (MNI), mean sample abundance was 218.7 (MNI). In all, the community structure both in terms of species composition and dominance structure was in general quite similar. The community core was invariantly formed by ten euconstant species, each of which apperared in more than 50% of samples. Yet, particularly in the earlier section of the covered period (MIS 22-17), the community structure was considerably enriched samples by regular appearance of diverse recedent and subrecedent elements including the taxa representing index species of EMPT period (*Macroneomys brachygnathus, Petauria voigtstedtensis, Dicrostonyx simplicior, Lagurus transiens, Spermophilus dietrichi*). LAD *Beremendia fissidens* and FAD *Sorex minutissimus, Lemmus/Myopus, Pteromys volans, Neomys newtoni* or *Sicista subtilis* in that time are worth of mentioning.

In general, the faunal history of EMPT can be characterized by (i) establishing the axial community structure (perhaps during MIS 22 or earlier), (ii) enriching community structure by appearance of novel recedent elements including alien distant immigrants during subsequent stages MIS 21-17, (iii) reduction of diversity during the glacial stages terminating Q2 stage of Late Biharian (MIS 16) and subsequent climatic cycles forcing the phenotype rearrangements of resident taxa (e.g. *Mimomys savini* to *Arvicola*, *Lasiopodomys gregaloides* to *anglicus* etc.).

Correlations of the studied sites with a morphostratigraphic sequence of river terraces suggest an abrupt uplift of the region during MIS 22-17 responding obviously to global tectonic processes promoting onset of the EMPT and related environmental rearrangements.

Session 137: Geological and climate forcings on human groups / ancient societies, and their feedbacks

Environmental Risks and Societies: From hunter-gatherers to the industrial civilization

Prof. eric Fouache [1]

1. *Sorbonne Université UR Médiations*

Environmental risks fall into two categories: natural risks and risks induced by the interaction between human action and environmental dynamics. Natural hazards, which only become risks insofar as their consequences affect human societies, are unchangeable and can be listed as follows: meteorite impacts, volcanic eruptions, earthquakes, tsunamis, mass movements, climate change and extreme weather events (hurricanes, storms, droughts, bushfires…), epidemics. Depending on the areas of civilization and the historical periods, those risks were more or less understood and taken into account. The very slow progression of human groups on the surface of the planet – estimated at 5 km per generation for the Neolithic period, for example – has facilitated the acquisition of the pragmatic skills necessary for survival, but it was not until the contemporary era that proper concepts were available to explain those phenomena. Our civilization is the first to have the capacity to reconstitute past hazards, to determine risk zones and to be able to at least partially model future developments. The risks induced by the interactions between human action and environmental dynamics have continued to increase as the population grew and the ecumene was conquered. The hunter-gatherers and farmers of the Neolithic period coped with the risk of famine or starvation in different ways, while the cohabitation between man and domesticated animals, the emergence of cities and commercial exchanges favored the spread of new diseases and the risk of epidemics. Over the 300,000 years that have elapsed since the appearance of Homo Sapiens, human societies have proved to be resilient in the long term and on a global scale, when faced with both cycles of climatic fluctuations and variations in sea level and disasters triggered by human action. Paradoxically enough, the more developed societies are, the more complex their functioning is and the higher the cost of their reconstruction or reorganization is. On a planet where no more space can be considered as natural, will we succeed together in finding the necessary compromise between the protection of biodiversity and societal balance which includes satisfying the needs of the populations?

Neanderthals' technological change and environmental adaptation at the onset of MIS 4 at the edge of the Adriatic-Po region

Dr. Davide Delpiano [1]***, Dr. Laurence Bourguignon*** [2]***, Dr. Alessandra Livraghi*** [3]***, Prof. Marco Peresani*** [4]

1. *Department of Prehistoric and Anthropological Sciences Faculty of Humanities, University of Ferrara C.so Ercole I d'Este 32, 44 100 Ferrara, Italy,* ***2.*** *INRAP,* ***3.*** *IPHES Catalan Institute for Human Palaeoecology and Social Evolution. Tarragona, Spain.,* ***4.*** *Department of Humanities, Prehistoric and Anthropology Sciences, University of Ferrara*

Along the northern edge of the Adriatic-Po region plain and in the Prealpine belt of Italy, the climatic worsening related to the stadial phase of Marine Isotopic Stage (MIS) 4 is marked by the expansion of Alpine ice coverage and widespread loess accumulation, while the pollen cores record a mosaic of boreal forest and steppe with the occasional presence of warm-temperate taxa. Consistently, we report substantial changes in the cultural complexes and technological behaviours of Neanderthal groups which populated the Great Adriatic-Po Region (GAPR). While Levallois Mousterian is by far the most common lithic techno-complex up to MIS 5, in MIS 4 there is an increase in technological diversification associated with higher versatility and duration of the produced blanks. These are well exemplified by the Quina and demi-Quina scraper, a long-live, multi-purpose retouched tool which was considered the pivot of the productive ramifications typical of these contexts. In support to these assumptions, we present the case studies of De Nadale cave, a single-layered Mousterian site located in the Berici hills, and of the small lithic assemblage from Fumane cave BR6 unit, a layer framed in a well-known and representative sequence for the Late Middle Palaeolithic located in the Lessini Mountains. These lithic assemblages show the adoption of diversified strategies having much in common with the contemporary Western European Quina classic sites, however distinguishing from the latter for an application of more diverse knapping methods and techniques aimed at producing both thick, portable Quinoid blanks, and ready-to-use thin flakes and bladelets. Contextual information available from paleoenvironmental, zooarchaeological, petroarchaeological and functional analysis concur to correlate this technical behaviour to a planned strategy in response to a seasonal and organized mobility and a moderate rarefaction of resources. In constrained ecological contexts, Quina production could represent an optimal adaptation in order to maximize the effectiveness of lithic tool-set in respect to the demanded functional needs. The recorded differences could reflect local adaptations related to the emergence and spread of Quina concept in the GAPR during the last glacial cycle.

Birth, life and death of a lithic technological tradition: exploring the influence of climate on the apparition, generalization and disappearance of the Rayssian during the Middle and Recent Gravettian in France (32–26.5 ka calBP)

Dr. Anaïs Vignoles [1]***, Dr. William Banks*** [2]***, Dr. Laurent Klaric*** [3]

1. *TEMPS - UMR 8068, Université Paris X Nanterre,* ***2.*** *PACEA, Université de Bordeaux-CNRS, Pessac,* ***3.*** *TEMPS - UMR 8068, CNRS, Université Paris X Nanterre*

A frequent hypothesis in archaeology links material cultures variability to their environmental contexts. In this study, we reflect on the cultural and environmental factors that influence the appearance, generalization, and disappearance of the Middle Gravettian Rayssian lithic tradition. It is defined as a unique method used to produce hunting weapon implements and that differs conceptually from those used before (Noaillian) and after (Recent Gravettian) it. The set-up and termination of this tradition are chronologically associated with periods of high climatic instability, such as the cold and abrupt Heinrich event 3 for its appearance or the GI 4 climate amelioration for its disappearance. However, the reality of a causal link between technological and ecological variability needs to be evaluated via a quantitative and interdisciplinary approach aimed at better integrating archaeological and paleoenvironmental data.

We evaluate the extent to which this technological trajectory was influenced by the exploitation of different environmental conditions using the approach termed eco-cultural niche modeling. To do so, we chose relevant climatic variables to represent the environment and constructed a critical inventory of sites that can be assigned to the Noaillian, the Rayssian, and the Recent Gravettian. Their eco-cultural niches were then modeled, statistically evaluated and compared.
Our results indicate that technological changes and shifts in sites' geographic distribution are associated with eco-cultural niche dynamics in both environmental and geographic dimensions. Building on these results, we propose an interpretive scenario that highlights the role of environmental factors as well as their interaction with social factors (e.g., subsistence strategies, territorial organization, transmission biases) in the delineation of mechanisms involved in the Rayssian cultural trajectory.

Tracing human-environment interactions using high-resolution palaeoclimatic shell proxies from Franchthi

Ms. Danai Theodoraki [1], ***Dr. Niklas Hausmann*** [2]

1. *Leibniz Center for Archaeology (LEIZA)/Johannes Gutenberg University Mainz,* ***2.*** *Leibniz Center for Archaeology (LEIZA)*

In this presentation we will demonstrate how the archaeological shell record can provide valuable insights on human-environment interactions and the palaeoclimate on a human-time scale. Our method combines effectively sclerochronology with spectroscopy and chemical isotope analyses in order to extract high-resolution climatic data. Our aim is to contribute to the reconstruction of the climate of the past and its impact on past communities during the Early Holocene. For this purpose, we employ *Patella* shells as it has been shown that they preserve in their elemental composition site-specific high-resolution information on past climatic and seasonal conditions. Limpet shells from Franchthi, a coastal prehistoric site in southern Greece, have been chosen for analysis as it constitutes a well-investigated site in the Eastern Mediterranean. By applying our methods on the palaeoenvironmental shell archive while considering other palaeoenvironmental proxies, we intend to reconstruct climatic variability on a local, site-specific, scale and determine to what extent human activities were influenced by long- or short-term trends of the climate. Furthermore, our method can approach temporal sub-annual scales that would have been perceived by the inhabitants of the site. Overall, this work intends to examine the ways in which the prehistoric inhabitants of the site were affected in terms of subsistence and social practices by potential fluctuations in the local paleoenvironmental conditions through the archaeomalacological record as well as inherent high-resolution paleoenvironmental datasets.

Seasonality and possible forcings on millennial-to-orbital scale hydroclimatic changes in southwest Mexico and central Mesoamerica during the latest Pleistocene, Holocene and last 2 ka

Mr. Agesandro García-Arriola [1]***, Dr. Priyadarsi D. Roy*** [2]***, Ms. Irma Gabriela Vargas-Martínez*** [3]***, Ms. Ma. Patricia Giron-García*** [4]***, Dr. Jason H. Curtis*** [5]

1. *Posgrado en Ciencias del Mar y Limnología, Universidad Nacional Autónoma de México, Ciudad de México,* ***2.*** *Instituto de Geología, Universidad Nacional Autónoma de Mexico, Ciudad de México,* ***3.*** *Carrera de Ingeniería Geológica, Facultad de Ingeniería, Universidad Nacional Autónoma de México, Ciudad de México,* ***4.*** *Instituto de Geología, Universidad Nacional Autónoma de México, Ciudad de México,* ***5.*** *Department of Geological Sciences, University of Florida, Florida, United States*

Speleothems from central Mesoamerica in southwest Mexico with growth-hiatus have documented the influences of climate change and the dynamics of paleo-monsoon over the late Pleistocene and Holocene. The results of this study provide new data and a continuous register of palaeohydrological and palaeoecological conditions by reconstructing the responses of allochthonous and autochthonous components of a lacustrine ecosystem at Coatetelco over the last 18 cal ka that is presently an important source of surface water for agriculture in the region, and possibly played a vital role in the flourishing and demise of Xochicalca culture over the last 2 ka. Sediments deposited in this perennial lake (precipitation: ca.1085 mm/a) with its wettest condition in autumn and a dominantly volcaniclastic watershed, provided an opportunity to evaluate the hydroclimatic changes in millennial to orbital scales over the latest Pleistocene (deglaciation), the Holocene and last 2 ka with respect to different atmospheric and oceanic forcings as well as varying insolation. Stratigraphic changes in Ti, $CaCO_3$, $\delta^{18}O_{carb}$ and $\delta^{13}C_{carb}$ in inorganic fractions and TOC, $\delta^{13}C_{org}$ and C/N in the organic fractions suggested wetter conditions during the Bølling–Allerød (B/A) interstadial, early to middle Holocene (EMH, ~11.5-6 cal ka BP) and the Pre-Classic Period of Mesoamerican chronology, contemporary to the Escarpa phase of the Xochicalca culture. In the orbital-scale, the wetter phases of B/A and EMH were contemporaries with intervals of high spring and summer insolation. This possibly reflects changes in seasonality of the wet conditions in the region since the deglaciation. In the millennial-scale, however, the wet phases were forced by the latitudinal shifts in mean position of the ITCZ. Sediments of arid 6–4.2 cal ka BP and YD showed geochemical similarity with sediments of the Post-Classic drought, coeval with abandonment at Xochicalco. Seasonal insolation at orbital scales modulated southerly ITCZ might have forced the first two droughts and ENSO possibly forced the drought that caused cultural demise at Xochicalco.

Roles of different climatic factors on human population change in Eurasia between the Last Glacial Maximum and the early Holocene

***Dr. Yanyan Yu* [1], *Dr. Feng He* [2], *Dr. Stephen Vavrus* [2], *Dr. Amber Johnson* [3], *Prof. Haibin Wu* [1], *Dr. Wenchao Zhang* [4], *Dr. Qiuzhen Yin* [5], *Dr. JUNYI GE* [6], *Dr. Chenglong Deng* [7], *Prof. Michael Petraglia* [8], *Prof. Zhengtang Guo* [9]**

Archaeological records document a significant expansion of populations from the Last Glacial Maximum (LGM, ~23-19 ka) to the early Holocene (EH, ~9 ka) in Eurasia, which is often attributed to the influence of orbital-scale climate changes. Yet, information remains limited concerning the climatic factor(s) which were responsible for conditioning demographic patterns. Here we present results from an improved Minimalist Terrestrial Resource Model (MTRM), forced by a transient climate simulation from the LGM to the EH. Simulated potential hunter-gatherer population densities and spatial distributions across Eurasia are supported by observed archaeological sites in Europe and China. In the low latitudes, potential population size change was predominantly controlled by precipitation and its strong influence on plant and animal resources. In the middle-high latitudes, temperature was the dominant driver in influencing potential population size change and animal resource availability. Alternate regional responses of potential populations to climate change across Eurasia - owing to variations in available food resources between the LGM and EH - have broader implications on climate-human population interactions, including a better understanding human dispersal during the Late Pleistocene.

Changes in limiting factors of forager population dynamics in Europe between the Last Glacial Maximum and 8ka BP

Dr. Alejo Ordonez [1], ***Prof. Felix Riede*** [1]

***1.** Aarhus University*

Population dynamics in humans set a framework for genetic, cultural, and linguistic evolution. Multiple studies have shown coupling between demographic changes and shifts in environmental variables linked to productivity, eco-physiological limits, and seasonality. However, most of these statistical models assume constant effects on environmental variables and human population density through time. Here, we evaluate this assumption using a phenomenological statistical approach to evaluate changes in the limiting environmental factors – a factor or variable that restricts growth, abundance, or distribution of a population in an ecosystem – on population density from 21k to 8k years before present. Based on a global ethnographic hunter-gatherer dataset, we built a series of Generalized Additive Models (GAMs) to describe changes in human population density as a univariate function of temperature and precipitation variables related to available energy, seasonality, and productivity. These univariate GAM models were projected over Europe for the envaulted period using centennial average-conditions of each predictor derived from a transient downscaled climatic simulation (SynTraCE-21). Whichever variable at a site × time-step predicts the lowest population density is considered the limiting factor. Between the Last-Glacial Maximum (LGM) and the start of the Holocene, the most dominant limiting variables across Europe show district patterns linked to key climatic change. At a continental scale, energy availability was the main factor limiting population density between the LGM and the onset of the Younger Dryas (YD). During and after the YD, and until the 8kaBP, seasonal water availability was the main limiting factor to population density. The regional disaggregation of patterns in limiting factors shows strong differences between Fennoscandia, Southern, Central, and Eastern Europe. Changes within and across these regions are linked to the Bølling-Allerød interstadial and the start/end of the YD. Our results show how the main limiting factors for forager population density change over time and space, setting the dynamic stage for genetic, cultural, and linguistic evolution.

An abrupt change in vegetation and pollen production during the Late Boreal: implications for hunter-gatherer communities in northern Belgium during the 9.3 ka event

Dr. Frederike Verbruggen [1], ***Prof. Philippe Crombé*** [2]

1. BIAX Consult Biological Archaeology & Environmental Reconstruction, 2. Ghent University

Hunter-gatherer societies rely primarily on their environment for vital resources such as fresh water, edible plants, game, fish and wood. Environmental changes likely have had a large impact on Mesolithic societies and may have led to adaptations and innovations. Middle Mesolithic innovations along the southern North Sea basin (Belgium, southern Netherlands, northern France) include transformations in lithic technology regarding hunting gear and the increased use of exotic raw materials. Moreover, there are indications of a regional decrease in site densities, as well as changes in burial practices.

Early Holocene vegetation changes in northwestern Europe are well-documented and reflect the colonization and spread of various trees and herbaceous plants as climate changed after the last ice age. The stable oxygen isotopic records of the Greenland ice sheet reveal several small-scaled climatic changes, such as the cooling events at 8.2 and 9.3 ka. Relatively short-lived events may often remain unnoticed in vegetation reconstructions due to the sampling resolution, and in the case of the 9.3 ka event, the limited availability of organic-rich archives that span the Boreal. However, recently peat comprising the entire Boreal was found in the Grote Nete Valley in the Province of Antwerp, Belgium. A high-resolution pollen and macrofossil analysis of this well-AMS-dated peat record allowed a detailed reconstruction of the Boreal vegetation.

Pollen assemblages indicate that birch-pine woodland in the late Preboreal shifted to pine-dominated forests in the Boreal. After the initial expansion of hazel, followed by oak and elm from the early Boreal onward, a prominent and abrupt reduction of the pollen concentration, by up to 95% over several spectra, is observed during the second half of the Boreal. This sharp decline affects all plants and coincides with a decrease in pollen percentages of thermophilous trees and an increase of the cold-tolerant pine. The age model suggests this shift in pollen concentration and vegetation composition likely reflects a climatic cooling at 9.3 ka.

The implications of this Boreal vegetation change for Middle Mesolithic hunter-gatherer communities will be discussed in the light of resource stress in the gradually drowning landscape of the North Sea basin.

Holocene climate changes and human occupation in northern Europe – divergent developments on the prehistoric coastal and inland settlements

Dr. Petro Pesonen [1], ***Dr. Miikka Tallavaara*** [1], ***Prof. Erlend Kirkeng Jörgensen*** [2], ***Dr. Frederik Schenk*** [3], ***Dr. J. Sakari Salonen*** [4]

Department of Geological Sciences, Stockholm University, Stockholm, 4. Department of Geosciences and Geography, University of Helsinki, Helsinki, Finland

Spatially synchronous population fluctuations are widespread phenomena in nature. These fluctuations are detected also among disjunct populations of Holocene coastal hunter-gatherers in northern Europe. The synchrony appears to be a result of similar responses to positively correlated environmental variability, thus following the so-called Moran effect. Here, we focus on a northernmost part of Europe and compare population and climate trajectories between coastal Arctic Ocean and inland areas of eastern Fennoscandia.

We reconstruct human population dynamics using summed probability distributions of c. 3000 radiocarbon dates from archaeological contexts to inquire the spatiotemporal patterns in the human population development in this vast geographical area. In addition, we use quantitative pollen-based temperature reconstructions across northern Fennoscandia as well as climate model simulations to assess the climate dynamics and possible correlation between climate and human population fluctuations.

We find that coast and inland show synchronous population fluctuations. However, these fluctuations are negatively correlated between coastal and inland areas. We align population reconstruction with the temperature reconstructions and climate model data to see if the opposing patterns of population trajectories could be explained by differences in climate trajectories between coastal and inland areas or if similar climate trajectories had opposing effects on the suitability of coast and inland areas for hunter-gatherer populations of northern Europe.

Furthermore, we assess the signals of cold Holocene abrupt climate events, associated with cold temperatures in northern-hemisphere climate proxy data, and discuss which of these centennial climatic disturbances correlate with the archaeological proxies and what was their possible effect on coastal and inland population development and divergence.

The 4.2 ka event in the Himalaya in light of vegetation and precipitation change and its influence on the Harappan culture in the Indian subcontinent

Dr. Frank Schlütz [1]***, Prof. Michael Zech*** [2]***, Prof. Roland Zech*** [3]***, Prof. Bruno Glaser*** [4]***, Dr. Lyudmila Shumilovskikh*** [5]***, Prof. Frank Lehmkuhl*** [6]***, Prof. Wolfgang Zech*** [7]

1. *Institute for Pre- and Protohistoric Archaeology, University of Kiel,* ***2.*** *Heisenberg Chair of Physical Geography with Focus on Paleoenvironmental Research, Institute of Geography, Technische Universität Dresden,* ***3.*** *Physical Geography, Institute of Geography, Friedrich Schiller University Jena,* ***4.*** *Institute of Agricultural and Nutritional Sciences, Martin Luther University Halle-Wittenberg, Halle (Saale),* ***5.*** *Department of Palynology and Climate Dynamics, Georg-August-University,* ***6.*** *RWTH Aachen University,* ***7.*** *Department of Soil Science, University of Bayreuth*

For many human cultures of this time, the drought event of 4.2 ka was one of the most consequential climatic events during the Holocene. Its strong, devastating influence is well known for the Mediterranean, Egypt, Mesopotamia, and beyond. In a broader sense, the 4.2 ka event even marks the beginning of the Meghalayan, the youngest period of the Holocene. The geologic type locality or Global Boundary Stratotype Section and Point is located in Mawmluh Cave in the Indian Himalayas.

We conducted detailed geochemical, sedimentological, and palynological analyses on a 15 ka drill core from Lake Panch Pokhari in the Nepalese Himalaya to determine how Holocene climate history is reflected by changes in vegetation, landscape, and precipitation. This section is situated in an important geographical transition region. While the summer monsoon plays a dominant role in terms of precipitation, westerly winds dominate here precipitation and moisture in winter and spring and are therefore critical for plant growth and crop thriving early in the year. Higher snowfall in winter also affects the albedo of the Tibetan plateau and controls the strength of the summer monsoon.

In the pollen record, we can identify the 4.2 ka event by a decrease in summer monsoon related species but an increase in tree taxa associated with higher winter precipitation. This indicates that thee 4.2 ka event was accompanied by a profound shift in the relative strength of the winter westerly wind and the summer monsoon, which temporarily led to sustained changes in annual precipitation patterns. This appears to have strongly influenced the composition and species selection of crops grown by the Harappan culture in the northwestern Indian subcontinent. The late Harappan culture ended during a second climate event that again brought higher proportions of winter precipitation and lower monsoonal summer rains by 3.4 ka.

Protohistoric oases as a response to aridity? A view from Bronze Age northern Oman

Dr. Lucas Proctor [1]***, Dr. Tara Beuzen-Waller*** [2]***, Dr. Katharina E. Schmitt*** [3]***, Dr. Conrad Schmidt*** [4]

1. Institute for Archaeological Sciences, Goethe University Frankfurt, 2. Soil science and geomorphology working group, University of Tübingen, 3. Institute of Geosciences, University of Mainz, 4. IANES, University of Tübingen

We present a case-study, centered on the development of oasis agricultural systems in Oman, to illustrate the complexities inherent in linking climate forcing and societal responses when working with ancient archives, particularly regarding questions of causality and synchronicity. The origin of oases in Oman is sometimes presented as an adaptative response to the onset of aridity at the end of the Holocene Humid Period around 5,000 BP. Many components of the oasis agricultural system seem to have first appeared in the region during the Early Bronze Age (ca 5,100–4,000 BP), including (semi)permanent settlements, crops, and water management. However, evidence for these is rarely found together, but rather spread across different archeological sites and dates. Furthermore, records relating to fluctuations in rainfall, surficial water and groundwater levels show asynchronous responses to aridity due to the resolution of recordings and the time lag of some phenomena. The onset of aridity, therefore, may start anywhere within a 1,000-year interval, depending on the archive employed. Further compounding the issue, it is challenging to disentangle climate induced- vs. anthropic changes in vegetation change in the zone of pastoral activities surrounding oases from site-based datasets.
Within the frame of the UmWeltWandel project, we have mobilized a multidisciplinary approach that includes archaeobotany, palynology, geomorphology, archaeology, and malacology, to study human-environment interactions in the EBA archaeological complex at al-Khashbah, Oman. We argue that a clear, well-dated tipping point in local paleoenvironmental records is required to situate any climate forcing event in time. We then demonstrate, using a range of examples including al-Khashbah, the chronological, archaeological and palaeoclimatological complexities inherent in trying to identify the origin of oases in Oman and question the immediate and causal character induced by the notion of “adaptative responses” in the study of this development.

Impact of Neoglacial cooling on human activity in West Greenland

Dr. Astrid Strunk [1], *Dr. Sascha Krüger* [1], *Dr. Jens Fog Jensen* [1], *Dr. Catherine Jessen* [1]

1. National Museum of Denmark

Present climate change is the most urgent challenge to the global population. However, this is not the first time that humans are confronted by climatic shifts that demand drastic changes in ways of life – or demise. We present a new, local reconstruction of climate at ancient Inuit hunting grounds in the UNESCO World Heritage area Aasivisuit-Nipisat, West Greenland. We use lake sediment and apply a wide palette of climate proxies, including: palynology, chironomid $d^{18}O$, lake chemical composition, and stable isotopes. In contrast to most of the existing climate reconstructions in Greenland, our record is focused on the last 1500 years, and we thereby offer a very high resolution of a period with drastic climate changes and high human activity in the area. Our multi-proxy approach offers a robust and detailed reconstruction and we find evidence of stable conditions followed by a cooling and drying trend - the Neoglacial cooling - that forced change of Inuit hunter-gatherers' migration patterns.

Collapse of the Maya civilization related to persistent drought

Ms. Josefine Axelsson [1], ***Prof. Qiong Zhang*** [1]

1. Dept. of Physical Geography and Bolin Centre for Climate Research, Stockholm University, Stockholm, Sweden

A period of severe droughts between the eighth to eleventh century CE was unprecedented in Maya prehistory and played a vast role in the regional collapse of the Maya civilization. Previous paleoclimatological and archaeological studies suggest that the mechanisms behind the extensive drought periods could be attributed to solar variability, North Atlantic climate variability, a shift of the Intertropical Convergence Zone, El Niño southern oscillation (ENSO) variability, deforestation, changes in tropical cyclone frequency or changes to the interoceanic sea surface temperature (SST) gradient.

In this study, we aim to verify the above-mentioned hypotheses through analysis of our simulation for the last millennium using a fully coupled global climate model EC-Earth3. Global climate models have the advantage of demonstrating teleconnections in the climate system. Although the Maya lowlands are a small-scale region, the cause of regional climate change can be due to remote forcing.

In essence, a 300-year persistent drought during the eighth to eleventh century CE in Maya lowlands is observed in the EC-Earth last millennium simulation. Our analyses of different climate aspects identified several contributors to the persistent drought. The climate variability within the North Atlantic is reduced, ENSO variability is enhanced with more frequent El Niño events, the hurricane genesis is reduced in the eastern Pacific, and the interoceanic SST gradient between the eastern Pacific and the tropical Atlantic is enhanced. Changes in deforestation can not be detected in the reconstruction, and a slight increase in solar irradiance is negligible as they are the inputs of climate forcings in the model.

Vegetational responses to climatic trends, specifically droughts, during the Norse settlement period in Southern Greenland

Dr. Sascha Krüger [1], ***Dr. Astrid Strunk*** [1], ***Prof. Raymond S. Bradley*** [2], ***Dr. Isla S. Castañeda*** [2], ***Dr. Tobias Schneider*** [3], ***Dr. Zhao Boyang*** [2], ***Dr. Catherine Jessen*** [1]

1. *National Museum of Denmark,* ***2.*** *Department of Geosciences at the University of Massachusetts,* ***3.*** *Lamont-Doherty Earth Observatory, Columbia University*

The Norse arrived in southern Greenland and were settled in farming communities for around 500 years before disappearing and a wide variety of causes have been suggested for their demise. Recently a study by Zhao et al. (2022) from sediments from a lake on a Norse farm identified an increase in the occurrence of droughts during the 15th century AD and suggested that these droughts negatively affected hay-making which kept the vital livestock alive through the winters. However, while the effect of droughts on local hay-making can be observed in recent years, the larger regional scale pollen data during the later Norse period contrastingly shows that concentrations of grass pollen increased during this period. To resolve this apparent dichotomy a high-resolution palynological reconstruction using the same lake samples gives the local pollen-influx data proximal to the settlement which is then compared to more distal vegetational reconstructions and existing climatic data.

Climate and cultural changes NW Arabia (Mid–Holocene)

Mr. Amer Alsouliman [1]

1. University of Catania

since 1972 when they had the first meeting the United Nations Conference on the Human Environment in Stockholm, Sweden,
and Twenty years later, at the historic Earth Summit in Brazil in 1992, the United Nations sought to help Governments rethink economic development and find ways to stop polluting the planet and depleting its natural resources, produced the Rio Declaration, which had 27 principles, which reflected human beings' responsibility for sustainable development.
the Convention of Combat Desertification, Dec. 1996. And other conferences and Conventions 1997, 2000, 2002, 2005, 2008, 2010, 2012, 2013, 2015, .. 50+ in Stockholm this summer 2022.
2022 witnessed serious effects of global climate change. Rivers and lake disappeared, aridity even in Europe. Higher temperatures. 15000 persons in Europe died last summer because of the global warming. thousands of forests hectares flamed up this summer. Heavy floods in dried areas.
After all, the international community has not succeeded in curbing the excessive consumerism of the earth's resources, and the systematic destruction of the ecosystem searching for global imbalanced welfare, nor has it imposed the necessary solutions avoid humanity what so called "collective suicide".
Water is playing an important role in the past and present in demography and civilizations. concentrated around water and shrinking far away from water. Qulban Bni Mura and Rajajil witnessed one of the most important water management systems and strategies in the northwest Arabia. the climate change of the mid - Holocene in the northwest Aribia during the transition to the aridity left behind water management systems and strategies. The paleo - environment, paleo - climate and climate changes have been affected on the water resources of the northwest Arabia. This forced the people to establish water management systems and strategies adapt and deal with the extreme environmental conditions and less water in the northwest Arabia. This contribution is shedding the light on the water management systems and strategies of the chalcolithic pre-oasis culture of the northwest Arabia, Furthermore It will clarify how human being part of climate change solutions in the past, while the human nowadays is causing of climate changes.

Session 138: Wet Environments and Human Communities: Interaction and Resilience in the Holocene and Antiquity

‘Where Land and Waters Meet’; 10,000 years of human eco-dynamics within a ‘Wildscape’

Prof. Nicki Whitehouse [1]***, Prof. Henry Chapman*** [2]***, Dr. Kimberley Davies*** [3]***, Dr. M. Jane Bunting*** [4]***, Dr. Benjamin Gearey*** [5]***, Dr. Michelle Farrell*** [6]***, Dr. Philip Barratt*** [7]

__1.__ Department of Archaeology, University of Glasgow, UK, __2.__ University of Birmingham, __3.__ Institute of Modelling Socio-Environmental Transitions (IMSET), Bournemouth University, Poole, Dorset, BH12 5BB, UK, __4.__ School of Environmental Sciences, University of Hull, __5.__ University College Cork, __6.__ Coventry University, __7.__ University of Nottingham

Archaeological records indicate that humans have long been attracted to resources available within river and wetland ecosystems, with settlement and economic activities occurring around the wetland-dryland interface. Moving waters connect these places, weaving the threads of the landscape together, and impacting lifeways well beyond their boundaries.

Here, we explore changing wetland-dryland human eco-dynamics, across inter-connected river-mere-wetlands, to understand how these places were used and transformed over time. Our case study is the Humberhead Levels landscape, eastern England, where there has been a long history of palaeoenvironmental, geoarchaeological and archaeological study. Today the land cover is mostly intensive agriculture, with a few protected areas centred on the remnants of heavily exploited lowland ombrotrophic mires. Lidar imagery, historical maps, accounts, and the sediments underlying the fields tell a different story; until the 17th century, it was a landscape of inter-connected rivers, meres, wetlands and marshes, with extensive areas of open water, sometimes tidal, always deeply connected by sea and freshwater, with human settlement and activity clustered on islands of higher ground. The rivers and wetlands were extensively utilized throughout prehistory for their resources and as routeways, whilst in the Roman and historic periods they were transformed for navigation and control, then diverted, drained and canalized, representing a way of life and adaptation to living-with-water that can be traced back over thousands of years.

An extensive archaeological database has allowed us to infer the nature and focus of human activity and land use – from the Mesolithic to the post-Medieval period - whilst pollen records provide a land cover history. By reconstructing the temporal palaeogeography and dynamics of the ‘wildscape’ it is possible to understand the complex patterns of human activity, interactions and how these riverscapes and wetlands were used over space and time. The story that emerges is one that is intimately connected to the wetlands, distinctive and unique and yet widely connected beyond the wetlands themselves, whilst emphasising long-term continuity of human-environment relationships over time.

A combined geoarchaeological and bioarchaeological approach at Vix (Burgundy, France) to reconstruct human-environment interactions since the Iron Age: the case of the Fontaine des Abîmes

Ms. Mégane Mignot [1], Dr. Caroline Schaal [2], Ms. Alexandra Valayer [3], Dr. Marine Rousseau [2], Prof. Jean-Pierre Garcia [1], Dr. Bruno Chaume [1], Prof. Hervé Richard [2], Dr. Émilie Gauthier [4], Dr. Amélie Quiquerez [1]

1. *Laboratoire ArTéHis, UMR 6298 CNRS, Université de Bourgogne, Dijon, France,* **2.** *Laboratoire Chrono-Environnement, UMR 6249 CNRS, Université de Bourgogne Franche-Comté, Besançon, France,* **3.** *Université de Franche-Comté, Besançon, France,* **4.** *Laboratoire Chrono‑Environnement, UMR 6249 CNRS, Université de Bourgogne Franche-Comté, Besançon, France*

The Hallstatt principality of Vix is above all famous for the burial mount of "*la Dame de Vix*" and its exceptional archaeological material, especially Greek and Etruscan imports. On a plateau overlooking the Seine River, a settlement with a quasi-urban spatial organization and monumental apsidal buildings unique for the period, was fortified by a vast network of ramparts (45 ha). From there, a local aristocratic power controlled the valley during the 6th and the beginning of the 5th centuries B.C.

This site of major importance for European Protohistory is located in a karstic region with several resurgences emerging in its immediate vicinity. However, questions related to the uses of these water sources remain little discussed. Through a study combining geoarchaeology, bioarchaeology and archeoecology, we aim to describe with high resolution, the relationships between the hydrogeomorphological and environmental evolutions of a karst resurgence, and socio-cultural practices linked to the water resource.

A 238 cm core was collected close to the spring at *La Fontaine des Abîmes*, less than 500 m from the famous tumulus. Geoarchaeological (stratigraphy interpretation, granulometry, geochemistry) and bioarchaeological analyses (palynology and carpology) were conducted on the core, as well as ^{14}C dating.

This integrated approach highlights changes in hydrological and environmental dynamics over the last two millennia. The alternation between clay decantation phases and organic sediment depositions reveals variations in the water regime. Landscape composition alternates between a forested environment (woodland edge/alluvial forest) and a more open environment (fields/meadows). Moreover, the association of biotic and abiotic assemblages with archaeological evidence provides information about the modalities of human activities at this site. The *Fontaine des Abîmes* area was strongly impacted by agriculture in the Iron Age (750-50 BC). Human impact seems also visible during Antiquity (50 BC-500 AD) when a change in depositional environment causes a transition from clay to peat. Then during the Middle Ages (500-1500 AD), palynological and carpological remains suggests a shift in land use towards pastoralism. Proxies used seem to have the same dates of their tipping points and this combined approach shows how increases in human impact may provoke rapid responses in the ecosystem.

Erosion history, landscape dynamics and human presence during the Holocene in the Lake Țaga catchment, Transylvanian lowlands, Romania

Mr. Gheorghe Badaluta [1], ***Prof. Marcel Mindrescu*** [1], ***Dr. Angelica Feurdean*** [2], ***Prof. Dirk Nowacki*** [3], ***Dr. Simon Hutchinson*** [4], ***Dr. Gabriela Florescu*** [1]

1. *Stefan cel Mare University of Suceava,* ***2.*** *Faculty of Geosciences and Geography, Goethe University, Frankfurt, Germany,* ***3.*** *Goethe-Universität Frankfurt am Main,* ***4.*** *University of Salford*

Climate change is predicted to increase soil erosion worldwide, as a result of an increase in the frequency of extreme climatic events (e.g., torrential rains and droughts). The effects of climate change, superimposed on increasing anthropogenic pressure will affect all types of land use and ecosystem services, particularly in lowlands, which are densely populated and therefore more exposed to climate-related risks. Increasing erosion and landscape degradation are already visible in the lowland areas of Central-Eastern Europe, where there is little information on their past environmental dynamics and the extent of human transformation of these landscapes. This limits estimation of the potential future risks posed by environmental change in a warmer world.

Lake Țaga, in the Transylvanian lowlands holds a 7.2-m long sedimentary sequence spanning the mid-late Holocene, thus potentially allowing us to fill in knowledge gaps in the evolution of this area and potential drivers of landscape change. To reconstruct catchment erosion history, the sediment core was analyzed for elemental geochemistry, particle size and mineral magnetic proprieties to define erosion patterns, depositional characteristics and lake-catchment interactions. Furthermore, local archaeological surveys and published extra-local data on past fire disturbance, vegetation and climate dynamics contributed to the reconstruction of human habitation dynamics in relation to land-use/landcover change.

We found three intervals of greater erosion during the last 6000 years. Firstly, prior to 4200 yr BP, erosion was mainly induced by climate variability and the instability of river channels in the catchment. The second interval, between 3800-3000 cal yr BP, and the third interval spanning the last 1800 years of soil erosion and sediment deposition were driven by human activities, such as deforestation, the extension of agricultural land and finally direct intervention in the water body. In addition, two intervals of greater stability could be identified (4200-3800 cal yr BP and 3000-1800 cal yr BP), which coincided with negative NAO modes and lower than average temperatures.

The Taga Lake sediment archive offers new perspectives on landscape scale environmental changes and the processes of erosion and lacustrine deposition and their interaction with anthropogenic effects and climate variability on a millennial time scale.

Middle Holocene climate changes and human impact in Sardinia: the contribution of new geochemical proxy data

Mr. Gianbattista Marras [1] ***, Dr. Federica Sulas*** [1] ***, Prof. Charles French*** [1]

1. *University of Cambridge*

Multidisciplinary palaeoenvironmental research has elucidating elucidated aspects of the relationships between human settlements and their environments across the Mediterranean region at times of rapid climate changes occurred during the Holocene. However, the climate history and the interactions between humans, climate, and environment in Sardinia, the second largest island of the Mediterranean, remain poorly understood. Building on and expanding from recent research in the Rio Posada basin, eastern Sardinia, this work discusses the results of geochemical and statistical analyses of sedimentary archives covering the last 8000 years BP. Firstly, Principle Component Analysis (PCA) was performed to understand the geochemical composition of lithostratigraphic units. Secondly, we tested the potential of geochemical ratios (Sr/Ba, Ti/Ca and K/Ti) to detect evidence of climate change in mid-Holocene lagoonal deposits. Whilst the PCA results showed that the geochemical variability of each lithostratigraphic unit follows a distribution linked to strong (weak) influences with geogenic and environmental-related elements, the unit of lagoonal facies yielded the highest variability and did not cluster according to a single factor influencing the geochemical distribution. This variability was subsequently framed by the results of the geochemical ratios that recorded a pattern of alternating peaks in the K/TI and Ti/Ca, which are synchronous with low (high) values of the Sr/Ba ratio. These developments occurred at periods of higher rainfall and erosion rates recorded across the western Mediterranean, including North Iberia and North Africa, between 7.5 - 7.2, 7 - 6.8, 6.3 - 6 ka BP. These findings show the potential of geochemical profiling to investigate past climate changes and offer new insights into Mid-Holocene human-interactions in Sardinia. Nevertheless, a higher sampling resolution and the comparison with different regional climate proxies are necessary to improve the reconstruction of the climatic history of Sardinia and of the societal responses to past climate changes.

From settled mainland to abandoned islands: how landscape transformation tested resilience of Neolithic inhabitants of the Oldenburger Graben wetlands, NE Germany

***Dr. Dragana Filipovic** [1], **Dr. Jan Piet Brozio** [1], **Dr. Katharina Fuchs** [2], **Dr. Lucy Kubiak-Martens** [3], **Dr. Tania F.M. Oudemans** [4], **Prof. Johannes Müller** [1], **Prof. Wiebke Kirleis** [1]*

***1.** Institute for Pre- and Protohistoric Archaeology, University of Kiel, **2.** Institute of Clinical Molecular Biology, University of Kiel, **3.** BIAX Consult Biological Archaeology & Environmental Reconstruction, **4.** Kenaz Consult & Laboratory*

In prehistory, the area of Oldenburger Graben comprised a Baltic Sea fjord and later a coastal lagoon. The Neolithic settlements located here and in the surrounding zone are some of the best-investigated in northern Germany. They have offered a substantial body of data on the material culture, built and natural environment, and human subsistence in the period from the end of the 5th to the first centuries of the 2nd millennium BC (the Nordic Early, Middle, Young and Late Neolithic). Situated next to and, for much of its history, connected to the Baltic Sea, the Oldenburg wetland area was significantly influenced by the post-glacial sea level rise resulting in the local evolution from brackish to marine to freshwater environment, with implications for the soil and vegetation cover. In this presentation, we show how the dynamic landscape shaped the nature of human activity and the duration of Neolithic occupation. First, we summarise the findings of geomorphological and palaeoecological investigations in the area, which enable a reconstruction of the changes in the environment in the time just before and during the Neolithic. Then, we look at the evidence of human habitation, food production, diet and cuisine using the data from archaeology (material culture), archaeobotany, food remains, human osteology and stable isotope analysis of botanical and human remains. We interpret diachronic changes in the size and number of domestic sites and the agricultural land use as adaptations to the declining landscape affordances, which tested the resilience of the local lifestyle. The abandonment of sites along the coastal mainland and on peninsulas-turned-islands may signal that limits of resilience were ultimately reached. We discuss the extent of adaptability of the Neolithic inhabitants of the Oldenburger Graben, and how the present can learn from the past.

Palaeoenvironmental dynamics and human-landscape interactions at the Bolsena Lake (Central Italy) between the 2nd millennium and 5th century BCE

Dr. Andrea Babbi [1], ***Dr. Alessandra Celant*** [2], ***Dr. Paolo Maria Guarino*** [3], ***Dr. Mauro Lucarini*** [3], ***Dr. Fabrizio Michelangeli*** [2]

1. Institute of Heritage Science of the National Research Council of Italy ISPC-CNR, Montelibretti Rome, 2. Dipartimento di Biologia Ambientale, Sapienza Università di Roma, Roma (Italy), 3. Dipartimento per il Servizio Geologico d'Italia - ISPRA

During the Late Holocene, wet environments faced remarkable changes in relation to rapid climate fluctuations and increasing human impact on ecosystems. The intricate interplay of climate, human history, and land-use systems stands as a multifaceted research subject, requiring the integration of different scientific disciplines with different perspectives on human-wet environment relationships.

The archaeological site of Bisenzio, located on the SW coast of the Bolsena Lake, represents an ideal testbed to investigate past environmental changes and their effects on the livelihoods of the human community that thrived between the 2nd millennium and the beginning of the 5th century BCE.

A transdisciplinary approach combining different investigation strategies and research methodologies, such as underwater cartography achieved through interferometric side scan sonar and UAS surveys, stratigraphic archaeological soundings, sedimentological and palynological analysis of sediment cores, as well as the study of in situ palaeobotanical and archaeozoological remains, allowed to delineate some preliminary insights on landscape changes, water resources, and the geo-hydrological network at Bisenzio during that time.

The high-resolution bathymetric surveys provided updated isobath contours for the nearshore zone, revealing a more articulated morphology of the lakebed than that highlighted by the relief made some decades ago. These new data improve our knowledge on the underwater region of the archaeological site enabling more accurate interpretations of the submerged functional structures.

The results of boreholes drilled along the currently emerged area have provided evidence of sedimentary sequences of high-energy streams, with relevant thicknesses containing fragments of ancient anthropogenic artifacts.

Exploratory pollen analysis of sediment cores from the offshore zone revealed a depositional hiatus that is coherent with high-energy environment in the proximity of the archaeological site. Preliminary chronological assessment, based on 3 radiocarbon dates, highlighted consistent results.

Palynological and palaeobotanical investigations of archaeological samples from domestic contexts provided crucial information on cultivated, ruderal, and synanthropic plant species related to human activities at the site.

This work offers an overview of the first results of the ongoing international 'Bisenzio Project' which aims to reconstruct both the salient aspects of palaeoenvironmental dynamics and resilience strategies implemented by humans in a changing ecosystem.

Plant subsistence on the lakeshore: exploring human-environment interactions through rich waterlogged plant remains

Ms. Amy Holguin [1]***, Prof. Mike Charles*** [1]***, Prof. Amy Bogaard*** [1]

1. *School of Archaeology, University of Oxford*

The Late Neolithic settlement of Ploča, Mičov Grad, Lake Ohrid, North Macedonia, is one of many lakeshore sites in the southern Balkans. The area's location renders it pivotal for understanding the establishment of agriculture in temperate continental Europe. Despite this, wetland sites in this region have rarely been subject to systematic archaeobotanical study. As part of the international and inter-disciplinary ERC-funded EXPLO project, excavations at the pile-dwelling site of Ploča, Mičov Grad aim to shed light on the way its occupants adapted Neolithic subsistence practices to their lakeshore setting. Here, a cultural layer up to 1.7-m thick, associated with the settlement, was extracted through lake cores, rich with waterlogged archaeobotanical material and dated to the mid-5th millennium BCE. This record shows that the community used a wide range of plants including cultivated cereals and pulses, oil-seed crops and gathered fruits and nuts. The settlement lay within a mosaic landscape, centred upon the wetland interface between the oligotrophic lake and the imposing Galičica mountain range. The excellently preserved botanical remains attest to clear recurrent patterning in land and plant use by a lakeshore community in this diverse landscape.

Holocene human impact on different altitudinal belts in Julian Alps, Slovenia

Ms. Nina Caf [1], ***Dr. Pierre Sabatier*** [2], ***Dr. Andrej Šmuc*** [3], ***Dr. Nives Ogrinc*** [4], ***Dr. William Rapuc*** [2], ***Dr. Maja Andric*** [5]

1. *ZRC SAZU, Institute of Archaeology,* **2.** *Université Savoie Mont Blanc, CNRS, EDYTEM,* **3.** *University of Ljubljana, Faculty of Natural Sciences and Engineering, Department of Geology, Aškerčeva 12, 1000 Ljubljana, Slovenia,* **4.** *Jožef Stefan Institute,* **5.** *ZRC SAZU Institute of Archaeology*

Lake sediments are natural archives of long-term changes in the sensitive alpine environment. Climatic fluctuations and human influence contribute significantly to these changes, affecting vegetation, sedimentary processes around the lake and the chemical state of the lake. In the area of the Julian Alps (southeastern Alps), palynological, sedimentological and geochemical analyzes were carried out on three lakes at different altitudes (Lake Bohinj, 520 m a.s.l., lowland; Lake jezero na Planini pri jezeru, 1450 m a.s.l., montane belt; Lake jezero v Ledvicah, 1830 m a.s.l., subalpine belt), mainly, to compare the main factors affecting environmental changes at different altitudes.

Economic activities drove people to alpine environments, where they exploited the environment for various purposes. In the highlands, the appearance of anthropogenic indicators (*Plantago lanceolata, Sporormiella*) points to the beginnings of pastoralism already in the Neolithic, around 7500 BP. In the Early Bronze Age human impact increased, which is reflected in more archaeological sites, and coincides with other alpine regions. At Lake jezero v Ledvicah two fire events occurred (1800 and 1100 cal. BP), possibly to expand pastures. Around 430 cal. BP pastoralism in the montane belt became so intensive that caused major eutrophication of the Lake jezero na Planini pri jezeru.

In the Iron Age, the lowlands were probably more densely populated than the highlands with many important archeological sites. Increasing human impact probably resulted in major deforestation in the area in order to obtain enough wood for metallurgical purposes, which caused erosional processes in the lake. In the lowlands and montane belt, human-induced erosion and eutrophication significantly affected the lakes environment. In contrast, Lake jezero in Ledvicah in the subalpine belt, remained largely unaffected despite the recognized human influence from prehistoric times. Thus, comparing human impact at different altitudes, shows that it began earlier at higher altitudes, while it had greater impact on the lake's chemical state in the lowlands and montane belt.

Palaeoenvironmental and land-use reconstruction at the Neolithic site of Palù di Livenza (Northern Italy): a palynological perspective

Dr. Jessica Zappa [1], ***Dr. Paola Torri*** [1], ***Prof. Alessandro Fontana*** [2], ***Dr. Nicola Degasperi*** [3], ***Dr. Michele Bassetti*** [3], ***Prof. Anna Maria Mercuri*** [1], ***Dr. Roberto Micheli*** [4]

Palù di Livenza is a Neolithic pile-dwelling site, inscribed in the UNESCO World Heritage List since 2011. Investigations coordinated by Soprintendenza ABAP-FVG brought to light an impressive amount of archaeological and palaeobotanical data for the knowledge of the life in a wetland zone during the Neolithic. The Palù basin is a wet site that recorded environmental transformation through time and also the phases of early Holocene are preserved, that are rarely present in other sites of Northern Italy. The palynological studies in these contexts can be particularly informative because pollen is very well preserved and abundant in peaty sediments and its analysis allows to reconstruct a clear image of the vegetation and its changes through time. In this study, we present the palynological analyses performed on three sequences, two sampled on-site and one cored off-site. The on-site record (40 samples) come from trenches inside the archaeological site, while the off-site record (21 samples) was cored in the basin of the Livenza, 300 meters south of it, up to a depth of 6 m. On average 300 pollen grains per sample were counted. In the most ancient layers of the off-site sequence, a high presence of arboreal pollen (AP) is found, indicating a forested environment dominated by the mixed oakwood and some hygrophilous taxa, suggesting the presence of few wet areas around the site. From the middle of the sequence, the oakwood gradually decreases in favour of the hygrophilous taxa (both arboreal and non-arboreal taxa), indicating the establishment of a wetter environment. Cereals, API (Anthropogenic Pollen Indicators) and LPPI (Local Pastoral Pollen Indicators) are present throughout the sequence in little but significant amount. A comparison with the analysis of the on-site records is useful to understand the range of the human influence and to better characterize and quantify the human impact on the vegetation surrounding the site.

This study is included in a PON project aimed at reconstructing the biodiversity, the environment and the human/environment dynamics in Northern Italy from the Neolithic period to the end of the Bronze Age.

A 5 thousand-years history of environmental changes in the Argive Plain (Peloponnese, Greece) inferred from the new pollen record of Lake Lerna

The study provides new pollen data from a sediment core taken in the area of Lake Lerna (Peloponnese, Greece). We have combined palaeoenvironmental and archaeological evidence from the Argive Plain, in addition to the palaeoclimatic reconstruction obtained from isotopic data of the same core and other regional proxies. Our aim is to reconstruct the environmental history of the region dominated by human activities already since the mid-Holocene.

The core recovered in 2016 has a total length of 5 m and covers the last 5000 years. The age-depth model is based on 6 AMS radiocarbon dates of plant remains and 2 dates of organic-rich sediment. The analysis of pollen grains and other palynomorphs was carried out on 84 sediment samples. The mean sampling resolution is 6 cm and the mean chronological resolution is 76 years.

Results show that the interaction of climate with a variety of cultural, political, and socio-economic factors transformed the vegetation of the plain and caused its long-term degradation. Before ca. 4000 BP the coring site was a fen and oak woodland prevailed in the uplands, whereas cereals were cultivated in the plain. Afterward, despite local wet climatic conditions, inferred by the isotopic record, a forest retreat was evidenced coinciding with increased human pressure. In particular, activities linked to the presence of Mycenaean palatial centres modified the landscape and resulted in expanding pasturelands. In the lake the abrupt expansion of macrophytes suggests that human management possibly produced a permanent hydrological change. From the Archaic period, the increasing human pressure in association with drier conditions caused landscape instability. Roman times coincide with forest regeneration under wetter conditions, whereas the landscape was shaped by intensive olive cultivation and pastoral activities. An economic landscape primarily based on pastures was established from the Byzantine period onwards, stressing the relationship between lower precipitation and increasing pastoralism in the Peloponnese. The dominance of open environments continues until modern times, when conditions were drier, and the present-day wetland formed at the expense of the lake.

The human and lake at the Bronze and Iron Age sites located in the Samica River valley (western Poland, Central Europe) in multi-proxy palaeoecological records

Prof. Piotr Kołaczek [1]***, Dr. Monika Karpińska-Kołaczek*** [1]***, Prof. Iwona Hildebrandt-Radke*** [2]***, Prof. Mariusz Gałka*** [3]***, Prof. Monika Rzodkiewicz*** [4]***, Dr. Jakub Niebieszczański*** [5]

Water availability is among the crucial factors influencing settlement development. Palaeoecological reconstructions, based on numerous proxies from peat and lacustrine deposits, are vital to reconstruct past settlements and human impact on local forests and lakes. In this study, we focused on the archaeological microregion in Bruszczewo village in southern Greater Poland (western Poland; Central Europe), which was inhabited by people from cultures of the Bronze and Iron Ages organised around the vast former lake. In this study, analyses of pollen, non-pollen palynomorphs, plant macrofossils, geochemical, and sedimentological markers were applied to reconstruct human impact on local ecosystems. Our study revealed at least one period of lake transgression at ca. 1880-1690 cal. BCE. From that period, wooden construction was found at an archaeological site adjacent to the shoreline. It was interpreted as a fascine built to prevent houses from the lake waters and/or to stabilize the shoreline from erosion. A pollen-inferred increase in human impact was identified at ca. 1630-1570 cal. BCE, and it was probably related to the presence of representatives of Unetice Culture. At that time, *Carpinus betulus* became a much more important forest component, perhaps, at the cost of *Corylus avellana*. The next distinct acceleration of human activity, marked by pollen data (increase in Cerealia type, *Secale cereale* percentages), was identified at ca. 1020-910 cal. BCE (Lusatian Urnfield Culture). An increase in diatom concentration in lacustrine sediments was simultaneous to both stages of increased human impact. What is interesting, there were almost no diatom valves in the sediment layers parallel to periods of (pollen-inferred) low human impact. This might be interpreted by the inflow of nutrients to the lake during periods of more intensive settlement, which stimulated a rise in water trophy (perhaps acidity). This improved conditions for the preservation of diatom valves in sediments preserving from their dissolving. The distinct lake terrestrialisation was identified between ca. 810±30 cal. BC and 790-540 cal. BC, but this did not weaken the human activity on former lake shores, as revealed by pollen and archaeological data.

This study was funded by the National Science Centre grant no. 2019/33/B/HS3/00193.

Reopening the case for a climate-induced population decline during the Late Bronze age Solar Minimum: Insights from an annually-resolved lake record.

Ms. Amy Walsh [1]***, Dr. Anna Bloxam*** [2]***, Prof. Simon Blockley*** [1]***, Dr. Poppy Harding*** [3]***, Dr. Markus Czymzik*** [4]***, Prof. Ian Candy*** [1]***, Dr. Alice Milner*** [1]***, Prof. Peter Langdon*** [5]***, Dr. Ian Matthews*** [1]***, Dr. William Bowden*** [2]***, Prof. Helen Bennion*** [6]***, Dr. Celia Martin-Puertas*** [1]

There is significant interest in the resilience of past populations to abrupt climate change and environmental stress. While the postglacial period is relatively stable, several widespread environmental downturns with important socio-economic impacts, are recognised to be linked to different climate forcing mechanisms. One event that has been the focus of significant attention, occurs around 2.8k cal. BP, coincident with the Homeric Grand Solar Minima (GSM). Debate surrounds the association between the timing of the solar-induced abrupt climatic oscillation and an observed population collapse at the end of the Bronze Age in northwestern Europe. Given this period falls within the ^{14}C calibration plateau, records with robust and precise chronological control are required to evaluate human responses to rapid climate and environmental change. Here we present a multi-proxy study of a unique varved record from the British Isles in the context of this discussion, Diss Mere, Norfolk. The Diss chronology, based on varve counts, cosmogenic dating (^{14}C and $^{9}Be/^{10}Be$) and tephrochronology provides unprecedented chronological control and a synchronisation tool to compare the Diss Mere record with other sites. We present a diatom-based wind record, a stable isotope-based hydrological record and a pollen-based landscape reconstruction from the same sediments, which allow us to compare the timing of the solar forcing, climatic and environmental response with minimal chronological uncertainty. We have remodelled existing radiocarbon dates for the British and Irish archaeological sites, along with data for East Anglia and show evidence for a Bronze Age population decline according to the most updated IntCal20 curve. Our results indicate the climatic response was synchronous and in-phase with the GSM and the regional population decline. Locally, palynological and spore data suggest that the climatic change did not have a significant impact on the vegetation but indicates a coeval reduction in human pressure on the landscape. Therefore, our study calls upon the chronological reassessment of the event in records and reopens the potential for a direct solar induced climate shift to impact on populations in Late Bronze Age Europe.

Landscape change during the Roman period in Southern Britain at Fishbourne Roman Palace

Mr. Joe Shakespeare* [1], *Dr. Mark Hardiman* [2], *Prof. Rob Scaife* [3], *Dr. Robert Symmons* [4], *Dr. Garry Scarlett* [2], *Dr. Adele Julier* [2]

***1.** School of Biological Sciences, University of Portsmouth, Portsmouth, **2.** University of Portsmouth, **3.** University of Southampton, **4.** Fishbourne Roman Palace*

Britain's past tells a tale of a human impacted landscape throughout the Mid to Late Holocene. Notable changes often occurred during periods of cultural exchange such as in the Bronze Age and Roman invasion. During the mid to late Holocene, a distinct trend of woodland clearance was observed. Forest previously dominated by *Quercus, Corylus* and *Alnus* was cleared with high levels of Poaceae pollen indicating a more open environment. The Roman invasion of Britain has previously been found to have impacted landscapes by intensifying farming efforts and through the introduction of exotic taxa. There is, however, a relative paucity of palaeoecological records covering the Roman period from the South of Britain.

Fishbourne Roman Palace, constructed in 43 AD, expanded upon in 73 AD and abandoned in 270 AD, is a site of spatial and temporal significance as it is one of the first Roman sites in Britain. Pollen was recovered from excavations of the site in 1971 and 2002, but due to less-than-ideal conditions for pollen preservation it was not abundant and there was evidence of preferential preservation of taxa with thicker walls. Salt marsh sediments, however, have a higher likelihood of yielding well preserved pollen due to their water-logged, anoxic nature. A sediment core of 193 cm was taken from salt marsh sediments 1km from Fishbourne Roman Palace, on the western bank of the Fishbourne Channel. The sediments are composed mainly of fine silts and clays containing some macro plant remains. A radiocarbon date from a piece of wood recovered from the core from 160 cm depth returned an age of 200 – 400 AD, with the base of the core therefore likely capturing the very start of the Roman invasion of Britain.

Pollen and charcoal records from these salt marsh sediments will be presented and used to reconstruct landscape scale changes associated with the Roman construction, occupation and abandonment of Fishbourne Roman Palace. By developing our understanding of the past of the British landscape, current debates around the conservation of heritage sites, including topics such as rewilding, can be informed by this long-term perspective.

Peruvian wetlands as archives for pre-Hispanic responses to late-Holocene climate and environmental change

Dr. Josephine Handley **[1]*****, Prof. Nicholas Branch*** **[2]*****, Mr. Daniel Teeling*** **[3]*****, Dr. Alexander Herrera*** **[4]*****, Dr. Carlos Farfan*** **[5]*****, Prof. Jose Iriarte*** **[6]**

1. *Geography, Faculty of Environment, Science and Economy, University of Exeter, UK,* ***2.*** *School of Archaeology, Geography & Environmental Science, University of Reading, Whiteknights, Reading, RG6 6AH, UK,* ***3.*** *University of Reading,* ***4.*** *Universidad de los Andes,* ***5.*** *Universidad Nacional Federico Villareal,* ***6.*** *University of Exeter*

Wetlands located within the key agricultural belt of the Peruvian Andes (3000-4000m a.s.l), provide valuable records for socio-economic responses to climate and environmental change during the Late Holocene. Both previous studies and our recent research has illustrated that pre-Hispanic societies were able to cope with periods of major climatic variability, such as during the Medieval Climate Anomaly (MCA) and the Little Ice Age (LIA), by adapting water storage and transportation networks (reservoirs, canals, water catchment features and wet pastures) and agricultural practices (construction of terraces, multi-cropping, burning, and agroforestry). Communities responded to variation in natural resources, such as water availability, by modifying wetlands and constructing reservoirs. Wetlands would have acted as a buffer for ongoing climate change, providing a source of water for irrigated agriculture. The palaeoenvironmental records therefore indicate an apparent stability with continuous land-use throughout prehistory. Some of these wetlands also show evidence for human modification and adaptation of natural basins in order to increase water storage capacity and capitalise on periods of increased precipitation (e.g., LIA). This, in turn, would have provided greater water security for growing populations during periods such as the Late Horizon, when the Inca empire was expanding across large parts of Peru. We have provided an improved understanding of these human-wetland interactions in the Peruvian Andes using high-resolution analysis from a transect of sites across different environmental zones. We will present the results from a new multi-proxy study using radiocarbon-dated sediment geochemistry, pollen and non-pollen palynomorphs, alongside phytoliths and archaeological evidence from agricultural terraces. These records have demonstrated the potential of using mid-high-altitude wetlands for the detection of both longer-scale regional climate variability (MCA and LIA) and short-term climatic fluctuations (El Nino). Understanding how pre-Hispanic societies interacted with wet environments in the past is important for future land-use, water, and soil conservation practices. The future preservation of these wetlands is also highly important for both climate change regulation and for conserving a valuable archive of human-environment interactions.

Wet and Dry: a comparative approach to environmental evidence from the broch of Tirefuir and the nearby loch of Balnagowan.

1. *University of Cambridge,* ***2.*** *University of Southampton,* ***3.*** *Trinity College Dublin,* ***4.*** *Royal Holloway, University of London,* ***5.*** *University of Cardiff,* ***6.*** *Royal Holloway, London,* ***7.*** *Cabinet office, London,* ***8.*** *Simon Fraser University,* ***9.*** *Nottingham Trent University,* ***10.*** *Department of Archaeology, University of York,* ***11.*** *Department of Geography, Royal Holloway University of London, London, United Kingdom,* ***12.*** *Independent Researcher,* ***13.*** *Southampton University,* ***14.*** *Queen's University Belfast*

This-presentation-will-compare-the *dry* evidence-from-the-stratigraphy-of-Tirefuir broch midden-and-the-*wet* evidence-from-the-pollen-profile-of-the-loch-of-Balnagowan, a-mere 500 m from-the-archaeological-site, from-the-island of-Lismore, located-close-to-Oban-in the-west-of-Scotland. Recent research has calibrated a time series from both these locations, and the-paper-will-focus-on-the-period-400 BC-to-600 AD to-interpret-the complementary-evidence-from-the-two-sequences-towards an understanding of human interaction with the local environment, in-all-its-dimensions. The-island-has-a-distinctive limestone-geology-complicated-by-igneous-and-basaltic-intrusions-which-are-detectable in-the-isotopic-base lines, drawn-from-soil and-plants. The island-is-accessible-at-the-northern-end-across-a-strait of less than 1 km (with some intermediate islands), with relative ease at an appropriate time of the tide.

The-Balnagowan-pollen-sequence-covers-the-late-Glacial-and-much-of-the-full-Holocene, but-for-the-sake-of-this-comparison-we-concentrate-in-this-paper-on-the-part-of-the-later Holocene-contemporary-with-the-main-occupation-of-the-broch. For-this-purpose, radiocarbon-dates-have-been-applied to refine this period. The main arboreal decline on the island appears to have taken place at about 3900 BP (1950 BC). By the time of the occupation of the broch in about 400 BC (2350 BP), there appears to have been an open landscape with a light birch, alder, hazel coverage alongside a substantial presence of heather and grasses. The appearance of cereal pollen (barley) appears to coincide broadly with the arboreal decline and is identified through the phase of occupation at the broch. New evidence of fungal spores from the same palynological horizons have enhanced the environmental picture with evidence of grassland indicators covering the past 3600 years and two of these key dung fungal spores, *Sordaria* and *Sporomiella*, typically indicate the presence of grazers and are associated with domestication in archaeological contexts.

The midden of the broch of Tirefuir has provided a good complementary understanding of the consumption and patterning of resources from the local island landscape and its near continent, by combining evidence from plant macrofossils, charcoal and animals. The principal domesticates (sheep, cattle and pig) have been studied not only in terms of their relative proportions and age/sex profile at death, but also by isotope analysis (carbon, nitrogen and strontium). aDNA studies of the sheep and cattle will also provide complementary evidence of their place in the broader genetic mapping of the British Isles. Alder, birch, hazel, ash, Scot's pine, cherry type, oak and willow were present amongst recovered charcoals. Oats and Barley were prominent amongst the cereals. Cattle were the dominant domestic species followed by sheep and pigs. Some evidence of site formation processes is provided by micromorphology.

The-presentation-will-bring-together-these-complementary-data-from-wet-and-dry-sources-to-produce-the-best-case-comprehensive-model-of-human-interaction-with-the-environment-for-this-small-island-community-of-Argyll-during-the-Iron-Age.

Session 139: Holocene Global Landuse

The "first farming" in ALCC modelling – the challenges posed by terminology in past land use and land cover modelling

***Prof. Jennifer Bates* [1], *Prof. Marco Madella* [2], *Dr. Austin "Chad" Hill* [3], *Prof. Nicki Whitehouse* [4], *Prof. Kathleen Morrison* [3]**

***1.** Department of Archaeology and Art History, Seoul National University, Seoul, **2.** CaSEs – Department of Humanities, Universitat Pompeu Fabra, Spain; School of Geography, Archaeology and Environmental Studies, The University of the Witwatersrand, South Africa, **3.** Department of Anthropology, University of Pennsylvania, **4.** Department of Archaeology, University of Glasgow, UK*

Our ability to accurately reconstruct past environments is critical for understanding many aspects of the earth system. Information on past land use is currently provided by anthropogenic land-cover change (ALCC) scenarios. ALCC scenarios provide data essential for earth system modeling of the past, present, and future. The relationship between the first and last part of this is critical – how does past data inform future modelling? Historical and archaeological scholars are key to the development of better ALCC scenarios and earth system models. Throughout the Holocene, the development of new lifeways including agriculture, pastoralism, arboriculture, urbanism, extractive industries and all the nuances within these, created new ways in which the landscape could be, and was, impacted and changed. These developed alongside and in addition to the myriad ways that the many hunter-gatherer-fisher-forager lifeways and land use could and were changing environments. Understanding how and, particularly for earth systems models, when new land uses came about and the impact they had on land cover is essential. While ALCC scenarios have been widely applied in earth system modeling studies, they are subject to major limitations, including differences in proxy scale, a lack of incorporation of past surplus or capital accumulation, and most importantly, significant differences between ALCC scenarios with regard to starting assumptions. As a case study, the deep archaeological "origins of agriculture" debate bring with them temporal and regional variability in terminology and 'markers' for identifying this 'horizon' in the human past. The blurred nature of the boundaries between hunter-gatherer-fisher-foragers, early cultivators and early agriculturalists seen in archaeological discussions has yet to be fully translated to ALCC scenarios, and has resulted in a diversity of approached and boundaries forming. In this paper the nuances of the terminologies used in three ALCC modeling approaches are explored and how the concepts of 'agriculture' and the 'first agriculture' are being approached. The implications of defining and pining down these messy processes are considered, and how this much debated topic can be integrated into the clean ALCC and earth systems models desired is explored. The result is both ontological and epistemological issues for modelling down-the-line.

Pollen-based reconstruction of land cover change in northern China during the Holocene

Mr. Yuanhao Sun [1]

1. College of Earth and Environmental Sciences, Lanzhou University

Fossil pollen data are essential for reconstructing ancient vegetation and land-cover changes. Here, we propose a novel methodological strategy to reconstruct the regional land-cover and actual plant cover from pollen assemblages using MAT-estimated actual vegetation cover to correct the REVEALS-estimated cover of individual plant taxa. Subsequently, we reconstructed the land cover change in northern China during the Holocene using the above strategy. At the regional scale, the vegetation composition of the past 6,000 years and the spatial dynamics of main land cover types (*Pinus*, coniferous trees, deciduous trees, grassland, and bare ground) in 6ka, 3ka, and 0ka were obtained. The results show that the land cover changes may have been spatially migrated due to the influence of climate in the past 6000 years. Meanwhile, the reduction in vegetation cover, especially forest cover, may have been significantly influenced by human activities. At the local scale, we reconstructed the land cover changes in the Daihai basin and the alpine Gonghai area during the Holocene, which reveal diverse vegetation succession patterns in different regions and geomorphologic contexts. We propose that changes in the intensity of human activities was a major cause of the observed regional disparities in vegetation succession. In larger basin/plain areas, the favorable climatic conditions of the mid-Holocene promoted increased human activity; while later, population pressure, the increased demand for resources, and political factors may have triggered the diffusion of human populations from basins to the mountains or previously undeveloped areas, with resulting effects on their vegetation succession.

Was there a pre-modern forest transition in the eastern Mediterranean?

Prof. Neil Roberts [1], *Dr. Jessie Woodbridge* [1], *Prof. Ralph Fyfe* [1]

1. University of Plymouth

The ‘forest transition theory’ describes the historical turnaround in land use from net forest loss (i.e., deforestation) to net forest gain (Mather *Area*, 1992). It has been linked to scarcity of woodland resources at the time of the forest minimum (e.g., timber and charcoal), and a subsequent shift to fossil fuels for energy supply. The timing of the forest transition has been region-specific, for example, taking place during the early 19th century in northern Europe linked to the Industrial Revolution. In this region it followed a multi-millennial trend towards net forest loss that is clearly recorded in pollen records (Roberts *et al.*, *Sci Rep.* 2018). A similar long-term decline in forest cover is evident in pollen data from the west and central Mediterranean (Woodbridge *et al.*, *J Biogeog*. 2018; Fyfe *et al.*, *VHA* 2018). However, synthesised pollen data show a different trend in parts of the eastern Mediterranean during the Late Holocene (Roberts *et al.*, *Holocene*, 2019). In south-central Anatolia and the southern Levant, for example, arboreal pollen (AP%) reached a minimum during Classical times, and a net increase in woodland cover is inferred for the last ~1300 years. Consequently, we can ask the question of whether the forest transition here occurred in pre-modern times, unrelated to a stage model of economic development. Instead, woodland recovery was triggered by agricultural land abandonment in Late Antiquity, which led to landscape “rewilding” and reforestation. This model does not take account of tree crops, such as olive groves, which peaked during the Beyşehir Occupation land-use phase (>2300-1300 Cal BP), nor does it reveal shifts in species composition of secondary woodland towards taxa such as pine and evergreen oak and away from deciduous trees along with conifers, such as cedar and fir. In reality, the decline and recovery of eastern Mediterranean forests during the last two millennia represents one of several cycles of deforestation and afforestation that have taken place in this region since Neolithic times.

12k-6k in the Korean Peninsula, a big data synthesis of land use and climate change across the Holocene

Mr. Matthew Conte [1], ***Prof. Jennifer Bates*** [1], ***Mr. Yongje Oh*** [1], ***Dr. Austin "Chad" Hill*** [2], ***Prof. Marco Madella*** [3], ***Prof. Nicki Whitehouse*** [4], ***Prof. Kathleen Morrison*** [2], ***Mx. Korean Working Group LC6k*** [1]

1. *Department of Archaeology and Art History, Seoul National University, Seoul,* ***2.*** *Department of Anthropology, University of Pennsylvania,* ***3.*** *CaSEs – Department of Humanities, Universitat Pompeu Fabra, Spain; School of Geography, Archaeology and Environmental Studies, The University of the Witwatersrand, South Africa,* ***4.*** *Department of Archaeology, University of Glasgow, UK*

Human societies have managed and modified Earth's landscapes for thousands of years, altering global patterns of biodiversity, ecosystem functioning, and climate. Anthropogenic modifications and land use accelerated with the emergence of agriculture. This pace of change will only accelerate further with the land changes to come under the 4th Industrial Era. The extent, trajectory, and implications of these changes are still not fully understood, and the implications of our long-term history for future climate change predictions need more research. The trajectories of change are needed to accurately model our impacts now and going forwards, and historical and archaeological scholars are key to the development of these Anthropogenic Land Cover Change (ALCC) scenarios and earth system models. Such important classification and documentation of past land cover and importantly land use practices has been done in many regions, but in the Korean Peninsula systematic data synthesis remains to be done in a comprehensive way that links human land use to changing land cover. Through the methods of the Land Cover 6k project, the Korean Working Group has been approaching land use change over the Holocene, mapping and modelling changes with a view to providing data for ALCC scenario building. In this paper we outline the mapping from the first stages of this project focusing on 12k and 6k. These timeslices show the early Holocene warming period and the arrival of domesticates into the Korean Peninsula. The impact of changing food availability and lifeways is mapped relative to settlement patterns and land uses, comparing traditional datasets (settlement distributions and excavation data) with C_{14} distributions. In particular the issue of data availability and accessibility is discussed in a region fraught with the impacts of modern geopolitics.

Early to Mid-Holocene Land Use Transitions in South Asia: a New Archaeological Synthesis of Potential Human Impacts

Dr. Austin "Chad" Hill [1], ***Prof. Jennifer Bates*** [2], ***Prof. Marco Madella*** [3], ***Prof. Nicki Whitehouse*** [4], ***Prof. Kathleen Morrison*** [1], ***Mx. South Asia Working Group LC6k*** [1]

1. *Department of Anthropology, University of Pennsylvania,* ***2.*** *Department of Archaeology and Art History, Seoul National University, Seoul,* ***3.*** *CaSEs – Department of Humanities, Universitat Pompeu Fabra, Spain; School of Geography, Archaeology and Environmental Studies, The University of the Witwatersrand, South Africa,* ***4.*** *Department of Archaeology, University of Glasgow, UK*

While it is clear that current human impact on the earth system is unprecedented in scope and scale, much less is known about the long-term histories of human land use and their effects on vegetation, carbon cycling, and other factors relevant to climate change. Current debates over the possible importance of human activities prior to the last few hundred years cannot be effectively resolved without evidence-based reconstructions of past land use and its consequences. The goal of the PAGES LandCover 6K working group is to reconstructing human land use and land cover over the past 12,000 years. In this paper, we present the first large-scale synthesis of archaeological evidence for human land use in South Asia at 12 and 6kya, a critical period for the transition to agriculture, arguably one of the land use transitions most consequential in terms of human impact on the Earth system. Perhaps the most important narrative we can pick out is that while there are some shifts in land use across these timeslices, hunter-gatherer-fisher-foragering remained the dominant land use, and within this there was a mosaic of strategies exploiting diverse and complex landscapes and ecologies. This is not necessarily a new conclusion – it is not new to state that South Asia is comprised of many niches, but demonstrating the deep time history of how people have adapted to these and adapted them is an important step for modelling the impacts of people and thinking about their footprints in a longue-duree perspective. Despite the new development of food production by 6kya, by overall area, foraging life ways continued as the dominant land use practice into the 6kya time slice. This is not to say that the development of agriculture and food production was not unimportant – it is the beginning of a land use that eventually comes to dominate the sub-continent, but at 6kya is restricted to specific contents. Across 12kya to 6kya and different land uses the use of mosaic ecologies, diverse strategies and the importance of water as a resource stand out as shared themes.

Human-Environment Dynamics Through the Holocene in the Mourne Region, Northern Ireland

Ms. Helen Essell [1], ***Dr. Gill Plunkett*** [1], ***Dr. Kirstin Lemon*** [2]

1. *Archaeology & Palaeoecology, School of Natural and Built Environment, Queen's University Belfast,* ***2.*** *Geological Survey of Northern Ireland*

Uplands are widely perceived as marginal within the landscape. This is not solely due to their geographical isolation; upland environments are highly susceptible to the negative effects associated with periods of climatic deterioration. A rich archaeological record, however, attests to human presence in uplands through the Holocene, though little is understood about the chronology and nature of activities, critically raising questions of whether, and if so to what extent human agencies shaped upland landscapes. Here, we examine human-environment interactions in the context of the Mourne Mountains, Northern Ireland. Existing palaeoenvironmental research shows that a wooded landscape existed in the Mourne uplands in prehistoric times. This starkly differs to the heath-covered slopes present today, but the natural and/or human agencies which shaped this landscape remain uncertain. Through palynological analysis of blanket peat deposits from across the region, this study seeks to disentangle the environmental and human past of the Mourne uplands during the Holocene. Deep peat sequences illustrate the long-term vegetational and climatic history of the region. Palaeoenvironmental records collected from the vicinity of archaeological and historical sites in the Mourne uplands and adjacent lowlands provide insights on the environmental footprint of past occupation and land-use. This multi-scalar study enables the nature and periodicity of human activity to be contextualised against the long-term evolution of the Mournes landscape and address questions of how past populations interacted with their environment and fared under climatic stresses. This work considers the resilience and adaptability of 'marginal', upland communities to climatic and in turn environmental change, providing lessons for present and future populations who face pressures similar to those of societies in the past.

Vegetation responses to exploitation of mountainous areas in the Iron Age and Middle Ages

Prof. Kari Loe Hjelle [1], *Ms. Kathrine Stene* [2]

1. Department of Natural History, University Museum of Bergen, University of Bergen, 2. Museum of Cultural History, University of Oslo

People have always used mountains, but their impact on vegetation was probably minor until transhumance practices came into use, in Norway especially from the Iron Age (the last ca. 2000 years). The utilization and occupation in the Iron Age and the Middle Ages underwent several changes due to climatic conditions, demographic patterns, social and economic changes. The material from mountain regions, especially the activity up to the Viking Age, has mainly been interpreted as seasonal occupation, linked to the nearby low-lying agrarian societies by the fjords and main valleys. The establishment of farms and population growth in the first part of the Early Iron Age resulted in limited areas for cultivated fields, pastures, and fodder collection on and around the farms, influencing the use of the mountain areas. The increasing utilization of mountainous landscapes is also emphasized as important elements in the development of political centers in the (Late) Roman Iron Age. From around AD 300 roman imports appear more frequently in some lowland areas. The cluster of the objects are often interpreted as economic and political centers that took part in long-distance exchange networks, were the products from the mountains, in particular iron and reindeer antlers, were central. All ironmaking in prehistoric and medieval Norway is based on bog ore. In South Norway most places where iron was extracted were in the lower parts of mountainous areas, which were wooded. Archaeological data, mainly house remains and iron production sites, and palynological data, including LRA-estimated vegetation cover and samples from archaeological contexts, from the Flåmsfjella in western Norway, are presented. Utilization of mountain resources, tree cover changes and habitations/settlements in a long-time perspective, are discussed, with emphasis on the Iron Age and the Middle Ages. We specific address questions of when animal husbandry/grazing and iron extraction/making are established in the landscape – does this happen gradually or abruptly and is it possible to identify periods of more intensive use by combining our datasets.

Session 140: Quantifying climate change in Australasia: challenges and opportunities

Two glacial cycles of terrestrial paleoclimates from maar craters in northern New Zealand

Dr. Paul Augustinus [1], **Dr. Leonie Peti** [2], **Dr. Benjamin Läuchli** [3], **Dr. Timothy Shanahan** [4]

1. University of Auckland, 2. School of Environment, The University of Auckland, 3. School of Environment, University of Auckland, 4. The University of Texas at Austin

Continuous and high-resolution records of terrestrial paleoclimate spanning at least the Last Glacial Cycle (LGC) are scarce in the Southern Hemisphere mid-latitudes. Contained in the deep maar lakes of the Auckland Volcanic Field (AVF), Auckland, New Zealand, we have suitable records of deep lake sedimentation that span back to at least 193 ka that provide the continuous and laminated sediment records required for the identification of abrupt climate events in addition to the millennial-scale climate cycles. We have developed robust age models for the Pupuke (ca. 0 to 50 ka), Orakei (ca. 15.6 to 132 ka) and Onepoto (ca. 9 to 193 ka) maar lake sediment sequences with chronologies underpinned by AMS ^{14}C, luminescence dating, tephrochronology, magnetic paleointensity times-series and meteoric ^{10}Be influx. In addition, the multi-method refinement of the dating of these maar lake sediment records, in tandem with the repeated occurrence of well-dated marker tephra layers from multiple volcanic centers in most AVF maar lake sequences, allowed the refinement of the age models for the less well-dated maar lake sediment cores. These well-dated AVF maar lake sequences provide the fundamental frameworks for high-resolution multi-proxy paleoclimate analyses from northern New Zealand that span the LGC. The approach includes: micro-XRF scanning with elemental variability-inferred lake water column stability and sediment influx events; thin-section micro-facies characterization of depositional units, and the nature of rapid microfacies changes at facies boundaries; organic matter TOC, δ^{13}C, TN and δ^{15}N, pollen-inferred Mean Annual Temperatures; and biomarker-inferred past temperature and precipitation variability. The main aim of the project is the identification and search for climate teleconnections regionally, between the southern polar region and the Southern Hemisphere subtropics, as well as to search for inter-hemispheric climate linkages. Our finely laminated and well-dated AVF maar lake sequences retain the properties required to identify not only of past climate events and their timing, but also their drivers so that they constitute valuable records of LGC paleoclimate from the southwest Pacific region.

30-years of paleoenvironmental variation in the northern Great Barrier Reef reconstructed from Little Ice Age giant clam shell geochemistry

Mr. Bohao Dong [1]***, Dr. Amy Prendergast*** [2]***, Prof. Sean Ulm*** [3]***, Dr. Kotaro Shirai*** [4]***, Prof. Russell Drysdale*** [5]***, Prof. Ian J. McNiven*** [6]***, Dr. Vladimir Levchenko*** [7]***, Mr. Henri Wong*** [7]

1. *School of Geography, Earth and Atmospheric Science, University of Melbourne, Victoria, Australia,* ***2.*** *School of Geography, Earth and Atmospheric Sciences, University of Melbourne, Victoria, Australia,* ***3.*** *ARC Center of Excellence for Australian Biodiversity and Heritage, College of Arts, Society and Education, James Cook University, Cairns, Queensland, Australia,* ***4.*** *The University of Tokyo,* ***5.*** *University of Melbourne,* ***6.*** *ARC Center of Excellence for Australian Biodiversity and Heritage, Monash Indigenous Studies Center, Monash University, Clayton, Victoria, Australia,* ***7.*** *Australian Nuclear Science and Technology Organisation, Lucas Heights, Australia*

The Little Ice Age (LIA) was a cold climatic interval from around 1300 to around 1850 CE. Most palaeoenvironmental reconstructions of the LIA come from high-latitude, Northern Hemisphere continental archives, including ice cores, tree rings, and lake deposits. There is a significant gap in our understanding of the effects of the LIA in the Southern Hemisphere marine environment. This study begins to fill this research gap by providing LIA-aged high-resolution marine proxy archive from the northern Great Barrier Reef.

Giant clams (*Tridacnidae* spp.) have a widespread distribution in the subtropical-tropical Pacific region. Compared with other archives, giant clams have advantages including high growth rate, clear increment bands and long lifespans, enabling long continuous reconstructions. The clear annual and daily shell increments can provide monthly, and even ultra-high resolution (daily), palaeoenvironmental reconstructions. By analysing the geochemical composition of giant clam shells, we can faithfully reconstruct palaeoclimate records, including SST, SSS, DIC, daily light cycles, rainfall, marine primary productivity and extreme weather events.

In this research, we have used multiple traditional and novel techniques, including microscopy, XRF, EPMA, AMS ^{14}C dating, IRMS, ICP-AES and LA-ICP-MS to analyse LIA giant clam shell growth patterns and geochemical compositions (δ^{18}O, Sr/Ca, Mg/Ca, Ba/Ca) to reconstruct seawater parameters and environmental changes in the northern Great Barrier Reef (GBR), Australia. Our initial results show that the shell records a 28- to 30-year palaeoenvironmental snapshot. The reconstructed LIA temperature range is □2 □ lower than modern instrumental records from the northern GBR and □0.6 □ lower than the average temperature between 1000 CE ~ 2000 CE. The Sr/Ca ratio results provide information about whether the solar output was lower during the LIA, whilst Ba/Ca ratios provide indications of rainfall or extreme weather events in this area during the 30-year snapshot. This project provides much needed ultra-high-resolution LIA palaeoenvironmental reconstructions from the Great Barrier Reef, enabling us to better assess the potential drivers of the LIA and its impacts on the Southern Hemisphere.

Kimberley monsoon rainforests - new Holocene palaeoenvironmental records from northwest Australia

Dr. Rachel Rudd [1]***, Ms. Charmaine Howie*** [2]***, Ms. Teresa Dixon*** [2]***, Prof. Patrick Moss*** [3]***, Prof. Hamish McGowan*** [2]

1. Max Planck Institute of Geoanthropology, Jena, Germany / The University of Queensland, Brisbane, Australia, 2. The University of Queensland, 3. University of Queensland

The Kimberley in northwest Australia is a region of archaeological significance, with a long history of human habitation accompanied by a long and diverse sequence of rock art. Understanding the climatic history of this region through the late Quaternary provides important environmental context to the archaeological history and insight into the spatial and temporal variability of the Indonesian-Australian summer monsoon, yet developing palaeoenvironmental records from this region is challenged by the ephemeral nature of lakes and wetlands. Speleothems and mound springs have been used as palaeoenvironmental archives in the Kimberley, but further records are needed to discern spatial variability and to strengthen palaeoclimate modelling of the Australasian region.

Monsoon rainforests in the Kimberley are small, discrete patches of diverse vegetation embedded in a eucalypt savanna landscape. These ecological communities are significant for their species richness, their role as a refuge and food source for fauna, and as a cultural resource for Aboriginal people. Rainforest taxa have persisted in the Kimberley through arid periods in the past, as evidenced by the presence of rainforest taxa in the macrobotanical record from Carpenter's Gap for over 47,000 years. However, little is known about how the extent of these rainforests, and their consequent availability as a resource, has varied through time. The sediments accumulating at rainforest patches provide an opportunity to study not only variability in the rainforests themselves, but also the surrounding savanna environment.

Here, we present records of environmental variability from the sediments of three monsoon rainforest sites. Variability in the abundance of rainforest taxa and changes in fire activity through time, inferred from pollen and charcoal preserved in the sediment, indicate changes in rainforest extent associated with regional environmental conditions. These records, in conjunction with previous speleothem and mound spring palaeoclimate records, elucidate monsoon variability, and provide insight into the environment experienced by inhabitants of the region through the Holocene.

The age and climatic significance of block deposits in southeast Australia

Prof. Timothy Barrows [1], ***Dr. Stephanie Mills*** [2], ***Prof. Keith Fifield*** [3]

1. University of Portsmouth, 2. School of Earth, Atmospheric and Life Sciences, The University of Wollongong, Wollongong, NSW 2522, Australia, 3. The Australian National University

Pleistocene glaciation was restricted in Australia to only the highest parts of the Snowy Mountains and Tasmania. However, periglacial activity was much more widespread. Periglacial landforms can be found down to 600-700 m in the Southern Tablelands and lower than this further to the south. Block deposits in the form of blockstreams and block slopes become common at higher elevations. Because of their association with freezing, block deposits hold considerable potential to quantify past climate change, but their dating and interpretation has been controversial. In this talk we will present new findings from a dating and mapping campaign of both high and low elevation block deposits in southeast Australia. The lowest altitude periglacial deposits have been identified on Black Mountain in Canberra and on the Southern Tablelands. The deposits constitute scree slopes, and associated alluvial fans and valley. Their age of formation was restricted to the coldest parts of the last glacial cycle. In Victoria, large-scale deposits occur above 900 m in the Mt Hotham region. The morphology of these deposits and their surface architecture supports their formation involving large-scale frost heave. 3D modelling supports the idea that pits in the surface are ice-melt collapse features. We present new exposure ages for blocks in these deposits using the cosmogenic nuclides ^{36}Cl and ^{10}Be. The re-establishment of forest at the end of the Pleistocene in the area is dated using radiocarbon. The deposits formed during the last glacial cycle and were not restricted to the last glacial maximum. Based on modern analogues, we estimate that mean temperatures were at least 8 °C colder than at present when the deposits formed.

Disentangling drivers of environmental change in Alpine Australia: A multi-proxy approach to understanding climate- and anthropogenic-driven change in the Holocene

Dr. Lydia Mackenzie [1]***, Prof. James Shulmeister*** [2]***, Prof. Douglas Clark*** [3]

1. School of Earth Sciences, Zhejiang University, 2. University of Canterbury, 3. Department of Geology, Western Washington University

Disentangling the effects of climate change and anthropogenic activities on the environment is a significant challenge in palaeoenvironmental research. Alpine ecosystems are particularly sensitive to environmental change and are therefore ideal places to study long-term human-environment interactions. This study reconstructs landscape evolution in the alpine region of south-eastern Australia since the late Holocene by analysing pollen and spores, charcoal data, µXRF results, and physical proxies from Lake Cootaptamba (2048 m elevation). Charcoal data from 13 alpine sites show that local and regional fire activity peaked between 8000-5 ka cal BP. Data from Lake Cootaptamba and three pollen records from nearby sites above 1000 m show that both rainforest and wet sclerophyll vegetation types increased across the alpine region at this time.

These results suggest that an increase in precipitation in the mid-Holocene allowed vegetation communities to expand. The increase in regional precipitation and biomass led to increased fire activity. By 5 ka cal BP the climate regime in south-eastern Australia was influenced by increasing El Niño Southern Oscillation events, with variable precipitation leading to regional vegetation changes and a fire regime limited by biomass availability in the alpine zone. Paleolimnological results from alpine zones are compared to radiocarbon data from the Australian Archaeological Database to identify human presence during the Holocene. This study shows that over the last 2 ka cal BP increased erosion, vegetation community composition and changing fire regimes correspond with increased human occupation of the alpine zone. This multiproxy and multisite approach demonstrates how palaeoenvironmental studies from sensitive ecosystems can identify human traces and disentangle natural and anthropogenic drivers of change during the Holocene.

Reconsidering Holocene hydroclimate in eastern Australia

Ms. Asika Dharmarathna [1], Mr. John Tibby [1], Dr. Haidee Cadd [2], Dr. Jonathan Tyler [1], Dr. Cameron Barr [1], Dr. Jonathan Marshall [3]

1. University of Adelaide, 2. ARC Centre of Excellence for Biodiversity and Heritage, School of Earth, Atmospheric and Life Sciences, University of Wollongong, 3. Queensland Department of Environment and Science

Temperature reconstructions from the Southern Hemisphere mid latitudes indicate moderate Holocene variability. By contrast, Holocene hydroclimate reconstructions from the Australian mid latitudes, while limited in number, exhibit substantial centennial to millennial variation. Hence, understanding the nature and causes of this variability is important.

It has been argued that early to mid-Holocene climates on the coastal margin of eastern Australia were markedly wetter than present, but progressively dried over the last 5000 years. This drying has been invoked to explain changes in human population behaviour and density; increases in fire activity; and mammal extinctions on the Australian mainland. A variety of drivers is suggested for late Holocene drying. Of these, the El Niño –Southern Oscillation (ENSO) is the most prominent. In particular, strengthening of ENSO (notably the El Niño phase) has been used to explain climate drying from ~10 to 45°S.

Here, we present new data that prompt a refinement of these interpretations. A compilation of radiocarbon dates from perched lake sediments on K'gari (Fraser Island), in the subtropics of east-coast Australia, indicates a period of sedimentation hiatus interpreted as aridity from approximately 7,400 to 5,000 a. This, in many ways, directly contradicts the hypothesis that weaker ENSO resulted in climates wetter than today for this period.

An additional hydroclimate record from Lake Surprise, in the temperate volcanic plains of western Victoria, indicates a more variable early to mid-Holocene regional hydroclimate than previously inferred. This record, derived from diatoms, scanning XRF data and oxygen isotopes from aquatic cellulose, shows that the early to mid-Holocene (11,800 - 4,500 a) experienced substantial centennial-scale variability characterised by both the wettest Holocene climates, but notably some of the driest.

The study seeks to explain the differences between these localities (and existing work) by discussing the role of the southern westerly winds and the south-east trades

An 800,000-year record of terrestrial temperature in the Indo-Pacific Warm Pool

Ms. Meredith Parish [1], ***Prof. James Russell*** [1], ***Prof. Hendrik Vogel*** [2], ***Prof. Satria Bijaksana*** [3], ***Mr. Alexander Wilk*** [1]

1. *Department of Earth, Environmental, and Planetary Sciences, Brown University,* ***2.*** *Institute of Geological Sciences & Oeschger Centre for Climate Change Research, University of Bern, Bern, Switzerland,* ***3.*** *Faculty of Mining and Petroleum Engineering, Institut Teknologi Bandung*

The Indo-Pacific Warm Pool (IPWP), with its high sea surface temperatures and deep atmospheric convection, plays an important role energizing Earth's atmospheric circulation. Proxy records and climate model simulations indicate cooler and drier conditions in the IPWP at the Last Glacial Maximum (LGM) compared to modern. Climate model simulations point to greenhouse gas forcing as the dominant control on temperature in the IPWP during the last deglaciation. However, alternative forcings, including insolation, have been proposed to control temperature in the IPWP, and we do not have any quantitative terrestrial paleotemperature records from the IPWP that extend beyond the LGM. We produced an 800,000-year terrestrial temperature record from a continuous sediment record from Lake Towuti, located in the center of the IPWP on Sulawesi, Indonesia. The temperature reconstruction is based on the relative abundances of temperature-sensitive lipids that compose the membrane of bacteria (branched glycerol dialkyl glycerol tetraethers; brGDGTs). The Lake Towuti terrestrial temperature reconstruction covaries with global benthic d^{18}O rather than local insolation, pointing to greenhouse gas concentrations, ice sheets (albedo and/or topography), or sea level as the dominant control of IPWP terrestrial temperature. The covariation IPWP terrestrial temperature with global benthic d^{18}O during the past 800,000 years, highlights the importance of understanding the impact of both remote and local forcings on IPWP climate. Inferences from the climate model simulations, which identified greenhouse gas concentrations as the dominant forcing of temperature in the IPWP during the last deglaciation, can potentially be extrapolated to earlier in the Quaternary period. A dominant control of greenhouse gas concentrations on terrestrial temperature would raise concerns about how climate in the IPWP will continue respond to anthropogenic greenhouse gas emissions in coming decades.

Session 141: How can the Quaternary sciences contribute to scientific assessment of biodiversity, ecosystems, and nature?

Use-inspired paleo-perspectives are critical for saving the planet and building strong 21st century scientific careers.

Dr. Jonathan Overpeck [1]

1. University of Michigan

The planet and its biosphere are under unprecedented threat from human activity, most notably via climate change plus unsustainable land and water-use. Few drivers of deleterious global change are slowing, and many are worsening at an accelerating rate. Strangely, many scientists – the ones who understand the threats and implications the most - are choosing to do little to ensure a more just and sustainable future for the planet. Quaternary scientists have the expertise to understand how the Earth system works and how society might avoid a future of large climate change, biodiversity crisis, and much more. Quaternary scientists also often have the knowledge needed to help build more resilient human systems and adapt to environmental change that cannot be avoided. More needs to be done to ensure that the paleoenvironmental perspective is tapped by society to build a just and sustainable future.

There are many ways Quaternary scholars can do more to serve society. Engaging with society to communicate and discuss the implications of science for society is critical. Expanding our research and education efforts to be more use-inspired and usable by society is critical. Ensuring all students getting a university education understand what's at stake and what can be done, no matter what careers they choose to pursue, is critical. The sheer number of Quaternary scientists in the world highlights the impact we all could have if we all work together to be a 21st century forces for change – we won't save the planet with scholarly publications and citations alone.

Over the last 20 years, paleo-perspectives have become integral to climate assessments, both IPCC and national. Now is the time for more scientists with understanding of Earth system behavior over the Quaternary to step up and ensure that biodiversity and ecosystem assessments are also strongly informed by paleoenvironmental science. The work is time-consuming, but it is also uniquely powerful in building strong international 21st century academic careers. Learning to communicate with society's decisionmakers is essential to having real impact and to saving the planet for future generations.

Quaternary extinction and colonization dynamics alter long-term functional trait diversity in Caribbean reptiles

Dr. Melissa Kemp [1]

1. *The University of Texas at Austin*

Reptiles have experienced significant biodiversity decline throughout the Quaternary, with extinction and extirpation events linked to anthropogenic impacts. At the same time, introductions of novel reptiles into ecosystems have rapidly increased. These extinction and colonization dynamics influence functional diversity (the suite of functional traits present within an ecosystem) and the prevalence of ecosystem services that humans depend upon such as pest control, pollination, and seed dispersal. The extent to which reptile functional diversity–and by extension, ecosystem services–have changed over the Quaternary remains poorly understood. Here, I quantify function diversity change in Caribbean reptiles, a species-rich insular fauna. Traits such as body size, diet, and habitat affinity are used to partition species into functional entities (FEs): groups of species with similar traits that are expected to provide similar ecosystem services. Archaeological and paleontological data are used to reconstruct ecological communities through time for seventeen islands, with an emphasis on ancient, native extant, and modern (native extant plus introduced) faunal assemblages. I find that several key FEs are lost due to extinction. Extinction caused the most significant losses of functional diversity on small islands, which lost up to 67% of their native FEs. On the other hand, functional redundancy on large islands served as a buffer to major functional diversity loss in the past. Species introductions not only increase functional diversity, but they shift the functional space of reptile assemblages, meaning that introduced species exhibit novel functional trait combinations not found in extinct or native taxa. These shifts in functional diversity leave many native FEs and the communities that they support vulnerable to additional biodiversity loss. I also identify places that have retained a significant amount of native functional diversity, indicating that the anthropogenic history of an island contributes to present-day conservation prospects. This research provides critical data on long-term functional diversity change in a taxonomic group whose contributions to ecosystem function are understudied and often undervalued, and provides a path forward for conservation management.

Ecosystem Resilience In The Face Of A Changing World: Preliminary Results from Jonkershoek

Ms. Glory Oden [1]***, Prof. Lindsey Gillson*** [1]***, Prof. M. Timm Hoffman*** [1]

[1]. *Plant Conservation Unit, University of Cape Town, South Africa.*

Global projections surrounding ecosystem vulnerability and biodiversity loss have heightened in recent decades due to climate change and land use. Mediterranean Type Ecosystems (MTEs) are projected to be highly vulnerable to global change due to changes in plant available moisture, changing fire regimes, and introduced species. Jonkershoek Nature Reserve, an MTE in Western Cape South Africa has undergone environmental monitoring since the early 20th century, but is bereft of insights on millennial-scale vegetation change, climate, fire, and herbivory, which have significantly shaped the landscape. Long-term data spanning the period before anthropogenic climate change and intensive land use are needed to assess these impacts and inform management and restoration.

A 104 cm wetland core, from a Fynbos-Forest Ecotone was analyzed to reconstruct the vegetation, herbivory, and fire history. Over the past 5000 years, forest taxa did not show a significant increase, providing support for the idea that fynbos is resilient to forest encroachment. This may be attributed to fire-vegetation feedback, which excludes fire-sensitive forest taxa from fynbos areas. The high rainfall at this site may further buffer fynbos resilience.

Results show that prior to 345 BP, grasses and dry-adapted species had dominated the fynbos vegetation, with minimal fires and less grazing. The high rainfall at this site may buffer fynbos resilience. Post-colonial anthropogenic influence since the 17th century is noticeable because of the introduction of alien species and increased herbivory. Such processes may have affected the landscape at community level, resulting in a corresponding change in the fire regime. Extreme fire events are evident in the core from 220 BP. A decline in Poaceae pollen is concurrent with an increase in Restionaceae and Ericaceae pollen types.

Long-term monitoring of landscapes at millennial scale offers an in-depth understanding and interpretation of contemporary changes for setting sounder restoration and management objectives. Despite biome scale vegetation resilience, strong anthropogenic influence and change in fire regimes in recent centuries is an aberration in terms of the longer history at the site and can be attributed to increased fuel load due to fire suppression. Preserving the ecosystem while revising the burn policy is suggested.

Relevant conservation metrics linking past and future biodiversity change

Prof. David Nogues-Bravo [1]

1. *Center for Macroecology, evolution and Climate. University of Copenhagen*

Knowledge on past biodiversity change is essential to anticipate and manage the responses of species and ecosystems to ongoing global change. However, we face the challenge to develop harmonized indicators that can capture over time relevant dynamics for integrating them in widely used conservation metrics, including IUCN Red List, Living Planet Index or the Essential Biodiversity Variables. Here I will discuss the prospects and challenges to develop such metrics linking Quaternary and Anthropocene temporal realms. I will present several examples for visualizing how the integration of paleo-records and contemporary data provides novel venues for bringing Quaternary disciplines into the conservation arena with a special emphasis on metrics relevant for genetic diversity, species abundance and functional diversity.

One more way for Palaeoecology to contribute to conservation biology; discovering the endangered hidden species, the case of the liverwort Riella (Riellaceae)

Dr. Morteza Djamali [1], ***Dr. José Gabriel Segarra-Moragues*** [2]

1. *Institut Méditerranéen de Biodiversité et d'Ecologie, Aix-en-Provence, France,* ***2.*** *Universitat de València, València, Spain*

Palaeoecology can contribute to conservation biology mainly through helping (i) to understand biological invasions, (ii) to reconstruct biodiversity and dynamic equilibrium between extinction, migration, and persistence, and (iii) to detect and delimit the glacial and interglacial refugia as conservation targets. The ecological and palaeoecological literature is becoming increasingly rich in examples illustrating one of the above cases. In this study we present another potential of palaeoecology serving to conservation biology which is underestimated by both conservationists and palaeoecologists. The basic idea is that in some biogeographical territories in which the biodiversity is not still poorly documented, (e.g. biodiversity hotspots), high-quality palaeoecological records can reveal the presence of 'hidden taxa' which have not been recorded in modern fauna and flora. We present the specific case of the liverwort genus of *Riella*(Riellaceae) in the lake and wetland environments of the semi-arid regions of Southwest Asia. Members of this family are commonly present in Quaternary palaeoecological records but almost absent in modern flora of the region. In the face of the ongoing anthropogenic climate change, several hidden species of this genus are seriously endangered and have to be urgently protected within their natural habitats. Our palaeoecological findings can contribute to pinpointing the most promising sites for botanical exploration and for conservation of the last living species of the genus in the drylands of Southwest Asia.

Changes in plant diversity and vegetation structure based on REVEALS reconstructed vegetation of Europe during the Holocene

Land use and land-cover change are the greatest drivers in biodiversity loss and thereby loss of ecosystem functions. [M1] To improve the understanding of current processes in diversity and its impact on ecosystem functions and global environmental changes, knowledge of past interactions between diversity, vegetation structure and land use is needed. We use here the 3rd generation of REVEALS vegetation estimates (Serge et al. (unpub.) at European-wide scale based on large pollen dataset (1606 sites) to explore the vegetation structure and diversity change during the Holocene. Space-time constrained clustering of the REVEALS estimates of Serge et al. (unpub.) revealed 6 dominant vegetation types: (1) Mediterranean vegetation, (2) open (anthropogenic)[lm2] vegetation, (3) *Abies-Fagus* forest, (4) broadleaved mixed forest, (5) needle-leaved mixed forest, (6) cold pioneer vegetation. Changes in location, size, floristic composition and diversity within the vegetation types characterized 4 phased during the Holocene. α-Diversity as the floristic richness, richness of abundant species, and evenness was explored, as well as β-diversity defined as the variation between grid cells of the same vegetation type. Additionally, temporal turnover within vegetation type was explored. Generally, open vegetation types (VT1 and VT2) showed higher β diversity and lower evenness than forests. The first phase was a pioneer phase until 9500 calBP with cold pioneer vegetation and the second phase was widely distributed broadleaved mixed forest until 5500 calBP. Both phases have low human impact resulting in relatively low β-diversity but high evenness. Afterward, extensive land use started in the third phase resulting in a change towards open anthropogenic vegetation, *Abies-Fagus* forest and mixed needle-leaved forest. From 1700 calBP on, land use intensified, marked by the expansion of open (anthropogenic) vegetation and increasing abundance of *Cerealia* and anthropogenic indicators. Evenness dropped, as well as β-diversity. The forest vegetation types change their composition towards open anthropogenic vegetation. In general, vegetation composition harmonizes, evenness drops extremely, and open anthropogenic vegetation dominates throughout Europe in most recent time windows.

The paleogeographic vision. Unveiling the ghost of time to assess ecosystems and develop conservation and restoration actions.

The current anthropogenic Global Change has pushed Earth into an environmental emergency. Increasing our knowledge of how the Earth's biodiversity responds is an urgent and challenging task. Integrating paleoecology into ecological research will increase our understanding of long-time ecological processes relevant to biodiversity and conservation. In this regard, islands are an open lab to exemplify what driving forces have shaped island communities and their biodiversity. Here we have studied terrestrial and aquatic biota of lake sedimentary records from the Azores archipelago. We show how the human colonisation of the archipelago overtakes the impact of natural variability (climate and volcanoes) on local and regional biodiversity. However, site-specific features (geography, lake and catchment morphometry) result in different responses, including ecosystem resilience and recovery after environmental fluctuations and perturbations. We discuss the main problems and possible solutions (e.g., machine learning approach) for using paleoecological records to assess biodiversity. We also recognise the difficulty of applying widespread conservation and restoration policies due to site idiosyncrasies. For instance, the existence of ecological tipping points could compromise the effectiveness of conservation and restoration policies by incurring disproportionate costs or damaging the current socioeconomic system.

Contribution of the Quaternary sciences to find the balance between action and laissez-faire in Ecology

Quaternary Sciences can provide empirical data prefigurating realistic future ecosystem changes. This is particularly helpful for managers looking at finding a suitable balance between implementing restoration actions and "laissez-faire", in the light of the climatic projections.

Here we present a case study of Historical Ecology applied to a Mediterranean wetland (Bagliettu peatbog, Corsica Island): 1) to reconstruct 3900 years of insect and plant ecological successions and changing habitats, 2) to identify respective and cumulative roles of past disturbances (i.e. geomorphic evolution, climate changes, land use) in the shaping of ecological communities, and 3) to discuss conservation status in the light of the long-term dynamics. This type of peat-bog within the Mediterranean bioclimate is very rare and thus deserves protection. Our findings reveal that this peat-bog has thrived several millennia of evolution with relative resilience to centennial-scale aridity events. However, reduced wetland connection due to a multimillennial-long trend of river incision play a major role in the recent degradation of wetland, unlikely reversible at our human scale. With the added effects of anthropogenic disturbance, which has been identified as increasing in the fossil record, the disappearance of the ecosystem might occur independently of changes in the precipitation regime even if reclamation actions are initiated.

Another peat-bog located in the same river valley (Valdu), is probably a more valuable target for conservation. Indeed, a closer position to the aquifer makes this wetland comparable to a young stage of the geomorphic evolution of Bagliettu, and thus more suitable to achieve goals of long-term conservation.

Predicting extinction risk from future climate change with the paleorecord

Dr. Damien Fordham [1]

1. *University of Adelaide*

Accurately predicting biodiversity loss from climate change requires a detailed understanding of the ecological characteristics that make some species more susceptible to declines and extinction. However, the ecological attributes that increase extinction risk from climate change are poorly resolved. This is because ecological responses to climate change are complex and hard to quantify correlatively. I will show how biological data from the late Quaternary can be combined with simulation models to disentangle complex interactions between ecological traits, climate and other threats. I will then show how this is enabling species responses to climate change to be contextualised and integrated into future biodiversity projections and policy. By providing a more complete understanding of the ecological mechanisms that regulate species' responses to climate change, the paleorecord can help identify and conserve the species that are most vulnerable to future climate change.

Quaternary marine palaeoecology, molecular biology and geochemistry; challenging the shifting baseline syndrome

Prof. James Scourse [1], ***Prof. Kristine Bohmann*** [2], ***Dr. Paul Butler*** [1], ***Prof. Oliver Craig*** [3], ***Prof. Callum Roberts*** [4], ***Prof. Bernd Schöne*** [5]

1. *Centre for Geography and Environmental Science, University of Exeter,* ***2.*** *Globe Institute, University of Copenhagen, Denmark,* ***3.*** *Department of Archaeology, University of York,* ***4.*** *University of Exeter,* ***5.*** *Johannes Gutenberg University Mainz, Institute for Geosciences, Mainz, Germany*

The palaeoecological and geochemical interpretation of Quaternary marine sequences has hitherto been dominated by the requirement for physical environmental proxies for palaeoclimatic and sea level reconstructions. Yet these sequences, and other marine biotic archives, such as coral, coralline algae, molluscan shell, fish and marine mammal bone, also contain a wealth of information on past biodiversity and ecosystem functioning. Marine sedimentary sequences are usually investigated for selected groups e.g. diatoms, and/or groups that represent significant geochemical carriers e.g. foraminifera, and only very rarely is the totality of the preserved fossil assemblage analysed. When well-dated these data can provide insights into the richness of past ecosystems, the role of keystone species, and provide ecological baselines that challenge the “shifting baseline” syndrome. Even these more comprehensive analyses, however, can only capture a fraction of former marine ecosystems because of taphonomic loss. Novel approaches to marine ecosystem reconstruction, including sedimentary environmental DNA (eDNA) and compound specific stable isotope geochemistry, are now able to provide insights into the total biodiversity of former marine ecosystems, and ecosystem functioning, respectively. Combined with classical palaeoecological approaches, these techniques together provide powerful integrative tools for the reconstruction of marine ecological baselines. Such reconstructions provide evidence-based targets for marine conservation biology and an informed basis for the rewilding of the oceans.

Linking paleoecology, archaeology and history; an innovating approach to investigate how human activities have modified the natural forest trajectories in the Southern French Prealps

Ms. Emma Gamba [1]***, Ms. Delphine Isoardi*** [2]***, Ms. Alexia Lattard*** [2]***, Ms. Florence Mocci*** [2]***, Mr. Robin Veyron*** [3]***, Ms. Brigitte Talon*** [1]

1. *Institut Méditerranéen de Biodiversité et d'Ecologie, Aix-en-Provence, France,* ***2.*** *Centre Camille-Jullian, CNRS, Aix-Marseille Université, Maison Méditerranéenne des Sciences de l'Homme,* ***3.*** *Aix-Marseille Université*

Reconstructing the forest trajectories in Quaternary time-scale and disentangling the impact of human activities from natural forcings on those trajectories is essential for conservation and effective management of the forest heritage. The knowledge of the recent ecological history of forests provides a means of apprehending their functioning and designing conservation and restoration strategies for their future, facing the ongoing global change. A detailed reconstruction of forest dynamics can be achieved by cross-correlating historical and archaeological data with palynological, archaeo- and pedo-anthracological data. The first difficulty is to find chronological matches between the information provided by different archives treated in different disciplines. Another difficulty is the substantial quantitative and qualitative disparity of the available sources. Nevertheless, we hypothesize that i) cross-referencing of these different sources with complementary spatio-temporal resolutions, can improve our understanding of the history of mountain socio-ecosystems and ii) that pedo-anthracology can make a significant contribution. In this study, we show the interest of comparing and contrasting these different natural and historical archives. To test our hypothesis, we take as 'system model', three mountain forest ecosystems in the southern French Pre-Alps (Lauzet-sur-Ubaye, Prads-Haute-Bléone and Thorame-Basse) and apply a systematic pedoanthracological investigation along several altitudinal transects. For the first site, both historical and palaeoecological data were available, for the second site, only historical data were accessible and for the third site, historical and archaeological data were both available. The first results and radiocarbon dates obtained confirm the interest and potential of interdisciplinarity in the reconstruction of past forest dynamics. This has made possible to highlight the significant role of agro-sylvo-pastoral practices in modulating the spatial distribution of the forest for Le Lauzet-Ubaye and Prads-Haute-Bléone. Furthermore, for the latter sites, the forest composition would not have been deeply affected by pastoral activities. This is yet to be determined for the Thorame-Basse site, which has been the subject of numerous reforestation campaigns in the last centuries, with the introduction of non-native species. Our results will help to better consider the human disturbance on forest functioning, when designing conservation and management strategies and have applications in species distribution modelling (SDM).

Reconstructed lake food webs reveal ecosystem-level responses to late Holocene climate and human-induced changes across the Azores Archipelago

The UN Decade on Ecosystem Restoration aims to prevent, halt, and reverse the degradation of aquatic ecosystems across the planet. Addressing this challenge requires a comprehensive understanding of how ecosystems have changed over time to better support decisions on identifying, prioritizing, and optimizing restoration actions. Lake ecosystems are well-known "sentinels of change", providing valuable insight[AHH1] s into past and ongoing environmental changes. Multiproxy palaeolimnological reconstructions allow identifying long-term changes during the Late Holocene in the condition of lakes and correlate changing conditions to environmental and climate drivers over a range of temporal scales. Palaeoecological data is increasingly used to set baselines of changes in biodiversity, although such baselines are often limited to population or community-level changes in aquatic ecosystems. Food-webs represent energy flows between species or groups of species and provides a framework for understanding species' roles within ecosystems and the mechanisms through which biodiversity influences ecosystem function. Recent developments in food-web ecology have revealed that functional traits (i.e., ecologically meaningful features of species measurable at individual level) are effective predictors of trophic interactions and can be used to approximate the overall structure of aquatic food-webs. This study uses lake sediments to reconstruct past environments and aquatic trophic structures (i.e., paleo food-webs) across five different lakes in the Azores archipelago (North Atlantic Ocean). Recent investigations of Azorean sediment records have shown substantial reorganizations in community composition (or regime shifts) over the last millennia because of archipelago-level climatic changes, catchment-level vegetation changes and lake-level fish introductions. Ecosystem regime shifts in Azorean lakes vary in speed and magnitude as a function of the environmental and anthropogenic drivers leading to a redistribution of species richness and abundance across trophic levels. Incorporating ecosystem-level baselines in global change research provides a novel perspective supporting future conservation and restoration actions.

What can we learn from changes in pollen type diversity?

The ongoing biodiversity crises calls for a better understanding of past changes in floristic diversity, with a need for baselines beyond monitoring periods. Pollen analysis is probably the best suited technique available to provide such information, while it comes with several challenges. Pollen grains can rarely be identified to plant species or even genus level, but still pollen type richness in samples increases following a latitudinal gradient from the boreal forest zone to the Mediterranean. Across such large regions changes in pollen type diversity correspond to changes in plant richness suggesting that pollen type richness may be a good indicator of past changes in plant richness. Postglacial pollen diagrams from western Europe document strong shifts in pollen type richness over the postglacial, however, these patterns strongly correlate with the proportion of arboreal pollen in the samples. Surely, open vegetation types contain more plant species compared to dense temperate forests, but temperate trees also produce much more pollen than most herbaceous plants in western Europe. Therefore, it remains uncertain how to interpret these changes. Few modern and simulation studies have recently investigated the relationship between plant diversity and pollen type diversity. Based on these insights we explore past trends in pollen type richness in connection to climate induced shifts in forest cover and manmade de- and afforestation. A focus will be on pollen data from Switzerland and the high-resolution analysis from Eversener See in Northern Germany. We will explore if the onset of the current biodiversity crises and decline in floristic diversity is documented in existing diagrams.

It’s time to widen our gaze: how a simplified world view blinds our attempts to understand the past, present and future

Prof. Michael Fletcher [1]

1. *University of Melbourne*

Contemporary landscapes are the product of past processes. A failure to recognise or understand these past processes limits our capacity to manage environments sustainably. While Quaternary science has a long history of attempting to understand how people have modified the planet, our science and hypothesis generation are often framed through a dehumanising lens. This is particularly the case in the global south and other more recently European colonised landscapes in which Indigenous and local peoples have lived in and managed for millennia. In these places, the baseline assumption is that landscapes are the product of natural (i.e. non-human) processes. Within this paradigm, attempts to assert human agency in accounting for landscape change in long occupied landscapes using the palaeo-record suffer a disproportionate and inappropriate burden of proof. This burden requires either unequivocal evidence of human agency or the elimination of other potential processes, leaving humans as the most parsimonious explanation. The former is near impossible in palaeo-science, while the latter is most often achieved by identifying trends that are anomalous to what would be expected “naturally”. This framing denies the fact that people have and continue to leverage natural processes in their engagements with the world.

In this talk, I will unpack how dehumanising long-occupied landscapes robs us of the ability to truly understand the past and how this results in inappropriate management solutions to our environmental challenges. I argue that engaging with people who view the word differently, such as Indigenous and local peoples, can result in more appropriate epistemological frameworks that allow a more successful approximation of the past, leading to better outcomes for management approaches. It is my contention that this is one of the greatest contributions that Quaternary sciences can make to the future.

Integrating extant and Quaternary biodiversity assessment through shared priority metrics: palynological data as an archive of phylogenetic diversity

Dr. Phillip Jardine [1]

1. Westfälische Wilhelms-Universität Münster, Institut für Geologie und Paläontologie, Münster, Germany

Quantifying past biodiversity change and understanding its drivers are key contributions that palaeoecologists can make to inform environmental and conservation policy. Integration of neo- and palaeo-ecological datasets requires the use of shared metrics, however, meaning that we need to focus our attention on those variables being used to assess and manage biodiversity in modern systems, such as Essential Biodiversity Variables (EBVs). While taxonomic diversity – the number of species and their relative abundances in an assemblage – is included in the EBVs and is readily calculated from palaeoecological datasets, there is an increasing awareness that this metric only captures a portion of the information needed to understand biodiversity change and make informed conservation decisions. Phylogenetic diversity (PD) incorporates information on the amount of evolutionary history contained in an assemblage of taxa, and can therefore provide a more detailed assessment of biodiversity gains and losses through time and space, and their underlying causes and consequences. To date, however, PD has been underexplored by palaeoecologists, and it is not currently known how well variations in vegetation PD across broad spatial scales are captured by palynological assemblage data. Here, I compare estimates of PD from North American surface palynological samples and vegetation plots, and show that palynological data represent the overall variations in vegetation PD well. This suggests that historic variations in PD, and their relationship to climatic, environmental, and human land use changes, should be recoverable from (sub)fossil palynological archives. Utilising ecologically-relevant metrics such as EBVs should be a priority to increase the relevance of palaeoecological research for assessing current and future biodiversity change.

Session 142:
Palaeoecology and restoration ecology

The value of long-term history of small and fragmented old-growth forests for restoration ecology

1. *ISEM, Univ Montpellier, CNRS, IRD, EPHE, Montpellier, France,* ***2.*** *Department of Agricultural, Forest and Food Sciences, University of Torino, Grugliasco, Italy,* ***3.*** *Biotechnical Faculty, University of Montenegro, Podgorica,* ***4.*** *Department of Land, Environment, Agriculture and Forestry, University of Padova, Legnaro*

Primary and old-growth forests are of great value for sustainable forest management and restoration as they offer templates to develop close-to-nature forest management practices aimed at emulating natural processes and features in second-growth forests. In Europe, primary and old-growth forests are very rare, generally small, fragmented, and less abundant (< 3% of the total forest area) than on other continents. Current fragments are arguably remnants of formerly larger extents of primary and old-growth forests, which have been increasingly embedded in humanized mosaic landscapes and are still often threatened along fragment edges by land-use activities (e.g. logging) and anthropogenic disturbances (e.g. fire ignitions). However, the legacy effects arising from complex interactions between natural and human disturbances that eventually led to their fragmentation are often weakly constrained.

Here, we used stand-scale paleoecology, an assessment of contemporary forest structure, and dendrochronological data from the edge of the Biogradska Gora old-growth forest (Dinaric Alps, Montenegro), one of the largest in Europe, to provide new insights into the long-term dynamics of these fragmented ecosystems.

The records support the notion that historical land-use pressure (cereal crop cultivation, cattle herding, fires) reduced the extent of old-growth forests. Conversely, land abandonment in the mid-14th century (approximately at the time of the Black Death pandemic) as well as the formal protection since the late 19th century prevented intensive land use, and has strongly reduced biomass burned in recent times. These land-use changes allowed for the expansion and persistence of forest stands in the buffer zone, which may offer suitable habitat for the expansion of disturbance-sensitive old-growth stands. Thus, in addition to unfolding the historical legacies that led to the fragmentation of primary and old-growth forests, our study also shows that the protection of buffer zones is of importance to promote native forests.

Past, present and future perspectives of European megafauna and their ecological impacts

Mr. Marco Davoli [1], Prof. Jens-Christian Svenning [1]
1. Aarhus University

Severe, size-biased defaunation has degraded European megafauna assemblage after the arrival of *Homo sapiens* during the late Pleistocene and the encroachment of human modern society in ecosystems thereafter. Thus, there is a call for ambitious megafauna-community restoration policies to rewire pivotal dynamics of ecosystems resilience and of biodiversity structuring. However, managing human-megafauna coexistence in the hybrid wild-anthropic cultural landscapes of Europe is non-trivial, notably with such landscapes rapidly transforming under the global environmental changes of the XXI Century. We used fossil records and ecological traits to estimate, mainly via habitat modelling, European megafauna biogeography at a time prior the arrival of *Homo sapiens* in Europe, the Last Interglacial (cc. 127,000 years ago). We described how megafauna extinctions and consequent environmental degradation affect present ecosystems viability compared to such 'natural baseline'. We explored how megafauna assemblages were degraded by humans throughout history, notably comparing the role of overhunting vs. habitat fragmentation. Furthermore, we estimated future megafauna distribution and population densities under scenarios of climate and land-use changes, in combination with different rewilding strategies, to find best trade-offs between the need to restore ecological dynamics and the risk for human livelihoods. European megafauna community biomass has dropped by 93.8% from the Last Interglacial to the present. Functional diversity has dropped by 90.8% for herbivores and 83.3% for carnivores. Vegetation consumption has dropped by 88.3% and meat consumption by 68.5%. As a result, the structure of present ecosystems strongly deviates from the evolutionary norm, notably due to decreased functional heterogeneity. While during the Pleistocene megafauna extinctions were mainly driven by overhunting, the spreading of farmlands in Europe from the Neolithic culture have added an equal threat to megafauna viability in the form of habitat fragmentation, which effects skyrocketed during the last 1000 years. Restoring megafauna-mediated ecological processes in line with the ecosystems' evolutionary norm is possible via reintroductions and by letting megafauna expand their current distribution, but at the cost of a very high potential for conflict. Alternative rewilding implementations, such as controlling population densities via culling, may be more pragmatically approaches in the light of human-megafauna coexistence potential in the Anthropocene.

A multi-proxy reconstruction of Holocene vegetation and treeline dynamics in Central Switzerland

Ms. Ursula Huonder [1], ***Mx. Laura Dziomber*** [1], ***Dr. Erika Gobet*** [1], ***Prof. Willy Tinner*** [1], ***Dr. Christoph Schwörer*** [1]

1. Institute of Plant Sciences & Oeschger Centre for Climate Change Research, University of Bern

Anthropogenic climate change increasingly affects life on Earth. Human societies are impacted by rising temperatures, droughts, fires and floods, which also affect plants, creating new ecosystem challenges. In the Alps, the future temperature rise is projected to be almost twice as high as on the global average, which will lead to severe changes in alpine ecosystems and associated services. Palaeoecological archives such as alpine lake sediments can be used to reconstruct past vegetation dynamics. The rapid temperature increase of 2-4 °C at the onset of the Holocene is a possible analogue to current climate warming, thus understanding past responses of alpine vegetation to temperature increases may provide new insights in future vegetation trajectories.
We are currently investigating sediment samples from Golzerensee, a mountain lake situated in Central Switzerland on the northern alpine boundary. The lake lies at an elevation of 1.411 m a.s.l., in the transitional zone between the montane and subalpine vegetation belts. Here, we present a multiproxy reconstruction of local to regional vegetation dynamics during the Late Glacial and Holocene at Golzerensee, based on pollen, macrofossil and charcoal analyses. Emphasis is placed on vegetation responses to climatic changes such as the Younger Dryas cold period or the rapid warming at the beginning of the Holocene, as well as the effects of human land use on vegetation. Specifically, we are interested in the timing of local forest establishment and the drivers of mountain forest compositional change under rapidly warming climate. The ultimate goal of this study is to assess the response of mountain vegetation in the Swiss Alps to future global change and identify palaeo-based restoration strategies that will help maintaining Alpine biodiversity and ecosystem services. For instance forests growing under warmer-than-today summer conditions during the Holocene Thermal Maximum ca. 10.000-5.000 years ago may provide useful guidelines to support future forest diversity and provisioning services.

Climatic and anthropogenic impacts on Holocene vegetation dynamics in Eastern Switzerland.

Mx. Laura Dziomber [1], ***Dr. Maria Leunda*** [2], ***Ms. Lisa Gurtner*** [3], ***Dr. Erika Gobet*** [1], ***Prof. Willy Tinner*** [1], ***Dr. Christoph Schwörer*** [1]

1. Institute of Plant Sciences & Oeschger Centre for Climate Change Research, University of Bern, 2. Institute of Plant Sciences & Oeschger Centre for Climate Change Research, University of Bern & Swiss Federal Institute for Forest, Snow and Landscape Research, 3. Institute of Plant Sciences, University of Bern

Mountain vegetation is particularly affected by climate change. Despite the growth of monitoring programs assessing the impacts of current global change on alpine ecosystems, there is still an insufficient use of long-term studies in conservation biology to understand ecosystem responses on long timescales. Paleoecology has made important contributions to the reconstruction of vegetation responses to past environmental and societal changes based on multiproxy studies including biotic proxies such as pollen and plant macrofossils preserved in lake sediments.

The last climate change of a similar magnitude and rate as projected for this century occurred during the transition between the last Ice Age and the Holocene interglacial (ca. 11,700 years ago), when temperatures rapidly increased by 2-4 °C within less than a century. Additionally, mountain vegetation in the Alps has been affected by millennia of human land use. Understanding the response of vegetation to rapid temperature increase and human impact is a fundamental prerequisite to produce accurate and reliable predictions of future mountain vegetation and mitigate climate change impacts.

We present our multiproxy study of a sedimentary record from Lai da Vons (1991 m a.s.l.), an alpine lake situated at the treeline ecotone in Eastern Switzerland. Our results based on geochemical analysis (XRF), pollen, charcoal, and high-resolution macrofossil analyses, reveal that the first trees already established locally 13,500 years ago, in response to rising temperatures. Closed forests dominated by conifers like *Pinus cembra*and *Larix decidua* expanded after the Early Holocene warming. From 9,500 years cal. BP onwards, when summer temperatures were warmer than today and moisture availability comparable, *Picea abies* and *Abies alba* spread. During the past 6,500 years, increasing human impact as indicated by several cultural indicators led to a progressive opening of the landscape and a diversification of local species composition in the open lands, but impoverished monospecific forests. This development was interrupted during the past ca. 70 years by spontaneous afforestation in response to land use changes related to globalization. We conclude that restoring the original diverse forests in combination with low-intensity pastoralism will be key to preserve future plant species diversity and mitigate adverse climate change effects.

Holocene REVEALS pollen-based land-cover reconstructions in Europe - exploring dynamics in diversity and resilience over time

Ms. Maria Antonia Serge [1]***, Ms. Caterina Röhm*** [1]***, Prof. Ralph Fyfe*** [2]***, Dr. Didier Galop*** [1]***, Dr. Tierry Klein*** [3]***, Dr. Agnes Lagnoux*** [4]***, Dr. Laurent Marquer*** [5]***, Dr. Florence Mazier*** [1]

Land use and land-cover changes are ranked as the greatest driver of declines in nature and biodiversity. Thereby it is crucial to enhance our understanding of natural landscape interactions and anthropogenic-induced changes to evaluate the effects of future climate and land-use changes on European ecosystems, landscapes and biodiversity.

As part of the Terranova project (H2020-msca-itn-2018), we present here the "third generation" of pollen-based estimates of plant cover in Europe using the REVEALS (Regional Estimates of Vegetation Abundance from Large Sites) model at a spatial resolution of 1°x1° (ca. 100 km x 100 km) for consecutive time windows over the last 11.7 ka cal BP. This new reconstruction improves the spatial cover of the last generations of REVEALS reconstructions with a large number of additional pollen records in particular from the Mediterranean area. We discuss methodological issues using alternative datasets of relative pollen productivities (RPPs), one of the key input parameters. After validation with the modern vegetation dataset, the RPP-means dataset 1 (31 taxa) was found to be the most suitable for Europe.

This new dataset provides unique possibilities to explore spatial-temporal changes in past land-cover and biodiversity over long time periods. The aims are (i) to recognize vegetation types during the Holocene and its movements and shifts from the last glacial maximum to the present time (ii) to derive past diversity indices (α and β-diversities) within each of the biogeographic regions and (iii) to identify the species contributing to the groups and the β-diversity.

According to the identification of six vegetation types during the Holocene (Röhm et al., in prep), REVEALS estimates are explored. The aim is to identify resilient stable states and transitions in Europe and to which environmental variables they are mainly related. We bring to light the effect of homogenization of vegetation in the properties of ecosystems, like the loss of ability to absorb environmental changes, that negatively affect resilience in recent times.

Old flames: the relationship between cultural burning and fire histories on Gunaikurnai Country, Australia

Ms. Harriet Magee [1]***, Dr. Simon Connor*** [2]***, Dr. Shira Maezumi*** [3]***, Dr. Michela Mariani*** [4]***, Prof. Michael Fletcher*** [5]***, Gunaikurnai Land and Waters Aboriginal Corporation*** [6]

1. *School of Geography, Earth and Atmospheric Sciences, University of Melbourne, Melbourne,* ***2.*** *School of Culture, History and Language, College of Asia and the Pacific, Fellows Rd., The Australian National University, Acton,* ***3.*** *Department of Archaeology, Max Planck Institute for the Science of Human History,* ***4.*** *University of Nottingham,* ***5.*** *University of Melbourne,* ***6.*** *Gunaikurnai Land and Waters Aboriginal Corporation*

The *Black Summer* 2019–20 fires burned nearly half of the forest estate across Gunaikurnai Country (East Gippsland), Victoria, Australia. How these catastrophic fires were caused — by climate change and/or land management — has been the subject of political and academic debates. These debates have emphasised the reinstitution of Australian Aboriginal cultural burning to help mitigate such catastrophic bushfires. Australian Aboriginals and Torres Strait Islanders have used cultural burning for millennia (amongst other purposes) to reduce fuel levels and the risk of high-intensity bushfires, akin to *Black Summer* fires. While the call to reinstate cultural burning is based on reservoirs of traditional knowledge and practice, there is limited empirical data on pre-British Invasion vegetation and fire dynamics. This data gap represents a barrier between this fire approach becoming policy and practice in a managed landscape. Changes in pre- to post-Invasion vegetation (i.e., fuel) and fire in Eucalypt-forest in the Point Hicks area, East Gippsland, Australia are investigated using palaeoecology and dendrochronology of fire-sensitive trees. I will analyse the fossil charcoal and pollen in the sediments of two proximal wetlands which are critically located in the *Black Summer* bushfire zone. Radiometric dating, geochemistry, and Fourier Transformed Infrared (FTIR) Spectroscopy will be used to anchor changes in time, understand erosion shifts and catchment dynamics, and infer fire temperatures from charcoal, respectively. To enhance the fire history reconstruction, I will use dendrochronology to investigate the influence of past fires on fire-sensitive pines (*Callitris rhomboidea*) stand dynamics. Here, I will present key findings from this Masters research to highlight the use of palaeoecology in ecosystems management.

Ecosystem response to climate change and human impact in South Carpathian alpine lakes: can we define restoration targets?

Mountain lakes in the South Carpathians have undergone rapid ecological changes due to intensive mountain grazing, warming and consequent trophic level increase over the last century. In this study multi-proxy analyses of short sediment cores from the Retezat, Pareng and Fagaras Mountains were used to determine preindustrial reference conditions and reconstruct the rate of ecosystems change in response to stressors.

By the high-resolution (2 cm) study of 4 alpine lake gravity cores covering the last 250 years, our aim was to identify early warning signals of critical transitions and define regional safe and just operating space (RSJOS).

Multi-proxy analyses included Pb210/Cs137 dating, chironomid, diatom, pollen, cladocera, SPDU (chlorophyll-derivatives), LOI, TOC, TN, C/N ratio and geochemical analyses are in progress on Lake Latoritei (1530 m), Lake Belea (2034 m), Lake Ana (1940 m) and Lake Peleaga (2122 m).

The results of the ecological regulation analysis showed that deep, high-mountain lakes were transformed and entered the cautious status between ~1926-1950. Before the turnover date, the reference state was characterised by higher abundance of Micropsectra insignilobus-type and Heterotrissocladius marcidus-type in their chironomid fauna. All three deep lakes were characterised by a move from an equal share of collector-gatherer and collector-filterer feeding guilds towards collector-filterer dominance.

Turnover for several ecosystem components was detected in the lower lying, shallow Lake Latoritei around 1850. The preindustrial reference state was characterised by high abundance of Tanytarsus mendax-type. In this lake the transition of feeding guilds reflected the shallowing and submerged aquatic expansion via the prevailing dominance of shredders and collector-gatherers.

Multivariate data analyses from Belea and Latoritei furthermore suggest that changes in the chironomid fauna can be best explained by the ongoing increase in the summer mean temperatures, which was the dominant driver, followed by human disturbance. We expect a similar trend in the case of Lake Peleaga and Lake Ana.

The common feature of the four pollen records was the late 18th century (1780-1795) deforestation in the sub-alpine spruce forest zone, followed by intensified forest cover loss between AD 1950 and 1980.

Keywords: RSJOS analysis, chironomids, human impact, climate change, mountain lakes

Landscape history in the Central highlands of Madagascar: its implications for the conservation and management of the open and mosaic ecosystems

Dr. Andriantsilavo H.I. Razafimanantsoa [1]***, Prof. Lindsey Gillson*** [2]***, Prof. William Bond*** [3]

1. *Plant Conservation Unit, University of Cape Town, South Africa.,* ***2.*** *Plant Conservation Unit, University of Cape Town South Africa.,* ***3.*** *Department of Biological Sciences, University of Cape Town, South Africa*

Open and mosaic ecosystems are often classified as degraded or secondary forests, particularly in the tropic where climatic conditions are favorable for forest development. This assumption is associated with the current high deforestation rate and other human-made activities observed in this region promoting reforestation projects. This is the case in the Central Highlands of Madagascar, which is narratively thought to be forested but currently dominated by open grassland ecosystem. However, the origin and nature of the landscape and its drivers of change are not clear and scientific debates are still ongoing either the region's grassland is natural or anthropogenic driven. Distinguishing ancient from derived open ecosystems has important management and conservation implications. Here, we aim to understand the environmental history in the Central Highlands of Madagascar before and after human settlement (ca. 2 cal. ka BP) to provide guidance for the landscape restoration and management. We used pollen, stable carbon isotopes, charcoal, and dung fungal spores from a core retrieved in Lake Dangovavy covering the mid-Holocene. Results revealed that at least since ca. 6.3 cal. ka BP, vegetation surrounding the lake has been dominated by a mosaic of open grasslands and ericoid scrubland compressing forest patches of variable elevation. Before human settlement (6.3–2 cal. ka BP), the mosaic landscape was more resilient despite low to moderate variation of fire and herbivory activities recorded in the area. After human settlement, vegetation remained stable between 2 and 1.1 cal. ka BP associated with low fire and herbivory activities. However, it shifted to a more open grassland dominated during the last 1100 years associated with high fire frequency and herbivory activities. Massive declines in ericoid shrubland and forest patches were recorded in the area, and it was associated with increasing human impact and probably aridification in the region. These results indicate the natural presence of open and mosaic ecosystems in the Central Highlands, which predate human settlement and are worthy of conservation. These inform restoration focus on taxa linked to forest patches while managing fire regimes to a moderate level for maintaining ancient open ecosystems.

Applications of palaeoecology to ecosystem restoration and management in the Mediterranean region

Dr. César Morales [1]

1. Institute of Plant Sciences & Oeschger Centre for Climate Change Research, University of Bern & Departamento de Ciencias de la Vida, Universidad de Alcalá

In the past few years, increasing attention has been paid to the application of palaeoecological records to guide ecosystem conservation, restoration, and management. In this communication, I will summarise several recent case studies from southern Europe drawing on the applied use of palaeoecological data to different ecological questions. Specifically, I will focus on the protection and restoration of mires and relict temperate tree species threatened by increasing densities of wild herbivores, on the natural range of variability of fire disturbance affecting pinewoods and the consequences of altering such fire regime, and on assessing the composition and structure of the 'natural' vegetation. The results highlight the potential of palaeoecological investigations on the relatively recent past to guide present and future conservation and restoration efforts in areas with a long and intense history of land use like the Mediterranean region.

Mapping the Moor: Palaeoenvironmental reconstructions to inform conservation management at Hatfield Moors, South Yorkshire, UK

Dr. Michelle Farrell [1], ***Prof. Henry Chapman*** [2], ***Dr. M. Jane Bunting*** [3], ***Prof. Nicki Whitehouse*** [4], ***Dr. Benjamin Gearey*** [5], ***Dr. Kimberley Davies*** [6], ***Dr. Philip Barratt*** [7]

1. *Coventry University,* **2.** *University of Birmingham,* **3.** *School of Environmental Sciences, University of Hull,* **4.** *Department of Archaeology, University of Glasgow, UK,* **5.** *University College Cork,* **6.** *Institute of Modelling Socio-Environmental Transitions (IMSET), Bournemouth University, Poole, Dorset, BH12 5BB, UK,* **7.** *University of Nottingham*

Palaeoenvironmental datasets have considerable potential for informing present-day conservation management, but their application is often limited by their relatively low spatial and temporal resolution. Recently developed algebraic models of pollen dispersal and deposition can translate point-source pollen data from multiple sites into quantified reconstructions of past land-cover. The Multiple Scenario Approach (MSA) provides a framework for applying these models which generates spatially explicit land-cover reconstructions for identified timeslices. The temporal resolution of palaeoenvironmental sequences is also improving through application of techniques such as Bayesian modelling of chronological information.

Applications of the MSA to date have focused on reconstruction of archaeological landscapes at a regional scale. These reconstructions have a relatively coarse spatial resolution due to the dispersed nature of pollen sites in these landscapes. Another limitation has been a lack of contemporary input datasets (e.g. grids of topography and substrate), which are used to constrain placement of vegetation communities to produce hypothetical maps of land-cover for which pollen assemblages are then simulated and compared with empirical pollen data. Whilst the MSA reconstructions undertaken to date have produced a broad-scale picture of land-cover change over time, they have not provided the detailed information at a fine spatial scale that is needed by conservation managers.

Building on previous work at Hatfield Moors, South Yorkshire, UK which produced detailed reconstructions of pre-peat topography and mire extent from its mid-Holocene origins to present, we apply the MSA to land-cover reconstruction at this site. Hatfield is part of the Humberhead Peatlands National Nature Reserve, the largest area of lowland raised bog in Britain. These peatlands have been heavily impacted by drainage and industrial peat extraction, primarily since the 17^{th} century, and current restoration efforts aim to manage vegetation and water levels in an attempt to reinstate the vital ecosystem services provided by healthy, functioning peatlands. This paper presents the results of palaeoenvironmental modelling using the MSA to establish the processes of peat development and ecological succession during the mid-Holocene and inform effective conservation management of the site.

How paleoecology can support peatland restoration

Dr. Katarzyna Marcisz [1], ***Dr. Sambor Czerwiński*** [2], ***Prof. Piotr Kołaczek*** [2], ***Prof. Mariusz Lamentowicz*** [2], ***Dr. Dominika Łuców*** [3], ***Prof. Michał Słowiński*** [4]

Ecosystem management and restoration are currently challenged by rapid climate change and rising anthropogenic pressure. Many ecosystems in various geographical locations may undergo critical transitions due to rapidly changing climate. Often, management techniques used in the past are no more efficient and need modifications or a different course of action. Palaeoecological research can provide crucial information on long-term ecological transitions, disturbance events, and the response of organisms (e.g., plants, microorganisms) to environmental changes and human impact. This can then be translated to ecological modelling and is valuable for biological conservation, restoration and management. Among ecosystems that require proper management policies are peatlands, one of the essential carbon stocks worldwide that are significantly affected by global warming and land use changes. The linkages and feedbacks between peatland microbial communities, vegetation composition and hydrological conditions are complex and thus require specific management strategies and monitoring tools. This contribution will present examples of how paleoecology can help define and track past disturbances and ecological transitions, as well as provide suitable management strategies for peatlands. Given examples will include fire disturbance events, effects of peat extraction on peatland hydrological status, and management of peatlands in forest plantations.

Study funded by the National Science Centre, Poland, grant no. 2020/39/D/ST10/00641.

Palaeoecology and Peatland Restoration: Embedding the Practitioners' Perspective

Ms. Jessica Gauld [1], ***Dr. Emma Shuttleworth*** [1], ***Dr. William Fletcher*** [1], ***Mr. Kevin Feeney*** [2], ***Mr. Mike Longden*** [3], ***Mr. Martyn Walker*** [3], ***Mr. Anthony Da Silva*** [3]

1. *School of Environment, Education and Development, The University of Manchester, Manchester, United Kingdom,* ***2.*** *Cheshire Wildlife Trust, UK,* ***3.*** *The Lancashire Wildlife Trust, UK*

The persistence of a major research - practice gap prevents palaeoecology from achieving its full potential in supporting restoration ecology. Healthy peatlands contribute to climate resilience and provide a haven for biodiversity; thus, their restoration is a vital endeavour and academic research can provide a robust evidence base to inform restoration. However, the value of palaeoecology for guiding peatland restoration is hindered by a lack of effective science - practice communication. Therefore, this project aims to address the prevailing research - practice gap and increase research impact by developing a process of research - practice collaboration. This case study will focus on three lowland raised bogs under conservation management in the Greater Manchester region, UK. Each site has been subject to direct and indirect anthropogenic disturbance, including peat cutting, drainage for agriculture, and pollution, and have been under conservation management for time periods spanning from recent years to several decades. This study details an approach for early-stage collaboration, specifically focusing on methods for engaging research end-users in key preliminary phases of research design. Early engagement with key project stakeholders is essential for maintaining research relevance to practice, thus, increasing research impact by facilitating the integration of results into practical settings. In this study, a combination of meetings, site visits, surveys, and workshops are used to refine palaeoecological research aims and prioritise research questions in the context of practitioner needs and constraints in peatland restoration practice. In addition to honing the research focus, this process created space for practitioners to offer experiential knowledge regarding the site histories and restoration works. This is essential for ensuring that recommendations made from palaeoecological research are practically feasible and align with practitioner needs. This phase of collaboration will feed into the focus and methodology of the palaeoecological research. It will be part of an overarching iterative process of practitioner engagement that will continue throughout the project timeline and include the dissemination of research into suitable formats that enable the implementation of the results into restoration targets or management plans.

The future of the past : Potential practial applications of paleoecological findings in ecosystem managements

Dr. k. anggi hapsari [1], ***Dr. Tim C. Jennerjahn*** [2], ***Prof. Hermann Behling*** [1]

1. *University of Goettingen,* ***2.*** *Leibniz Center for Tropical Marine Reserach (ZMT), Bremen*

Paleoecology can provide long-term ecological information, e.g., ecosystem resilience and natural regeneration, that is difficult to obtain using experiments or observations, but that is critical to develop effective conservation and restoration strategies. It is therefore not surprising to find a statement such as: *"…conservation and restoration can be improved using paleoecology…"* in paleoecology-related publications. However, there is a dearth of examples on how paleo-information can be practically applied in restoration beyond defining pre-human-intervention baselines. Here we present examples of practical applications of paleo-information on ecosystem managements drawn mainly from our work in Indonesia. Paleo-information can help readjusting the goals and targets by providing examples and reflection on what conservation and/or restoration targets are attainable. Information on how natural succession works allows refining the restoration design. Moreover, information on ecosystems' natural resilience and the types of socioeconomic activities that are *"resilience-friendly"* can help addressing related governance and socioeconomic aspects. Paleo-information can also provide invaluable input in policy making and help overcoming public skepticism towards ecosystem conservation and restoration.

Define safe and operating spaces of freshwater lake ecosystems in China

Prof. Ke Zhang [1]

1. State Key Laboratory of Lake Science and Environment, Chinese Academy of Science

Global lake ecosystems are under formidable threats in the Anthropocene. Scientists and managers are facing pressing challenges to define a safe operating space for successful lake management in the future. Achieving these goals requires a clear understanding of the nonlinear trajectories of ecosystems' response to changes in multiple interacting drivers at multi-decadal /centurial scales. Based on a synthesis and analysis of paleo-environmental records of more than fifty lakes across China ranging from the 1850s-2010s using multiple statistical methods, we identify the tipping points, magnitude, and frequency, rate of changes, as well as pre-impact conditions of biogeochemical variables of the different lakes. Furthermore, we develop metrics for characterizing the lake ecosystem safety, quantify the safe boundary values and develop regional safe and operating spaces for the lake ecosystem in China. This analysis provides new insights and empirical evidence for identifying the safe operating spaces and restoration targets in degraded aquatic ecosystems, demonstrating that long-term paleo-environmental records can have great potential to inform regional environmental management.

A palaeo-perspective on Insect Armageddon: disentangling the multiple drivers of chironomid diversity

Dr. Stefan Engels [1] ***, Prof. christine lane*** [2] ***, Ms. Elo Wilkinson-Rowe*** [2]

1. Birkbeck, University of London, 2. University of Cambridge

Anthropogenic changes to the environment are leading to a decrease in global biodiversity, where the insect fauna has been particularly affected with decreases in diversity reported across the globe. The loss of insects is a major problem, as changes to the insect community threaten ecosystem functioning as well as global food security. Most datasets used to assess changes in insect biodiversity are based on decadal-scale ecological monitoring results, and this short time-window does not allow to separate the effects of individual anthropogenic impacts which are simultaneously impacting on our freshwater ecosystems. There is therefore a need for long-term data to better understand the processes that govern insect diversity dynamics. Chironomids are among the most abundant insects in lake ecosystems, are sensitive to environmental change, and as parts of their larval exoskeleton preserve well in lake sediment records, they provide a unique source of information on long-term insect population dynamics. We reconstructed decadal as well as centennial scale changes in the chironomid faunas of a set of lakes in west Norway. Through comparing the chironomid assemblages of surface sediment samples collected during fieldwork in 2019 to findings from 1996 we show that individual lakes show site-specific responses to climate and land-use change. Whilst ca. half of the 20 sampled lakes show only minimal change in their chironomid fauna over the last 23 years, the other lakes show a change in assemblage composition, the arrival of taxa new to the region, or, in one case, the complete disappearance of chironomids from at least part of the lake. The analysis of gravity cores obtained from two of the lakes provides a centennial-scale perspective on the recent chironomid dynamics, showing that assemblage change on longer timescales had a larger amplitude than observed over the last decades. Each lake showed unique site-dependent changes in the chironomid fauna, illustrating that whilst chironomid diversity responds sensitively to external drivers, the expression of the response is non-linear. We conclude that palaeoecological results provide unique insights on insect dynamics and can be of key importance to inform and improve restoration and conservation efforts aimed at protecting vulnerable lake ecosystems.

Tracing the legacy of environmental change and human impact in North Sulawesi, Indonesia, to inform mangrove restoration and management

Ms. Rachael Holmes [1], ***Prof. Ulrich Salzmann*** [2], ***Prof. Rignolda Djamaldudin*** [3], ***Dr. Juan-Carlos Berrio*** [1], ***Dr. Emma Hocking*** [2], ***Prof. Mark Williams*** [1], ***Prof. Iskandar Siregar*** [4], ***Prof. Agus Trianto*** [5], ***Dr. Aiyen Tjoa*** [6], ***Dr. Marco Fussi*** [7], ***Prof. Karen Diele*** [8]

1. *School of Geography, Geology and the Environment, University of Leicester,* ***2.*** *Geography and Environmental Sciences, Northumbria University, Newcastle,* ***3.*** *Faculty of Fisheries and Marine Science, Sam Ratulangi University, Manado,* ***4.*** *Department of Silviculture, Faculty of Forestry and Environment, IPB University, Bogor,* ***5.*** *Faculty of Fisheries and Marine Sciences, Diponegoro University, Jawa Tengah,* ***6.*** *Faculty of Agriculture, Tadulako University, Sulawesi Tengah,* ***7.*** *The Joint Nature Conservation Committee (JNCC), Peterborough and Center for Conservation and Restoration Science, Edinburgh Napier University,* ***8.*** *Center for Conservation and Restoration Science and School of Applied Sciences, Edinburgh Napier University*

Sulawesi‘s mangroves are some of the most floristically diverse globally and have been subject to widespread deforestation and degradation, which has intensified since the 1980s. Governmental and community-based projects have conducted mangrove restoration and rehabilitation activities in Sulawesi, but project outcomes are rarely assessed. It is within this context that the “Comparing Biodiversity and Ecosystem Services of Restored and Natural Mangrove Forests in the Wallacea Regions” (CoReNat) project aims to make evidence-based recommendations to guide future restoration actions throughout Wallacea and Indonesia. CoReNat is a collaboration between Indonesian and UK based research institutions taking an interdisciplinary approach to assess the outcomes of mangrove restoration in North Sulawesi.

To better understand mangrove responses to long-term environmental change and disturbance, we present palaeoecological data (palynology, diatoms, charcoal and spheroidal carbonaceous particles (SCPs)) from three ^{14}C and ^{210}Pb dated cores from two areas in North Sulawesi: 1) a nearly 8,000 year old record from a mangrove lagoon on Mantehage Island, Bunaken National Park; and 2) two Late Holocene high-resolution records from estuarine mangrove stands in Likupang, one taken from a site restored around 2000 CE following the establishment of aquaculture ponds in the 1990s and the other, with no recent history of deforestation, serving as a reference. Combined, the records document substantial changes in mangrove composition in response to long term Holocene climate and sea level changes. Abrupt late Holocene hydrological and vegetation change in the Mantehage record has enabled us to assess mangrove recovery following large-scale disturbance. The non-deforested Likupang site provided no evidence for human impact over the last 200 years, indicating its suitability as a reference site for use by the CoReNat project in their contemporary comparison of natural and restored mangrove stands.

Session 143:
Environmental responses to climatic and human impacts in endangered biodiversity hotspots: past and present for future

Ecological response on environmental change in tropical South America during the late Quaternary

Prof. Hermann Behling [1]

1. Department of Palynology and Climate Dynamics, Georg-August-University

Detailed records on vegetation and environmental changes during the late Quaternary, based on pollen, charcoal and multivariate data analyses, provide insights on past ecological response on environmental changes. Several examples from South America will be presented. Studies from the Ecuadorian Andes as well as from the lowlands and highlands of Brazil reflect interesting ecological responses to climate change, fire and human impact. Results from continental records from the lowlands and highlands in Brazil as well as marine records show that the response of ecosystems on large scale climate change can be within centuries or decades. Studies from different regions indicate how tropical ecosystems evolved to what they are today. Furthermore they show how sensitive ecosystems are to climate change and how ecosystems responded to natural and anthropogenic environmental changes during the past. This knowledge will help us to understand how ecosystems might change under the ongoing Global Change.

Late Quaternary Araucaria forest and Campos (grasslands) vegetation dynamics inferred from a high-resolution pollen record from southern Brazil

Dr. Daniela Piraquive-Bermúdez [1]***, Prof. Hermann Behling*** [2]***, Dr. Thomas Giesecke*** [1]

1. *University of Goettingen,* ***2.*** *Department of Palynology and Climate Dynamics, Georg-August-University*

The forest-grassland vegetation mosaics are very contrasting ecosystems, differing from their structure to functionality. Their controlling factors and their heterogeneity have been very intriguing aspects that fascinate researchers worldwide. To date, few natural remains of these ecosystems still exist, such as the *Araucaria* and Campos region in southern Brazil. Different paleoecological studies account for the vegetation and climate history of the region, documenting changes like shifts between woodlands and grasslands during the last Glacial period (~44000 cal yr BP) until the Late Holocene. However, uncertainty remains about whether the system shifts are rapid or gradual. We reconstruct for the first time in high-resolution (decadal to sub-decadal) the paleoecological history of the *Araucaria* forest-Grassland mosaics in Paraná State during the Holocene to interpret better vegetation shifts and improve our understanding of the dynamics of these subtropical ecosystems. Our data support and complement the paleoecological history of the region, adding details on the systems shifts where gradual vegetation changes are recorded. In addition to the general trend of climatic development, Lagoa Dourada documents for the first time in southern Brazil all three climatic events: the 8.2 ka event, the 4.2 ka event and the Little Ice Age, suggesting that the geographical setting of the lake might have influenced the expression of regional climate, and therefore classifying the study area as a sensitive location in the highlands of Paraná State.

Climate and human effects on a northeastern brazilian Cerrado over the last 800 years

Dr. Sergio Santos Xavier [1], ***Prof. Francisca Soares de Araújo*** [1], ***Dr. Marie-Pierre Ledru*** [2]

1. Universidade Federal do Ceará, 2. ISEM, Univ Montpellier, CNRS, EPHE, IRD, 34095

Understanding vegetation dynamics is essential to interpret long-term ecological changes under different precipitation regimes and land use scenarios. Northeastern Brazil has been subjected to both climatic and anthropic disturbances in recent centuries. In this region, high-resolution pollen reconstructions are challenging due to the semiarid conditions that predominate since the Late Holocene. However, when achievable, they provide insights about landscapes changes in a densely populated region that is rich in both biodiversity and archaeological sites. This study presents a high-resolution record, SAC18 sediment core collected on Cerrado ecotone in the full protected area of Sete Cidades National Park, north of Piauí State. Multiproxy analyses, pollen, charcoal and grain-size showed 800 years of Cerrado species reorganisation during dry and wet intervals. The beginning of the record was marked by a dry episode, with presence of a drought resistant taxon *Curatella* (wild cashew tree) and coincided with the Medieval Climate Anomaly (950-1250 CE). Almost no fire activity was observed between 1210 and 1300 CE, related to reduced human presence during the dry period. A wetter interval began in 1400 CE, with expansion of the palm swamp and the moisture-related tree/herbaceous taxa Myrtaceae and *Spathiphyllum*, which was synchronous with the Little Ice Age (1400-1700 CE). During this humid phase, agriculture practices were observed by the presence of *Zea mays*. The limited biomass burning with no deforestation at the beginning of the wet interval shifted to extensive fires and deforestation after 1650 CE, giving an age for the arrival of European colonists in the north of Piauí State. Fires stopped after the creation of Sete Cidades National Park in 1961 CE, resulting in the expansion of the Cerrado aboreal cover. This study provides novel knowledge about past human occupation of Northeastern Cerrado, defined by three types of land use practices (indigenous, colonists and protection policy) and shows how important it is to include historical aspects of the landscape for future conservation scenarios.

Vegetation and fire responses to late Quaternary climate and human forcing in Santa Catalina Island (California, USA)

***Dr. Ana Ejarque* [1], *Prof. R. Scott Anderson* [2], *Ms. Ana Verhulst-Casanova* [3], *Dr. Reyes Luelmo-Lautenschlaeger* [1], *Dr. Emmanuelle DEFIVE* [4]**

1. ISEM, Univ Montpellier, CNRS, IRD, Montpellier, 2. School of Earth & Sustainability, Northern Arizona University, Flagstaff, AZ, 3. GREMA, IRF, Université du Québec en Abitibi-Témiscamingue, Amos, QC, 4. Geolab, CNRS, Clermont-Ferrand

Situated west of Los Angeles, and having experienced a lesser urban development than the adjacent continental coast, the California Channel Islands (CHIS) are acknowledged as one of the few remaining natural Mediterranean ecosystems in southern California. However, our knowledge of the long-term ecology of this island biodiversity hotspot is still sparse. Most of the available paleoenvironmental information performed on the CHIS focuses in the Holocene, while the information for earlier periods, such as the Late Pleistocene, is still fragmentary.

We present multi-proxy palaeoenvironmental analyses including pollen, non-pollen palynomorph, charcoal and sedimentology in a 520-cm depth record obtained at Echo Lake on Santa Catalina Island, one of the few existing natural wetland basins in the CHIS. The study has allowed us to reconstruct vegetation and fire dynamics during three main periods of lake occurrence within different climatic conditions and anthropogenic pressures: 1) Marine Isotope Stage (MIS) 3 at ~38 ky cal BP, when coastal conifers dominated the landscape; 2) the Late Pleistocene-Holocene (MIS2-1) transition between 13.2 and 8.8 cal BP, a period when conifer woodlands were replaced by more open scrub and grassland, with changing fire dynamics and the arrival of human communities; and 3) the historical period when native flora and landscapes were impacted by agricultural practices introduced by American settlers.

By analyzing vegetation and fire dynamics prior to and after prehistoric and colonial settling we will have a better understanding on how Mediterranean island ecosystems have been impacted by, and responded to, long-term natural climatic and human forces. This is essential for present management and potential restoration of island habitats in a context of climate change and increased population and development pressure in southern California.

Palaeoecological insights in coastal landscape evolution. Late Holocene vegetation changes in Southern California

Dr. Reyes Luelmo-Lautenschlaeger [1]***, Prof. R. Scott Anderson*** [2]***, Dr. Nathalie COMBOURIEU-NEBOUT*** [3]***, Dr. Yannick Miras*** [3]***, Prof. Alexander R. Simms*** [4]***, Dr. Luc Beaufort*** [5]***, Dr. Ana Ejarque*** [1]

1. *ISEM, Univ Montpellier, CNRS, IRD, Montpellier,* ***2.*** *School of Earth & Sustainability, Northern Arizona University, Flagstaff,* ***3.*** *CNRS, HNHP (UMR 8194), Museum National d'Hisoire Naturelle,* ***4.*** *Department of Earth Science, University of California, Santa Barbara, Santa Barbara,* ***5.*** *Aix Marseille University, CNRS, IRD, INRAE, College de France, CEREGE, Aix-en-Provence, France*

The California coast is a Mediterranean biodiversity hotspot attesting to a long and rich anthropogenic history over the last ~13.000 years. Human migration, trading and colonization have had a direct impact on biodiversity and vegetation structure and distribution. Southern California (SoCal) has witnessed intense landscape management and different land-use strategies through time, especially during the Late Holocene, and particularly over the last ~250 years, when urban development and the introduction of agricultural practices in coastal areas ultimately became a major threat to coastal biodiversity and natural resources.

In this study we present palaeoecological results obtained in the Santa-Barbara coastal region as part of the MeSCAL Agence nationale de la recherche (ANR) project, which aims to analyze the vegetation composition and distribution, biodiversity, and landscape transformation following natural dynamics and/or prehistoric and colonial migrations and settling over the last 4000 years in SoCal. High-temporal resolution pollen and non-pollen palynomorphs analysis has been conducted over the Late Holocene section from the marine core MD02-2503, obtained ~ 20 km offshore of the Santa Barbara coast.

Palynological datasets have been integrated with available paleoclimatic series and continental palynological datasets, as well as with archaeo-historical information of human mobility, settling and coastal landscape management. This has allowed us to calibrate regional and local changes in biodiversity, vegetation composition and land-use, and to discriminate those transformations due to environmental, climatic and/or anthropic dynamics. This research helps to place in value the role played by anthropogenic-climate interaction in shaping the current floristic richness, vegetation and landscape diversity in Santa Barbara coastal region. This study provides new tools for future management and ecological conservation of this endangered biodiversity hotspot in SoCal.

Dinocysts and others Non-Pollen Palynomorphs from the Mar Piccolo basin (Taranto, southern Italy) at the Pleistocene-Holocene transition

Mr. NICCOLO' DEGL'INNOCENTI [1]***, Mr. Gabriele Niccolini*** [1]***, Prof. Adele Bertini*** [2]***, Prof. Giuseppe Mastronuzzi*** [1]***, Prof. Massimo Moretti*** [1]

1. *Department of Earth and GeoEnvironmental Sciences, University of Bari,* ***2.*** *Dipartimento di Scienze della Terra, Università degli Studi di Firenze, Via La Pira 4, I-50121 Firenze, Italy*

The Mar Piccolo (Taranto, southern Italy) is a semi-enclosed basin with a low hydrodynamism, fed by both an ephemeral network of streams and sub-aerial and submarine karstic springs. The Mediterranean water exchange is ensured by two channels that connect the Mar Piccolo to the Gulf of Taranto (northern Ionian Sea). Here we present the results of dinocysts, Non-Pollen Palynomorphs (NPPs) and morphosedimentary analyses carried out in the portion of core S05B (29.15 m thick) including the Pleistocene-Holocene transition. The basal record includes palynological assemblages (e.g., *Zygnemataceae*) typical of pond freshwater paleoenvironments with flowing streams probably fed exclusively by karst springs, interspersed with moments of high accumulation of organic matter (e.g., *Trachelomonas*). The first significant occurrence of marine dinocysts (at 23.91 m from the base) attests the ingression of saline waters from the Gulf of Taranto and the instauration in the Mar Piccolo of prevalent brackish conditions. However, dinocysts show a quite discontinuous stratigraphical distribution marked by disappearance vs occurrence events, in a prevalently very low water column. The portion including the tephra, dated at 8.9 ka (at 18.50 m), towards the top of the record, corresponds to an interval marked by an increase in dinocysts concentration during a saline water input from the Gulf of Taranto. The latter possibly correlates to the Melt Water Pulse - 1c (MWP-1c; at ca 9.4 ka - 8.3 ka). Just after (18.06 m) cold dinocysts increase possibly as a response to the 8.2 ka event. A subsequent new strong decrease (from 18.06 to 16 m) in the saline water supply together with an increase of the springs freshwater contribution mark the top of the record characterized by a new organic rich phase.

Paleoenviromental reconstruction of Mar Piccolo (Taranto, Southern Italy) at the transition Pleistocene-Holocene

Mr. Gabriele Niccolini [1], ***Mr. NICCOLO' DEGL'INNOCENTI*** [1], ***Prof. Adele Bertini*** [2], ***Prof. Giuseppe Mastronuzzi*** [1], ***Prof. Massimo Moretti*** [1]

1. *Department of Earth and GeoEnvironmental Sciences, University of Bari,* ***2.*** *Dipartimento di Scienze della Terra, Università degli Studi di Firenze, Via La Pira 4, I-50121 Firenze, Italy*

Morphoclimatic changes have been traced by palynological (pollen and palynofacies) and morphosedimentary analyses of the sediment of the S05B core retrieved from the Mar Piccolo basin (southern Italy) throughout the Pleistocene-Holocene transition. From 29.10 to 25 m, the analysis of organic matter both structured and amorphous one suggests an early environment characterized by very shallow water and anoxic ponds. Steppic (e.g., *Artemisia*, *Ephedra* s.l.) and halophyte pollen taxa (e.g., *Armeria,* Amaranthaceae) dominate suggesting prevalent arid climatic conditions on the land. Salt marshes were submitted to several freshwater inputs, as attested by the increasing in Cyperaceae, and freshwater algae. The expansion of freshwater marshes apparently developed under anoxic/disoxic conditions of the bottom and still arid atmospheric conditions. However, at the beginning of the Holocene, a sudden increase of several arboreal taxon (e.g., *Quercus pubescens*, *Pinus*) mark the instauration of progressively warmer and humid conditions. The arrival of marine waters in the basin promotes increasingly oxygenated conditions of its bottom as attested by the organic matter content. Between 26 m and about 16 m, at least six abrupt increases of the open vegetation (steppes, salt marshes and freshwater marshes) have been detected. They represent sub-millennial climatic changes, possibly related to Bond events with the younger one, just above the Pomici di Mercato tephra (at 18.5 m, dated at 8.9 ka), approximating the 8.2 ka (Bond event 5). The detection of such rapid arid events contributes to the chronological framework reconstruction of the sedimentary basin infill. Insights on the resilience of the Mar Piccolo ecosystems, maintenance of biodiversity under the effects of latest Quaternary climate change including current global warming will be developed.

Palynological analysis of mosses and sub-recent surface sediments from the Orbetello and Burano coastal lagoons (central Italy)

Mr. Matteo Pili [1]***, Ms. Sara Rosso*** [2]***, Prof. Adele Bertini*** [1]***, Dr. Cécile Vittori*** [3]***, Dr. Gilles Brocard*** [4]***, Mr. Fabio Cianchi*** [5]***, Mr. Marco Leporatti Persiano*** [6]***, Dr. Jean-Philippe Goiran*** [4]

1. *Dipartimento di Scienze della Terra, Università degli Studi di Firenze, Via La Pira 4, I-50121 Firenze, Italy,* ***2.*** *Dipartimento di Scienze della Terra, Università degli Studi di Torino, Italy,* ***3.*** *UMR 5133 Archéorient, Maison de l'Orient et de la Méditerranée, Université de Lyon (UdL), France,* ***4.*** *Archéorient, UMR 5133, University of Lyon 2-CNRS, 7 rue Raulin, 69007 Lyon, France,* ***5.*** *WWF Oasi Laguna di Orbetello,* ***6.*** *Supporto tecnico-scientifico Regione Toscana, Sistema di gestione 2022*

The Orbetello and Burano lagoons (southern Tuscany, Italy) together with the neighbouring areas, are preserved by Natural State Reserves. They are also Sites of Community Importance and Special Protection Zones and Wetland of International Values (Ramsar Conventions on Wetlands). These are unique examples of ecosystems in terms of naturalistic richness and biodiversity despite their preservation is now threatened by the effects of global warming, water pollution, growing anthropic impact, the latter especially evident in the Orbetello Lagoon.

Samples of mosses around the lagoons and at sediment–water interface have been collected from several locations. All samples have been processed at the Palynological Laboratory of the University of Florence. The study of modern and sub-recent palynological assemblages and their relationship with present-day vegetation permitted paleoecological reconstructions as well as the identification of pollen indicators from different environments or plant communities. Sub-recent pollen spectra exhibit assemblages dominated by Mediterranean and sub-Mediterranean arboreal/shrubs taxa (especially *Quercus ilex* but also deciduous *Quercus* and *Pinus)*. The herbaceous vegetation taxa (e.g. Amaranthaceae, Cyperaceae and Poaceae) show different occurrence and abundance in the different pick-up points pointing out local expansions or retractions of specific environments and their associated vegetation. The anthropic impact is attested by the massive occurrence of *Olea* as a result of the introduction of this crop since ancient times but also by more recently introduced exotic plants (e.g. *Eucalyptus*). *Ruppia* and algae acme phases pointed out several environmental episodes, which have been related to anthropic or climate impacts as well as to their interplay (such as eutrophication, lowering of water level, etc.). Other already available palynological records documenting the last 7 ka in the same and closer sites are also evaluated.

The incoming integration with parallel studies, in the same two sites, devoted to ostracods and molluscs will allow a detailed reconstruction of recent environmental changes and response to anthropic impact and global warming, in both aquatic and on land environments, in these important hotspot areas of the central Mediterranean.

An assessment of the human-driven physical harm on the seabed of Augusta Bay (Southern Italy, Western Ionian Sea), achieved by geophysical investigations and direct samplings

Dr. francesca Budillon [1], Dr. Marco Firetto Carlino [2], Dr. Sara Innangi [1], Dr. Salvatore Passaro [1], Dr. Renato Tonielli [1], Dr. Fabio Trincardi [3], Dr. Mario Sprovieri [4]

1. *Istituto di Scienze Marine, Consiglio Nazionale delle Ricerche, ISMAR-CNR,* ***2.*** *Istituto Nazionale di Geofisica e Vulcanologia (INGV),* ***3.*** *Consiglio Nazionale delle Ricerche - DSSTTA CNR,* ***4.*** *Istituto per lo Studio degli Impatti Antropici e Sostenibilità in Ambiente Marino, Consiglio Nazionale delle Ricerche*

In this study we explored the extent of the human-driven physical impact on the continental shelf of the Augusta Bay (Southern Italy, Western Ionian Sea), by means of swath bathymetry, side-scan sonar images and Chirp sonar profiles, as well as direct seabed samplings. The Augusta Bay includes the Rada di Augusta, a wide littoral sector sheltered by breakwaters and engaged in harbour activities, and the Priolo inlet, both listed in the National Remediation Plan (NRP) by the Italian Ministry of Environment. Indeed, extensive petrochemical and industrial activities, military and commercial maritime traffic, as well as agriculture and fishery activities, have resulted in a highly complex combination of impacts on the marine environment and seafloor.

Our investigations highlighted that at least seven categories of anthropogenic footprints, i.e., anchor grooves and scars, excavations, trawl marks, generic targets, dumping trails, isolated dumping and dumping cumuli, are present at the seafloor, with higher concentrations observable in the central sector of the bay, between 50 and 100 m bsl. The practice of dredge spoil dumping, possibly long protracted during the last century, has altered the seafloor morphology of the central continental shelf, by forming a mounded deposit, with acoustic features noticeably different from those of any other shelf lithosome originated by natural processes. An original thematic map of the seafloor, describing the seemingly natural sediment facies and the marks of the anthropogenic disturbance, was drawn up useful as a reference benchmark, relative to the early 2000s, for future monitoring or, in general, for spatial planning actions. Finally, a semi-quantitative evaluation of the human-driven harm to the seabed was provided by ranking discretized portions of the shelf area, in function of the occurrence of multiple anthropogenic stressors. This procedure could offer crucial advances to learn more on the effects of human impact on the delicate seafloor environment and its ecosystem and, consequently, provide a solid basis for environmental protection and restoration.

Reconstruction of the dry forest in north-western Madagascar during the late Holocene and its relevance to biodiversity conservation

Mr. Fetra Randriatsara [1], ***Prof. Lindsey Gillson*** [1], ***Dr. Estelle Razanatsoa*** [2]

1. *Plant Conservation Unit, University of Cape Town South Africa.,* ***2.*** *Plant Conservation Unit, University of Cape Town, South Africa.*

Madagascar's western dry deciduous forests have been identified as priority conservation ecosystem due to the high rate of endemism and intense anthropogenic pressure. Deforestation, interpreted without empirical understanding of landscape history and fire regimes, results in generalized assumptions of landscape degradation and condemnation of local community land-use. These assumptions have led to policies of general tree planting and fire suppression throughout the island. However, the extent of change, its relative importance and interactions between climate and humans over time are poorly understood particularly in the northwest part of the island. This raises question for what conservation management should be planned as reference conditions are lacking. In this research information and changes over time in open vegetation in the northwest Madagascar are explored. The vegetation dynamic and its relationship with human activities (herbivory and fire) are studied using fossil pollen, dung fungal spores and microscopic charcoal from two sediment cores. The first core is a relatively young (c□100 BP), presenting opportunities for understanding recent changes of landscape. The second covers a much longer timespan (c□2000 BP) and gives insight into how vegetation has changed since human settlement. Preliminary results show that the vegetation was a mosaic of dry forest and grassland. It was dynamic at both sites during the last century and two millennia. The dominance of Poaceae and tree families such as Fabaceae, Arecaceae (Palm) and Apocynaceae between ~2500 Cal BP and ~1750 Cal BP is characteristic of an open vegetation in the western region. Despite the increasing of anthropogenic signals in the coprophilous fungi spores and charcoal records, the vegetation was resilient. Shrub and tree were present along the core even though their percentage were slightly decreasing from ~1000 BP. During the last 100 years, the vegetation was a grassland mosaic with abondance of herb, shrub, and scattered tree. This study provides an exploration of vegetation changes in response to fire and herbivory activity through different time scales. This can provide information for a conservation management plan to the dry ecosystem in the western region of Madagascar, with a particular focus on ecosystem restoration and fire policy.

Anthropogenic vulnerability of biodiversity hotspots of Greater Virunga Landscape of the Albertine Rift, East Africa

Prof. Charles Twesigye [1]

1. *Kyambogo University*

This study aims to provide information for the management of wild species in the Albertine Rift of East Africa. The Greater Virunga Landscape of the Albertine Rift has faced historical and continuing threats due to armed conflict, population pressure for land, poaching and fluctuations in political support for conservation. The Landscape supports extraordinary biodiversity and a large human population. Anthropogenic Climate Change is expected to have severe impacts on biodiversity and people. We assessed the climate change vulnerability of mammals, birds, fish, and plants, and gathered detailed information on their use by humans. Overall, this study presents the results of threats to the region's biota. The need for enhancing the productivity of fisheries triggered the introduction of non-native fish, causing dramatic changes to local species. The extensive translocation of Nile tilapia (*Oreochromis niloticus*) is one of the major factors in this respect. Using 10 microsatellite loci and Mitochondrial DNA Sequencing, we amplified a total of 128 individuals to investigate the genetic structure of *O. niloticus* from the Albertine Rift Lakes in comparison to the Lake Victoria Basin populations. The Nile tilapia genetic structure was congruent with both geographical location and anthropogenic activities. For example, most of the populations have gone through a reduction in genetic diversity, which can be a consequence of bottleneck caused by overfishing, genetic erosion due to fragmentation or founder effect. The anthropogenic activities promoted artificial admixture among the East African Nile tilapia populations. These events contribute to outbreeding depression which in turn compromises the sustainability of the species in the region. Freshwater fish, plants and mammals have emerged as the most heavily utilized taxa. Agricultural activities and increased population density were the most significant drivers of the established land use land cover changes. This study has shown accelerated loss of key land cover biomes; grasslands, bush lands, and tropical high forests mediated by anthropogenic factors and leading to reduced landscape heterogeneity thus potential to significantly affecting ecosystem services supply in this region. The hotspots of Land use/land cover change was predominant on privately owned land, refugee settlement area, and areas with oil and gas industry developments.

Human induced switch in coastal ecosystem dynamics: Proxy records from Western Indian Estuary

Dr. Rajani Panchang [1]***, Ms. Tejaswini Khasase*** [2]***, Mr. Vibhas Shevde*** [3]***, Dr. Ravi Bhushan*** [4]***, Dr. Gyana Ranjan Tripathy*** [3]

1. *savitribai phule pune university,* ***2.*** *Marine Bio-geo Research lab for Climate & Environment (MBReCE), Department of Environmental Science, Savitribai Phule Pune University,* ***3.*** *Department of Earth & Climate Science, Indian Institute of Science Education & Research Pune,* ***4.*** *Geosciences Division, Physical Research Laboratory, Ahmedabad 380 009*

Estuarine sedimentary records from India have rarely been exploited to reconstruct past environmental or climatic history. In a deliberate attempt to assess the potentials of such estuarine sedimentary archives a 1 m sediment core was collected in the lower tidal flats of an important estuary, along the Central West Coast of India. Coupled measurements of Pb-210 and Cs-137 helped generate reliable geochronology with a resolution of 2 to 3 years per sample on the core and asserted its suitability for reconstruct of high- resolution climatic records. Downcore variability of Foraminiferal and clay mineral assemblages as well as sediment textures were generated as proxy records for reconstructing century long environmental and hydrological conditions in the estuary. This study also compares the proxy records vis. with instrumental records for climate which show very good correlation throughout the length of the core. It is interesting to note that every drought period instrumentally recorded in the past century is manifested in the study area by the clay mineral assemblage. The present study demonstrates the sensitivity of clay minerals at smaller time scales and validates their applicability in high resolution monsoon reconstructions. The foraminiferal assemblage shows a switch in ecosystem dynamics complementary to increased development and urbanisation in the watershed of the estuary under study.

Conservation status of biological resources and archaeological remains of the historical and ecotouristic site of Yaoui (Centre-Benin) in a context of anthropic pressures

Prof. Ismaïla TOKO IMOROU [1]

1. *University of Abomey-Calavi*

The conservation of historical sites and related natural resources is of paramount importance for the preservation of past achievements. This research focused on the biological resources and archaeological remains of the Yaoui ecotourism and historical site (Central Benin). The site is located in a crystalline peneplain zone and is characterized by a series of three hills with altitudes varying between 276 and 461 m. The goal of this research conducted by a multidisciplinary team is to inventory the biological resources and archaeological remains of the site. The methodological approach used is floristic inventory techniques, archaeological excavation methods and diachronic analysis from sentinel images of 2016 and 2021. A total of 142 plant species divided into 49 families were identified within a diversity of plant communities with the presence of species with national and international conservation status. The site has archaeological potential including a sub-rock shelter inside which is erected the altar of a deity. Variously decorated pottery shards and anthropic mounds were inventoried, some of which are about 1 m high. With regard to the archaeological material, several places with high concentrations of ceramics were found on the surface of certain mounds. It should be remembered that anthropic mounds are accumulations of sediment in the form of mounds due to human activities where material witnesses of these activities can be identified such as pottery shards, pipes, millstones, wheels, bones, ash, etc. Between 2016 and 2021, the spatial mutations observed were more in favor of anthropogenic formations including plantations and crops and fallow land. The main factors of pressure on natural resources identified on the site are agricultural practices, logging and palm wine indices, carbonization sites. In the face of such practices, it is essential to take measures to preserve the integrity of the site.

Multi-tracers unravel the threats to coastal ecosystems dependent on groundwater during droughts

Ms. Carla Dodd [1], *Dr. Hayley Cawthra* [2], *Prof. Gudrun Massmann* [3], *Dr. Gavin Rishworth* [4]

Department of Zoology & African Centre for Coastal Palaeoscience & DSI/NRF Research Chair: Shallow Water Ecosystems, Institute for Coastal and Marine Research (CMR), Nelson Mandela University, Gqeberha 6031, South Africa

Groundwater resources can supplement diminishing surface water supplies in regions such as semi-arid South Africa which receives less than half the global mean annual precipitation. These resources are generally underdeveloped and many of the country's large cities rely on surface water instead for potable supply. An exception is seaside villages, where groundwater is an important residential water source. For the most part, however, groundwater is considered a reliable emergency resource during drought conditions. Due to population growth, socioeconomic development and effects of climate change, several South African water supply systems are severely constrained. Local governments are injecting water from coastal springs to main water supply pipelines where it is blended with surface water. Groundwater-dependent ecosystems, such as the actively precipitating supratidal microbialite ecosystems, occur along the southern South African coast and have recently been studied. The intricacies of these ecosystems are being illuminated through ongoing investigation, and they may be negatively impacted by large-scale groundwater abstraction. These ecosystems are especially important in terms of palaeoscience, heritage and biodiversity as they are considered partial analogues for Archaean stromatolites and host endemic biological species. Yet, little is known regarding the groundwater origin and dynamics on which the microbialite pools rely for accretion. This local multi-tracer study presented here (including stable environmental isotopes, trace organics, and age tracers) is the first attempt to investigate the nature of the groundwater entering Eastern Cape microbialite pools in terms of its source, anthropogenic inputs, and residence time. This is especially relevant regarding the multi-year drought in the region and the conservation management of these microbialite systems in the face of increased groundwater use.

Session 145: Climate Records from Coastal Systems

Coseismic subsidence, accommodation space, and the preservation of storm and tsunami deposits in coastal ponds on Anegada, British Virgin Islands

Dr. Jessica Pilarczyk [1], ***Dr. Michaela Spiske*** [2], ***Ms. Ayla Nguyen*** [1], ***Mr. Anthony Giang*** [1], ***Dr. Isabel Hong*** [3]

1. *Department of Earth Sciences, Simon Fraser University,* ***2.*** *Universität Basel,* ***3.*** *Villanova University*

Land-falling hurricanes pose an economic and environmental hazard to Atlantic Ocean and Caribbean Sea coastlines. Patterns of their frequency and intensity under a warming climate remain unclear in part because detailed long-term records are limited to only a few locations, but also because of uncertainties associated with interpreting the geologic record (e.g., preservation/erosion of older deposits, distinguishing between storm and tsunami deposition, availability of accommodation space). We improve upon this uncertainty by utilising datasets obtained from more than a decade of coastal investigations on Anegada, British Virgin Islands, including: (1) historical, geological, and modelling studies of tsunami deposits originating from both far-field (e.g., 1755 Lisbon tsunami) and near-field (e.g., originating from the Puerto Rico trench) tsunamis; (2) modern sedimentological analogues and post-event field surveys of landfalling hurricanes; and (3) onshore and offshore surface sediment samples for use in provenance analysis. This study uses the existing datasets as a basis for comparison on a series of overwash deposits preserved within coastal salt ponds on Anegada. Accommodation space within the salt ponds has been influenced by geomorphologic changes along the coast due to inundation by unusually large tsunamis and possible coseismic subsidence associated with Puerto Rico trench earthquakes. As a result, the overwash record on Anegada can be patchy and susceptible to erosion by subsequent marine inundation events. To ensure the longest and most complete record of overwash deposits, we accessed areas within salt ponds where accommodation space is maximised and potential reworking by subsequent events minimised. We used *Homotrema* taphonomy and elemental geochemistry to reveal differences between storm and tsunami deposits, where tsunami deposits contain Br and high abundances of *Homotrema* fragments that are generally vibrantly coloured, suggesting scouring and transport by tsunami, followed by rapid burial on the coast. In contrast, hurricane deposits are characterised by both Br and Ti and near equal abundances of bleached and non-bleached *Homotrema,* suggesting that at least 50% of the sediment was sourced from reef flat areas close to shore. Constraining the origin of overwash deposits at this location is essential to the establishment of effective coastal hazard mitigation policies.

Late Holocene paleostorm reconstruction based on XRF core scanning and sedimentological data from two coastal ombrotrophic peat cores, the Magdalen Islands, Québec, Canada

Mr. Antoine Lachance [1], ***Dr. Matthew Peros*** [2], ***Dr. Jeannine-Marie St-Jacques*** [1], ***Dr. Pierre Francus*** [3], ***Dr. Nicole Sanderson*** [4]

1. Concordia University, 2. Bishop's University, 3. Institut national de la recherche scientifique - Quebec, 4. Département de Géographie, Université du Québec à Montréal

Storms are pervasive dangers to coastal communities in Eastern Canada and, under future climate scenarios, these extreme weather events are projected to increase in frequency and intensity. However, the impacts of climate change on storm variability have not been studied extensively in this region, in part due to the short and incomplete instrumental storm record. Here we present a new, high-resolution record of storms over the late Holocene, based on the analysis of cores of 3.25 m and 7.00 m length from two ombrotrophic peatbogs on the Magdalen Islands, in the Gulf of St. Lawrence. The cores were dated by ^{14}C and ^{210}Pb, with the bottommost peat sediments dating to ~4920 BP and ~4720 BP, respectively. We applied principal component analyses (PCA) using 10 elements measured by XRF core scanning to understand sediment provenance. Our results indicate the presence of aeolian sediments from local beach sand and sandstone cliffs characterized by the presence of K, Ti, Si, and Zr. We used a combination of aeolian sand and titanium content to identify allochthonous sediments that were deposited during extreme weather events, and validated these using the instrumental hurricane record from the Magdalen Islands from the past 150 years. Our storm reconstruction indicates a particularly active period between 1400-1650 CE, when heightened activity was also identified in other studies from the northwestern North Atlantic, as well as a notable increase in storms since 1930 CE. While warm sea-surface temperature (SST) anomalies seem to have contributed to more frequent storms since 1930 CE, the 1400-1650 CE active period occurred during the Little Ice Age (LIA), a period of generally cooler SSTs in the North Atlantic. Our study is the first to use ombrotrophic peat cores to track storm frequency in eastern North America, as well as one of the northernmost on the continent, and highlights the ambiguous impacts of SSTs on mid-latitude storms. Future research should focus on understanding the climatic factors that control storm variation in Eastern Canada, especially over the last millennium.

Reconstruction of hurricane events over the last millennium based on sedimentary records from a coastal lagoon at Cayo Coco, Cuba

Prof. Felipe Matos Pupo [1], ***Dr. Matthew Peros*** [2], ***Prof. Eduard G. Reinhdardt*** [3], ***Dr. Nicole Sanderson*** [4], ***Dr. Thomas Bianchette*** [5], ***Dr. Roberto González-De Zayas*** [6], ***Prof. Alexey Valero Jorge*** [7]

Instituto de Meteorología*

Sediments from coastal lagoons provide continuous records of past hurricane activity. In this investigation, multiple proxies from two cores taken in Laguna Larga (Cayo Coco, Cuba) were analyzed. Based on ^{210}Pb and ^{14}C dating, grain size, and geochemical analyses by XRF core scanning, nine hurricane-induced sedimentological deposits (including both present and past events) covering the last ~900 years BP, were identified and compared with historical hurricane records for the period 1851-2021. A sand layer believed to have been deposited by Hurricane Irma (category 5 on the Saffir-Simpson wind scale), which struck Cayo Coco in September 2017, is associated with an abrupt increase in water level in the lagoon (as detected by data loggers) as well as profile changes at the adjacent beach. The sedimentary units coinciding with the hurricane events were characterized by a higher fraction of sand and minerals, lower organic matter content, and abrupt increases in elements of Ca, Sr, Zr and Br. During the period of study, hurricane activity was found to be related to variation in the El Niño/Southern Oscillation, which permitted a reconstruction of the long-term history of hurricanes in the region and the pattern of these systems in the province of Ciego de Ávila to be interpreted. Given the location of the study area, these results are important from a paleoclimatological perspective, but also in the context of archaeological studies and tourism.

Changes in Estonian climate (1951-2020) and associated coastal behaviour

Ms. Katre Luik [1], _Prof. Ilya V. Buynevich_ [2], _Prof. Jaak Jaagus_ [3], _Dr. Are Kont_ [1], _Dr. Reimo Rivis_ [1], _Prof. Ülo Suursaar_ [4], _Dr. Hannes Tõnisson_ [1]

1. Institute of Ecology, Tallinn University, 2. Department of Earth and Environmental Science, Temple University, 3. Institute of Ecology and Earth Sciences, University of Tartu, 4. Estonian Marine Institute, University of Tartu

Recent intensification of coastal processes is attributed to regional warming, which in Northern Europe, is manifested during colder seasons. In Estonia, warmer winters, longer sea-ice-free periods, and unfrozen beach sediments contribute to erosion during intense storms. Accumulation in deposcenter has also substantially increased, therefore, climatic fluctuations likely impacted the large-scale coastal behaviour. This study investigates the relationships between several climatic parameters and the character and intensity of coastal processes. Changes in air temperature, storminess, and sea-ice cover during 1951–2020 have been analysed at nine sites. To assess the relationships between climate forcings and shoreline response, patterns and rates of erosional-accretionary trends were analysed using GPS geo-location, topographic maps, and photographic materials. The mean annual temperature increased by 2.2–2.6°C during most of the months and the total number of sea-ice days decreased (at some sites, by a factor of two). According to recent studies, the northward shift of cyclone trajectories in Estonia enhanced the westerlies and reduced the northerlies. However, our findings indicate the opposite trend - an increase of storm impact from the N-NE and a reduction from the westerly directions. An increase in N/NE storms has been particularly evident during the past decade, though we have not detected statistically significant changes in storminess. Until the late 1980s, coastal processes were relatively slow and stable. Regime shift in climatic conditions in the late 1980s - early 1990s triggered a rapid intensification of coastal processes. Velocity of coastal processes increased up to 5-fold. Erosional trends extended into transport areas, while the total down-drift accumulation also increased. A new character of coastal processes emerged in 2011: several north-facing beaches began to erode, with high ridges forming to the S-SW. Less than a decade later, erosional indicators such as coarse lag and heavy-mineral concentrations are being covered by new ridges that now buffer these sites from wave impact. On Cape Kiipsaare (Saaremaa Island), sites dominated by erosion since the 1980s, now have a large sandy ridge formed during the past decade. Many similar patterns are likely preserved in ancient ridges (strandplains). Future research will focus on analysing these patterns in greater detail.

Weathering Extremes: storm surges, coastal landforms, two castles and medieval climate change, Scotland.

Dr. Eileen Tisdall [1]***, Dr. Richard Tipping*** [1]***, Dr. Morvern French*** [2]***, Dr. Stefan Sagrott*** [2]***, Dr. Jason Jordan*** [3]***, Dr. Tim Kinnaird*** [4]***, Dr. Aayush Srivastava*** [4]

1. *Biological & Environmental Sciences, University of Stirling, Stirling, FK9 4LA, Scotland,* ***2.*** *Historic Environment Scotland,* ***3.*** *Coventry University,* ***4.*** *University of St. Andrews*

Strandplains and barrier beaches are associated with storm surges. However, they are often underutilised as a way to define storm surge events because of their complex morphology and the interaction between relative sea level change and sediment supply. The study site, Caerlaverock, on the west coast of Scotland is at the confluence of the River Nith and the Solway Firth. The Solway is a sediment rich estuary which is prone to storm surges as low pressure systems move quickly northwards up the coast from the southwest.

Caerlaverock's two Medieval castles sit on mid Holocene marine shoreline terraces, relative sea level is considered to have been stable until the last few decades. Seaward lies an extensive prograding strandplain, we propose that this strandplain was formed by increased sediment supply driven by extreme storm events that encouraged both progradation and erosion.

Here we present palaeoenvironmental research that further define the nature and timing of these storm surges. Sediment records from coastal landforms, barrier beaches and related lagoons, as well as sediment traps associated with the archaeology indicate that a series of very large storm surges impacted the coastline, temporarily raising sea level by >2.5m. Here a combination of AMS ^{14}C and OSL dating have been used to better constrain the chronology, resolving the timing of these events and linking these storm surges to changes in northern hemisphere atmospheric circulation and the North Atlantic Oscillation. It is thought that the coastline had experienced significant storminess between 250 BC to AD 1600, with events occurring several human generations before the castles were planned or constructed as well as when they were occupied.

The interdisciplinary nature of this research, the use of novel sediment records and the establishment a secure chronology demonstrates that these smaller scale coastal landforms can provide detailed records of environmental change. Making it possible to link them to larger scale hemispheric climate drivers and determine the impact that these events had on people living on these dynamic coastlines.

Relative sea-level change during the Common Era in Norway: new data from intertidal basins and salt marshes

Mr. Max Holthuis [1] ***, Dr. Chantel Nixon*** [1] ***, Dr. Malin Kylander*** [2] ***, Dr. Willem van-der-Bilt*** [3] ***, Dr. Jake Martin*** [1] ***, Dr. Thomas Lakeman*** [4]

1. *Norwegian University of Science and Technology,* ***2.*** *Stockholm University,* ***3.*** *University of Bergen,* ***4.*** *Geological Survey of Norway*

New sea-level index points (SLIPs) from low-elevation isolation basins, salt marshes, and intertidal basins bridge the gap between postglacial and instrumental relative sea-level (RSL) data in Norway. Most RSL curves in Norway, constrained by SLIPs from isolation basins, imply steady RSL fall to modern sea level during the late Holocene. While there is a general lack of SLIPs younger than ca. 2000 years, the few curves with one or two SLIPs younger than 2000 years BP hint at accelerated rates of sea-level fall during this period. Conversely, tide gauge records from localities in southwestern and northeastern Norway indicate that RSL may have been rising since ca. 100 years ago. Initial geochemical analyses of sediment cores from southwestern Norway suggest that marine influence has been increasing during recent centuries, possibly due to rates of eustatic sea level rise overtaking residual glacio-isostatic adjustment (ca. 1-2 mm yr^{-1}). In this presentation, the XRF data will be presented and interpreted alongside CT core scans and new results from stable isotope and microfossil analyses on multiple cores from salt marshes and protected, intertidal basins with bedrock sills in southwestern and northeaster Norway. New SLIPs from these sensitive and diverse coastal regions of Norway help to constrain RSL change during the last 2000 years, and provide a basis for improving quantitative projections of future RSL change.

A Holocene shell midden record of marine radiocarbon reservoir and nitrogen isotope changes from northernmost Chile: implications for upwelling and past human occupation

Prof. Claudio Latorre [1], ***Dr. Chris Harrod*** [2], ***Mrs. Susana Monsalve*** [3], ***Ms. Tania V. Villalón*** [4], ***Dr. Calogero Santoro*** [5]

1. *Pontificia Universidad Católica de Chile,* ***2.*** *Universidad de Antofagasta,* ***3.*** *Instituto de Alta Investigación, Universidad de Tarapacá,* ***4.*** *Departamento de Ecología, Pontificia Universidad Católica de Chile,* ***5.*** *Universidad de Tarapaca*

Shell middens are prehistoric human refuse mounds found throughout coastal northernmost Chile (18-20ºS) where they span more than 9000 years. By radiocarbon dating samples of marine and terrestrial origin along a given stratigraphic horizon from multiple shell middens, estimates of marine reservoir departures from the global marine 14C calibration curve (ΔR) can be obtained. These departures are mostly due to shifts in upwelling intensity as different water masses have different apparent ^{14}C ages. Our well‐replicated ΔR chronology is based on 192 ^{14}C AMS dates from multiple coeval shell middens along 100 km of coastline and spans more than 9,000 years. ΔR values were remarkably stable from 9.2 – 6.7 ka implying very stable upwelling and highly productive marine ecosystems. These values are highly variable between 6.5 – 4.6 ka, with a prominent and well-replicated negative excursion between 5.4 – 5.1 ka. Values increased until 4.3 ka and then remained stable until 3.5 ka. Large fluctuations resumed between 2.9 – 2.0 ka with values during the last 1.5 ka remaining stable and in good agreement with pre-bomb ΔR estimates. We further measured δ^{15}N from 810 samples of sessile bivalves (mytilids) from one of our shell-midden sites (Caleta Vitor) to assess the impact of past shifts of upwelling on nitrogen cycling. Early Holocene sites have high δ^{15}N values (18-34 ‰) whereas Middle Holocene shell middens show much lower values (averaging 17.25 ‰). Starting at 3.5 ka, bivalves show a large 5-6 ‰ drop in δ^{15}N values after which they averaged c. 21 ‰ until 2.1 ka. A shell midden dated to c. 0.5 ka shows lower δ^{15}N values averaging c. 14 ‰ coeval with ΔR values close to 0 ^{14}C yrs BP. Taken together, our record implies that stable upwelling during the Early and Late Holocene was interrupted by strong millennial-scale environmental fluctuations during the Middle to Late Holocene. Such variability is linked to changes in the long‐term behavior of El Niño‐Southern Oscillation (ENSO) and the South Pacific High (SPH) and had profound consequences for past coastal populations which saw major collapses in northern Chile during the Middle to Late Holocene.

Reconstructing Holocene fire records using dune foot-slope deposits at the Cooloola Sand Mass, Australia

Dr. Nicholas Patton [1], Prof. James Shulmeister [1], Dr. Quan Hua [2], Prof. Peter Almond [3], Prof. Tammy Rittenour [4], Ms. Johanna Hanson [1], Mr. Aloysius Grealy [5], Mr. Jack Gilroy [5], Dr. Daniel Ellerton [6]

1. University of Canterbury, 2. ANSTO, 3. Lincoln University, 4. Utah State University, 5. The University of Queensland, 6. Stockholm University

In this study, we assess charcoal records from aeolian deposits within the Cooloola Sand Mass, a sub-tropical coastal-dune system in eastern Australia, to determine whether they can be used as a proxy for Holocene fire history. We excavate four profiles in depositional wedges at the base of dune slipfaces (foot-slope deposits) and calculate charcoal concentrations for three size classes (180-250 µm, 250-355 µm, and 355 µm-2 mm) at predetermined depth intervals. Age-depth models are constructed for each profile using radiocarbon measurements (n=46) and basal OSL dates (n=4). All records appear intact with little evidence of post-depositional mixing as demonstrated by minimal age-reversals and consistent trends in charcoal concentration and accumulation rates (CHAR) amongst size classes. Aggregating all four records, we generate a ca 7 cal ka BP terrestrial fire history that depicts distinct peaks representing periods of increased local fire activity: ca. < 0.1, 1.1-0.3, 2.2-1.8, 3.6-2.6, and 6.7-5.3 cal. ka BP. Our findings parallel regional records and highlight their utility as an ecological and geomorphological record that is both spatially continuous and abundant across the landscape. As dune fields are much more common than wetlands and lakes in semi-arid and arid areas, these deposits have the potential to increase the spatial resolution of fire records globally.

Session 147: Sea-Level, Ice-Sheet, and Earth system evolution: understanding the past to constrain the future

One or two peaks? Rates of Holocene sea level rise using sea-level data from the southern north sea.

Dr. Sarah L Bradley [1]***, Mr. Bas Blank*** [2]***, Dr. Freek Busschers*** [3]***, Dr. Kim M. Cohen*** [4]***, Dr. Marc Hijma*** [5]***, Dr. Wouter van der Wal*** [2]

1. *Department of Geography, University of Sheffield,* ***2.*** *Faculty of Aerospace and Engineering, Delft University of Technology, Delft, Netherlands.,* ***3.*** *TNO Geological Survey of the Netherlands, Utrecht, Netherlands,* ***4.*** *Dept. of Physical Geography, Faculty of Geosciences, Utrecht University,* ***5.*** *Deltares Research Institute, Department of Applied Geology and Geophysics, Utrecht, Netherlands*

In contrast to the numerous land-based collections of Holocene relative sea level (RSL) data, there are relatively few early Holocene records that are continuous and from the offshore area. This will impact on how well the rates of early Holocene sea-level rise are constrained, which is key to understanding early Holocene deglaciation patterns and future rates of sea-level change. We addressed this gap by conducting a dedicated offshore data-collection campaign across the southern North Sea. This area has evolved from a large continental shelf to the current submerged landscape as global sea level rose driven by the deglaciation of the major continental ice sheets and the subsidence of the Eurasian ice sheet (EuIS) forebulge

Our new and updated dataset of 88 sea level index points and 78 limiting points, extends from 13 ka to 3 ka BP and is corrected for both paleo-tidal changes and ongoing background tectonic subsidence. The combined dataset show that RSL rose steadily at a rate of ~ 8 mm/yr, with two pronounced peaks of ~15 mm/yr at 9.3 ka and 8.2 ka BP.

To understand what was controlling these rapid peaks in sea level rise, we used both a 1D and 3D GIA model combined with two alternative reconstructions for the EuIS complex. We found that across the study region the spatial variation in RSL was controlled by the EuIS, contributing over 50% of the total signal in the central North Sea, increasing to over 80% close to the current coastline. Removing the predicted EuIS signal from our new dataset we will provide new estimates of the rates of Holocene sea level rise and the possible existing of two periods of rapid sea level rise during the Holocene.

Noisy Input Generalised Additive Models for RSL Change along the East Coast of North America

Ms. Maeve Upton [1], ***Prof. Andrew Parnell*** [1], ***Dr. Niamh Cahill*** [1], ***Dr. Andrew Kemp*** [2], ***Dr. Gerard McCarthy*** [1]

1. Maynooth University, 2. Tufts University

The 2021 Intergovernmental Panel on Climate Change report highlighted how rates of sea level rise are the fastest in at least the last 3000 years. As a result, it is important to understand historical sea level trends at a regional and local level in order to comprehend the drivers of sea level change and the potential impacts. The influence of different sea level drivers, e.g thermal expansion, ocean dynamics and glacial isostatic adjustment (GIA), has changed throughout time and space. Therefore, a useful statistical model requires both flexibility in time and space and have the capability to examine these separate drivers, whilst taking account of uncertainty. Our project aims to develop statistical models to examine historic sea level changes for North America's and Ireland's Atlantic Coast. For our models, we utilise sea-level proxy data and tide gauge data which provide relative sea level estimates with uncertainty. The statistical approach employed is that of extensions of Generalised Additive Models (GAMs), which allow separate components of sea level to be modelled individually and efficiently and for smooth rates of change to be calculated.

The model is built in a Bayesian framework which allows for external prior information to constrain the evolution of sea level change over space and time. The proxy data is collected from salt-marsh sediment cores and dated using biological and geochemical sea level indicators. Additional tide gauge data is taken from the Permanent Service for Mean Sea Level online. Uncertainty in dating is extremely important when using proxy records and is accounted for using the Noisy Input uncertainty method.

By combining statistical models, proxy and tidal gauge data, our results have shown that current sea level along North America's east coast is the highest it has been in at least the last 15 centuries. The GAMs have the capability of examining the different drivers of RSL change e.g. GIA, local factors and barystatic influences. Our models have demonstrated that GIA was the main driver of RSL change along North America's Atlantic coast, until the 20th century when a sharp rise in rates of sea level change can be seen.

Multi-evidences of MIS 3 marine deposits from Baeksu tidal flats, southwest coast of Korea suggest much higher relative sea-level than previously we thought

Ms. Serin Lim [1], ***Dr. Jin Cheul Kim*** [2], ***Dr. DhongIl Lim*** [3], ***Dr. Yongmi Kim*** [2], ***Prof. Tae Soo CHANG*** [1]

1. *Faculty of Earth and Environmental Sciences, Chonnam National University,* ***2.*** *Korea Institute of Geoscience and Mineral Resources (KIGAM),* ***3.*** *Library of Marine Samples, Korea Institute of Ocean Science and Technology*

Reconstructing of sea-level position during Marine Isotope Stage 3 (MIS 3, 29-57kyrs BP) is challenging due to the highly dynamic climate conditions, as recorded in Greenland and Antarctic ice cores. Global mean sea level (GMSL) has been documented to vary in the range of -55 to -80 m at 44 ka. However, the location of the GMSL at that time is still controversial due to a lack of data, especially in continental marginal seas. More recently, some works suggest that GMSL during MIS 3 reached -35 to -40 m based on analysis of sediment core records with the revised ICE-5G ice history and GIA model, implying that the sea level during MIS 3 may be much higher than previously documented. In this regard, we analyzed two borehole cores from the Baeksu tidal flats, the southwest coast of Korea (the eastern Yellow Sea) to constrain the sea level changes during MIS 3. Sedimentary facies of the cores were analyzed with geochemical and micropaleontological compositions, providing information for better understanding the depositional environments of each facies. Age models of the cores was reconstructed by OSL dating. Our results reveal that the tidal deposits are stratigraphically composed of 1) basal fluvial gravels, 2) mudflat/saltmarsh (MIS 5e), 3) saltmarsh/mudflat (MIS 5a/b), 4) gravelly spit/mudflat (MIS 3), 5) tidal flat/intertidal shoreface/sandy beach deposits (Holocene) in ascending order. They are grouped into two sequences by subaerially exposed, oxidized layer, with an unconformity-bounded subsequence. Conclusively, three transgressive depositions are recorded, but one regression deposition is only represented by basal gravel lag and oxidized layer. Notably, ichnofacies and the heterotrophic dinoflagellate assemblages highlight that the mud deposition, corresponding to MIS 3, was accumulated in tidal environments. Considering constant tidal range and previous GIA model results during the last Pleistocene in the eastern Yellow Sea, the sea level during MIS 3 was likely in the range of -14 to -18 m. However, the actual cause of such higher sea-level remains still under discussion. In addition, records of MIS 3 deposition in the sediment cores from additional locations will be necessary for defining the high frequency of sea level curve.

Distinction of relative sea level driving forces in the Southern Adriatic during the Late Holocene

Prof. Sanja Faivre [1]***, Prof. Tatjana Bakran-Petricioli*** [2]***, Prof. Marijan Herak*** [3]***, Mrs. Jadranka Barešić*** [4]***, Prof. Davor Horvatić*** [5]

The relative sea-level (RSL) change is a sum of effects of processes acting on different scales. The high-resolution study of RSL change based on *Lithophyllum* rims allows us to distinguish local from regional and global contributions. The studied islands in the Southern Adriatic are part of Elafiti island group. They are located near the external front of the Dinarides where seismicity in Croatia attains one of the highest levels. Studying the RSL markers: *Lithophyllum* rims, *Lithophaga lithophaga* borehole upper limits and tidal notches we identified two uplifted palaeoshorelines, 60-90 cm and 25-40 cm above MSL. The high-resolution geochronology built on algal rims enabled the distinction of coseismic uplift events from subsidence periods. As a result, we provide new, field-based reconstruction of palaeoearthquakes and describe spatial patterns of differential uplift, providing new data on active tectonics at the Elafiti islands.

Two major seismically triggered uplift events have been differentiated at the Elafiti related to the Pelješac-Dubrovnik fault zone pointing to repeated earthquakes of magnitudes exceeding Mw = 6.5. The earlier, older events, caused larger displacements (60-80 cm) related to 4th to 6th century AD and 750-1100 AD earthquakes, while the later, younger events, revealed on average lower displacements (40-55 cm) corresponding to the 1520 AD quake and the 1667 Dubrovnik earthquake.

The distinction of local coseismic displacements of RSL change together with the obtained regional glacio- and hydro-isostatic adjustment estimates of 0.34 mm/yr allow us to approach the global contribution. The global sea-level component revealed low amplitude variations <±0.20 m corresponding to previous observations.

The RSL change generally vary between of 0.3 to 0.4 mm/yr while after 1800 cal AD the rates of RSL change increased up to 1.4 mm/yr, confirming the acceleration of RSL rise. This high-resolution study allows us to better approach the driving mechanisms of RSL change, thus providing new insight into the late Holocene sea-level history of the southern Adriatic, which is of utmost importance for the improvement of future predictions and for seismic hazard assessment. This research was supported by Croatian Science Foundation HRZZ-IP-2019-04-9445–Relative sea-level change and climate change along the eastern Adriatic coast–SEALeveL.

The use of the Last the Glacial Maximum to improve projections of future Greenland

Dr. Ruza Ivanovic [1], ***Dr. Lauren J. Gregoire*** [1], ***Dr. Jonathan Owen*** [1], ***Dr. Sam Sherriff-Tadano*** [1], ***Dr. Tamsin Edwards*** [2], ***Dr. Charlotte Lang*** [3], ***Dr. Niall Gandy*** [4], ***Ms. Violet Patterson*** [5], ***Dr. Robin Smith*** [3], ***Prof. Jonathan Gregory*** [3], ***Dr. Lachlan Astfalck*** [6]

Climate and ice sheets are projected to change substantially in future centuries, evolving beyond anything observed in the recent past. Yet, models used for projecting future ice sheet behaviour (and associated sea level rise) are often only calibrated for modern climate conditions. This raises the fundamental question: do our models have sufficient flexibility and core predictive skill to simulate the out-of-sample conditions of the future?

When applying a version of the recently developed FAMOUS-ice coupled climate-ice sheet model to the Last Glacial Maximum, the simulated North American ice sheet collapsed. The model had been calibrated to reproduce modern ice well, but our subsequent palaeo application revealed unexpected behaviours when simulating very different climate conditions from today.

Here, we present a large ensemble of several hundred coupled climate-ice sheet simulations of modern and future Greenland, and the Last Glacial Maximum North American ice sheets. With this ensemble, we explore the influence of uncertainty in the model inputs (parameter values). We evaluate model performance against a new suite of metrics for characterising ice sheet and climate conditions at the Last Glacial Maximum and present, and we identify versions of the model that optimise model performance in both time periods. With this improved model, we project future ice sheet evolution (RCP8.5), and examine the relationship between past, present and future ice sheets with each model configuration in order to understand how constraints on past ice sheets influence future projections.

Information from the past may not narrow down the uncertainty in our future projections, but the increased flexibility and predictive skill of models that have been assessed against palaeo data produce more robust projections with higher confidence in the results.

New constraints on Late Pleistocene relative sea-level changes in northwest Scotland- Beach to Basins: GIA Feedbacks

Dr. Louise Best [1], **Prof. Alexander Simms** [2], **Dr. Tom Bradwell** [3], **Dr. Regina DeWitt** [4], **Prof. Jeremy Lloyd** [5], **Dr. Sarah L Bradley** [6], **Dr. Jeremy Ely** [7], **Dr. Samuel Kachuck** [8], **Dr. David Small** [5]

Reconstruction of past ice sheet behaviour and relative sea-level changes provide important analogues of how contemporary systems may respond to climate change. Due to the presence of the British and Irish Ice Sheet and the Minch Ice Stream during the Last Glacial Maximum, the northwest of Scotland provides critical records for testing models of the interplay between ice-sheet retreat, glacio-isostatic adjustment, and relative sea-level changes. We provide new constraints on Late Pleistocene (~17-14 ka) relative sea-level limits and changes from raised beaches and isolation basins along the former Minch Ice Stream. These features provide ages of the first ice-free conditions and the oldest relative sea-level records following the last glacial maximum. Such data are key to improving GIA models for this region, whose estimates of relative sea-level change deviate by as much as 100 m during this time period. By improving the understanding of sea-level change along the former ice stream, we can also investigate the importance of sea-level feedbacks to marine-based ice sheets during their retreat, providing insights into potential behaviours of contemporary marine-based ice sheets.

5000 years of relative sea-level change in New Jersey: Quantifying the roles of sediment compaction and glacial isostatic adjustment

Dr. Jennifer Walker [1], ***Dr. Tanghua Li*** [2], ***Prof. Matthew Brain*** [3], ***Dr. Timothy Shaw*** [4], ***Dr. Niamh Cahill*** [5], ***Prof. Don Barber*** [6], ***Prof. Robert Kopp*** [1], ***Prof. Adam Switzer*** [4], ***Prof. Benjamin Horton*** [4]

__1.__ Department of Earth and Planetary Sciences, Rutgers University, NJ, USA., __2.__ Earth Observatory of Singapore, Nanyang Technological University, Singapore, Singapore, __3.__ Durham University, __4.__ Earth Observatory of Singapore, Nanyang Technological University Singapore, __5.__ Maynooth University, __6.__ Bryn Mawr College

Stratigraphic data from salt marshes provide accurate reconstructions of Holocene relative sea-level (RSL) change and necessary constraints to models of glacial isostatic adjustment (GIA), the dominant driver of late Holocene RSL rise along the U.S. mid-Atlantic coast. However, salt-marsh sediments are prone to compaction, which can result in an overestimation in the rate of reconstructed RSL rise. RSL reconstructions must consider the contribution of local processes such as sediment compaction to accurately decipher the driving processes.

Here, we compare compacted and compaction-free mid- to late-Holocene RSL records from a salt marsh in southern New Jersey. One record uses basal peats that have minimal sediment compaction because they overlie an incompressible substrate. Ages of the 14 basal sea-level index points range from 1211 ± 56 to 4414 ± 112 years BP. Using a spatiotemporal statistical model, the basal peat record shows that RSL rose 8.6 m at an average rate of 1.7 ± 0.1 mm/yr from 5000 years BP to present. The second record utilizes a continuous ~9 m, 5000 year-long, compaction-prone core consisting of peats and muds. We used a geotechnical model to estimate post-depositional lowering (PDL) resulting from sediment compaction and found a maximum PDL estimate of ~0.65 m in the middle of the core at ~5.5 m depth. Initial results from radiocarbon dates of the continuous core show an offset up to ~1 m compared to the basal samples, highlighting the influence of sediment compaction within deep continuous sequences of salt-marsh sediment.

Our compaction-free record also allows us to compare RSL changes with an ensemble of 1D (laterally homogenous) and site-specific 3D (laterally heterogeneous) GIA models. The models tend to overestimate the magnitude of RSL rise over the last 5000 years and do not reproduce the linear trend revealed by the RSL data. These discrepancies may imply the ice-equivalent sea-level signal in the ice models needs to be refined. The continued divergence of RSL data and GIA models highlights the importance of testing a wide array of ice-model and viscosity-model parameters to simulate GIA histories that more precisely fit site-specific RSL data along the U.S. mid-Atlantic coast.

Simulating Antarctic Ice Sheet evolution from the mid-Pliocene to present day and beyond

Mr. Christian Wirths [1], ***Dr. Johannes Sutter*** [1], ***Prof. Thomas Stocker*** [1]

1. *Climate and Environmental Physics and Oeschger Centre for Climate Change Research, University of Bern, Switzerland*

The retreat of the Greenland and the Antarctic ice sheet (AIS) and the resulting sea level rise is one of the major long-term challenges posed to humanity by anthropocentric climate change. While Antarctic ice masses would increase sea level up to ca 58 meters when completely melted, the response of the ice sheet to drastic changes in the climate system is still very uncertain. Especially, during the mid-Pleistocene Transition (MPT) the role of Antarctica both as a driver and responder to climate change is unknown. Thus, and in expectation of the results of the Beyond EPICA Oldest Ice project, it is important to gain a better understanding about the role of Antarctica in and on the climate system and sea level change throughout the Pleistocene.

Here, we use the Parallel Ice Sheet Model (PISM) to simulate the transient evolution of the AIS from the mid-Pliocene, through the MPT, to present day and into the future. We force the model with a climate matrix approach which interpolates between individual climate model snapshots from PMIP4 following different climatic forcing time series. The climate matrix approach enables us to account for the main feedbacks relevant for ice sheets as well as giving the opportunity to investigate the response of Antarctica to individual forcings (e.g., orbital, CO2, sea level).

With our study we aim to better understand the evolution of Antarctica during the Pleistocene and how it changed during the MPT. Further, we want to clarify the influence of the individual forcings and related processes onto those changes. Findings from this study will not only help to improve our understanding of past sea level changes but also inform on potential Antarctic trajectories.

Underestimated vertical land motion component in sea-level projections – a case study from the Oka estuary, northern Spain

Dr. Tanghua Li [1]***, Dr. Ane García-Artola*** [2]***, Dr. Jennifer Walker*** [3]***, Prof. Alejandro Cearreta*** [4]***, Prof. Benjamin Horton*** [5]

Basque Centre for Climate Change, Leioa, Spain, __5.__ Earth Observatory of Singapore, Nanyang Technological University Singapore. & Asian School of the Environment, Nanyang Technological University, Singapore, Singapore.

Long-term trends of vertical land motion (VLM) are an important component in relative sea-level (RSL) projections, especially at regional to local scales and over the short to medium term. However, VLM is difficult to derive because of a lack of long-term instrumental records (e.g., GNSS, tide gauge) and their sparse distribution globally. Geological data reveal RSL histories over thousands of years and their comparison with glacial isostatic adjustment (GIA) models can isolate the long-term VLM signal. The geological VLM signal can be validated with nearby GNSS data and incorporated into sea-level projections.

Here, we present a case study from the Oka estuary, northern Spain. We apply two GIA models for the Atlantic coast of Europe with different ice model inputs (ICE-6G_C and ANU-ICE) but the same 3D Earth model. Both models fit well with the late Holocene RSL data along the Atlantic coast of Europe, with misfit statistics < 1.5, except the Oka estuary region, where both models show notable misfits with misfit statistics > 3.8. The significant misfits of both models in the Oka estuary region are indicative of local subsidence during the late Holocene. Moreover, the nearby GPS (station SCOA) with records > 17 years shows a VLM rate of -1.16 0.53 mm/yr compared to -0.15 0.40 mm/yr to -2.48 0.37 mm/yr elsewhere along the Atlantic coast of Europe. The VLM rate of SCOA accounts for the misfit between the GIA models and RSL data in the late Holocene. The VLM rate incorporated in IPCC AR6 projections in Oka estuary is ~0.35 mm/yr, which is only ~30% of the derived long-term VLM rate of -1.16 0.53 mm/yr, underestimating the projected sea-level rise rate by 17 - 25% by 2030 and 12 - 18% by 2050 under the five Shared Socioeconomic Pathway (SSP) scenarios (SSP1-1.9, SSP1-2.6, SSP2-4.5, SSP3-7.0, SSP5-8.5).

Multiproxy late-Holocene sea-level reconstructions along the South African coastline

Dr. Lauren Pretorius [1]***, Dr. Sarah Woodroffe*** [1]***, Dr. Kelly Kirsten*** [2]***, Dr. Jemma M. Finch*** [3]

1. *Durham University,* ***2.*** *Department of Geological Sciences, University of Cape Town, Cape Town,* ***3.*** *School of Agricultural, Earth and Environmental Sciences, University of KwaZulu-Natal, Private Bag X01, Scottsville, 3209*

Global mean sea level is predicted to rise by up to 0.8 m by the year 2100 according to the latest IPCC report. The southern African coastline is vulnerable to sea level rise due to a lack of detailed understanding of past sea-level changes and coastal evolution and how to use this knowledge to adapt to future sea-level rise. To understand how South African coastlines will respond to future sea level rise and mitigate appropriately using risk-based strategies, it is important to understand sea level behaviour and coastal evolution from the recent past. In South Africa, sea level records from the Holocene have low spatio-temporal resolution due to the poor preservation of appropriate sea level proxies and lower-precision radiocarbon dating techniques previously available. Existing records are discontinuous with large vertical error, making these records unreliable analogues for sea level change in the near future. We explore new methods of RSL reconstruction using a multiproxy approach to produce high precision RSL reconstructions (+/- ~10 cm or less) over the last two millennia from temperate saltmarshes. We combine new modern diatom assemblage data with existing foraminifera data from two South African salt marsh sites, the Berg and Kromme estuaries, to build the first multiproxy regional Bayesian Transfer function for southern African sea-level reconstruction. We compare model performance and analogue closeness of single, multiproxy, regional and site-specific transfer function methods to achieve the best balance in performance and precision. We apply the best performing transfer function to fossil foraminifera and diatom assemblage data to produce a sea level curve for the region. This reconstruction helps to constrain how much higher RSL has been than present during the late Holocene, thus providing insight into appropriate mitigatory measures that the South African coastal authorities can employ as part of a sea level adaptation strategy.

Reconstruction of relative sea-level change using phreatic overgrowths on speleothems in the Kvarner area (Croatia)

Prof. Nina Lončar [1]***, Prof. Sanja Faivre*** [2]***, Dr. Blaž Miklavič*** [3]***, Prof. Bogdan P. Onac*** [4]***, Dr. Jadranka Barešić*** [5]***, Dr. Victor Polyak*** [6]***, Prof. Yemane Asmerom*** [6]

1. *University of Zadar, Department of Geography,* ***2.*** *1University of Zagreb, Faculty of Science, Department of Geography,,* ***3.*** *University of Guam, Water and Environmental Research Institute,* ***4.*** *University of South Florida,* ***5.*** *Ruđer Bošković Institute, Radiocarbon Laboratory,* ***6.*** *University of New Mexico*

The research of relative sea-level change along the eastern Adriatic is conducted within the SEALeveL project (HRZZ-IP-2019-04-9445) funded by Croatian Science Foundation. We present results of Holocene relative sea-level changes in the Kvarner area obtained from the first phreatic overgrowths on speleothems (POS) discovered in Croatia. Initially discovered in Mallorca, POS has been found and used as a sea-level marker in only a few world locations. Nonetheless, these researches confirmed that POS is a reliable sea-level index point. POS are carbonate incrustations that form around submerged speleothems and cave walls in coastal caves where sea-level controls the groundwater level. It precipitates at the very top of the water column, i.e. at the water-air interface, their occurrence is restricted to a limited zone of tide-induced groundwater level variation. Since their occurrence directly identifies the height of the sea-level at the time of the carbonate deposition which can be accurately dated using radiometric methods. Our POS samples were collected by SCUBA cave diving in a submerged part of Medvjeđa špilja Cave on Lošinj island (Kvarner region) at several depths between ~1 and 2 m, below mean sea level. XRF and XRD analyses revealed fibrous calcite resembling aragonite. For dating, both the U-Th and radiocarbon methods were used providing insight into Holocene relative sea-level changes. At 3 ka BP the relative sea level was around 1 m below the actual mean sea level. The results from Mali Lošinj island are further integrated into the composite 5000 yrs. relative sea-level curve reconstructed from various markers from the western and eastern coast of Istria.

Coastal indicators of sea level changes in the northwest Africa from the Upper Pleistocene to the Holocene

Dr. Driss Chahid [1] ***, Prof. Matteo Vacchi*** [2]***, Prof. Larbi Boudad*** [1]***, Prof. Marta Pappalardo*** [3]***, Dr. Arnaud Lenoble*** [4]

Relict evidence of sedimentary and geomorphic features, such as marine notches, coastal caves, and beach deposits represent very good indicators to infer climatically- or tectonically-induced variation of the sea-level trough time. Along the Atlantic coast of Morocco, the raised occurrence of these morphological features was often correlated with the paleo-shorelines formed during the last interglacial period (Marine Isotopic Stage 5, MIS5). However, this area was also characterized by a mid-Holocene highstand (about 6 to 4 ka BP) of isostatic origin. For this reason, it is presently complex to clearly define the ages of the paleo-shorelines in nortwestern Morocco and disentangle between Holocene and last Interglacial sea-level still stands. In addition, the sea-level framework is complicated by the late Quaternary tectonic activity which resulted in variable vertical motions of the coast.

Here we present an updated assessment of the altimetric and chronological variability of the paleo-shorelines along the Morocco coast. In particular, we coupled new data derived from geomorphological and sedimentary analysis performed in the Rabat-Témara area which were compared and contrasted with the already available data along the mid-norther Morocco coast. The results of this analysis provided fresh insights into the altimetric variability of the different RSL stillstands since the Late Pleistocene.

Evidence of sea level changes in Southern Mozambique during the Holocene

Dr. Sandra Mucavele [1], ***Dr. Elin Norström*** [2]

1. *Department of Geology, Faculty of Scieences, Eduardo Mondlane University,* ***2.*** *Department of Physical Geography, Stockholm University*

Palaeo sea-level changes have been reconstructed from diatom stratigraphy on sediment cores from southern Mozambique, dated by radiocarbon AMS method on shells and bulk sediments. Two sediment sequences were analysed. One was retrieved in Lake Lúngue located c. 30 km north of Xai Xai municipality and 5 km from Malehice Locality and has an outlet toward the Limpopo River flood-plain on its western side. The other core was collected in Macassa Bay, located in Inhambane Province c. 25 km south from Vilankulos municipality. Bulk dates from Macassa Bay displayed a bottom age of c. 4650 BC (c. 6650 cal yrs BP) while shell dates performed on the gastropod *Mellanoides tuberculatta* from Lake Lúngue indicated that the bottom of the core is dated to AD 740 (1210 cal yrs BP).

In both sequences diatom results are interpreted to represent sea-level and climate proxies. Two periods of high sea-levels stand were identified that occurs at c. 4650-4350 BC (6600-6300 cal yrs BP) and c. 2650 BC-AD 1050 (4600-1000 cal yrs BP) in Macassa Bay. The former period is concordant with the global sea-level transgression during the Holocene Climatic Optimum. The site was under freshwater influences between these two periods c. 4350-2650 BC (6300-4600 cal yrs BP). Terrestrial conditions were established in Macassa Bay probably related to to sea-level lowering, sediment input and organic productivity increase. In Lake Lúngue the bottom of the sequence up to AD 910 (1040 cal yrs BP), followed by non-permanent connection to the open sea from AD 910 – 1130 (1040-1130 cal yrs BP), characterized by sporadic incursions of the sea. Marine influences in Lake Lúngue are inferred to have ceased between AD 1130 (820 cal yrs BP) and AD 1360 (590 cal yrs BP). The sea-levels reconstructions from Macassa Bay and Lake Lúngue are in accordance with sea-level curves from SW African coastline (Compton, 2006), but slows less agreement of records from NE coastline of South Africa (Ramsay & Cooper, 2002). The non-phasing could partially be attributed to dating uncertainties.

Key words:

Sea-level diatoms radiocarbon dating Macassa bay Lake Lúngue

New constraints for an early Holocene relative sea-level lowstand from southwest Norway

Dr. Thomas Lakeman [1]***, Dr. Anders Romundset*** [1]***, Dr. Matthew Simpson*** [2]***, Dr. Martin Klug*** [1]

1. *Geological Survey of Norway,* ***2.*** *Norwegian Mapping Authority (Statens Kartverket)*

New data from submerged bedrock basins spanning more than 50 km of coastal southwest Norway (between Farsund and Tregde), place new constraints on the age and depth of an early Holocene lowstand. Submarine basin stratigraphy, determined using subbottom echosounder data and sediment cores, includes buried lacustrine facies, documenting sea-level regression to depths of ca. 10 m below modern sea level. New postglacial relative sea-level histories from the region constrain the age of the lowstand to between about 9 and 11 ka BP. Ongoing retrieval of sediment cores, geochronological and paleoenvironmental analyses, and stratigraphic mapping will further delimit the depth and timing of the lowstand in the study area. Of particular interest are regional variations in i) the duration of the lowstand, as well as ii) the rates and onset of the Tapes transgression. New geophysical modelling, utilizing an expanded database of sea-level index points, is aiming to further clarify the precise origins of these sea-level trends, and includes new estimates of the magnitude and uncertainty of glacioisostatic adjustments following the last glaciation. The results provide important new benchmarks for coastal archaeology, Holocene paleoenvironmental change, and geodynamics.

Insights into Holocene relative sea-level changes in the southern North Sea using SLIPs and an improved microfauna-based transfer function

1. *Geological Survey of Belgium, Royal Belgian Institute of Natural Sciences, Brussels, Belgium,* ***2.*** *Lower Saxony Institute for Historical Coastal Research, Wilhelmshaven,* ***3.*** *Marine Research Department, Senckenberg am Meer, Wilhelmshaven,* ***4.*** *Institute of Geosciences, Friedrich Schiller University Jena, Jena, Germany,* ***5.*** *Marine Research Department, Senckenberg am Meer, Wilhelmshaven, Germany,* ***6.*** *Institute of Geography, University of Cologne,* ***7.*** *Energy, Environment & Society, University of Dundee, Nethergate, Dundee, Scotland,* ***8.*** *Renard Centre of Marine Geology, Department of Geology, Ghent University, Ghent,,* ***9.*** *Department of Earth Sciences, University of Coimbra, Coimbra, Portugal,* ***10.*** *Institute of Geography, Heidelberg University, Heidelberg, Germany*

Detailed reconstructions of relative sea-level (RSL) histories and their controlling mechanisms are crucial in order to manage coastal-protection challenges, especially in light of global warming and rising RSL. This study contributes to unravelling Holocene RSL change on the East Frisian North Sea coast in high resolution with a new approach for the German Bight. For the first time, a RSL transfer function (vertical error: 29.7 cm ~11% of the mean tidal range) based on a combined training set of benthic foraminifers and ostracods from the back-barrier tidal basin of Spiekeroog is applied to the Holocene record of the back-barrier tidal basin of Norderney. A transfer function is an empirically derived equation, which relates the elevation of modern surface samples to the relative species frequency of modern microfaunal associations. If applied to the Holocene record, the palaeo-water depth is determined from the relative species frequency of fossil associations, providing sea-level index points (SLIPs) with a direct relation to the RSL.

The resulting RSL curve for the tidal basin of Norderney shows a deceleration in RSL rise between 6000 and 5000 cal BP. The smallest possible error envelope (~1m) is based on the good suitability of salt-marsh layers between 5000 and 4000 cal BP. The presented RSL curve provides an approach towards the closure of the common data gap of peat-based curves for the southern North Sea related to a lack of basal peats in the youngest age range, and verifies regional differences in glacial isostatic adjustment.

This approach will be applied to further areas of the North Sea, starting with the Shetland Islands, where RSL data and successful reconstructions are barely existing. This will allow to more accurately assess run-up heights of palaeo-tsunamis that are recorded onshore and offshore of the Shetland Islands (NORSEAT Project).

Session 148: Climate-glaciers interactions in mid-latitude mountains

The Little Ice Age over the Western Himalaya, India

Dr. Vikram Singh [1], *Dr. Krishna G. Misra* [2], *Prof. Arun Deo Singh* [3], *Dr. R R Yadav* [4], *Dr. Akhilesh Kumar Yadava* [2]

1. *Department of Geology, University of Lucknow, Lucknow, Uttar Pradesh, India,* **2.** *Birbal Sahni Institute of Palaeosciences, 53-University Road, Lucknow-226007, India,* **3.** *Department of Geology, Banaras Hindu University, Varanasi-221005,* **4.** *Wadia Institute of Himalayan Geology, 33 GMS Road, Dehradun 248001,*

The Little Ice Age (LIA) and the Medieval Warm Period (MWP) are the major climatic episodes of the last millennium. However, the exact timing and duration of these climatic episodes over different continents are spatially varied. The LIA is a period of glacial expansion when temperature significantly dropped in the Northern Hemisphere. However, limited proxy records restrict our understanding to identify the hydrological impact of the LIA over the Himalaya. Here, we investigated a network of sixteen moisture-responsive tree-ring chronologies from Jammu and Kashmir, northwest Himalaya to evaluate the spatial and temporal span of the LIA in the region. The tree-ring-width chronologies of Himalayan cedar and neoza pine were used to develop the annual (previous year October to current year September) precipitation record for the Jammu and Kashmir region. The 635 years (AD 1383-2017) precipitation record revealed three distinct centennial scale phases; early (AD 1383-1650s), middle (AD 1650s-1850s), and late (AD 1850s-2017). Among the three phases, the middle phase reflected stable precipitation with prolonged pluvial conditions, which suggests the LIA influence during AD 1650s-1850s over the western Himalaya. However, the early and late phases of the reconstruction record high-magnitude droughts, which do not endorse the LIA impact over the western Himalaya during these periods. The observed LIA influence was tested using independently developed precipitation, drought, and river flow records of the western Himalaya. The reconstruction skills and its large-scale teleconnections were also explored using the hydrological records from Central Asia. The hydrological records deduced from tree-rings, caves, ice cores, and lakes over the Himalaya and Central Asia are in accordance with identified pluvial LIA conditions over the western Himalaya, while observed high-magnitude droughts in early and late phases do not support that the north-west Himalaya witnessed LIA influence before AD 1650s.

"Weißseesptize glacier (Central Eastern Alps): a 6000 thousand years paleoclimatic and paleoenvironmental reconstruction"

For a long time, alpine ice core research has focused on a few suitable drilling sites in the Western European Alps, until the discovery of the Ötztal ice man made researchers aware of the millennial-old ice preservation even at lower altitudes glaciers in the Eastern alpine sector. Indeed, despite their highly sensitive mass balance to climate change, glaciers in the Eastern Alps may offer long records and a broad range of proxies, including stable water isotopes and various inorganic and organic impurities, as in the case of the Weißseespitze (WSS) summit ice cap (Central Eastern Alps, 3500 m a.s.l.), where about 6000 years appear locked into about 10 m of ice. Therefore, in March 2019, a group of scientists led by Andrea Fischer carried out a mission on the Weißseespitze glacier to drill two parallel ice cores down to bedrock, and potentially save around 6.7 ± 0.4 ka cal, from a surface probably older than 1963. One of those shallow ice cores was then analyzed at Ca' Foscari (UniVe), extracting levoglucosan, insoluble dust particles and conductivity data through the new CFA system, achieving a high-spatial resolution (down to 1 cm for levoglucosan). In addition, water stable isotopes ($\delta^{18}O$, δD), major ions (Na^+, Cl^-, Br^-, K^+, Mg^{2+}, Ca^{2+}, NO_3^{2-}, SO_4^{2-}, NH_4^+, MSA^-), carboxylic acids (acetic, glycolic, oxalic, malonic, succinic, glutaric), and trace elements (^{7}Li, ^{9}Be, ^{51}V, ^{52}Cr, ^{55}Mn, ^{59}Co, ^{60}Ni, ^{63}Cu, ^{66}Zn, ^{71}Ga, ^{74}As, ^{77}Se, ^{85}Rb, ^{88}Sr, ^{107}Ag, ^{111}Cd, ^{115}In, ^{137}Ba, ^{205}Tl, ^{208}Pb, ^{209}Bi, and ^{238}U) were measured off-line, crucially contributing to the WSS paleoclimatic and paleoenvironmental reconstruction, while providing interesting comparisons with the nearby Mt Ortles ice cores. This huge dataset was then digested through Positive Matrix Factorization (PMF), from which a predominant sea-salt and biomass burning contribution was pointed out (58.5% of the total). Results appeared in-line with the outcomes from the preliminary age model, which would bind the start of the record to the end of the XVII century, though requiring for new constraints to minimize the fit function uncertainties.

Eastern Alpine ice cores and summit soils: Two sides of the same coin telling stories about tipping points?

Dr. Andrea Fischer [1]***, Dr. Pascal Bohleber*** [2]***, Prof. Margit Schwikowski*** [3]***, Dr. Martin Stocker-Waldhuber*** [1]***, Dr. Thomas Fickert*** [4]***, Dr. Monika Bolka*** [5]

1. *Institute for Interdisciplinary Mountain Research, Austrian Academy of Sciences,,* ***2.*** *Ca' Foscari University of Venice,* ***3.*** *Paul Scherrer Institute, Villigen, Switzerland,* ***4.*** *German Alpine Club, Baden-Wuerttemberg Branch,* ***5.*** *Universität Wien*

Summits which became ice free in recent years are blossoming, demonstrating a quick shift from ice to vegetation cover. While the ice core records in Eastern Alps indicate cooler periods, summit soils might indicate warm periods. Investigation of ice core summit sites exhibited basal ages of millena, with an elevation dependent onset of the reglaciation. If the coexistence of plants and ice as observed today is a very short time effect of rapid warming or if this could be a more persistent feature can be revealed by studying multiple complementary pairs of soil and ice datings.

The ice core from the summit of Weißseespitze (Ötztal Alps, Austria, 3500 m), revealed a glacier cover of the summit which lasted for about the past 5900 years. Close to the ice core site, today the blossoming flowers benefit from older layers of soil, dating between the Holocene Optimum about 7000 years, but also two later periods. The thickness of the soils layers separated by fine silty layers roughly corresponds to lower bog records as Oberfernau (Stubai, Austria).

As blossoming summits have been observed recently also for Jamtalferner (2950m) and Hochkönig (2900 m), and soils seem to be present there also, dating those soils might infer information on past warm periods, once contamination by aeolian sediments and recent roots can be quantified or even excluded.

Post-LIA time-lapse analysis of ice volume changes in the Marmolada Glacier (Dolomites, Italian Alps)

***Prof. Roberto Francese* [1], *Prof. Aldino Bondesan* [2], *Dr. Massimo Giorgi* [3], *Dr. Stefano Picotti* [3]**

***1.** University of Parma - Dipartimento di Scienze Chimiche, della Vita e della Sostenibilità Ambientale, **2.** University of Padova - DISSGEA, **3.** INOGS - Trieste*

The Marmolada Glacier is the largest and most extended glacier of the Dolomites. It holds the highest part of the Northern Slope of the Marmolada developing along a large front about 3 km wide. It has been divided into various areas according to its morphology, orography, and ice flow.
The glacier has been studied and systematically measured with scientific criteria since the early years of the last century, also for the interest related to the construction of the hydroelectric basin; its evolution, with some temporal gap, is therefore quite well known. The morphology of the glacier starting from the early ’900 is carefully depicted in topographic maps which have been digitized and are part of a GIS project containing tens of maps, aerial photographs, lidar point clouds and satellite images. The retreat of the glacier and the ice collapse from the front of the Marmolada Glacier occurred in 2022 is analyzed in detail, considering the bedrock morphology obtained by GPR surveys and relating temperature trends to glacier withdrawal.

Ascertaining the response of glacier dynamics to a changing climate since the Little Ice Age (LIA) in the semi-arid region of North-western Himalaya

Dr. Pritam Chand [1], ***Mr. Ishtiaq Ahmed*** [1], ***Mr. Sachin Kumar*** [2]

1. *Department of Geography, School of Environment and Earth Sciences, Central University of Punjab, Bathinda, Punjab (India),*

2. *Symbiosis Center for Distance Learning, Symbiosis International University, Pune, India*

The Hindu Kush Himalaya (HKH) has the largest concentration of glaciers outside the Polar regions. Long-term records of glacier fluctuations since the Little Ice age (LIA) are essential to understand the intricacies of glacier-climate interactions and linkages to post-LIA climate warming, and consequences on future meltwater supplies across the HKH region. However, the studies pertaining to the nature of long-term glacier fluctuations since LIA and particularly deglaciation following the LIA maxima (LIA_{max}) are virtually non-existent for the Himalayan region. Such gaps have been tried to be filled up by a multi-data integrated approach (MDIA) which primarily includes the mapping of glacial geomorphological signatures such as moraine stratigraphy and associated absolute chronology, the historical archives (repeat photographs, old topographical maps, published reports), climate proxies (mainly tree rings and lake and lacustrine sediment geochemistry), high-resolution remote sensing data (for palaeo-ice surface reconstruction to ascertain the long-term glacial extent and related volume changes) and extensive field observations in the Chandra-Bhaga valley of North-western Himalaya. The initial result identified three periods of LIA advance during the past millennium: a late Holocene advance around 800–900 CE, a second advance stage around 1300-1600, and a third advance stage during 1800-1900. The study finds a continuous recession trend of glaciers since the post-LIA_{max}. Moreover, the study didn't find any interruption by intermediate phases of advance (at different times) across the studied glaciers. Despite evidence for climatic control over glacier fluctuations, the individual glacier response is likely to have been modulated by glacier topographical (e.g. area, elevation, altitudinal range, slope, and aspect) and surface characteristics (e.g. debris-covered) in the basin. The results show mean equilibrium line altitude (ELA) rise (ΔELA) for all the studied glaciers on a basin scale is 75 m with minimum and maximum ΔELA for the individual glacier of 29 and 149 m respectively. More analyses are being carried out, and the outcomes will be discussed in context, in order to anticipate the future evolution of glaciers across the understudied Himalaya Region.

A paleoclimatic record from the isotopic composition of the Mt Ortles ice cores, Eastern Alps, Italy

Dr. Giuliano Dreossi [1], ***Dr. Paolo Gabrielli*** [2], ***Dr. Michele Brunetti*** [3], ***Dr. Luca Carturan*** [4], ***Prof. Barbara Stenni*** [5], ***Prof. Carlo Barbante*** [6]

1. Institute of Polar Sciences - National Research Council of Italy (ISP-CNR), 2. Byrd Polar and Climate Research Center, The Ohio State University, Columbus, OH 43210, 3. 3. Ca' Foscari University of Venice, 6. Institute of Polar Sciences, National Research Council (ISP-CNR))

The vast majority of low and mid latitude mountain glaciers have been quickly retreating over the last decades, lowering the possibility of the preservation of climatic records in their ice. While several drillings have been carried out in the Alps for the last 50 years, very few attempts to obtain temperature reconstructions from the isotopic records of Alpine cores have been successful.
The presence of a dense network of meteorological stations, which have been operating for over two centuries, as well as the proximity to a densely populated and developed area, make the Alpine glaciers a unique spot to obtain paleoenvironmental and paleoclimatic information through ice coring.
In autumn 2011, four cores were drilled on the Alto dell'Ortles glacier (3859 m a.s.l.), three down to bedrock at an approximate depth of 75 m. The glacier is currently transitioning from a cold to a temperate state: the firn can reach the pressure melting point, while the ice below 30 m of depth is still cold. Carbon-14 determination on Water Insoluble Organic Carbon (WIOC) supported a time scale dating back to ~7000 years before present, making the Ortles paleoclimatic record one of the very few in the Alps covering most of the Holocene.
A refinement of the Ortles chronology was obtained through a novel approach: here we compare the $d^{18}O$ records from core #1, #2 and #3, based on the revised chronology, to the instrumental temperature series since XVIII century, using different low-pass gaussian filters with increasing sigma values. The linear regression between temperature and isotopic data shows an increasing R^2 and slope when increasing the sigma of the low-pass gaussian filter. While few periods are characterized by opposing trends, the overall agreement between temperature and $d^{18}O$ is robust.

Through the ice of a melting glacier: chronological approaches and land use reconstruction from an Adamello glacier core (Italian Alps)

Dr. Daniela Festi [1]***, Dr. Theo Jenk*** [2]***, Dr. Nicola Alessi*** [3]***, Prof. Stefan Zerbe*** [4]***, Dr. Camilla Wellstein*** [4]***,***
Prof. Margit Schwikowski [2]***, Prof. Klaus Oeggl*** [5]***, Prof. Valter Maggi*** [6]

Glacier ice cores from mid latitudes are capable of retaining important information on past climate and anthropic activities at high time resolution. However, Alpine glaciers are particularly sensitive to the current climate warming, which is seriously compromising their persistence. The present extensive ablation and the potential vanishing of these glaciers are leading to the loss of unique climatic and environmental archives. Here, we present chronological and palynological results from a 46 m deep ice core extracted from the Adamello Glacier (3100 m a.s.l.), the deepest and most extended glacier in Italy. Integrating the results of radionuclides ^{210}Pb and ^{137}Cs with annual layer counting derived from pollen and refractory black carbon concentrations we were able to obtain a reliable timescale. Our outcome indicates that the glacier surface is about 20 years older than the drilling date of 2016, and that the 46 m ice core reaches back to around 1944. Additionally, for the period of 1995–2016 the mass balance at the drilling site (former accumulation zone) decreased on average of about 1 m w.e. a^{-1} compared to the period 1963–1986. The palynological record obtained from the core has been employed to reconstruct past land use changes in the Adamello area. Pollen inferred vegetation trends have been calculated using pollen indicators obtained from a database of vegetation-plot observations, and the reliability of these trends is evaluated by comparison with spatially explicit tendencies reconstructed according to a time-series of land-cover maps. We found that the Adamello pollen record well represents the natural vegetation types as the temperate and the riverine forests, as well as the anthropic vegetation (crops and alien species) and that from the 1980s a thermophilisation took place.

ADA 270: palaeoclimate evolution of the past centuries from the Adamello Glacier

Dr. Clara Mangili [1], ***Dr. Roberta Pini*** [2], ***Dr. Claudio Artoni*** [3], ***Dr. Deborah Fiorini*** [4], ***Dr. Serena Lagorio*** [5], ***Prof. Valter Maggi*** [4]

__1.__ Dept. of Environmental and Earth Sciences, University of Milano Bicocca, __2.__ CNR - IGAG, Laboratory of Palynology and Palaeoecology, __3.__ Dipartimento di Scienze dell' Ambiente e della Terra, University of Milano-Bicocca, __4.__ University of Milano-Bicocca, __5.__ Dipartimento di Scienze Ambientali, Informatica e Statistica, Università Ca' Foscari di Venezia

Alpine glaciers are sensitive natural archives for reconstructing past climate and environments through time, in and around the glaciers.
The Adamello Glacier, located in the Central Italian Alps, has an extension of ca 14,35 km^2 (2020) between 2560 - 3420 m asl, and it is the deepest Italian glacier. The ELA (Equilibrium Line Altitude) is located at ca 3000 m asl. The glacier was chosen for a coring campaign that took place in 2021 and led to the recovery of a 224 m ice core (ADA 270). Preliminary estimate for the age of the core bottom could be around 1000 years ago; the core would span the time interval from around the Medieval Warm period to today.
The core, stored at the EUROCOLD facilities at the University of Milano-Bicocca (https://eurocold.disat.unimib.it), is being studied at subannual resolution by means of a multiproxy approach that includes oxygen and deuterium stable isotopes, black carbon, dust, diatoms and microbotanical content (pollen and spores), plus the measurements of the radionuclides ^{210}Pb and ^{137}Cs.
The pollen analysis of this core is oriented towards the reconstruction of regional past ecosystems. The samples so far analyzed document the presence and good preservation of palynomorphs. Seasonality of the pollen signal seems to be preserved, with *Corylus* and other taxa being the spring signal while *Pinus*, *Ostrya* and many more taxa being the summer signal of the flowering season. Different species of diatoms have been also observed. The results of the first few months of research will be presented and compared to the visual stratigraphy of the core and the hyperspectral analyses carried out on the same core.
The main targets of the research will be: (i) documenting the effects of anthropic activities on natural environments during the Industrial Period; (ii) the impact of World War I on the alpine environment; numerous battles were fought between the Italian and the Austro-Hungarian Armies on the Adamello Massif; (iii) climate and ecosystem reconstructions during the Little Ice Age and the Medieval Warm Period.

Session 152: Archaeological cave sediments: a key to decipher past human behavior and palaeoclimatic change

Site formation processes at two rock-shelter sites of the Pleistocene-Holocene transition in Kyrgyzstan (Central Asia)

Mrs. Greta Brancaleoni [1], ***Dr. Maciej Krajcarz*** [1], ***Dr. Svetlana Shnaider*** [2], ***Prof. Aida Abdykanova*** [3]

1. Institute of Geological Sciences, Polish Academy of Sciences, 2. L.N. Gumilyov Eurasian National University, 3. American University of Central Asia

At the foothills of the Alay mountain range, in the southern margin of the Fergana Valley, Obishir-5 and Obishir-1 are two archaeological sites of the Pleistocene-Holocene transition bearing archaeological material of the Obishirian culture. Additionally, the sites' importance has increased thanks to recent studies on the faunal remains which shed light on the Neolithization process in Kyrgyzstan and more ambitiously in Central Asia. In particular, the sites are located in front of two rock-shelters at the toe of largely karstified limestone cliffs in an high-elevated and arid intermontane basin of the southwestern Kyrgyzstan. Geoarchaeological investigations have been carried out to give geologic context to the archaeological record and for a better understanding of the site formation processes and post-depositional disturbances. A multi-aspect approach has been designed consisting of sedimentological, micromorphological, and geochemical analyses for the study of the sedimentary material, coupled with chronometric dating and the study of faunal assemblages, as well as artifact spatial distribution analyses. The information retrieved allowed to reconstruct the depositional history, traces of human-related activities, and paleoenvironment reconstructions at both sites. Importantly, the sites are both embedded in cliff-related talus deposits, but they faced slightly differing processes which were recorded throughout the sedimentary sequences. Confronting the Quaternary sequences at the two Obishir sites, the "human factor" emerged to be an important element in the accumulation, erosion and disturbance of the stratigraphic sequences. In particular, the adoption of micromorphological methods resulted to be a powerful tool in discerning differences amongst the two considered sites.

Evaluating the potential of limestone as a proxy for archaeological fire at Pech de l'Azé IV (France)

Mr. André Santana [1], *Dr. Vera Aldeias* [1]

1. ICArEHB - Interdisciplinary Center for Archaeology and the Evolution of Human Behaviour, University of Algarve

Archaeological sediments are a valuable source of information to infer past human activities related to fire. Over the past few decades, increasing research concerning the effects of fire on the archaeological record has shown that sediments exposed to heat are irreversibly altered and can contribute to answering key questions related to burning events, such as the spatial distribution of combustion features, the intensity and frequency of heating, and the integrity of thermally altered deposits. However, comparatively few studies have dealt with the thermal behaviour of specific inorganic constituents (minerals, rocks) in archaeological sediments. In this work, we present the results of a laboratory-based experiment designed to examine how heat affects limestone, one of the major components of cave deposits. This experiment was conducted on micro-contextualized samples from Layer 8 of the Middle Paleolithic cave site of Pech de l'Azé IV (Dordogne, SW France), where the use of fire by Neanderthals is well documented. Under a set of controlled conditions, experimental samples were subjected to different temperatures and subsequent alterations were recorded using a variety of macro- and micro-scale techniques, including colourimetry, micro-FTIR, petrographic microscopy, and SEM-EDS analysis. By systematically documenting and evaluating the archaeological relevance of these alterations, we aimed to create a baseline reference against which archaeological sediments could be compared and thermally classified. Our results indicate that some of the changes produced, especially those associated with the colour and the microstructure of the samples, can be used to distinguish unheated (<200 ºC) from heated (>400 ºC) limestone with relatively high confidence, and that limestone exposed to temperatures above 700 ºC becomes friable and may be nearly impossible to identify in archaeological settings. In combination with other well-established proxies, we believe that the approach hereby proposed is suitable for the recognition of ancient fire in caves and other carbonate-rich environments.

Sandstone cave sediments: a geoarchaeological assessment

Ms. Irini Sifogeorgaki [1]

1. *Faculty of Archaeology, Leiden University, Einsteinweg 2, 2333, CC, the Netherlands*

The site formation processes of cave and rockshelter archaeological sites are the subject of many geoarchaeological studies. Karstic cave deposits have been intensively studied, while similar contexts in quartzitic bedrocks (sandstone and quartzite) have received less attention. In this talk, I review common aspects of the formation of quartzitic caves through an extensive geoarchaeological literature review. I conduct a comparative analysis of sites around the world based on aspects including the climatic setting, bedrock mineralogy, site preservation (charcoal, bone), as well as geoarchaeological methods applied. In addition, I review a variety of geoarchaeological techniques used to conduct geoarchaeological studies on quartzitic caves. Standard bulk sediment analyses like granulometry, pH, and Loss on Ignition are often overlooked although they can provide important insights into the formation processes. To fully assess the depositional and post- depositional processes, micromorphological analysis needs to be conducted. My analysis demonstrates preservation conditions of the sites appear primarily affected by the moisture content of the sediments which, in turn, is often related to the bedrock hydraulics of the rockshelter. Finally, I suggest a workflow template for researchers (both archaeologists and geoarchaeologists) working on sandstone and quartzite rockshelter excavations.

A cautionary tale: Testing the chronology of Zambian cave site stratigraphies using amino acid geochronologies.

Ms. Chloë Baldreki [1]***, Prof. Larry Barham*** [2]***, Dr. Tom White*** [3]***, Prof. Kirsty Penkman*** [1]

The South-Central African region is increasingly thought to have played an important role within mammalian (including hominin) evolution during the Quaternary. Archaeologically, the region has yielded the Kabwe cranium (*Homo heidelbergensis* (*rhodesiensis*)), changing tool technologies and early pigment use (~265 ka). Ecologically, the region's current habitat is primarily dryland savannah, but there is evidence that during the Quaternary, there was an extensive palaeo-wetland, encompassing the Okavango delta, the Makgadikgadi pan and the Zambezi and Kafue rivers. This wetland would have provided both a migratory corridor between Southern and Eastern Africa, and an ideal environment for hominin habitation in its own right.

In Zambia, fossil preservation at cave sites such as Twin Rivers and Mumbwa Caves provide rare opportunities to study the region's archaeology and palaeoenvironments. Dating is crucial to understanding these sites individually, and especially when relating them to the wider evolutionary patterns; however the chronology of the region is not well understood.

Cave depositional histories are notoriously complex and can provide an especially challenging environment to date. Here we propose the use of amino acid geochronology, using the relative dating information from intra-crystalline protein degradation (IcPD) in fossils, as a tool for testing the chronology of cave site stratigraphies. IcPD exploits the time-dependent breakdown of proteins (racemisation, hydrolysis and degradation of amino acids) contained within biominerals (e.g. mollusc shell and teeth). Targeting the intra-crystalline fraction of protein minimises the effects of contamination, leaching and other impacts of the depositional environment, and provides direct dates on relevant fauna, on Pleistocene timescales.

Here we discuss the IcPD analysis of mammalian tooth enamel from 2 cave sites in Zambia, with more general implications for the reliability of interpreting associated archaeological and palaeoenvironmental material based on cave site stratigraphies.

Early Neanderthal frequentation in the Mediterranean: environments and processes from the sedimentary archive of the "Terre Rosse" at Grotta Romanelli (Apulia, Southern Italy).

Grotta Romanelli (Apulia, Southern Italy) is a key site in the Mediterranean Quaternary, preserving a unique sedimentary and geomorphological archive which encompasses the last 350 ka BP. The litho-, morpho- and chronostratigraphical setting of the infilling deposit has been recently reassessed, placing the oldest human frequentation of the cave between MIS 9 and MIS 7, roughly between 340 and 240 ka, therefore embracing Glacial and Interglacial cycles. Previously, the sediments in Grotta Romanelli were attributed to the Last Interglacial-Glacial cycle (124-20 ka).

The cave has provided important evidence of human and animal frequentation across the whole filling succession and ISU3 (also known as "Terre Rosse") yields hundreds of limestone tools referred to Middle Palaeolithic and thousands of vertebrate faunal remains. ISU3 is made of thinly layered planarly or cross-bedded silts, clays and sands typical of low-energy run off processes which affected deposits of aeolian origin and colluviated soil features washed into the cave and derived from the erosion of the leached, argillic soils covering the surrounding landscape. The age of ISU3 was constrained between ca. 200 ka and 110 ka by under- and overlying U/Th dates on speleothems although palaeobotanic evidence suggests an early Late Pleistocene age (MIS5).

Here, we present new sedimentological and micromorphological analyses, luminescence and U/Th ages coupled with geochemical, mineralogical and paleomagnetic investigations. These results offer new palaeoenvironmental insights about the context where these early Neanderthals lived in the southern Mediterranean Europe.

Reconsidering Mid-Upper Pleistocene natural and anthropogenic cave sediments at the Balzi Rossi archaeological area (Liguria, Northern Italy)

In the Pleistocene, the Mediterranean hosted a variety of environmental settings, including ecological refugia, and played a special role as hub for human dispersal across Europe. Western Liguria (Northern Italy), and especially the Balzi Rossi archaeological area, represent a hot spot to investigate how human populations have responded to Pleistocene environmental and sea-level variations. Local natural and anthropogenic cave sequences have been excavated since the XIX century, disclosing an extremely rich archaeological panorama. Unfortunately, the geological processes in charge of the formation of such deposits have been only occasionally considered. To avoid this lack of information, the SPHeritage Project (MUR grant: FIRS2019_00040, P.I.: M. Pappalardo) is investigating the Balzi Rossi area, with an interdisciplinary and multidisciplinary perspective, the human-environment interaction over the last 400,000 years, including geochronology, micromorphology, and other archaeological sciences. As most of the local archaeological sequences were removed at the beginning of the last century, we are combining the analyses of strips of anthropogenic sediments preserved in museums and remnants still preserved inside the rock shelters of the archaeological complex. Our geomorphological survey identified new sedimentary sequences preserving information on relative sea level changes, better constraining the time and steps of climate change, sea-level oscillations, and human settlements. The micromorphological investigation at the Cave of the Prince of Monaco highlighted that the sequences formed thanks to long-lasting activity of a freshwater spring that contributed to the formation (during the Middle Pleistocene) of beach deposits alternating with continental calcareous tufa showing different sedimentary facies and entombing evidence of human attendance of the site. Climate and sea-level changes modulated the shift from calcareous tufa precipitation to beach sediments formation. The comparison between open-air, natural sequences and those preserved at the ex-Casinò site allowed the identification of composite sequences alternating beach deposit, weathered into a red soil during MIS5e, then reworked and buried by slope sediments in the Upper Pleistocene, when the area was exploited by humans. Our results allow us to discuss a fresh interpretation of the formative processes and chronology of the major anthropogenic sequences preserved at the Balzi Rossi and the correlation between natural and anthropogenic evidence.

Contextualising the Pleistocene archaeological record of Southeast Asia: using a geoarchaeological approach

Prof. Mike Morley [1]***, Dr. Conor McAdams*** [1]***, Dr. Vito Paolo C. Hernandez*** [1]

1. *College of Humanities, Arts and Social Sciences, Flinders University*

Southeast Asia is a critically important region to our understanding of Pleistocene hominin evolution and demographics. The Pleistocene fossil and archaeological record of Southeast Asia is, however, patchy, often formed of elements that are small, scant, poorly preserved, and recovered from complex sedimentary environments. Nevertheless, such finds hold immense potential to rewrite what we know about the evolution of our species, our co-existing hominin ancestors, and the environments they adapted to and ultimately thrive within.

Geoarchaeology borrows concepts and methods from a range of Earth Sciences to help understand and interpret the archaeological and fossil record. Geoarchaeological analyses are gradually becoming more routine in their application to human evolutionary studies in some regions of the world, to both contextualise archaeological and fossil material, as well as providing an independent environmental proxy record that can document changes in site and catchment environment. Using high resolution geoarchaeological data it has been shown that critical fossils and artefacts can be published with highly resolved contextual data that increases confidence in the veracity of a given study. This is vital in Southeast Asia where tropical conditions can hamper our understanding of the archaeological and fossil record because poorly understood geomorphic processes that drive sediment diagenesis and accelerate taphonomic processes that might significantly affect fossils and artefacts.

Here I will: i) showcase the potential for a range of geoarchaeological analyses to provide critical contextual information for fossil and archaeology from the region (thus circumventing common issues such as inadequate stratigraphic—and geochronological—control); ii) evaluate how effectively such an approach is being used—or not—in the region (where tropical geomorphological processes are less well understood than in other major regions of human evolutionary analyses, such as Europe and Africa); and iii) look to the future to examine how we might better incorporate a geoarchaeological framework (including emerging and state-of-the-art analytical techniques) into all archaeological and palaeontological projects from the earliest stage.

Session 154: Quaternary research in South America: paleoclimate, tectonic, volcanic and surface processes

The Parana Delta (Argentina): a high-resolution record of the Holocene

Prof. John Holbrook [1]***, Mr. Rodney Stieffel*** [2]***, Dr. Daniela KROHLING*** [3]***, Dr. Juan Pablo Milana*** [4]***, Dr. Jimena Roldan*** [5]

***1.** Texas Christian University, **2.** Chevron Corp., **3.** CONICET and Universidad Nacional del Litoral (FICH-UNL), Santa Fe, **4.** CONICET and Universidad Nacional de San Juan (InGeo), **5.** CONICET and UNIVERSIDAD NACIONAL DEL LITORAL, SANTA FE*

The Parana Delta of the Rio de la Plata estuary borders some of the most populated areas of South America and builds from one of the ten largest rivers in the world, yet still is yielding new insights. While the lower part of the delta has received much attention, the upper part is only recently studied. Analysis of neotectonics, wave action, and sediment supply of this segment permits a more holistic story of delta evolution and reveals some unique aspects of evolution for this part of the South Atlantic coast. A depositional and chronological model of delta landforms and OSL and C14 dates is here presented. The complex history of the delta starts at sea-level highstand before 8,000 yr BP and lasting to 6,500 yr BP (+6.5 masl), continues through a falling stage at 6,500 yr BP to 4,500 yr BP (+5 masl), and levels into a lowstand (+2 masl) from 4,500 yr BP to Present. The initial highstand delta was fluvial-dominated, but altered to a mixed wave-dominated delta by ~8000 yr BP. The fluvial highstand delta predates the oldest beach cheniers of 8,100 yr BP, previously thought to be ca. 6,300 yr BP, and postdates the underlying transgressive muds at 9,300 yr BP. After a period of wave-delta propagation, relative sea-level began to fall and forced downstepping of the shoreface producing a falling stage systems tract. During this time, the waves refracted around intraestuary islands which altered the trajectory of chenier building. Starting ~2200 yr BP, the delta returned to a fluvial dominated delta system, which remains the case until today. The current delta has aggraded with sea-level rise since ca.1,000 yr BP. At well over 8,000 yr BP the South American shoreline here hit relative sea-level maximum relatively early, probably because of uplift, making the Parana a candidate for the oldest regressive Holocene delta in the world. At <37 Billion cubic meters the highstand delta volume is surprisingly small for a river this size. Uplift continued, forcing relative sea-level drop and downlap of a falling stage over the maximum flooding surface through middle Holocene.

Recent trenching studies on the major Algeciras fault in its crossing of the Eastern Cordillera of Colombia

1. *Universidad Central de Venezuela,* ***2.*** *Private Consultant,* ***3.*** *Servicio Geológico Colombiano,* ***4.*** *Universidad del Norte,* ***5.*** *Universidad Pedagógica y Tecnológica de Colombia,* ***6.*** *Universidad Nacional de Colombia, Medellín,* ***7.*** *Universidad Distrital Francisco José Caldas, Bogotá*

The major Algeciras Fault (AF), belonging to the Colombian Algeciras Fault System (AFS), is part of a continent-scale dextral system, originally named as the Eastern Frontal Fault System, extending for 1900 km from Ecuador to Venezuela, which splits the North Andean Sliver from South America in a process of NNE-directed tectonic escape. To assess the seismogenic potential of AF, which is a highly potential seismic threat to Bogotá, the *Geological Survey of Colombia (SGC)* –after carefully mapping the AFS at its oblique crossing of the Eastern Cordillera, along the Garzón Massif northwestern border, on the basis of Quaternary landforms of tectonic activity-, has excavated 4 paleoseismic trenches across its trace in the Huila Department: two in the Algeciras pull-apart basin in 2016 (Lagunillas, Santa Elena) and two to NE of Garzón in 2021 (Potrerillos, Miraflores School), 50 km apart to the southwest. Despite the evaluation of the Santa Elena trench is still pending, the Lagunillas trench, excavated across the basin shortcut strand, attests to seven Holocene Mw 7.0+ earthquakes, with an average recurrence of 1300-1400 years. In turn, both trenches at Miraflores were excavated across both strands of a restraining stepover. In fact, the Miraflores School trench seems to assess the same AF Algeciras-Tres Esquinas segment as the Lagunillas. This appears supported by that both trenches (Lagunillas and Miraflores School) disclose the same latest February 09^{th}, 1967 event. Besides, the AF slip rate deduced from the total deformation recorded at the Lagunillas site is about 0.7-0.8 mm/a, which is very similar to that of Miraflores (1.0 mm/a). In addition, the recurrence interval at Miraflores School is of ~ 1500 years, from the last three events. Instead, the Potrerillos trench, opened across a fault trench, bounded by two normal-dextral faults 10m apart, reveals that the SW-extending Garzón segment recurs much faster, at about 500-600 years, with latest events occurring roughly at 700, 1300 and 1800 AD. The trench-derived slip-rate of this segment is 4.0 ± 0.4 mm/a. Last, this segment seems responsible for the historical November 16^{th}, 1827 Mw 7.1 earthquake, which would support the independent behaviour of both AF segments.

Late Quaternary fluvial deposits in the Colombian Andes foothills: insights from tectonic and climate drivers

Dr. Fabiano Pupim [1], *Mr. Caio Breda* [2], *Ms. Caroline Leite* [2], *Dr. André Sawakuchi* [2], *Dr. Mauricio Parra* [2]

1. Federal University of São Paulo, Department of Environmental Science, 2. São Paulo University, Institute of Geoscience

Alluvial deposits are well developed and preserved in the Eastern Cordillera of Colombia's foothills as potential archives of tectonic uplift and climatic variations in a poorly studied tropical region. The main aim of this research is to investigate the evolution of the alluvial deposits in the upper Guaviare River basin in southern Colombia. We mapped landforms by visually interpreting the Landsat images and Copernicus digital elevation model (DEM; GLO-30) and used optically stimulated luminescence (OSL) dating in quartz grains to estimate burial ages. Our results show that most landforms were formed by alluvial and fluvial fans with distinct lobes, which are preserved as several terrace levels up to 120 m higher than the modern floodplain. Clast-supported massive gravels dominate the sedimentary facies of these alluvial and fluvial fans with rare and thin layers of coarse-grained sandstones. The current floodplains are related with braided to sinuous channels from up to downstream; gravels dominate their sedimentary facies, but sand layers are frequent. Prelaminar OSL ages indicate that the highest terrace level is not older than 100-150 ka, suggesting impressive high incision rates during the late Pleistocene and Holocene. Therefore, new OSL ages (in progress) will allow us to estimate the burial ages of the mapped landforms and give new insights into the timing and driving factors related to changes in the fluvial dynamic and landscape evolution of the tropical Andean piedmont. (FAPESP grant #2020/11047-1)

The glacier-climate history of Cordillera Pariacacá and Cordillera Huaytapallana, central Peruvian Andes, from the Late Pleistocene to Holocene

***Ms. Lucy Ashpitel* [1], *Prof. Matteo Spagnolo* [1], *Dr. David Fink* [2], *Prof. Brice Rea* [1], *Dr. José Úbeda* [3], *Mr. Ronald Concha* [4], *Dr. Anshuman Bhardwaj* [1], *Dr. Donal Mullan* [5], *Mr. Pool Vasquez* [6], *Dr. Rachel Oien* [7], *Ms. Krista Simon* [2], *Mr. Steve Kotevski* [2]**

1. School of Geosciences, University of Aberdeen, Aberdeen, UK, 2. ANSTO, 3. Universidad Complutense de Madrid, 4. Instituto Geológico, Minero y Metalúrgi, 5. Queen's University Belfast, 6. Instituto Geológico, Minero y Metalúrgico, 7. University at Buffalo

Peruvian glaciers are retreating steadily and rapidly. Cosmogenic exposure dating of moraines aids understanding of how glaciers have responded to past climate changes. In turn, this provides insights into how these vital meltwater resources may behave under predicted climate change. Cordillera Pariacacá and Cordillera Huaytapallana (~11.5 ºS), provide meltwater to a population of 11 million in Lima and ~500,000 in Huancayo respectively. No chronologies, however, exist for their moraine sequences and associated ice dynamics. This study provides the first glacial geochronology based on ^{10}Be exposure ages of moraines that likely span from the Last Glacial Maximum to the late Holocene.

The modern Peruvian climate and glacial dynamics have been linked to variations in Pacific sea surface temperatures, the InterTropical Convergence Zone and South American Summer Monsoon. The climate is also modulated by the Andean Mountain chain, which acts as a topographical barrier to advancing cold fronts and low tropospheric flows causing a rain shadow on its western flank. The climate of western Andes, where Pariacacá is located, is influenced by the Pacific Ocean and is arid. Conversely, the eastern Andes, where Huaytapallana is situated (~100 km east of Pariacacá), are more influenced by Atlantic Ocean conditions and are humid. Palaeoclimate studies from across Peru have inferred linkages between the Andean Holocene climate to both Atlantic and Pacific conditions. Data from this study, which compares glacial ages from Pariacacá and Huaytapallana, will help constrain the ocean and atmospheric controls on glacier surface mass balance in the central eastern and western Andes, how the controls differ between the two sides of the mountain chain and how they have developed since the Last Glacial Maximum.

In 2022 a field campaign was undertaken involving the universities of Aberdeen and Complutense de Madrid, and the Instituto Geológico, Minero y Metalúrgico Peru. 66 granitic and gneissic rock samples were collected from 14 moraines in the Huaytapallana and Pariacacá ranges. ^{10}Be cosmogenic dating of moraines is currently being undertaken at the Australian Nuclear Science and Technology Organisation. Results of this analysis along with palaeoglacier reconstructions for Pariacacá and Huaytapallana and comparisons to palaeoclimate will be presented.

Climatic and anthropogenic signals in the last 2000 years using diatoms and XRF in lake sediments from Cordillera Vilcanota in the central Andes

Mr. Christian Hans Quintana Zagaceta [1], ***Dr. Pedro Tapia*** [2], ***Prof. Justin Stroup*** [3], ***Prof. Meredith Kelly*** [4]

1. University of Bergen, 2. INAIGEM, 3. OSWEGO, 4. Dartmouth College

Lake Yanacocha is a tarn formation surrounding the Quelccaya Ice Cap and is considered a non-glacially fed, shallow and polymictic elevated Lake located in Cordillera Vilcanota. The results from diatoms analysis showed a steady population of small fragilaroids such as Staurosira venter and aulacoseiras alpigena and válida that reached maximum values of around 40 per cent relative abundance. The diatoms doubled their concentration and accumulation rates in the last 1000 years. The Diatoms Concentration and Staurosira venter had similar increasing trends and opposite to aulacoseiras. The clustering analysis identified five zones where zone 4 showed the lowest value of diatoms accumulation rate and richness species. The increase of clastic flux in Zone 2 might be driven by pre-incan anthropogenic activities including mining and agriculture. The maximum values of Fe registered in the XRF analysis in Zone 2 might have limited the production of aulacoseiras, due to their sensitivity to high metal concentrations, in addition to arid conditions. Processes of re-suspension of the sediments and wind-blown transport of diatoms valves from surrounding lakes, can be also considered as other possible causes for the rise of diatoms concentration, that decreased in Zone 1. The canonical analysis would suggest that most of the carbon content in the lake would come from littoral zones and surrounding vegetation composed mainly by mosses.

How did the 4.2 ka BP Cerro Blanco eruption impact the hunter-gatherer community of the Yocavil valley, NW Argentina?

Dr. Jose-Luis Fernandez-Turiel [1], *Dr. Juan-Pablo Carbonelli* [2], *Dr. Carlos Belotti López de Medina* [2]

1. Geosciences Barcelona (Geo3BCN-CSIC), Lluís Solé i Sabarís s/n, 08028 Barcelona, Spain, 2. IDECU, UBA-CONICET

Due to the intense anthropization of the landscape or the scarce research efforts on prehistoric populations of hunter-gatherers in the intermontane valleys of the Andes, occupation sites have been found on very few occasions. However, new perspectives in the Abra del Toro rock shelter in the Yocavil Valley (Catamarca province, Argentina) have opened up from recent and ongoing excavations. The stratigraphic record of the rock shelter shows a 1-m-thick volcanic ash deposit formed by aeolian transport from primary outer ashfall deposits. Geomorphological and sedimentological context, texture, glass and mineral content, whole-rock chemical composition, and radiocarbon dating prove that the tephra was derived from the 4.2 ka BP eruption of the Cerro Blanco Volcanic Complex in southern Puna (NW Argentina). This volcanic eruption is the largest documented in the world in the last five thousand years and covered the surroundings of the archaeological site with an ash layer of approximately 1 meter thick. The stratigraphic sequence of the Abra del Toro rock shelter allows us to hypothesize that there were three main occupational moments: two hunter-gatherer moments, separated by the record of the large volcanic eruption, and a subsequent agro-pottery period (Carbonelli et al. 2022. J. Archaeol. Sci. Rep. 45, 103629). The rock shelter after the eruption remained in the memory of the hunter-gatherer groups. Good visibility, accessibility, and proximity to water were attributes of this space that made it possible for it to be re-occupied after the eruptive event. Our next objective is to reconstruct, using proxy analysis, how the paleoenvironment was in the intermontane valleys before and after the eruption. The evidence of this Mid-Holocene catastrophic volcanic event in the Abra del Toro rock shelter opens the possibility of knowing its impact on the contemporary hunter-gatherer community and drawing conclusions for similar future volcanic crises.

Late Pleistocene-Holocene paleoenvironments and paleoclimate of a subtropical distributive fluvial system at the eastern Andean piedmont of South America

Dr. Alfonsina Tripaldi [1], ***Dr. ADRIANA MEHL*** [2], ***Dr. Paul Hesse*** [3]

1. *IGEBA-UBA-CONICET,* ***2.*** *INCITAP-UNLPam-CONICET,* ***3.*** *Macquarie University*

The eastern Andean piedmont of southern South America shows several distributive fluvial systems (DFS) formed by antecedent rivers that carry seasonal meltwater from the Andes Cordillera. One of them is formed by the Atuel and Diamante rivers after crossing the San Rafael tectonic block in deep canyons. Ongoing projects are studying the landscape and deposits of this DFS to reconstruct the late Quaternary landscape evolution, provide paleoclimatic inferences, and improve DFS facies models. Methodology includes geomorphologic mapping by remote sensing, field survey, facies analysis of pedosedimentary successions, coring and multiproxy analysis of wetlands, luminescence and AMS chronology. The fluvial dynamics is closely related to aeolian processes as the Atuel-Diamante DFS is under semiarid condition (rain shadow of the Andes Cordillera). The megafan is bounded by dunefields, and the fluvial landforms and deposits are modified and reworked by wind activity. Today, the Atuel-Diamante DFS is a 'misfit' fluvial system due to current interglacial conditions and anthropic intervention on the drainage network. In 1886 the Diamante river waters were artificially diverted to the east, later, in the last 70 years, hydroelectric power dams affected the fluvial regime of their lower basins. Also, the proximal part of the DFS was turned into an agricultural irrigated oasis, by introducing fluvial networks to supply water for irrigation, and soils became strongly salinized. Several landscape features reveal variable geomorphological and climatic conditions in the late Pleistocene-Holocene, like channel incision and fill terraces, wider paleochannels than present channels, a profuse aeolian cover over most the DFS, among others. The chronology shows a late Pleistocene-early Holocene record in an upper-most, 8 m thick, fluvial terrace, suggesting important fluvial aggradation during the last glacial termination and a significant change in the system with extensive incision at the early-mid Holocene. OSL ages show late Pleistocene dune formation and successive stages of dune building in the Holocene. These are associated with fluvial channels and surfaces formed and successively abandoned throughout the Holocene. Although the sand dunes are currently well-vegetated, our record shows that Holocene climate fluctuations have been sufficient to change the hydrological balance, activating sand dunes and diminishing river discharges.

Assessing hazardous faults in South America through collaborative networking

Dr. Carlos Costa [1], ***Dr. Franck Audemard*** [2], ***Dr. Alexandra Alvarado*** [3]

1. Universidad Nacional de San Luis, 2. Universidad Central de Venezuela, 3. Instituto Geofísico,Escuela Politécnica Nacional

The prehistoric displacement record of seismogenic faults constitutes a primary input layer for seismic hazard assessment (SHA). This is particularly relevant for areas where the recurrence interval of destructive earthquakes is larger than the time coverage provided by the seismic catalog. Destructive earthquakes onshore South America have occurred along faults whose seismogenic capability is known or suspected. Capital towns, fast-growing urban areas, and critical facilities settled nearby hazardous faults, underscore the significance of understanding the fault-related hazard. However, parametric data of many seismogenic faults in South America do not always illuminate their seismic capability, as some key parameters required for SHA are either unknown, not suitably surveyed, or exhibit significant discrepancies among themselves. The South America Risk Assessment project helped to update and upgrade previous compilation efforts under a network of local experts, with the aim of incorporating hazardous faults in an open-access seismic hazard source model for South America. Although regional data harmonization still needs to be improved, this effort allowed the integration under uniform standards of nearly 1600 Quaternary-active structures in a GIS-supported platform. Relevant fault parameters as to SHA, such as geometry, kinematics, and activity rate have been incorporated whenever possible. There is plenty of room and good perspectives in this field to contribute with sound data to issues of social impact and regional interest.

Morphodynamic analysis of fluvial megafans of the Southern Chaco plain, Andean foreland basin

Dr. Daniela KROHLING [1]

1. CONICET and Universidad Nacional del Litoral

Lowland areas of South America provide a natural laboratory for the research of large fluvial quaternary systems. The Chaco plain (ca. 840,000 km^2) represents the most extensive depositional system of the Central Andean foreland basin. This is an ideal tectono-geomorphic setting for generating some of the largest fluvial megafans of the Earth. Chaco megafans are under a humid tropical-subtropical climate and cover large remote and difficult-to-access areas. Their formative rivers, with a downstream decrease in discharge, are mainly connected through the Paraguay-Paraná axial fluvial system. This presentation focuses on the process-based understanding of the Chaco coalescent active megafans in Argentina (22°–31°S; Pilcomayo, Bermejo, Salado-Juramento and Dulce distributive fluvial systems, DFSs). Geomorphological analysis from regional to local scales mainly from remote-sensing data coupled with field and laboratory datasets (stratigraphy and sedimentology) provides new insights into the Quaternary dynamics of these multi-scale dispersal systems. Chaco megafans are particularly sensitive to climate forcing. Significant seasonal fluctuations in the discharge of their formative rivers through the influence of the South American Summer Monsoon were registered. Also, the high sediment input from their Andean catchments, the short-term sedimentation and channel avulsions to adjacent overbank areas are dominant in the construction of these mega-landforms. The required horizontal accommodation space and gradient for their development are closely related to the foreland basin tectonic configuration. Both climate and neotectonics, influence the spatial and temporal pattern of aggradation on these megafans. Highly dynamic fluvial processes dominated during the Upper Pleistocene. The sub-environment complexity along each megafan, deduced from an arrangement of landforms and stratigraphical data, is related to the avulsive behaviour. A partial avulsion is a dominant process in middle-distal Chaco megafan settings, with crevasse and terminal splays formation and overbank sedimentation. Distal zones are dominated by floodplain deposits, with isolated channel-fill bodies. Terminal splay sand sheets (aggradational lobes) covering mud-flat deposits are typical. Extensive floodplain-filling crevasse splays generate in the downstream part of the active river belt of megafans. Large wetlands dominate in distal reaches. A comparison between the Chaco DFSs and the fluvial megafans developed in the dry Central Andean piedmont is also presented.

Refining the chronology of Lujanian and Bonarian Stages

The late Pleistocene to Holocene sedimentary deposits in the Pampean Region of Argentina has traditionally been assigned to different stratotypes established more than a century ago by Ameghino (1879), the Lujanian, and Bonaerian. These Stages/Ages have been used as reference timescales for Argentina and other South American fossil sites. Nonetheless, there seems to be no consensus about the exact age and the litho- and biostratigraphic correlations of the Pleistocene units of the several sedimentary basins in the Chacopampean Plain geological province. This situation is also linked to the progressive change of geological time and its divisions, with the diversity of nomenclatures and the dual classification of deposits based on the content of fossils and lithological characteristics.

In order to further chronologically constrain the transition between Lujanian and Bonaerian, we have recently employed Electron spin resonance (ESR), U-series, and Optically Stimulated Luminescence (OSL) methods to date and tentatively correlate a series of localities in different basins in the northern (San Pedro,) and southern (Salto de Piedra and Cascada de Paleolama) Buenos Aires Provinces. These preliminary results may be used to compare these two regions, different formations and timescale traditionally used in Argentina that will extend to other basins in the Chacopampean Plain geological province.

Holocene environmental evolution of the Chile Chico Meseta based on lacustrine sedimentary records, Central Patagonia, Chile.

Ms. Carolina Franco [1], ***Dr. Antonio Maldonado*** [2], ***Dr. Christian Ohlendorf*** [3], ***Dr. Catalina Gebhardt*** [4], ***Dr. Amalia Nuevo Delaunay*** [5], ***Dr. César Méndez*** [5], ***Dr. María Eugenia de Porras*** [6], ***Prof. Bernd Zolitschka*** [1]

In order to assess the paleoenvironmental and climatic variabilities of Central Patagonia throughout the Holocene, a 3 m-long composite sediment record was recovered from one of the lakes (46,716º S, 71,844º W) of the Chile Chico Meseta (CCM). Owing to its altitude (~1000 m a.s.l.) and location relative to the Jeinimeni Range (JR), this volcanic plateau offers a unique setting to constrain glacier responses and related environmental dynamics.

Based on five radiocarbon dates, an age-depth model provides time control. This is supported by a fall-out tephra layer corresponding to the well-documented Hudson-H1 eruption (~8500 cal yr BP). Down core multi-element X-ray fluorescence scanning, loss on ignition (LOI), magnetic susceptibility, biogenic silica (BiSi) and grainsize-analyses were carried out. The elements Ca and Ti, relating to the basalts that form the plateau, as well as magnetic susceptibility and granulometry are interpreted as proxies for terrigenous input, whereas the incoherent to coherent radiation ratio (XRF proxy for organic matter), LOI and BiSi are considered as indicators for lacustrine productivity.

Our analytical results show that lacustrine sedimentation spans at least the last ~10,200 cal yr BP, indicating a minimum age for the onset of ice-free conditions and westward retreat of the JR glaciers from the CCM. Between 10,200 and 1000 cal yr BP, sediment proxies exhibit a general increment in minerogenic components, which is particularly pronounced between 5200 and 4500 cal yr BP. In contrast, the concentration of organic matter decreases. We attribute this major shift in sediment composition to an increase in allochthonous detrital transfer from surrounding rocks caused by intensified runoff and/or accelerated ice degradation. In combination with previous work on the moraine chronology from Central and South Patagonia, our outcomes suggest a relationship to the termination of the Middle Holocene glacier high-stand. Around ~1000 cal yr BP autochthonous sedimentation starts to increase again in the lake basin. Whether this shift back to a higher lacustrine productivity is related to local drivers or to regional recent cooling periods has yet to be addressed by upcoming studies.

This research is funded by ANID FONDECYT 1210042 and ANID Regional R20F0002 (Ministry of Science, Chile).

Glacier, vegetation, fire-regime, and climate evolution in central-west Tierra del Fuego (~54°s) since local ice-free conditions

Dr. Patricio Moreno [1], ***Dr. Fabrice Lambert*** [2], ***Dr. Rodrigo Villa-Martínez*** [3]

1. *Department of Ecological Sciences, Universidad de Chile,* ***2.*** *Pontificia Universidad Católica de Chile,* ***3.*** *Universidad de Magallanes*

By virtue of its position adjacent to the Drake Passage, Tierra del Fuego allows examining the vegetation and environmental history of the southernmost continental landmass outside Antarctica, and the evolution of the Southern Westerly Winds-Southern Ocean coupled system since the Last Glacial Maximum (LGM). We studied lake sediment cores from Lago Charquito, a small closed-basin lake in central-west Tierra del Fuego with a continuous record since ~17.2 ka. Ice-free conditions at the site imply a ~70 km retreat of the Bahía Inútil glacier lobe from its LGM position along a ~800-year interval, a trend that continued until its disappearance ~100 km upstream, ~700 years later. Our palynological data show an open landscape dominated by cold-tolerant shrubs and herbs between ~17.2-12.8 ka, with increases in precipitation of westerly origin at ~16.3 ka, ~14.7 ka, ~12.8 ka, between ~8.7-6.9 ka, and at ~5.7 ka. Warming at ~12.8 ka initiated an abrupt afforestation trend that stalled during the early Holocene (~12-8.7 ka) owing to a precipitation decline or enhanced rainfall variability and wildfires, and later resumed in response to stronger westerlies. We hypothesize that sparse *Nothofagus* populations inhabited the periphery of the Patagonian Ice Sheet (PIS) during the LGM and migrated toward the Andes contemporaneous with glacier recession as temperature rose during the Last Glacial Termination (T1). Besides establishing topographic and climatic barriers for land biota, the Patagonian Ice Sheet enabled corridors that permitted the connectivity of cold-tolerant hygrophilous plant populations along a humid fringe adjacent to its land-based perimeter, despite the presumably xeric conditions downwind from the PIS margin. Comparison with high-latitude paleoclimate records suggests that southward shifts/contractions of the westerlies toward or beyond Tierra del Fuego enhanced upwelling and ventilation of deep waters in the Southern Ocean. Northward shifts/expansions had the opposite effect, similar to the zonally symmetric weakening of the westerlies during the early Holocene. We observe that the time evolution of atmospheric CO_2 concentrations, high-latitude air and sea-surface temperatures, and sea level during T1 fall short in explaining the timing and abruptness of the Bahía Inútil glacier lobe collapse, and quite possibly multiple other glacier lobes from the PIS.

Paleoclimate and paleoceanographical interpretations using bioerosion ichnodiversity patterns in the southern South-Western Atlantic at Patagonia, Argentina

Dr. Sebastian Richiano [1], ***Ms. Luciana María Giachetti*** [1], ***Dr. Marina Aguirre*** [2]

1. Instituto Patagónico de Geología y Paleontología (IPGP, CONICET-CENPAT), Boulevard Almirante Brown 2915, Puerto Madryn, Chubut, Argentina., 2. University of La Plata

Marine Late Quaternary skeletal concentrations from Argentina are rich in mollusks, extending more than 3,000 km between the Río de La Plata and southern Patagonia, where those formed during MIS11, 9, 7, 5 and 1 are the best preserved along the SWA. In this work we will analyze Late Pleistocene, Holocene and modern Patagonian deposits, where detailed field and laboratory observations carried out on bulk samples, allowed to identify a great variety of bivalve and gastropod taxa which testify an interesting history of paleoclimate-paleoceanographical-changes to present. In the molluskan fauna a great variety of bioerosion traces were identified (up to 15 ichnogenera) made by porifers, bryozoans, annelids, other gastropods and brachiopods. In general, the most characteristic traces are those produced by bryozoans, polychaetes and predatory gastropods. No strict correlation is evident between ichnodiversity patterns through time or latitude, but it is possible to observe a linkage to local oceanographical/biotic controls. In modern samples, most of the ichnotaxa were made by bryozoans, showing a general trend of higher bioerosion degree and ichnodiversity at higher latitudes. This pattern is controlled by sea surface temperature and productivity, as several ichnodiversity peaks for modern localities match with well constrained conditions (substrate, salinity, coastal fronts). Similarly, this applies for the Holocene. By contrast, not for the Late Pleistocene, when dissimilar conditions probably prevailed, especially during the Last Interglacial (colder waters richer in nutrients) as a response to different paleocirculation settings (winds, currents, ocean fronts). An exception to this general pattern is observed at San Matías Gulf (northern Patagonia), where local paleo-oceanographical conditions control the water-productivity levels affecting the bioerosional patterns (i.e. upwelling currents related to the gulf opening). In conclusion, the macrogeographical distribution of trace fossils, at least for Patagonia, could be used for interpreting the strong linkage between Earth history-climatic cycles-atmospheric-oceanic circulation patterns and Late Quaternary biotic responses, illustrating future potential climate change consequences for nearshore communities.

Session 155: Linking land and sea - multiple approaches to investigating human-environment interactions in the coastal zone

Buried landscapes offshore Belgium: investigating the drowned Testerep peninsula

***Dr. Víctor Cartelle* [1], Dr. Ruth Plets [1], Dr. Thomas Mestdagh [2], Dr. Tine Missiaen [1], Mr. Wout Van Wesemael [1], Ms. Zoë Vanbiervliet [3], Dr. Soetkin Vervust [3], Dr. Pieterjan Deckers [3]**

The Belgian coastal plain is a unique landscape shaped by the interaction of natural processes and human activities. It was once a dynamic tidal environment of channels, sandflats, dunes and salt marshes, now transformed into a densely populated and developed region threatened by relative sea-level rise, which also posed a risk to the coastal plain and its society through time. The interaction between geomorphology, past environmental conditions and the strategies developed by the people living in this landscape have shaped the large-scale coastal dynamics that have led to the present-day situation. This past evolution can offer valuable lessons for future actions to create a more sustainable coastline. This is the aim of TESTEREP, an interdisciplinary research project focusing on the evolution of the Belgian Middle Coast during the past 5000 years.

A large peninsula known as Testerep was once located on the Belgian coastal plain between the cities of Nieuwpoort and Ostend. The gradual degradation of the seaward side of the peninsula culminated in the historically and archaeologically attested abandonment of settlements in the 14th century, whilst the landward part has been heavily reclaimed. The offshore extent of the former peninsula has now been investigated by the combined analysis of high-resolution seismic profiles, magnetics, and sediment cores, revealing complex palaeolandscapes buried beneath the seabed. Large-scale channel belts are preserved to the east and the west of the former peninsula, pointing to the location of palaeo-valleys which migrated as the sea level rose. These channels are linked to a tidal environment preserved between the present-day coastline and a tidal sandbank. Here, acoustic anomalies recognised in the seismic records allowed the identification of several peat deposits cut by small tidal creeks, which represent former land surfaces subsequently drowned by the sea. Broad prograding bodies, corresponding to old coastal barriers, are found parallel to the coastline overlying a sub-horizontal transgressive surface. The reconstruction of the evolutionary phases of these paleo-landscapes will be used as the base for the morphodynamic modelling of the coastal evolution and the investigation of the erosional and depositional patterns that drove the coastline retreat.

Sedimentary multi-proxy records of human-induced environmental changes in the estuarine lake Nakaumi, southwest Japan

The coastal zone is a naturally vulnerable system and is subject to significant human-induced impacts such as eutrophication and pollution. We investigated the multiproxy records for 600 years in the sediment from Lake Nakaumi, an estuarine lake in Japan, to place the consequences of multiple stressors on coastal ecosystems into a larger temporal context.

We established the stratigraphy of bottom sediments at site Nk-3C in Lake Nakaumi based on the lithofacies, soft X-ray photography and CNS elemental analysis of three sediment cores. Using the age model inferred from ^{137}Cs, ^{210}Pb and ^{14}C dating, the core sediment is estimated to be deposited for the past 600 years, and the sedimentation rates ranges between 0.24 and 0.38 cm/yr.

From the 1400s to the mid-1900s, ostracode assemblages indicate the transition into more oxygenic environment in the bottom of Nakaumi. In this period, CNS elements indicate decreasing trends due to the dilution effect of increased clastic supply. This suggests the change of the mouth position of inflow rivers and the increase in water flow. Although the direct relationship could not be specified, the dominant horizons of a foraminiferal species, *Ammonia beccarii*, which coincides with the development of lamination in the corresponding stratigraphic level and the decrease in TOC and CN, are recognized three times during this period. After 1800 CE, the development of copper and molybdenum mines in the catchment areas are detected as a sharp increase in Cu and Mo concentration around 1900 CE. In the 1960s, CNS and many kinds of heavy metals show a rapid increase, the total abundance and ostracode diversity decreased, and eutrophic species of foraminiferas and diatoms increased. This rapid change indicates that the drastic shift in the aquatic environment was caused by loads of industrial and domestic wastes and the intense stagnation due to the construction of the port area. Multiproxy records which revert to the past value in the 1960s suggest the environmental recovery in Nakaumi. This reverting trend occurred much earlier than that of the metropolitan bay area such as Tokyo Bay and Osaka Bay in which the environmental degradation progressed more after the 1960s.

Sedimentary Records of Trace Metal Pollution in the Erdek and Bandırma Bays, Marmara Sea, Türkiye: History and Contamination Degree

Prof. Erol SARI [1], Dr. Çiğdem Sağlam ÖZEN [1], Dr. Tuğçe Arslan Kaya [1], Prof. Murat GUL [2], Prof. Mehmet Ali Kurt [3]

1. Istanbul University, 2. Muğla Sıtkı Koçman University, 3. Mersin University

The Erdek and Bandırma Bays in the southwestern part of the Marmara Sea have been adversely affected by increasing population, discharge of urban and industrial wastewater, densely used chemical pesticides and fertilizer heavily used in agriculture as well as domestic wastes and port activities. Sedimentological and geochemical analyzes of four core samples taken from Erdek and Bandırma Bays were investigated to evaluate the trace metal (As, Cr, Cu, Hg, Ni, Pb, V and Zn) pollution status, historical trends and contamination degree during the sediment deposition.

The core sediments consist mainly of clay (9-96%), silt (1–78%) and sand (0.1-20) with small amounts of gravel (0.1–7%). The range of As, Co, Cr, Cu, Hg, Ni, Pb, V and Zn concentrations in mg/kg in all core sediment samples are 0.5-28 (As), 0.1-21 (Co), 31-395 (Cr), 0.1-58 (Cu), 0.03-1.10 (Hg), 11-196 (Ni), 3-72 (Pb), 19-159 (V) and 6-255 (Zn). The results of CF and PLI reveal that the upper 20 cm core sediments in Erdek Bay were contaminated with Hg, Pb and Zn by both anthropogenic and lithogenic input via the Biga and Gönen streams. Furthermore, the upper 20 cm of MD72 and BK1 core sediments taken from Bandırma Bay were moderately polluted with As, Cu, Hg, Pb and Zn caused by the discharge of untreated industrial wastewater and domestic sewage from the surrounding area of Bandırma Bay. Moreover, lithogenic Pb-Zn was transported to Erdek Bay by Biga and Gönen streams from the Pb-Zn mineralized zones in the southern Sea of Marmara drainage area. C-14 dating reveals that As, Hg, Pb and Zn contamination in the study area was started about 400–500 years before the present based on preliminary sedimentation rate estimates and has increased intensely in the last century. The present study was supported by Research Fund of Istanbul University, project number FBA-2021-38098

Baseline assessment of metal contaminants at inshore reef settings

Dr. Tara Clark [1], ***Dr. Guia Morelli*** [2], ***Dr. Nicole Leonard*** [3], ***Dr. Valentina Rimondi*** [4]

1. *School of Earth, Atmospheric and Life Sciences, The University of Wollongong, Wollongong, NSW 2522, Australia,* ***2.*** *Institute of Geosciences and Earth Resources-IGG, National Research Council of Italy, Florence 50121, Italy,* ***3.*** *Radiogenic Isotope Facility, School of Earth and Environmental Sciences, The University of Queensland, Brisbane, QLD 4072, Australia,* ***4.*** *Department of Earth Science, University of Florence, Florence 50121, Italy*

As the Great Barrier Reef (GBR, Queensland, Australia) becomes increasingly threatened by unprecedented marine heat waves, it also remains at risk from ongoing coastal development. Yet despite current policy and management augmenting efforts to improve water quality by monitoring levels of sediment, nutrients and pesticides, there remains limited (available) baseline data on the presence of metals and metalloids in coastal waters, despite evidence for their toxic effects at elevated levels on a range of marine organisms. We present preliminary results of ongoing investigation on trace metal and metalloid concentrations in modern surface intertidal sediments as well as historical sedimentary deposits from cores collected from one of seven sites surveyed around popular inshore reef locations along the GBR.

Concentrations of As, Sb, Sn, Cd and Hg in twenty surface sediment samples from Edgecumbe Bay were found to be consistently 3-20 times enriched than average alluvial sedimentary values for Queensland. For two samples, levels of Cu exceeded commonly applied sediment quality guidelines, while Cr, Ni, Zn and Pb were above the range of concentrations defined for Queensland sediments in five samples, suggesting potential negative effects on biota. Modern concentrations were also found to be higher compared to historical deposits, chronologically constrained using uranium-thorium dating of adjacent coral material.

These results, although preliminary, provide a baseline understanding of these contaminants of emerging concern. Comparison with the other sites will provide an assessment of their ecological risk to local biota and will help ongoing monitoring of pollutants along the GBR for future conservation plans. This is especially important in view of increasing sediment input to the reef caused by abrupt weather events (cyclones, floods, storms) due to climate change.

Anthropogenic signatures and reference conditions in marine sediments from Italian coastal areas affected by different types of impact

Dr. Elena Romano [1], *Dr. Luisa Bergamin* [1]
1. ISPRA, Italian Institute for Environmental Protection and Research

Marine sediments are extraordinary archives of past events because they preserve many proxies of environmental changes, and sediment cores are suitable tools for reconstructing (paleo)environmental patterns. This work considered three marine sediment cores from earlier studies, collected at shallow water depths in front of sites that have been home to different types of past anthropogenic activities, causing different types and extent of contamination of marine sediments, and active in different historical periods. Grain size, metals, trace elements, and organic contaminants have been analyzed, and benthic foraminifera have been studied to be applied as environmental indicators. Moreover, a geochronological characterization was carried out based on different methods such as luminescence dating, ^{14}C, ^{210}Pb, and ^{137}Cs.

This work aimed to deduce general information on the characteristics of the anthropogenic signatures in marine sediments of Italian nearshore areas.

The different anthropogenic activities produced complex contamination in the three cores due to different parameters, whose high-resolution profiles were reconstructed along the depth. The geochronological characterization, integrated with historical information, allowed the attribution of significant changes in concentration patterns to well-known events. In addition, benthic foraminifera showed different responses to contamination, such as changes in assemblage composition, an increase of tolerant species, and a decrease in absolute abundance, which may be used as proxies of the ecological status.

From these case studies, it was deduced that: a) relatively high sedimentation rates of coastal marine areas allow to reconstruct of environmental changes at a decennial scale; b) the geochronological study needs to be integrated with historical information to attribute the changes of contaminant profiles to specific events; c) the first record of synthetic contaminants may be used as a chronological marker; d) the recovery of old uncontaminated levels provides reference conditions; e) each type of anthropogenic activity produces a mix of contaminants with different effects on benthic foraminifera that can be quantified and used as proxies for the (paleo)ecological status.

Foraminiferal Ba/Ca as coastal recorder of drought

Dr. Inda Brinkmann [1], ***Dr. Christine Barras*** [2], ***Dr. Tom Jilbert*** [3], ***Dr. Tomas Næraa*** [1], ***Ms. K. Mareike Paul*** [4], ***Dr. Magali Schweizer*** [2], ***Prof. Helena Filipsson*** [1]

Unprecedented drought and heatwaves have been increasing in recent years under global climate change. To assess drought periods in paleoclimate archives pre- and post-anthropogenic warming, reliable proxies are essential. In coastal regions, seawater barium (Ba) concentrations are directed by hydroclimatic conditions via riverine input of terrestrial-derived Ba, and can be inferred from biogenic calcite (Ba/Ca). Benthic foraminifera are abundant in coastal sediments and generally considered reliable geochemical proxies for high-resolution archives at the land-sea transition zone. However, the use of benthic foraminiferal Ba/Ca as indicator for terrestrial discharge specifically is rare and has never been validated. Here we explore the impact of the severe drought and heatwave over northern Europe in 2018, followed by a warm and wet year, on Ba/Ca of living (CTG-labelled) benthic foraminifera (*Bulimina marginata, Nonionellina labradorica*) from a Swedish sill fjord (Gullmar Fjord, northern Europe). Benthic Ba/Ca, derived from laser-ablation ICP MS, significantly correlates with riverine runoff during 2018–2019. In consultation with solid and dissolved trace elemental profiles we deduce that shallow-dwelling species are especially reliable as discharge proxy and propose potential mechanisms of Ba shuttling in the fjord's water column and sediment. While the drought-induced disruption of terrestrial Ba supply caused anomalously low benthic Ba/Ca signals, additional but minor Ba/Ca variability was introduced by distance to Ba-source, input of low-Ba seawater and species-specific vital effects. If these factors are considered, benthic foraminiferal Ba/Ca from near-coast environments has potential as a reliable proxy for continental hydroclimatic conditions, opening new opportunities to track drought histories throughout geological timescales.

A stormy past: a high-resolution Holocene storm reconstruction from a coastal bog, north-western Ireland

Dr. Jenny Sjöström [1], ***Prof. Antonio Martínez Cortizas*** [2], ***Dr. Frederik Schenk*** [3], ***Mr. Andreas Nylund*** [4], ***Dr. Richard Gyllencreutz*** [5], ***Prof. Richard Bindler*** [6], ***Dr. Daniel Ellerton*** [1], ***Dr. Malin Kylander*** [7]

Substantial uncertainties exist regarding how future climate change will affect storminess (a term that includes both frequency and intensity) in the eastern North Atlantic. Knowledge about spatiotemporal variations of past storminess can contribute to a better understanding of the mechanisms that govern storminess on centennial to millennial time-scales, which can shed light on the potential impact of external forcing on future storminess in climate models. Here, we present a unique storm record, covering the last 10 000 years, reconstructed from a coastal bog, in north-western Ireland. The sequence was analysed for grain size (Mastersizer 3000), chemical (EMMA-XRF), mineral (pXRD) and molecular composition (FTIR-ATR). The chronology is built on 11 AMS radiocarbon dates. The low inorganic content throughout the studied period, together with the grain size sorting, indicate that the minerals were mainly transported via aeolian pathways to the bog. The grain size analysis, conducted at decadal resolution, allowed differentiating between (fine) long-distance travelled dust, and coarser short-distance travelled sand particles. While the fine particles likely represent changes over a larger spatial area (e.g., changes in vegetation cover, dryness), the sand content likely represents regionally changing sea levels, dune building and periods of increased storminess. Increased storminess, inferred from the ratio between silt and sand sized particles, was recorded (cal BP) for the periods 6700–5500; 5070–4180; 3500; 3250; 2830–2480; 1940–1830; 1440–1100; 970; 510 and 290. The early Holocene was characterized by lower mineral input, finer grain sizes, and gradually drier conditions. Most of the storm episodes until 2000 cal. BP coincide with cold periods and wetter conditions, suggesting that an increasing thermal gradient between mid- and high latitudes, together with shifts in the sea-ice front affect the westerlies over the eastern North Atlantic. The de-coupling between regional climate and our record during the last 2000 years could be related to latitudinal shifts of the storm track, increasing human activity in the study area, local changes in source supply, or dating uncertainties. To resolve these uncertainties, additional paleostorm studies are required (e.g., north and south of our study location) together with paleoecological investigations (pollen, plant macrofossils).

The circulation of obsidian in the Strait of Sicily during the Holocene: A view from the Eastern Maghreb

The research presented here is part of a wider project carried out in the Eastern Maghreb which is aimed at detecting socio-cultural and economic changes among Epipalaeolithic Capsian and Neolithic groups in Northern Tunisia. The transition between the Early and Mid-Holocene in this region witnessed the gradual adoption of features that are usually associated with a Neolithic economy - within a hunting-gathering style of life: the presence of pottery, the introduction of domestic animal species, the appearance of pressure technique, and use of obsidian.

In particular, the discovery of obsidian artefacts in several archaeological sites of Central and Northern Tunisia, where sources of this material are not present, suggests that the Capsian and Neolithic groups of the Eastern Maghreb were undertaking seafaring activities across the Central Mediterranean, especially within the Strait of Sicily.

The five obsidian artefacts presented in this paper come from the Capsian sites of Sidi Aïch, in the Gafsa region, Khanguet Feriana, Khanguet N'am, and Oued Bou Haya, all in the Kasserine region, and from the Neolithic cave of Djebba, in the Beja Governorate. These artefacts were analysed through non-destructive and micro-destructive methods of elemental characterization: XRF, XRD, and LA-ICP-MS. The results were compared with those obtained from the analysis of geologic sources from Pantelleria and Lipari.

The application of these techniques reveals the Southern Italy provenance of the obsidian exploited for manufacturing the artefacts found in the Tunisian sites, and thus confirms that the human groups of the Eastern Maghreb were included in exchange networks across the Strait of Sicily.

Session 156: Multidisciplinary approaches of calcareous tufas and travertines: investigating environments and climates from Prehistory to today

Why is tufa not depositing anymore at lowland alkaline fen in Central Europe? Insights from monitoring and paleoecological data

Prof. Karina Apolinarska [1], ***Dr. Liene Aunina*** [2], ***Dr. Magdalena Marzec*** [3], ***Dr. Marcin Siepak*** [1], ***Prof. Danuta Michalska*** [1], ***Dr. Krzysztof Pleskot*** [4], ***Mr. Rafał Kiełczewski*** [1], ***Prof. Mariusz Gałka*** [5]

Tufa depositing alkaline fens, formerly abundant, have been decreasing in numbers since the mid-Holocene, first due to natural causes and recently due to human impact. Actions undertaken to protect and restore those ecosystems include restoring conditions favouring tufa deposition, which assures a proper substrate and allows for retention of low fertility of the fen by nutrient bonding during $CaCO_3$ precipitation. In the present study, we aim to: i) reveal the limiting factors for tufa accumulation at the alkaline fen in Turtul, Suwalski Landscape Park, NE Poland, holding the history of heavy $CaCO_3$ precipitation during the early and mid-Holocene; ii) evaluate the potential for reestablishing carbonate deposition. To complete our aim, we investigated the current fen ecosystem, which included botanical and malacological inventory and yearly monitoring of the physicochemical properties of the groundwater emerging at the fen and testing whether $CaCO_3$ precipitates there. Also, we studied the long-term responses of biotic and abiotic components of the fen ecosystem to environmental changes since the tufa deposition declined ca. 5400 cal yr BP. The decreased temperatures at the fen surface resulting from climate cooling and the entering of trees at the fen were likely responsible for the ceasing of tufa deposition in the mid-Holocene. At present, despite the unfavourable conditions for $CaCO_3$ precipitation, i.e., negative or neutral calcite saturation index, calcite crystals were observed in the spring and summer. Precipitation of calcite indicates the importance of the autotrophs, which absorb CO_2, locally increase pH and provide sites for $CaCO_3$ nucleation. The combined effect of global warming and cutting down the birch stands are likely to increase the temperatures at the fen surface, reactivate tufa deposition, and help restore the proper alkaline fen ecosystem. Currently, the calcium-rich substrate is indicated exclusively by *Carex paniculata* and two gastropod species, *Vertigo geyeri* and *Vertigo angustior*.

CO2 storage in tufa: non-traditional isotopes as quantitative identifiers of authigenic carbonate

Dr. Sonja Lojen [1], ***Dr. Tea Zuliani*** [1], ***Dr. Leja Rovan*** [1], ***Dr. Marko Štrok*** [1], ***Prof. Matej Dolenec*** [2], ***Dr. Barbara Horvat*** [3], ***Dr. Elvira Bura Nakić*** [4], ***Dr. Neven Cukrov*** [4]

The authigenic carbonate is a potent, but highly dispersed CO_2 sink, which has not been adequately quantified yet. Karstic tufa-precipitating streams are ideal settings for studying the magnitude of geological CO_2 fluxes because they encompass a traceable nexus of carbonate weathering, transport of particulate and dissolved inorganic carbon (DIC), CO_2 degassing and precipitation of secondary (authigenic) carbonate. The tufa represents a mixture of authigenic and detrital carbonate and non-carbonate bedrock weathering products contributed by surface run-off or atmospheric input; but carbonate in tufa can originate from different sources, too. To evaluate the potential of tufa as a CO_2 sink, the authigenic carbonate needs to be discriminated from detrital or soil carbonate and quantified separately. Although C and O isotope compositions in principle reflect the origin of carbonate, the quantification of carbonate sources is not always possible based solely on the C and O isotope compositions, in particular in lacustrine sediments. Recent investigations showed that the isotope fingerprints of tufa reflect the complexity of the local hydrology and that in such complex settings, U and Sr isotopes are better identifiers of authigenic carbonate than C and O isotopes. The quantification of authigenic carbonate, however, requires extensive characterization of local sources of detrital carbonate and dissolved load in the river and interstitial water.

We report on the use of U and Sr isotope fingerprints of bedrock, soil, tufa and dissolved metals for quantification of the authigenic carbonate in recent tufa formed at main barriers and in lakes at the Krka River (Croatia). The annual CO_2 storage in barrier tufa was calculated from carbonate precipitation rates (obtained using the Diffusion Boundary Layer model) and the estimated fraction of authigenic carbonate. In the studied system, it exceeded the annual CO_2 storage of temperate forests. In lentic environments, the sedimentation rate is the critical parameter for the determination of carbonate deposition, however, the net C fluxes to or from the sediment depend on the trophic status of the lake and the ratio of carbonate sedimentation rate and carbonate dissolution rate in the recent sediment.

Potential of MIS 5 and MIS 1 fluvial tufa deposits as palaeobotanical archives: examples from the Iberian Range (Spain)

The Iberian Range harbors tufa deposits associated with the current and past drainage network. These continental carbonates represent the external sedimentary response to the dynamics of karst systems and, therefore, constitute excellent palaeoenvironmental archives. Indeed, the well-preserved palaeobotanical proxies in the multiple fluvial tufa deposits along the range (e.g., Trabaque, Matarraña, Queiles, Val and Martín rivers) allow us to reconstruct both local and regional vegetation response to Upper Pleistocene and Holocene climate and hydrological variability. During MIS 5, chronologically placed between 130030 and 120610 yr BP, the vegetation in the southern Iberian Range was defined by Mediterranean pines (e.g., *Pinus pinaster* type), xero-thermophilous trees and shrubs (e.g., *Quercus ilex/coccifera* type, *Juniperus*, *Olea europaea*, *Cistus ladanifer* and Lamiaceae) and mesophilous trees, (e.g., *Alnus*, *Betula*, *Celtis australis*, *Corylus avellana*, *Fraxinus* and *Quercus faginea/pyrenaica* type) denoting a slightly milder and wetter climate than the present, while colder but still humid conditions are reconstructed for the 117000 ± 3500 yr BP and 103000 ± 4700 yr BP interval according to pollen and leaf imprints analysis (e.g., *Pinus nigra, Salix purpurea, S. eleagnos, Populus alba, Alnus glutinosa, Corylus avellana, Quercus faginea, Sorbus aria, Acer opalus, Fraxinus excelsior, F. angustifolia, Buxus sempervirens*, *Pistacia terebinthus*). During the Greenlandian (MIS 1, 9540-8380 cal yr BP) montane pine communities (*Pinus sylvestris/nigra* type), junipers and xerophilous taxa (e.g., Poaceae, *Artemisia*, Fabaceae, *Genista* type, *Helianthemum*) were the main landscape elements, while the riparian forests (e.g., *Corylus avellana, Castanea sativa, Juglans regia, Ulmus, Fraxinus, Salix, Populus*) and the Mediterranean woodland (e.g., *Quercus faginea/pyrenaica* type, *Quercus ilex/coccifera* type, *Pistacia, Rhamnus, Phillyrea*) acquired maximum representation during the Nordgrippian (MIS 1, 7590-5820 cal yr BP). The return of montane pinewoods synchronous to the depletion of mesophilous trees and the decline of tufa growing characterize the transition towards the Meghalayan (MIS1, ca. 4995-4060 cal yr BP) as consequence of increasing arid conditions at Iberian-scale.

Subannual-to-biannual-resolved travertine record of Asian Summer Monsoon dynamics in the early Holocene at the eastern margin of Tibetan Plateau

Dr. Hailong Sun [1]

1. State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, CAS

The response of decadal to centennial variations of Asian Summer Monsoon (ASM) intensity in the early Holocene to solar activities and/or earth internal forces remains a major question in quaternary research. In this study, we present a subannual–biannual-resolved (0.9–2 years) ASM intensity record spanning from 11.6 to 10.0 ka BP (before 1950 AD) inferred from a ^{230}Th-dated travertine δ^{18}O record at Zhangjia Ravine on the eastern margin of the Tibetan Plateau. The ASM intensity dynamics are consistent with North Atlantic climate changes recorded in Greenland ice cores and Cariaco Basin marine sediments in the early Holocene. This observation confirms the teleconnection between the ASM and North Atlantic climate. Our inferred ASM intensity variations are generally consistent with changes in sunspot number, implying a potentially instant response of ASM to solar activity at decadal-to-centennial timescales. There are several abrupt changes in the δ^{18}O sequence, which indicate that the ASM in the early Holocene was highly unstable. Comparison with marine records suggests that the Preboreal oscillation (PBO) event could be triggered by a freshwater outburst which the sudden release of thousands of cubic kilometers of the meltwater to the North Atlantic Ocean. Furthermore, the climate oscillations during the PBO were associated with the complex interplay of solar activity and freshwater outburst, the freshwater outburst may amplify the effect of solar activity when it was in the minima. The rapid warming after the PBO event may be controlled by the common mechanism that induced the Dansgaard–Oeschger warming events during the last glacial period. This study is not only important to understand the primary driving force of the ASM intensity in the early Holocene, but also essential for evaluate the probability of abrupt climate changes in the future.

Fall and rebirth of Holocene tufa in Slovak Karst (Western Carpathians) - a possible human influence

Prof. Michal Gradzinski [1]

1. Institute of Geological Sciences, Jagiellonian University, Kraków, Poland, e-mail: michal.gradzinski@uj.edu.pl

Several tufa complexes are known in the Slovak Karst. It is a typical karst area of a temperate climate built of Mesozoic carbonates, mainly Triassic in age. Carbonate plateaus are drained by karst systems which lead water to resurgences located in the valleys up to 300 m deep. Below the resurgences there are Holocene fossil tufa that exceeds 12 m in thickness. Two depositional systems were recognized within the tufas studied: (i) a perched springline transverse system, and (ii) a longitudinal fluvial depositional system.

The studied tufas flourished in the Mid-Holocene, namely in the Atlantic and Sub-Boreal times. Subsequently, they experienced substantial erosion and were incised, locally even down to their Mesozoic basement. Erosion was preceded by the instability of valley slopes, which resulted in the deposition of colluvium in the uppermost part and on the top of the tufa complexes. The instability was most probably caused by deforestation of karst plateau slopes. One can hypothesize that deforestation impacted the tufa depositional system in at least a twofold way: (i) via increase in the erosive capacity of streams, and (ii) via decrease in the dissolved calcium carbonate content of the stream water. It seems plausible that the forest retreat in Slovak Karst reflected growing pastoral or agricultural activity of prehistoric humans. Coincidence with establishment of the Kyjatice or Hallstatt culture in the area studied supports this view. Artefacts from these cultures have been found not only in tufas but also in numerous caves, including those near the tufa sites. The above scenario supports the theory that prehistoric humans influenced the cessation of tufa growth since they were responsible for deforestation, which in turn created conditions triggering the disintegration of tufa.

Whatever the factors that stimulated disintegration of tufa and incision of streams, they ceased to operate, as modern tufa is extensively growing at all the studied sites. Neither the precise time of the switch from disintegration to the growth of tufa nor the factors controlling it are known. One possible explanation is a partial regeneration of forests caused by low regulations in the mid 18th century in the Austrian monarchy.

Events recorded in travertine sequences in central Italy during the last glacial period

Dr. Mauro Brilli [1], ***Dr. Francesca Giustini*** [1], ***Dr. Nicolas Guyennon*** [2], ***Dr. Francesca Marchegiani*** [3], ***Dr. Stefano Nisi*** [3]

1. *CNR Istituto di Geologia Ambientale e Geoingegneria, 00015 Roma, Italy,* ***2.*** *CNR, Istituto di Ricerca sulle Acque, 00015 Roma, Italy,* ***3.*** *Laboratori Nazionali del Gran Sasso, INFN*

U-Th dating has shown that about 44 ka ago the accumulation rate of the main travertine plateaus of central Italy, Tivoli and Canino, about 100 km apart from each other, recorded a sharp decline. At Tivoli this event was also marked by an interruption in carbonate accumulation for at least 3-4,000 years. At Canino, an isotopic chronostratigraphy carried out on a travertine sequence that identifies the period 55 – 10 ka, confirmed the evidence that emerged through the dating of the Tivoli deposit; the isotopic curves have in fact identified a shift between 47 and 43 ka which correlates well with the decrease in the accumulation rate. Probably, this dramatic event has paleoclimatic causes which contributed to modulating the water tables in the respective hydrological systems and therefore the travertine depositional-erosional process. However, since Tivoli and Canino are endogenous travertines, both involved in the late Pleistocene tectonic activity, a tectonic control, that conditioned the rise of crustal fluids rich in CO2, could have played a crucial role.

The interplay of these two factors is difficult to evaluate in these contexts. A recent study on a drilling carried out on the right bank of the Tiber River valley, immediately north-east of Rome, has provided a significant contribution to clarifying this aspect. The core drilling showed the presence of a 3 m thick travertine body, lying below 8 m of recent alluvial deposits. It was studied for isotope and chemical stratigraphy, and U-Th dating. This travertine is associated with the rise of hypothermal, saline water and a deeply derived CO2 gas emission.

The chronostratigraphic investigation has shown that this travertine body was formed in the period 55-20 ka, and, despite the vastly inferior dimensional scale to the plateaus of Tivoli and Canino, it showed similar features, in particular the 44,000-year event in which the sharp decrease in the accumulation rate occurred. Chemo and isotope stratigraphy has described a temporal evolution of events in which climatic variations are superimposed on tectonic effects and has revealed that paleoclimate likely played a key role in triggering tectonic activity.

8.2 and 7.4 ka BP climatic events and human occupation recorded in travertine at Santovka (Slovakia)

Dr. Jan Petřík **[1]**, ***Dr. Katarína Adameková*** **[1]**

1. *Masaryk University*

The interrelation of climate change and human society in prehistory presents a multidisciplinary scientific problem, which could be revealed by research on fresh-water carbonate sediments. Such palaeoclimatic and archaeological archives were unearthed at the Santovka site (Slovakia), where travertine lake sediments of the Mid-Holocene age were discovered. Our intent was to directly compare evidence of human activity on the transition from the Mesolithic to Neolithic period with that provided by palaeoclimatic and palaeoenvironmental records. To achieve this, we intended to employ proven methods of geoarchaeology, isotopic geochemistry and palaeoecology, and our innovative applications of markers of human faeces. A considerable anthropic impact was represented by increased lipid coprostanol and charcoals during the second half of the 8.2 ka BP global climatic event. Abrupt drying of the lake environment at about 7.4 ka BP was contemporary with increased human activities associated with the Linearbank Keramik culture at the site.

New palaeoenvironmental investigations deduced from molluscan assemblages of a Middle Atlas tufa (Morocco)

Mr. Quentin Wackenheim [1], ***Dr. Nicole Limondin-Lozouet*** [2], ***Dr. Julie Dabkowski*** [2], ***Dr. Larbi BOUDAD*** [3], ***Dr. Jean-François Berger*** [4]

1. *Physical Geography Laboratory, UMR 8591 CNRS, Paris 1-UPEC University, Meudon, France.,* ***2.*** *CNRS-Laboratoire de géographie physique: environnements quaternaires et actuels (UMR 8591 Université Paris 1 Panthéon-Sorbonne, UPEC),* ***3.*** *Département de Géologie, Univ. Calcareous tufas provide a reliable sedimentary environment and favourable preservation conditions for the study of fossil land-snails assemblages. They represent a relevant bio-indicator and are complementary to other biological proxies (e.g. pollen, ostracods…) to describe the variability of the evolution of Mediterranean environments. However, the use of Holocene malacological assemblages is an approach that is gradually emerging in Morocco. Except for studies on continental molluscs linked to archaeological matters, continuous malacological sequences remain seldom conducted. In northeastern Morocco, several recent studies enable the construction of a first reference frame of palaeoenvironmental variations deduced from non-marine mollusc.
The Aït Said ou Idder tufa located in the Middle Atlas comprises a stratigraphic sequence that records part of the Late Pleistocene and the Middle Holocene. The multidisciplinary study of 3 outcrops of this deposit includes malacological and geochemical (oxygen and carbon stable isotopes) investigations. The evolution of malacological assemblages suggests first elements of the environmental context during D/O 8and MIS 5e. The Holocene succession presents a rich fauna of palustrine and hygrophilous taxa typical of wetlands and analogous to other malacological sequences of the Middle Holocene. In the upper part, more xero-resistant taxa develop and imply the first evidence of aridification during the second half of the Middle Holocene. The new malacological data obtained for the Aït Said ou Idder tufa are consistent with geochemical analysis obtained at the site and with regional palaeoenvironmental records.

The central Congo Basin contains the world's most extensive tropical peatland complex, which acts as a significant component in the global carbon cycle. Until now, limited radiocarbon dating indicated that peat formation began at least ~19,250 calibrated years Before Present (cal yrs BP). We analyse 31 radiocarbon dates from basal peat samples that provide new insights into the spread of peat across the basin. Our samples represent both interfluvial basin peatlands that are more common in the west of the region, and river-influenced peatlands that are more prevalent in the east. Here we show that peat first initiated in the central Congo Basin much earlier than previously believed. The oldest dates are from river-influenced peatlands on the floodplains of left-bank tributaries of the Congo River, indicating a high degree of channel stability in these rivers. Peat has been a persistent feature of the central Congo Basin for tens of millennia, but recent evidence of peat loss during past periods of severe drying raises questions about the stability of this globally-important carbon store in the face of future climate change and direct anthropogenic alteration.

Holocene environmental changes inferred from a Mauritia peatland palm swamp (aguajal) and an oxbow lake cores in the Madre de Dios region, southeastern Peru

Mauritia flexuosa dominated palm swamps (called *aguajales*) are typical peatlands in Madre de Dios River floodplains in southeastern Peru. To understand *aguajales* in that region, we investigated the late Holocene records of the local and regional vegetation dynamics, peatland evolution, organic carbon (C) accumulation, paleoclimate, and human impact using cores collected from the Los Amigos *Aguajal* (LAA) and oxbow lake (LAL) located within LAA.

LAA results show that the sedimentation started within shallow water, ponded on an impervious substrate within an abandoned river channel (1380–820 cal yr BP) located adjacent to a steep escarpment with *terra firme* (upland) rainforest and lateral to floodplain forests. This was followed by the development of a marshland (820–640 cal yr BP). A closed canopy *aguajal* established itself (640–300 cal yr BP) which later changed into an open canopy *aguajal* mixed with *Hedyosmum* (300 cal yr BP to present). Two major changes in peat and C accumulation rates were observed: An onset at 820 and a decrease after 520 cal yr BP. The peat and C accumulation rates in LAA were faster ca. 4 mm yr^{-1} and ca. 200 g m^{-2} yr^{-1} respectively, or similar to some *aguajales* in northern Peru.

LAL record, spanning the last 4260 cal yr BP, shows that the oxbow lake belonged to a meander of the Madre de Dios River, and was cut off at 1760 cal yr BP. The climate remained wet in 1760–640, but subsequently became less wet until the present except for the period of 610–540 cal yr BP. The charcoal results show that there was almost no human activity in the study area since 4260 cal yr BP. Comparison of LAL and LAA shows (1) the similarities and differences of vegetation dynamics on local and regional scales; (2) the main environmental changes in LAA may correspond to local moisture changes. LAL results show the opposite paleoclimate changes compared to the Peruvian Andes which might be related to elevation differences and/or non-climate disturbances influencing the existing records.

Mid- to Late Holocene vegetation changes and climate variability on the North Atlantic from Caveiro Lake margin peat record (Pico island, 38ºN, Azores archipelago)

A multiproxy study was applied to a 9m long record recovered from the peatland located at the NW margin of Caveiro Lake (Pico Island, Azores archipelago). Results of peat stratigraphy, elemental and stable isotope geochemistry on bulk organic matter and macrofossil analysis were used to infer past water levels and vegetation changes. From 6700 to 4300 cal yr BP, the sequence consists in a sedge peat with intercalations of tephra layers. During this period, high runoff events are recorded as layers with high mineral and transported woody remains, depicting high Total Organic Carbon (TOC>30%). From 4300 to 2750 cal yr BP the island undergoes a humid period that results in an important rise in water table. This is recorded by the accumulation of dark organic mud facies with low TOC/N ratios and abundant aquatic fauna. From 2750 cal yr BP, the Caveiro record depicts a terrestrialization characterized by the alternation of a dry phase dominated by a laurisilva shrub tree vegetation and a wetter phase consisting in a sedge-fen community that indicates a low water level, close to the surface. Dry shrub assemblage is interpreted from a peat rich in *Juniperus*, *Calluna*, moss and fern remains and high ∂^{13}C values (-26‰). Sedge-fen phases, instead, are recorded by the accumulation of peat made of Cyperaceae (chiefly *Carex*) and *Juncus* remains and lower ∂^{13}C values (-29‰). Lacustrine deposits associated with high water level are recorded as short events at 2530, 2060 and 1700 cal yr BP. The uppermost part of the sequence, from 1650 AD to the present, consists in Sphagnum peat. This finding is consistent with several records across Azores Archipelago: vegetation communities surrounding the lakes disappeared by human induced land use changes leading to *Sphagnum* dominated environments. Littoral communities are very sensitive to water level changes and therefore very adequate for reconstructing autogenic, environmental and precipitation changes. Because precipitation in Azores is mainly triggered by non-stationary interactions among North Atlantic Oscillation (NAO) and other climatic modes, this record contributes to a better knowledge of the role of long-term NAO changes and large-scale climate patterns of variability for the Holocene.

Late Holocene hydroclimatic changes across southern Patagonia reconstructed by peat bogs

Dr. Julie Loisel [1] ***, Ms. Kristen Sarna*** [1] ***, Dr. Zhengyu Xia*** [2] ***, Prof. Zicheng Yu*** [2] ***, Prof. Yongsong Huang*** [3]

The southern westerly winds influence weather patterns and water resources across the southern high-latitude regions, with important socio-economic impacts. The strengthening and poleward migration of these winds since the late 20th century also have implications for regional environmental change, including drought, wildfire, and sea-ice loss. However, it is challenging to recognize the natural variability of the westerlies and predict their future behavior, as those recent changes have been influenced by anthropogenic factors. Here we present a 4200-year-long record from a southern Patagonian peatland in a location that is sensitive to changes in the position/strength of the westerlies. Our $\delta^{13}C$ record shows a 6‰ increasing trend from 4200 to 1200 cal. BP, indicating a progressive, millennial-scale increase in peatland moisture. This long-term trend is attributed to an increase in moisture induced by strengthening SWW associated with a change in the mean state of the El Niño–Southern Oscillation (ENSO) system. Superimposed on this millennial trend are centennial-scale shifts in hydroclimate that persist into modern times. We suggest that a “paleo” Southern Annular Mode—that is linked to tropical Pacific climate, with dry events contemporaneous with positive phases and La Niña-like conditions—is responsible for this enhanced hydroclimate variability. Overall, our results point to millennial- and centennial-scale changes in hydroclimate during the Late Holocene that link tropical Pacific climate variability with the Southern Annular Mode and the southern westerlies, with far-reaching implications for future changes in the southern high latitudes, including CO_2 ventilation from the Southern Ocean.

Holocene dynamics of wildfires, vegetation change and carbon accumulation in Falkland Islands' peatlands

Dr. Clemens von Scheffer [1]***, Dr. Dmitri Mauquoy*** [1]***, Dr. David Muirhead*** [1]

1. *School of Geosciences, University of Aberdeen, Aberdeen, UK*

Large areas of the Falkland Islands/Malvinas are covered by peatlands. Their position in the South Atlantic puts them under strong influence of the southern westerly wind belt on the leeside of the Andes, resulting in relatively low annual precipitation and severe evapotranspiration. In one way or another, these factors also control naturally occurring wildfires. In addition to erosion, caused by the introduction of livestock a few centuries ago, a projected change towards higher wind intensity and less precipitation is another threat for the future of the Falklands' vulnerable peatlands and their ability to maintain the vegetation cover, to retain and store water, and to eventually accumulate peat and carbon.

To better understand these dynamics, cores from white grass (*Cortaderia pilosa*) and *Sphagnum* dominated peatlands are analysed. The main set of tools consists of looking in detail at past changes in the macrofossil record, the occurrence of macro-charcoal particles and the amount of carbon stored over different time periods. Identifying transitions from wet to dry-indicating vegetation and vice versa can give insight into former periods of climate change, and to potentially tie them to changes in the intensity and position of the westerlies. However, the mechanism behind layers with episodically high amounts of charcoal found in our records (i.e. a high frequency of wildfires), is not simple. Did wildfires spread because of drier conditions? Were they fanned by stronger winds? Or did wetter conditions favour the growth of more combustible material (vegetation)? One of the ways to tackle these questions is using Raman-spectroscopy on charred plant remains to gain information about the intensity of palaeo-wildfires.

Combining this approach with our collection of macrofossil data gives first insights into the Holocene evolution of selected sites on the Falkland Islands and the effects of regional climate changes.

Repeated forested peatland fires in sporadic permafrost zone in Western Canada

Dr. Niina Kuosmanen [1], **Dr. Minna Väliranta** [2], **Dr. Tuomo Wallenius** [2], **Dr. Sanna Piilo** [2]

1. Department of Geosciences and Geography, University of Helsinki, Finland, 2. Environmental Change Research Unit (ECRU), Ecosystems and Environment Research Programme, University of Helsinki, Finland

Wildfires have a crucial role in northern boreal peatland ecosystems as drivers of ecosystem functioning affecting vegetation composition and biomass, peat accumulation patterns and soil carbon (C) stocks. Especially, the northern permafrost peatland ecosystems are under pressure due to the climate warming and increasing anthropogenic impact. The frequency and severity of wildfires is predicted to increase in the future, and therefore knowledge of long-term natural fire dynamics and their effect on peatland functioning provide important information for peatland management and preservation policies.
To investigate long-term fire history and its effect on peat accumulation and peatland vegetation succession we analyzed macroscopic charcoal and plant remains from peat cores from five boreal peatlands located in sporadic permafrost zone in western Canada covering the past 1500 years. In addition, record of most recent fire events were derived from fire scars and documented fires on study area for the last 200 years. The regional long-term peatland fire patterns was examined by pooling together macroscopic charcoal records and calculating abundance of charcoal particles of each sample for each 100-year period over the last millennia.
All studied sites, except a northernmost palsa bog, demonstrate repeated fires throughout the study period suggesting that fires have been integral part of these peatland ecosystems in Western Canada. Compiled charcoal records indicate peak in fire activity with highest abundance of charcoal for the period from 1300s to1600s. Both, charcoal records and fire history from fire scars, suggest decreasing fire activity during the last two centuries. The clear and consistent post-fire increase in the abundance of *Sphagnum* mosses suggest relatively rapid recovery of the peatland ecosystem after burnings.

The regeneration pattern where pre-fire vegetation repeatedly recovers suggests that in long-term perspective fires may not necessarily have negative effect on peat accumulation. In conclusion, peatlands could remain as effective carbon sinks, if their natural state is preserved.

Holocene development, carbon accumulation, and fire regime characteristics in boreal peatlands

Mr. Daniel Coathup [1]***, Dr. Dmitri Mauquoy*** [1]***, Dr. Maarten Blaauw*** [2]***, Dr. David Muirhead*** [1]***, Prof. Graeme Swindles*** [3]***, Prof. Heikki Seppä*** [4]

Peatlands are the largest terrestrial carbon store on the planet, storing almost one-quarter of the global soil organic carbon stock, with 90% of this store residing in northern (boreal and subarctic) peatlands. However fundamental questions remain regarding the carbon sequestration potential of boreal peatlands in response to rising atmospheric temperatures, shifting precipitation patterns, and increasing frequency and severity of fire events. To understand how this carbon stock may respond to changing climate and fire risk, it is vital to understand the impact of past climate changes on peatland carbon accumulation.

This paper seeks to improve our understanding of peatland carbon dynamics in response to climate change in peatlands of Finland and European Russia. Considering their vast carbon stock, boreal peatlands are still relatively understudied, particularly for multiproxy studies. This is particularly true for European Russia which remains poorly studied and is largely absent from global syntheses on peatland dynamics. Further, peatlands in Finland are an excellent model ecosystem to study carbon dynamics and its relationship to climate, as they largely possess an undisturbed development history.

This paper addresses the knowledge gaps highlighted through a high-resolution, multiproxy, palaeoecological approach that will attempt to disentangle the drivers of carbon accumulation and reconstruct fire regimes across representative mire types for the boreal region. Four sites are under investigation, namely an ombrotrophic raised bog, an oligotrophic forested bog, a poor fen, and an aapa mire. To achieve this, a suite of established (plant macrofossils, testate amoebae, pollen, charcoal) and emerging (Raman spectroscopy) palaeoecological techniques are being employed. Raman spectroscopy has been extensively applied to charcoal material from modern soils, yet has the potential to provide insights on burning intensity during fire events. In particular, it may be possible to disentangle the effects of fuel type and moisture content on burning intensity and subsequent carbon losses. To date only one study has utilised Raman spectroscopy to reconstruct relative changes in burning intensity from peatlands and therefore this research provides the opportunity to explore a novel technique. The palaeoecological reconstructions will be complimented with robust Bayesian-age modelling chronologies, developed using ^{210}Pb and AMS ^{14}C derived dates.

Three peatlands – three stories of carbon accumulation: a case study from central Europe

Dr. Monika Karpińska-Kołaczek [1], _Prof. Piotr Kołaczek_ [1], _Dr. Katarzyna Marcisz_ [2], _Prof. Mariusz Gałka_ [3], _Dr. Katarzyna Kajukało-Drygalska_ [4], _Dr. Dmitri Mauquoy_ [5], _Prof. Mariusz Lamentowicz_ [1]

Peatlands, thanks to their capacity to capture CO_2 and long-term storage of organic carbon, play an essential role in the global carbon cycle. To better understand the patterns in carbon sequestration in time (the last ± 1500 years) and space, we reconstructed peat carbon accumulation rates (PCAR) in three peatlands (Jaczno, Głęboczek and Pawski Ług bogs) situated along the west-east gradient of northern Poland. Absolute chronologies retrieved from the Bayesian age-depth models based on high-resolution ^{14}C AMS dating provided good time control, whereas the selected time interval spanned a broad spectrum of human activity including population changes, from a major decline during the Migration period until the demographic explosion after the Industrial Revolution.

As our study aimed to find factors responsible for changes in carbon accumulation, we juxtaposed the obtained results with pollen, testate amoebae, plant macrofossil, and charcoal data. The results show that the investigated peatlands vary regarding local environmental conditions, patterns of development, vegetation and fire activity. The Głęboczek peatland (N Poland) is characterized by highly unstable environmental conditions, affected by numerous fires in the past. The Jaczno peatland (NE Poland) revealed relatively stable hydrological conditions for almost 900 years (from 1400 to 500 cal. BP), with generally high water levels and only several fire episodes, whereas Pawski Ług (W Poland) experienced an abrupt vegetation shift connected with the stabilisation of hydrological conditions and was almost not affected by fires. The highest PCAR was recorded in the Pawski Ług peatland (maximum = 271.3 g $C/m^2/yr$ and mean = 79.64 g $C/m^2/yr$). By contrast, another extreme was revealed by the Głęboczek profile, with a minimum equal to 2.63 g $C/m^2/yr$ and a mean 37.29 g $C/m^2/yr$. The Jaczno peat bog accumulated carbon with a mean rate of 74.6 g C/m2/yr, a maximum reaching 114.58 g $C/m^2/yr$ and a minimum equal to 18.22 g $C/m^2/yr$. Generally, the PCAR values were higher in the *Sphagnum*-dominated sections of the profiles with high shares of mixotrophic testate amoebae, unless fire hampered the process of carbon sequestration.

This study was funded by the National Science Centre grant 2015/17/B/ST10/01656.

Boreal and subarctic Canadian peatlands have accumulated large amount of carbon during the 20th century

Northern peatlands constitute one of the most important terrestrial reservoirs of organic carbon (C). In Canada, peatlands in the boreal and subarctic biomes cover nearly 11 million km^2 and contain approximately 103-184 Pg C. This stock represents five times the C estimated to be stored aboveground in the Canadian boreal forest. Within the last few decades, northern Canadian high-latitude regions have warmed more than twice as fast as the global average and this trend is expected to continue in the future. While methane emissions are projected to increase with permafrost thaw, recent studies suggest net gains in peat accumulation and vegetation biomass associated with longer growing seasons and warmer temperatures. In order to evaluate the potential changes in carbon accumulation since CE 1900, we quantified C stocks from 182 individual peat cores from the high-boreal and subarctic biomes of Canada. Results show that the C stock accumulated since 1900 CE between the peatlands of the two biomes are not significantly different. However since CE 1980, the ACAR (apparent carbon accumulation rates) and related C stocks in the subarctic biome where permafrost is degrading, have exceeded those from non-permafrost sites as peat accumulation (namely *Sphagnum*) increases with thaw. While the overall C balance and future sequestration rates remain uncertain, our results show that altered post-thaw landscapes favored an increase in peat and C accumulation during the 20th century. Due to the irrecoverable nature of the existing peatland carbon sink, the potential emissions offset from increased productivity, especially in relation to permafrost thaw, needs to be further investigated. A better quantification of the net carbon budget from the high latitudes ecosystems including plant productivity will help to improve climate-carbon cycle feedback models.

Searching for a missing nexus: long-term response of the microbial peatland food-web to critical environmental transitions in the last 1500 years

Prof. Mariusz Lamentowicz [1]***, Dr. Monika Karpińska-Kołaczek*** [1]***, Dr. Katarzyna Marcisz*** [2]***, Dr. Dmitri Mauquoy*** [3]***, Dr. Vincent E.J. Jassey*** [4]***, Prof. Michał Słowiński*** [5]***, Prof. Piotr Kołaczek*** [1]

Soil microbes like algae, fungi and testate amoebae, stored in the peat, represent soil food web and enable the reconstruction of complex ecological networks. In this study, we assume that soil microbes (e.g., algae, fungi and testate amoebae) stored in the peat represent soil food web and enable the reconstruction of complex ecological networks. In the past, these networks were affected by abrupt shifts in hydrology, chemistry and vegetation. Hence, our study aims to [1] explore past centennial food web snapshots during the last 1500 years, [2] identify links between non-pollen palynomorphs (NPPs) and testate amoebae (TA), [3] search for the missing links between TA and NPPs, [4] relate food web snapshots before and after the peat fire, and [5] assess the trajectory of the post-fire recovery of the peatland. We wanted to answer how food webs changed over a long-term scale, significantly how microbes responded to peatland fire, as fire is often connected with the increasing human impact leading to intensive land-use changes. We chose a peat profile from Northern Poland (Głęboczek peatland) to track the complex changes in microbial communities in the context of the regime shifts connected with wet/dry/fire transitions *in situ* and around the studied peatland. The site, Głęboczek peatland, was formerly studied in the context of the 6500 years of ecological and archaeological history in a lower resolution. The top 1 m part of the profile, sampled in 1-cm resolution, revealed a transition from fen to bog and then a shift into a burnt peat section and hiatus. The high-resolution data shows a considerable change in agglutinating testate amoebae community after the fire, suggesting openness and soil erosion with the input of the organic matter from the surroundings. NPPs and plant macrofossils indicate the wetness change and fire event. This study inspired us to question how to recognize local peat fires and better understand the past peatland response to the recent extreme stress, recovery and resilience.

Topographic and climatic controls over peatland types and their distribution on the Tibetan Plateau

Ms. Jingjing Sun [1], *Prof. Angela Gallego-Sala* [2], *Prof. Zicheng Yu* [1]

1. Northeast Normal University, 2. the University of Exeter

The Tibetan Plateau (TP) hosts a variety of mountain peatlands that are sensitive to environmental changes. However, we lack a basic understanding of environmental factors controlling the peatland distribution in the region. Here, we use a bioclimatic envelope model (PeatStash) and environmental analysis that utilise three peatland data sets from the well-studied Zoige peatland complex, all peat sites described in the literature across the TP, and an existing global peatland map (PEATMAP) to investigate major drivers of peatland distribution in the TP. Our results show that soil moisture and slope are key factors for peatland formation and persistence. Most peatlands captured by PEATMAP are in valley and flat areas (slope <5°) with sufficient soil moisture (Moisture Index (MI)>0.5) and mean annual temperature between -5 and 2℃. Also, we use the peatland complex in the Zoige region to ascertain the environmental space of this peatland type, as these peatlands are well-studied and mapped. The Zoige peatlands are distributed in regions with a gentle slope (<2°), mean annual temperature between 0 and 2℃, and MI greater than 1.7, which is much narrower environmental space than that from PEATMAP. We then use these thresholds to constraint the climate envelope model and to predict future changes in peatland distribution. Our results show that the climate envelope for Zoige peatland complex will shrink greatly under scenarios of low-to-high warming scenarios (SSP1-2.6 and SSP5-8.5). Modelling peatland distribution in the entire TP remains challenging because: 1) gridded climate data from limited observations are not sufficiently accurate, owing to the complicated topography; 2) different types of peatlands are characterised by different topographic, hydrologic and climate factors that add an extra layer of complexity; 3) PEATMAP for the TP region is inaccurate in many locations, presenting both false positives and false negatives. Improved peatland mapping with sufficient ground-truthing is urgently needed in order to understand drivers of peatland distribution in the TP, to make an assessment of carbon storage and other ecosystem services, and to predict the effects of climate change on these important ecosystems.

Recent changes in vegetation and testate amoebae in a subarctic fen

***Ms. Olivia Kuuri-Riutta* [1], Dr. Minna Väliranta [2], Dr. Annalea Lohila [3], Prof. Eeva-Stiina Tuittila [1]**

1. University of Eastern Finland, 2. Environmental Change Research Unit (ECRU), Ecosystems, Environment Research Programme, University of Helsinki, Finland, 3. Finnish Meteorological Institute

Northern peatlands store currently 415 Gt carbon (C), yet they remain a poorly understood feature in the current climate models. Increasing temperature and longer growing seasons may increase C sequestration and accumulation, but peatland drying recently observed throughout Europe, as well as in subarctic Russia and Canada, might have the opposite effect. Predicting the future of peatland C storage is complicated by changes in peatland vegetation: shrubs and trees are known to benefit from drying at the cost of mire forbs and mosses, which may lead to a transition from an open peatland into a closed forest within a few decades. This enhances decomposition, leading to C loss from peat, but it may be compensated by increased site-level photosynthesis and tree-biomass production. Enhanced fen-bog-transition has also been reported as a possible response to the drying and warming. As bogs tend to accumulate more carbon than fens, this could increase C accumulation. However, Sphagnum overgrowth of fen habitats has risen worries about possible biodiversity loss.

We will use paleoecological proxies – plant macrofossils and testate amoebae – to quantify changes in Lompolojänkkä peatland during the recent past. Climate change has been suggested to be the primary cause of drought-related changes in peatlands, but most of the studied peatlands are also affected by land-use originated anthropogenic impact. Lompolojänkkä is an ideal study site, as it is situated in a remote, scarcely populated area, where meteorological records are anyways available.

Four peat cores were collected from Lompolojänkkä mire margin in August 2020. Plant macrofossils were analyzed from the peat cores at 1– 4 cm intervals and testate amoebae at 1 – 2 cm interval. Pb-210 and C-14 dating methods were used to establish the chronology. We will show the changes observed in the plant and testate amoeba communities in Lompolojänkkä mire margin, and compare our dated peat records with the meteorological data from the site. Based on this knowledge, we interpret the implications for the mechanisms behind climate-induced changes currently observed in many northern peatlands.

Relationship between fire and mining activities over the late Holocene in a peat sequence in Northern Romania

Mrs. Anca Petras [1]

1. Stefan cel Mare University of Suceava

Relationship between fire and mining activities has consequence such as deforestation and mining, which overlap climate change, can cause changes in fire regimes and potentially increase the risk of fires, threatening vulnerable landscapes. The sedimentary charcoal is used for reconstructing regional changes in fire regime and anthropogenic effects of historical mining and local soil and bedrock erosion was also reconstructed using elemental geochemistry, magnetic mineral properties and particle size analysis. we analyzed sedimentary macroscopic charcoal morphological on sediments from the Taul Mare (TG) peat bog, in Lapus Mountains, northern Romania. Principal component analysis (PCA) was used to compare intensity in fire regime, charcoal accumulation rate (CHAR), geochemistry, magnetic mineral properties and particle size using PAST4.11 software. In late Holocene proxy may be interpreted as reflecting climate change caused by anthropogenic activity in special mining having consequence in landscapes with changes in fire regime. To understand the relationship between fire and mining activities, we surveyed published archaeological studies and traces of human settlement. The main results of PCA converge to conclude the following: fire activity increase following anthropogenic activities in the study area; increases in wildfire have generally been accompanied by episodes of increased landscape openness and expanded pastoral activities; the study area followed the mid-altitude mountains and proximity to landscape resources, pasture and mining. Temporally variation in fire severity may reflect climate changes (as shown by published regional palaeoclimate reconstructions) with, for example, warmer and drier condition. In conclusion our results show direct connection with statistically significant between fire severity and heavy metal concentration and direct link between fires and erosion (regardless of severity). This study offers information about previously unstudied environmental history in lowlands mountains, of the Northern Carpathians and emphasizes the importance of studies what can improve our understanding of the fire regime caused by mining activities.

Holocene development, functioning and decline of a Central European alkaline fen ecosystem

Mr. Rafał Kiełczewski [1]***, Prof. Mariusz Gałka*** [2]***, Dr. Krzysztof Pleskot*** [3]***, Prof. Karina Apolinarska*** [4]

1. *Institute of Geology, Adam Mickiewicz University, Poznań, Poland,* ***2.*** *University of Lodz, Faculty of Biology and Environmental Protection, Department of Biogeography, Paleoecology and Nature Conservation, Lodz, Poland,* ***3.*** *Geohazards Research Unit, Institute of Geology, Adam Mickiewicz University, Poznań, Poland,* ***4.*** *Institute of Geology, Adam Mickiewicz University, Poznań*

$CaCO_3$ depositing alkaline fens host many endangered species of plants and animals and act as an important carbon sink. These unique peat-tufa accumulating ecosystems become rare due to natural environmental changes and human impacts. Proper protection and restoration measures of alkaline fens require their functioning in long temporal scales to be thoroughly understood. In the present study we investigate the development, functioning and decline of the formerly $CaCO_3$ depositing cupola alkaline fen in Makowlany (north-eastern Poland). We aim to recognise the major drivers of the fen ecosystem evolution. Two sediment cores collected from the top and slope of the fen cupola were radiocarbon dated and analysed for geochemistry (loss on ignition at 550 and 950°C, macro- and microelements, $\delta^{13}C$ and $\delta^{18}O$) as well as plant macrofossil and mollusc compositions. Peat deposition at the fen started ca. 11200 cal yr BP; however, tufa deposition did not begin until ca. 10700 cal yr BP when permafrost thawing in the area enabled the circulation of deep groundwater that provided the ecosystem with elements necessary for calcite precipitation. Change in the chemistry of the fen surface favoured plants and molluscs typical of alkaline fens, including mosses, e.g. Tomentypnum nitens and gastropod Galba truncatula. The most optimal conditions for calcium carbonate precipitation, and therefore the development of the alkaline fen ecosystem with Cladium mariscus stands persisted between 8800 and 5800 cal yr BP, which was an effect of high temperatures and humidity associated with the Holocene Thermal Maximum. The gradual decline of sedimentary $CaCO_3$ since ca. 5600 cal yr BP likely records the temperature drop in central Europe. The increasing thickness of the sediments accumulated at the cupola could have also disabled the artesian waters from reaching the fen surface. Since then, brown mosses have been replaced with vascular plants.

Within the European peatlands subfossil tree trunks occur buried in organic deposits.
Identified on the basis of dendrochronological analysis, the phases of dying-off trees growing in peatlands as a result of long-term rise in water level, as well as the phases of trees germination during the peatlands drying, reveal the relationship between these phenomena and the phases of climate humidity growth/climate drying during the Holocene.
Currently, comprehensive studies encompass 9 peatland sites in Polish territory: Grel and Zawadowskie peatlands in the Carpathians, Podemszczyzna and Mosty peatlands in Southern Poland, Napoleonów in Central Poland and Imszar, Budwity, Rucianka and Krakulice peatlands in the Northern Poland. Some of them were formed during the Late Glacial (Podemszczyzna, Imszar), whereas the youngest one (Rucianka mire) was formed at the beginning of the Subatlantic Phase of the Holocene. Within all sites, mainly subfossil wood of bog pine (Scots pine: *Pinus sylvestris*) was used for dendrochronological analysis (within three sites there were also subfossil oak trunks *Quercus* sp.). On the basis of the wiggle matching method, several floating chronologies for bog pine were elaborated. The oldest of them (9980-9830 cal. BP) was compiled for the Podemszczyzna peatland in the Sandomierz Basin. Younger floating chronologies of bog pines from various peatlands in Poland have been compiled for the periods: 6790-6530; 4255-4060, 3130-2820, 2930-2290, 2170-1860 cal. BP. The youngest chronology (183 years), the end of which was dated at around 1179-1057 cal. BP, was developed for the Mosty peatland.
The results of dendrochronological analysis have been compared with the results of multi-proxy analyzes of peatland deposits, including pollen and non-pollen palynomorphs (NPPs), Cladocera, Diatoms, macrofossils and geochemical analyzes. For Rucianka and Budwity sites analysis of Chironomidae was also performed. These analyzes, supported by numerous ^{14}C radiocarbon dates, showed that the beginning of trees germination and colonization of peatlands by bog pines occurred during the phases of the climate drying, while the mass dying-off trees in peatlands took place during the phases of the climate humidity growth in the Holocene.
This study was supported with funds from the National Science Centre (NCN), Poland, grant No.

2017/25/B/ST10/02439 (2018–2022).

Peat sequences of the Somme Valley (Northern France): a 14,000 years long record of climate and anthropogenic forcing factors on bottom valley fluvial environments

Mrs. Chloé Garcia [1]***, Dr. Boris Brasseur*** [1]***, Dr. Pierre Antoine*** [2]

1. *EDYSAN (Ecologie et Dynamique des Systèmes Anthropisés) UMR 7058 CNRS-Université de Picardie Jules Verne – Amiens,* ***2.*** *CNRS, Universite Paris1*

At the scale of northwestern Europe, the valley bottoms of the River Somme basin make remarkable wetlands characterized by a significant fluviogenic peat accumulation (4 to 6 m on average). These fluviogenic peat (fen) sequences provide outstanding archives to describe the environmental evolution of northwestern France over the last 14,000 years. They are also fragile environments forming huge carbon sink. In this context, a research initiative has been initiated to highlight the respective roles of climatic and anthropogenic forcing factors (drainage, slope soil erosion) on peat formation/degradation processes and the modification of the related fluvial environments. The study is based on two stratigraphic transects of the valley (about 600 m each) based on more than one hundred manual boreholes and mechanical corings. The reconstruction of both sedimentation dynamics and palaeoenvironments evolution is based on a multiproxy approach combining sedimentology, geochemistry, palynology, and plant macro-remains identification, supplemented by forty-two ^{14}C dates. This work reveals that the first peat deposits were restricted to channel filling at the beginning of Lateglacial (14.6 - 14.0 ka cal. BP). This first peaty event was then interrupted during the Younger Dryas by the deposition of highly calcareous overbank silts ($CaCO_3$ > 40%) in the whole alluvial plain. Typical peat formation with high TOC values (> 45%) then restarted at the beginning of the Preboreal period around 12 ka cal. BP and rapidly extended to the full valley bottom (0.07 cm/year). During the Subboreal, the reactivation of the river flow is then indicated by the development of a deep meandering channel progressively filled in with laminated silty-organic deposits and a slower peat accumulation rate in the alluvial plain (0.03 cm/year). These modifications are contemporaneous with the generalized opening of the landscape (palynology), associated with the acceleration of anthropic erosion processes on the slopes during the Sub-Atlantic (2.9 ka cal. BP). Since the end of the Middle Age, organic silts fed by the erosion of loess soils have rapidly buried the peaty system, which is today essentially inactive and fossilized.

Peatland development in East European forest-steppe

Dr. Lyudmila Shumilovskikh [1], *Dr. Elena Volkova* [2], *Ms. Ekaterina Lukanina* [1]

1. Department of Palynology and Climate Dynamics, Georg-August-University Göttingen, 2. Tula State University

The East European forest-steppe forms a transition zone between humid broadleaf forests and arid steppes. Hot and dry summers do not favour peatland development, which more depends on the inflow of ground water. Consequently, genesis and development of forest-steppe peatlands are highly variable and strongly depend on local conditions. Forest-steppe peatlands especially *Sphagnum* dominated systems provide wide range of ecosystem cervices; therefore, have high nature preservation values. However, today they are facing frequent droughts and increasing agricultural intensification, very likely leading to their disappearance in the nearest future. The patterns of peatland formation in the East European forest-steppe since the late glacial are poorly studied. In order to close this gap, we investigated several mires in Kursk (Russian Federation) and Kharkiv (Ukraine) regions. Radiocarbon dated archives were studied for pollen, non-pollen palynomorphs, botanical macroremains, loss-on-ignition, micro- and macrocharcoals. Although some archives cover the last 15,000 years, formation of few peatlands (>30% of organic material) began in the Holocene. Starting points of organic accumulation vary considerably from 9000 yrs BP to the last few centuries. An increase in peatland development and carbon accumulation in the study region occurred in the late Holocene coinciding with an onset of the Holocene climate cooling and spread of broadleaf and pine forests, indicated by pollen data.

Session 158: The geomorphic signature of marine and continental Quaternary deposits

Timescales of erosion and sediment transport at the edge of the Colorado Plateau, USA: connecting upland sediment fluxes and down-valley fluvial processes over multiple glacial cycles

Mr. Spencer Staley [1], ***Dr. Peter Fawcett*** [1], ***Prof. R. Scott Anderson*** [2], ***Dr. Gonzalo Jiménez-Moreno*** [3], ***Dr. Vera Markgraf*** [2]

***1.** University of New Mexico,* ***2.** Northern Arizona University,* ***3.** Universidad de Granada*

Understanding the spatiotemporal scales of sediment production and transport across a landscape provides insight on the fidelity of stratigraphic records and is essential for predicting how surfaces we depend on may respond to climatic change. Unraveling the myriad processes that shape earth's surface through geologic time requires integrating various, widespread, and well-dated records. Here, we present a sediment core record of clastic flux into Stoneman Lake, Arizona, USA, a small (3.5 km^2), basaltic catchment high (2050 m) on the edge of the Colorado Plateau. End-member modeling of particle size data to identifies three sub-populations, fine dust, coarse dust, and local alluvium, whose modes are influenced by the weathering and transport histories of their source material. In combination with age control and density measurements, the volumes of these sub-populations are used to calculate the flux of each sub-population into the basin since ~ 230 ka, a period spanning the last two glacial cycles. Alluvial flux is high during warmer and dryer interglacials (Holocene, MIS 5 and 7) and increases dramatically following glacial terminations. Accumulation rate of the loessic (coarser dust) end-member increases during glacial episodes (MIS 2, 4, and 6) and likely corresponds to upwind fluvial aggradation occurring 25 – 45 km downslope to the south and southwest in the middle reaches of the Verde River. This concurrent record of sediment flux in an upland setting and activity in a downslope fluvial system suggests hillslope sediment mantles are produced during cooler and wetter glacials on 10^4-year timescales, stabilized by extensive forest canopies. Following a transition to warmer and dryer interglacial conditions, forests migrate and precipitation modes change, increasing runoff and liberating hillslope sediments on 10^2 -10^3 year timescales. Much of this sediment is stored in tributaries and doesn't feed into downslope fluvial systems until tens of thousands of years later when wetter glacial conditions increase discharge and tributary erosion. By exploring the temporal scale of sediment movement on the southwestern edge of the Colorado Plateau, we see that Quaternary climate changes act as a sediment pump, affecting sediment storage and the pace of transport between hillslopes, tributaries, and rivers.

Climate driven paleo denudation rates evolution in Madagascar and associated sediment sourcing to the Mozambique Canal since 900 ka.

Mr. Etienne Large [1], Dr. Julien Charreau [1], Dr. Pierre-Henri Blard [2], Dr. Germain Bayon [3], Prof. Eduardo Garzanti [4], Dr. Bernard Dennielou [3], Dr. Gwenael Jouet [3]

1. *CRPG Université de Lorraine,* **2.** *CRPG,* **3.** *Univ Brest, CNRS, Ifremer, Geo-Ocean,* **4.** *Dipartimento di Scienze dell' Ambiente e della Terra, Universita di Milano-Bicocca*

Denudation is the sum of chemical alteration and physical erosion. It is a key parameter controlling the evolution of the Earth's surface, the production of soils, the stability of relief or the evolution of orogens. Through silicate alteration and sedimentary fluxes that control the burial of organic carbon, denudation rates can influence climate. In turn, climate has a strong control over denudation through a number of processes such as precipitation or vegetation distribution. In order to understand the past evolution of the Earth's surface and to better predict future changes that will affect our habitat, it is necessary to constrain links that exist between climate and denudation. This requires precise quantification of past denudation rates.

At mid to high latitudes, denudation rates are strongly controlled by glacial and periglacial processes. Tectonic activity also has a strong impact on denudation, especially in rapidly uplifting orogens. Most studies reconstructing paleo denudation rates however, have concentrated on tectonically active and/or glaciated regions during the quaternary. To better comprehend the climate/denudation system, we propose here to reconstruct paleo-denudation rates from cosmogenic radionuclides in a region that has been affected neither by glaciers nor tectonic activity during the Quaternary, Madagascar. We measure cosmogenic ^{10}Be and ^{26}Al in quartz grains of turbidite layers from a marine sedimentary core that has been dated between 50 and 900 ka, and that was drilled on a terrace of the underwater Tsiribihina valley, in the Mozambique Canal. The ^{10}Be analysis of this core allows documenting paleo-denudation rates over several glacial-interglacial cycles, while the $^{26}Al/^{10}Be$ ratio gives us constraints on burial ages.

In order to investigate the sources of the terrigenous sediments brought from Madagascar to the Mozambique Canal during the past 900 ka, we use εNd, which is an efficient source tracer for ancient lithologies, such as in Madagascar (Mesoarchean to Neoproterozoic), as well as heavy mineral analysis/counting. Evolution of sediment sources also provide us with valuable information on the evolution of climate and precipitation in this region.

This integrated approach allows us to reconstruct climate affected paleo-denudation rates from a well delimited region during the Pleistocene.

Preliminary sectorization of the Zadorra drainage basin (Álava, Northern Iberia) evidencing Quaternary fluvial evolution

***<u>Mr. Iván Martín-Martín</u>* [1], Dr. Fernando Sarrionandia [2], Prof. Pablo G. Silva [3], Dr. Antonio Tarriño [1]**

1. Department of Geography, Prehistory and Archaeology, Faculty of Letters, University of the Basque Country (UPV/EHU), Tomás y Valiente s/n, 01006 Vitoria-Gasteiz., 2. Department of Geology, Faculty of Pharmacy, University of the Basque Country (UPV-EHU), Paseo de las Universidades, 7, 01006 Vitoria-Gasteiz., 3. Department of Geology, Escuela Politécnica Superior de Ávila, University of Salamanca (USAL), Hornos Caleros 50, 05003 Ávila.

The Ebro River, which constitutes one of the most ancient fluvial systems of the Iberian Peninsula (ca. 7.5-5.3 Ma), which onset is somewhat related with the Messinian Sea-level drop. Is the main fluvial catchment of N-NE Spain flowing into the Mediterranean from pre-Quaternary times. This study focusses on one of their main tributaries in its headwaters, the Zadorra River (Basque Country) which is 78 km long, with a catchment area of 1,398 km^2. According to preserved sedimentary deposits and geomorphological features, four distinct sectors) can be differentiated within in the present Zadorra drainage basin. Each sector reflects a particular evolutionary stage of the Zadorra fluvial system. From ancient to modern are: Sector 1 (415 km^2) comprises the present headwaters area of the Zadorra Basin and still preserves relatively large alluvial fans surfaces at basin margin locations, north and south. Here fluvial incision develops parallel to the regional strata bedding (N120E), generating a succession of “ridge and valley” structural reliefs by differential erosion in Cretaceous folded series illustrating a case of topographic rejuvenation. Sector 2 (343 km^2), to the north, outline to elongate N-S river basin heading in the higher reliefs of the Cantabrian-Basque Mountains, showing fluvio-karstic structures and periglacier-glacier landforms in the headwaters. In Sector 3 (141 km^2), at basin centre, the axial drainage shows a meandering pattern dissecting Pleistocene-Holocene lacustrine and distal fan deposits recording a previous semiendorrehic stage of the basin. However, its southern margin records the at least three stepped alluvial fan surfaces, the highest one at + 110 m above the Ebro River. Sector 4 (152 km^2), to the south, constitutes the present fluvial outlet towards the Ebro valley. It is constituted by a N-S transverse valley cutting the east-west structural reliefs bounding the Zadorra basin by the south. This represents the eventual capture of the rest of the afore described zones. Highest terraces recorded in this sector locate at + 60 m above the Ebro River, suggesting a Lower-Middle Pleistocene age for the eventual capture of the basin. Further studies on Quaternary landforms and geochronological analysis will help to refine a more detailed basin evolution.

A first look into new Pleistocene sedimentary records from the Upper Rhine Graben

Dr. Lukas Gegg [1], ***Ms. Felicitas Griebling*** [1], ***Ms. Laura Jacob*** [1], ***Ms. Nicole Jentz*** [1], ***Ms. Fiona Schwahn*** [1], ***Ms. Lena Stark*** [2], ***Dr. Ulrike Wielandt-Schuster*** [2], ***Prof. Frank Preusser*** [1]

1. *University of Freiburg, Faculty of Environment and Natural Resources, Institute of Earth and Environmental Science,* **2.** *Regierungspräsidium Freiburg, Landesamt für Geologie, Rohstoffe und Bergbau*

Sedimentary records containing evidence of past ambient conditions, flora and fauna, and geomorphic processes are the key to understanding and quantifying environmental change. Unfortunately, the preservation potential of deposits is typically low in terrestrial environments, and the resulting fragmentary, puzzle-piece character of continental sedimentary archives significantly hampers detailed reconstructions. This highlights the importance of, ideally long-lived and regionally significant, terrestrial sediment sinks.

One such sink is the Upper Rhine Graben (URG), a rift basin extending over >300 km from Basel, Switzerland, in the South to Frankfurt am Main, Germany, in the North. The URG has been subsiding since the early Cenozoic and has been filled by a kilometre-thick sediment sequence including up to ~500 m of Quaternary strata. Being fed by the Rhine river and its tributaries, the URG collects deposits derived from the Alps as well as from the graben shoulders including the Vosges mountains and the Black Forest.

We investigate the Quaternary sediment fill of the URG based on a set of drill cores spanning a longitudinal section of ~175 km length. In these cores diverse successions are recovered, including (glacio-)fluvial gravels and sands but also fine-grained lake sediments and loess as well as diamictic deposits. They are valuable windows into the past, and provide information on mountain glaciations, erosional and sedimentary processes, past environmental conditions and ecosystems.

Characterization and the volumes estimation of overflow deposits by a fossil branch of the Rhône, Bras de Fer (France), at the Little Ice Age through geomatics, sedimentology and geophysical tools

Ms. Anna Kharlanova [1]***, Mr. Claude Vella*** [1]***, Dr. Doriane Delanghe*** [1]***, Mr. Jules Fleury*** [1]***, Ms. Véronique Rinalducci*** [1]***, Mr. Yoann Quesnel*** [1]***, Mr. Minoru Uehara*** [1]***, Mr. François Demory*** [1]

1. *Aix Marseille University, CNRS, IRD, INRAE, College de France, CEREGE, Aix-en-Provence, France*

The extent and spatial footprints of glacial periods can be estimated from river sedimentary deposits. Thus, the morphology of the Bras de Fer, paleochannel of the Rhone, is the outcome of the climatic and hydraulic conditions of the Little Ice Age. The crevasse splay deposited on its right bank, and the palaeoforms of river braiding reveal a strong hydraulicity of this fossil distributary of the Rhone delta during its brief operation (1582-1711), whose dates are known through historical documents (Pichard and al., 2014).

The combination of GIS, sedimentology and geophysical methods facilitates the qualitative and quantitative study of river palaeoforms. The objective was achieved through the acquisition of very high-resolution, open-access spatial data (IGN, 2021), as well as improved sediment (Dean, 1974; Blott and Pye, 2012) and geophysical (Demory and al., 2019) characterization methods.

Quantifying of sedimentary volumes of the Bras de Fer is carried out by crossing a thin DTM (50 cm*50 cm) with different methods of stratigraphic recognition (core, ERT, trenches). Sedimentology analysis, magnetic susceptibility, C14, and OSL dating were used to characterize the deposits and define their age.

The stratigraphy of the sedimentary facies, combined with the particle size and organic matter (OM) and CaCO3 levels, specify the sedimentation processes of the area. The crevasse splay has coarser sedimentary fractions, with less OM and more CaCO3 than the anterior and posterior strata. Overall, the material applied is fine, ranging from fine sand to coarse silt, and contrasts with the particle size of the channel bed sediments.

The spatial distribution of accumulated sediments is determined by combining quantitative and qualitative data. A proximal-to-distal particle size gradient of the overflow materials was established as a function of the distance to the distributary palaeochannel, the Bras de Fer. Sediments are deposited preferably in the immediate vicinity of the bank rise, while distal deposits are mainly composed of coarser particles showing more hydrodynamic episodes.

Source-to-sink relation between the Romanian Carpathians and the Lower Danube Basin: an overview based on geochronology, lithology and geomorphology

Dr. Iulian Pojar [1]***, Dr. Mihaela Melinte-Dobrinescu*** [1]***, Mr. Andrei Gabriel Dragoş*** [1]***, Ms. Teodora Babos*** [1]***, Dr. Cornel Olariu*** [2]***, Dr. Tomas Capaldi*** [3]

1. *National Institute for Research and Development on Marine Geology and Geo-ecology – GeoEcoMar,* ***2.*** *Department of Geological Sciences, Jackson School of Geosciences, University of Texas at Austin,* ***3.*** *Department of Geoscience, University of Nevada, Las Vegas*

During the last 16 Ma, the Lower Danube course changed several times due to the geomorphological processes including the regional sea level changes, local tectonics, and sedimentary landscape evolution. The analyzed Quaternary sediments from the river deposits bring up-to-date strong evidence of the most eroded geological formations belonging to the Southern and Eastern Carpathians.

The recent Lower Danube sediments between Iron Gates Dam area and the Danube Delta are generally represented by clay, silts and fine to medium sands. We tried to identify the connection between the Lower Danube recent sediments and the main source of these sediments based on the detrital zircons (DZ) geochronology tool, lithology and tectonics factors.

A highly ranged spectrum of ages was identified using U-Pb geochronology on DZ, in the Danube River. Most of the DZ exhibit three major groups of ages: i) Cambrian-Ordovician, associated to back-arc basins and island arcs, linked to the Peri-Gondwana subduction (600 – 440 Ma); ii) Lower to Middle Carboniferous, from magmatic and metamorphic Variscan units (350 – 320 Ma), represented by dominant peaks in most analyzed samples; iii) Upper Cretaceous to Tertiary, younger than 100 Ma, possibly related to the Southern Carpathian Late Cretaceous Banatitic arc and to the Neogene volcanism of the Eastern Carpathians and Apuseni Mountains. Moreover, for the Lower Danube western tributaries the main sources of the DZ are the high-grade metamorphic rocks characteristic for the Danubian tectonic units of Dacia mega-unit. Some larger tributaries from the Lower Danube easternmost part show temporal disperse peaks on the DZ geochronology, feature probably reflecting successive processes of recycling. Notably, the most representative sources of DZ identified in the samples from easternmost Lower Danube tributaries are the Variscan metamorphites.

We conclude that the main source for Quaternary sediments of the Lower Danube are the metamorphic rocks of the Southern Carpathians, located between the Iron Gates and the Olt River basin. In the eastern Lower Danube, on the Romanian territory, a mixture of igneous, metamorphic and sedimentary rocks has been pointed out.

Flexure area, the gateway of the morphology and sedimentary structures of the upper slopes – NW Black Sea case

Dr. Gabriel Ion [1]***, Mr. Adrian Popa*** [2]***, Mr. Constantin Lazar*** [2]***, Mr. Vlad Apotrosoaei*** [2]***, Dr. Florin Duțu*** [2]

1. *National Institute of Marine Geology and Geo-ecology - GeoEcoMar,* ***2.*** *National Institute for Research and Development on Marine Geology and Geo-ecology – GeoEcoMar*

The flexure area of a marine basin is both the gateway and the witness regarding the sediment transport and deposition of sediments on the upper continental slopes. Usually in this area most of the canyons and channels are indented onto the outer shelf and from where the sediment supply is further delivered downslope. Here is also the place where the cold water cascading phenomena deliver large volumes of denser water to the continental slope. The amount of sediments mixed in the water mass is function of how far is the coastal area, the hydrographic network of the surroundimg land, currents and waves regime. The flexure zone and its adjacent areas are many times prone to dynamic phenomena as are tectonics and fluids expulsions. The convolution of the above mentioned environment and phenomena produces a diverse morphology and structures of the sedimentary bodies existing in the flexure and upper continental slope areas. The NW Black Sea is a very interesting and good example for all the phenomena mentioned above and due to several oscillations of the sea level the resulted morphologies and sedimentary structures are even more complex. In this part of the Black Sea the nowadays shelf is the widest and are present important features in terms of morphology and structure, as the Paleo-Danube canyon, other secondary canyons and large sedimentary edifices of the Danube and Dnieper deep sea fans. The Last Glacial Maximum – LGM lowered the water level just in the area of the present flexure zone and because of this at least one couple of regression-transgression has taken place. Specific morphologies and structures have been formed, that testify the erosion, construction of new system tracts, as well as features produced by the phenomena of fluid dynamics. The outer shelf area has a palimpsestic character due to several sea level changes that made that zone subaerial and then swept by regressive-transgressive waters. The paleo-hydrography of the subaerial times was complex and brought sediments to feed the flexure area and the upper slope. The specific morphology of the flexure area influenced the downslope delivery of water masses and sediments.

Mt Śnieżnica landslide fen and its palaeoenvironmental record – reconstruction based on geochemical proxy and radiocarbon dating

Dr. Łukasz Pawlik [1], *Dr. Daniel Okupny* [2], *Dr. Paweł Kroh* [3], *Mr. Piotr Cybul* [3], *Prof. Renata Stachowicz-Rybka* [4], *Mrs. Agata Sady-Bugajska* [5]

1. University of Silesia, 2. University of Szczecin, 3. Pedagogical University of Cracow, 4. Polish Academy of Sciences, 5. Silesia Museum in Katowice

In the present study, we analyzed a 4.4-m deep core excavated from the fen formed within the landslide body on the northern side of Mt. Śnieżnica in the Wyspowy Beskidy Mountains, the Outer Western Carpathians, southern Poland. In total, we analyzed 405 samples in terms of 29 geochemical components (e.g., nitrogen (N), carbon (C), sulphur (S), and the total organic carbon (TOC)) and physical properties, namely particle-size distribution, loss on ignition (LOI), and microcharcoal content. Additionally, to establish geochronology, we dated 27 samples of different biological materials using the Accelerator Mass Spectrometry radiocarbon method. A detailed examination of plant macrodetritus and wood anatomy supported our interpretation based on the geochemical data. The Mt. Śnieżnica landslide has probably formed ca. 14,000 cal BP in the first phase of the Allerød Interstadial. For almost 9000 years, there was no accumulation of organo-mineral material. At ca. 4400 cal BP, peat accumulation commenced. The peat accumulation begins with the global 4.2 Bond event of cold climate conditions. After another ca. 2000 years, the core sediments were dominated by limnetic mud, suggesting aquatic conditions in the landslide depression. This sudden shift in sedimentation characteristics is loosely linked to the boundary between the Subboreal and Subatlantic phases (ca. 2500 cal BP). The apparent dichotomy of the depositional record agrees with the reconstructed climatic conditions during the second part of the Holocene. Up to 3000 cal BP, the regional climate was warm and humid, which allowed fast biomass production and hillslope stabilization by trees. Forest fires occurred only at the beginning and end of this period (4400-3000 cal BP). After 3000 cal BP, the regional climate became cool and dry. In this period, we found evidence of intensified erosion, but it was unrelated to forest fire activity.

Sedimentary record of Holocene cave clastics as a model of an interglacial sequence? Insight from caves of Polish Jura (Poland)

Dr. Maciej Krajcarz [1]***, Dr. Magdalena Krajcarz*** [2]***, Dr. Magdalena Sudoł-Procyk*** [3]***, Prof. Marcin Szymanek*** [4]***, Prof. Jarosław Wilczyński*** [5]***, Dr. Michał Wojenka*** [6]

1. *Institute of Geological Sciences, Polish Academy of Sciences,* ***2.*** *Department of Geosciences, Biogeology, University of Tübingen, Hölderlinstraße 12, 72074, Tübingen, Germany,* ***3.*** *Institute of Archaeology, Faculty of History, Nicolaus Copernicus University in Toruń, Poland,* ***4.*** *Warsaw University, Faculty of Geology, Warsaw,* ***5.*** *Institute of Systematics and Evolution of Animals, Polish Academy of Sciences,* ***6.*** *Institute of Archaeology, Jagiellonian University in Kraków*

In many regions, including the Central Europe, the research on clastic cave sediments of the near-entrance facies has been focused so far on Pleistocene sediments. This bias was partially due to researchers' interest in the Palaeolithic, and partially due to the fact that Holocene sediments are usually poorly preserved, as a result of e.g. commercial exploitation of the deposits in 19th and 20th centuries. In Poland, famous researchers of cave sediments, such as S. Krukowski, W. Chmielewski and others, left the Holocene strata nearly without any comment. However, the excavations in the recent years have shown that the Holocene cave sequences show great scientific potential. In these sediments we find a record of climate change during the past several millennia, geomorphic processes, changes in fauna and vegetation, the anthropopressure, and the development of culture. Moreover, following the actualism approach, the Holocene sequences may be regarded as a model of an interglacial series; especially the sediments of the Lower/Middle Holocene, non-affected by the development of civilization, may be used for such approach.

In this paper we present the key and well-dated sequences of the Holocene near-entrance facies of cave deposits from Polish Jura (including: Shelter in Smoleń III, Żarska Cave, Perspektywiczna Cave, Cave above the Słupska Gate, and others). We search for common (thus, regional) and atypical (local) features in the sedimentary record and follow these correlations to formulate a regional scheme of the sedimentary sequence, including the main geomorphic events, weathering phases, and ecosystem changes. We also note any local deviancies in a sedimentary record, representing site-restricted disturbances caused for example by local topography, human impact and animal activity. Finally, we apply this litho-, allo- and climatostratigraphic model sequence to the Pleistocene sites in a search for analogous records. Of our particular interest are long profiles of Biśnik Cave, Nietoperzowa Cave, Ciemna Cave and Tunel Wielki Cave, where we may expect sediments from the last interglacials (MIS 5e, MIS 7, MIS 9).

The research was supported by the Institute of Geological Sciences PAS, an internal statutory task "Jaskinie" (2020-2023).

Landscape evolution in the Ganga-Sai interfluve in response to river dynamics and climate change via a meander cut-off lake of a plains-fed channel

Dr. Pavani Misra [1], ***Prof. Rajiv Sinha*** [2], ***Dr. Anjum Farooqui*** [3], ***Prof. Sampat Kumar Tandon*** [4]

1. *Institute of Ecology and Evolution, University of Bern, Bern,* ***2.*** *Department of Earth Sciences, India Institute of Technology Kanpur,* ***3.*** *Birbal Sahni Institute of Palaeosciences, 53-University Road, Lucknow-226007, India,* ***4.*** *Department of Earth and Environmental Sciences, Indian Institute of Science Education and Research Bhopal*

The floodplains lying to the north of the river Ganga in the Himalayan foreland basin act as transient storage for sediments derived from the Himalayan mountains. This fluvial terrain offers adequate groundwater supply and fertile fields to support the agricultural production and livelihood of a large population. The Ganga-Sai interfluve in the Central Ganga plains exhibits a broad suite of geomorphic features such as narrow meandering loops of streams, stretches of linear lakes representing sinuous abandoned channels and meander cut-offs, small ponds, and oxbow lakes. Regional and local-scale geomorphic mapping was carried out utilizing earth observation satellite imageries to comprehend the evolution of the linear array of meander cut-offs and oxbows in the Ganga-Sai interfluve. Results of the geomorphic analysis indicate that the belt of paleochannel remnants was formerly a part of the avulsed channel of the Sai river. Four stages of landscape evolution and development of various geomorphic features linked to channel migration in the Ganga-Sai interfluve region of the Central Ganga Plains between the Late Pleistocene and Holocene periods have been identified. Further, an oxbow lake (Baraila Tal) was chosen from this linear array of cut-offs, and three locations were excavated to examine the chrono-stratigraphic succession. Stratigraphic succession at Baraila Tal supported by sedimentology and stable isotope data from organic matter and micro-gastropod shells shows that this lake was previously a part of an active fluvial system, and the depositional environment transformed from a fluvial to a lacustrine system in response to geomorphic and climatic changes during the post-LGM period.

The Holocene graben of the Cotovelo River: a conspicuous active morphotectonic feature in the Brazilian Shield

Prof. Mario Teixeira Rodrigues Bragança [1], ***Prof. Luiz Fernando de Paula Barros*** [2], ***Prof. Déborah de Oliveira*** [3]

1. *Programa de Pós-Graduação em Geografia Física, Faculdade de Filosofia, Letras e Ciências Humanas, Universidade de São Paulo,* ***2.*** *Departamento de Geografia, Programa de Pós-Graduação em Geografia, Instituto de Geociências, Universidade Federal de Minas Gerais,* ***3.*** *Departamento de Geografia, Programa de Pós-Graduação em Geografia Física (FFLCH/USP); Programa de Pós-Graduação em Rede Nacional para Ensino das Ciências Ambientais (EESC/USP)*

Despite being preserved of orogenesis since the Early Paleozoic, the Brazilian Shield had experienced episodic epeirogenetic uplifting during the Phanerozoic, following Mesozoic and Cenozoic tectono-magmatic reactivations. The progressive opening of the Atlantic Ocean, the uplift of the Andean Chain, the macro-doming of central Brazilian Platform, the tilting of the northern part of the continent toward the Amazon/Orinoco basin low and Caribbean Sea, and the South America plate rotating clockwise are large scale internal processes controlling the geomorphodynamic at continental scale. In this context, fluvial dynamics and deposits are important tools in the investigation of endogenous control of depositional and denudational events of low magnitude at local scale. Therefore, geomorphological, sedimentary, geochronological, and hydrological data were assessed in order to investigate the continuing low rate active tectonic throughout the Late Pleistocene and Holocene, on the Western Brazilian Atlantic Shield, taken the Holocene graben of the Cotovelo River low valley as case. This graben accommodates a well-defined Northeast-Southwest oriented floodplain, delimited by 30 m-high, aligned shoulders, corresponding to Upper Pleistocene terraces, and results from an intraplate rifting. Deeply weathered sandstones under humid tropical climate supply a huge sediment load to the channel, creating a meander-like river pattern confined to an asymmetrical sedimentary basin, pointing to ongoing subsidence along normal parallel active faulting. Right margin tributaries carry significant amount of sediments to the floodplain, in alluvial fans. Indirect evidences allowed to propose vertical velocities for the active faults in the area, for a time scale of several thousand years, that integrates a significant number of geomorphic features and drainage anomalies such as channel diversion, anomalous bends, very young flying terraces, asymmetrical sedimentation, compressed meanders, impressively high and rectilinear scarps, etc. Based on 13 absolute OSL dating values, and in the recent fluvial history, the average slip rate of the graben was roughly estimated in 0.8 m^{-1}/ky since the Late Pleistocene. Thus, the Cotovelo River graben is a strong evidence of recent tectonic reactivation in intraplate environment and represents a benchmark of continental tectonic significance that provide specific information about the dynamic of landscape in the Western Brazilian Atlantic Shield and Eastern South America.

The different Late Quaternary morphotectonic evolution of the two main peri-Tyrrhenian grabens: Campania and Sele river coastal plains (southern Italy)

Dr. Ciro Cerrone [1], *Prof. Alessandra Ascione* [1], *Prof. Nicoletta Santangelo* [1], *Dr. Ettore Valente* [1]

1. Università degli Studi di Napoli, Federico II

The Campania sector of the southern Apennines is characterised by two wide coastal basins, namely Campania, in the north, and Sele plains, in the south.

Both represent peri-Tyrrhenian half-grabens sharing common features such as i) NE-SW trending master fault systems in the NW border; ii) thousands of meters thick basin infilling and, iii) carbonatic bedrock downthrown up to 3-4 km b.s.l. The formation of such half-grabens is due to the Late Miocene extension, still active, that caused the opening of the Tyrrhenian back-arc basin.

Even if during the Early Pleistocene the stratigraphic and structural setting, that led to the shaping of the Campania and Sele coastal plains is similar, their Late Quaternary evolution is quite different. In fact, while the Campania Plain records subsidence since Early Pleistocene and the formation of volcanic complexes during the Late Pleistocene, on the other hand, the trend of vertical motion, from subsidence to uplift, changes along the Sele Plain during the Late Pleistocene as testified by i) incision and terracing of the alluvial fill at the mountain foothills and, ii) presence of raised marine deposits on the coast.

In order to better constrain the Late Quaternary morphotectonic evolution of both plains, an integrated morphotectonic and morphostratigraphic work was carried out by geomorphological analysis of high-precision topographic data (1:5.000 scale maps and 5-m DEM resolution), field work and analysis of subsurface data from former and new shallow borehole logs.

New data provide a better definition of vertical movements during the Late Quaternary in the Campania and Sele plains by a detailed definition of the coastline changes as a consequence of the tricky interaction between sedimentary infill and sea level fluctuations.

The largest system of LGM continental dunes of the Italian Peninsula: the Dunes of Belvedere – San Marco of Aquileia (NE Italy)

Ms. Federica Vanzani [1], ***Prof. Alessandro Fontana*** [1], ***Dr. Livio Ronchi*** [1], ***Prof. Jacopo Boaga*** [1], ***Dr. Irka Hajdas*** [2]

1. *University of Padova - Department of Geosciences,* ***2.*** *Department of Earth Sciences, ETH Zürich*

Continental aeolian landforms and deposits related to Last Glacial Maximum climate conditions are typical features in Central and Western Europe, whereas they are unknown in the alluvial plains of northern Italy. Thanks to the analysis of aerial images, Lidar DEMs, Ground Probing Radar (GPR) profiles and field survey we identified a large system of dunes formed at the end of the Last Glacial Maximum in the coastal portion of the Friulian Plain, between the city of Aquileia and the Grado Lagoon. They are locally called "dunes of Belvedere–San Marco" and they cover an area of about 25 km^2, elongating in ENE-WSW direction. Their highest crests reach 10 m above sea level (asl), in contrast with the surrounding reclaimed coastal plain (-1 m asl). The deposits range from fine to medium-coarse sands, and concretions of cemented sand are abundant on the surface. In outcrops and GPR radargrams the cross sections document an internal structure made of few centimeters thick, 20-30° inclined foresets. They lay on top of the distal portion of the Isonzo River megafan, and their base and preserved top are radiocarbon dated to 21 ky cal BP. The new data allow to interpret the Belvedere – San Marco reliefs as a system of parabolic dunes, which currently represent the largest and most complex continental dune field in Italy. Moreover, the orientation of the dunes is concordant with that of Bora, a katabatic wind which blows in northern Adriatic and even today can reach peak velocity of 40 m/s. Similar winds, supported by the North European and Alpine ice caps could blow stronger and more frequently at the end of LGM and during the onset of deglaciation. Furthermore, the sparsity of vegetation due to the dry cold climate, and the large availability of sandy sediment, supplied by braided channels of the Isonzo River, created favorable conditions for the deposition of aeolian dunes. This discovery underlines the importance of wind-driven processes in the evolution of alluvial plain in northern Italy and suggests the presence of other continental dune systems with similar age, even on the present floor of the Adriatic.

The impact of Quaternary sea level changes on the development of depositional environments in the Kornati Channel (Adriatic Sea)

Dr. Dea Brunović [1], ***Ms. Ivona Baniček*** [2], ***Dr. Ozren Hasan*** [1], ***Dr. Ivan Razum*** [3], ***Dr. Nikolina Ilijanic*** [1], ***Dr. Slobodan Miko*** [1]

1. *Croatian Geological Survey, Department of Mineral Resources,* **2.** *Croatian Geological Survey, Department of Geology,* **3.** *Croatian Natural History Museum*

The glacial-interglacial cycles that occurred during the Quaternary affected many present-day coastal areas due to the significant changes in sea level that accompanied each cycle. Silled basins are especially sensitive to these changes. Thus, our study focused on obtaining a new record of the paleoenvironmental and sea level variability in the Kornati Channel silled basin by using multibeam bathymetry and high-resolution seismic data in combination with sediment core information. The investigated basin is a protected natural area, located in the central part of the eastern Adriatic. It comprises several adjacent sub-basins with different sill depths and numerous small islands some of which are nowadays submerged. The landscape is dominated by a steep escarpment that extends to a depth of 90 m below the present sea level. These submerged geomorphic features, which strongly influenced the evolution of the Quaternary environments, are well depicted in the obtained multibeam data. We recognized transitions between marine conditions during the interglacial highstands of sea level and terrestrial environment developed during the last glacial sea-level lowstand. The late Pleistocene-Holocene transgressive phase was a brackish-water environment, formed due to the karst features present in the investigated area. Changes in the depositional environments in different sub-basins primarily occurred as a result of the connection or disconnection of the Channel from the Adriatic Sea via sills at present-day depths of 30 and 50 m. Multiple sediment cores gave abundant direct evidence of these changes, whereas seismic data enabled stratigraphic correlation and reconstruction of the spatial distribution of the deposited sediments. Our study contributed to the understanding of the complexity of past environments developed along the karstified eastern coast of the Adriatic Sea. Furthermore, we revealed one of the longest Quaternary sedimentological records in the eastern Adriatic. The assigned MIS 3 age of investigated succession is important because records of this age are relatively rare in general.

This work was supported by the Croatian Science Foundation project QMAD (HRZZ IP-04-2019-8505).

Seismic-stratigraphy of Quaternary lowstand prograding wedges on the western margin of the Adventure Bank (central Mediterranean Sea)

Dr. Simona Todaro [1], ***Prof. Mauro Agate*** [1], ***Mr. Francesco Caldareri*** [2], ***Mr. Fabrizio Parente*** [2], ***Dr. Mariagiada Maiorana*** [1], ***Prof. Attilio Sulli*** [1]

***1.** Dipartimento di Scienze della Terra e del Mare, Università degli Studi di Palermo*, ***2.** Dipartimento di Scienze della Terra e del Mare, Università di Palermo, Italy*

Based on recently carried out morpho-batimetric and high resolution seismic investigations, a large field of coastal prograding sedimentary wedges has been discovered and investigated along the north-western sector of the Adventure Bank in the south-west Sicily offshore.

The Adventure Bank is located in the north-western sector of the Sicily Channel and represents a wide shallow waters area with average depth of 70-100 m; along its northern margin, the shelf edge lies at a depth between 80 and 170 m, and it is scoured by a few canyons headscarpements (Mazara del Vallo canyons, Egadi Valley).

During the sea level lowstands related to the cyclic eustatic changes occurred in the middle-late Quaternary, the Adventure Bank formed a wide emerged plateau and, along its north-western margin, a stack of wedge shaped, progradational sedimentary units developed.

The observed sedimentary wedges are composed of large dipping strata which prograde seawards downlapping on an extensive marine-to-subaerial erosional surface; individual clinoform horizons are up to 15 m high and display tangential or sigmoidal geometry; parallel to the shelf margin elongation, individual wedge displays lateral continuity up to 4,5 km. The top of the prograding wedges is truncated by a sharp ravinement surface that, landward, is draped by a thin, up to 2 m thick, seismic unit of gently dipping reflectors.

On the whole, the entire package of progradational wedges consists of superimposed levels of prograding clinoformed units separated by main downlap surfaces, and its deposition accounted for up to 1,5 km frontal accretion of the continental shelf margin.

A sequence-stratigraphy analysis of this sedimentary prograding package and a comparison with similar and coeval stratigraphic setting of others Mediterranean continental shelf margins, suggest these prograding wedges accumulated in a coastal environment as forced regressive sedimentary bodies during falling and lowstand stages related to the late Quaternary glacioeustatic sea-level changes generated by global climatic changes. The growth of shelf margin wedges has been largely controlled by paleotopography of the bottom downlap surface and by location of sediment supply entry points.

Session 159: Human-environment interactions in coastal areas: new ways to learn from the past

Between medieval land reclamation and storm surges – reconstructing man-environment interactions in the Wadden Sea of North Frisia (Germany)

Dr. Hanna Hadler [1], *Ms. Antonia Reiß* [1], *Dr. Dennis Wilken* [2], *Dr. Bente Sven Majchczack* [3], *Ms. Sarah Bäumler* [2], *Dr. Ruth Blankenfeldt* [4], *Prof. Claus von Carnap-Bornheim* [4], *Dr. Ulf Ickerodt* [5], *Dr. Stefanie Klooß* [5], *Prof. Wolfgang Rabbel* [2], *Dr. Timo Willershäuser* [6], *Prof. Andreas Vött* [6]

1. Johannes Gutenberg-University Mainz, Institute of Geography, 2. Christian-Albrechts-Universität zu Kiel, Institute of Geosciences, Kiel, Germany, 3. Cluster of excellence ROOTS, Christian-Albrechts-Universität zu Kiel, Kiel, 4. ZBSA, 5. ALSH, 6. Johannes Gutenberg University Mainz, Institute of Geography, Mainz, Germany

The coastal landscape of North Frisia (Schleswig-Holstein, Germany) has a very changeful geomorphological past. What is nowadays part of the UNESCO world heritage “Wadden Sea” was once an extensive cultural landscape. Yet, intense medieval man-environment interactions not only caused a rapid transformation of the natural landscape but also caused an increased coastal vulnerability that finally led to a storm surge-related permanent destruction of wide parts of the region.

Until today, much of the cultural heritage of medieval North Frisia has been preserved in the tidal flats and provides unique insight to so far little understood aspects of land reclamation measures, settlement structures and man-environment-interactions. Our main objectives were therefore to reconstruct selected areas of the drowned landscape on a micro-, meso- and macroscale to identify natural processes as well as human interventions with the environment to gain a better understanding of the medieval coastal landscape, its complex development and final destruction.

We combined different geophysical prospections methods (magnetics, seismics, electromagnetic induction EMI, electrical resistivity tomography ERT) with Direct Push sensing (Hydraulic Profiling Tool HPT, Cone Penetration Testing CPT) and vibracoring to provide insights to the tidal flat’s subsurface that - together with sedimentary, geochemical and microfaunal palaeoenvironmental parameter (PEP) analyses – allow for a detailed geoarchaeological reconstruction of the medieval. The geochronological framework is based on radiocarbon dating, archaeological age estimations of diagnostic finds, dendrochronology and historical reports.

Our results provide new insights into medieval land reclamation, cultivation measures and settlement activities that exceedingly modified most of North Frisia’s natural coastal landscape and increased its vulnerability against storm surges. The successful application of this interdisciplinary research approach also allows an extrapolation of our results to other Wadden Sea regions. Our reconstructions can even be considered a striking example for potential effects of future extreme events. Finally, we emphasize the urgent need for further investigations, as the cultural heritage preserved in the Wadden Sea archive is in itself highly vulnerable and already affected by strong erosion.

The dynamics of blue carbon sequestration in the Magdalena River delta, Colombia

Dr. k. anggi hapsari [1]***, Dr. Barend van Maanen*** [1]***, Dr. Dunia Urrego*** [1]

1. *University of Exeter*

Mangrove forests are unique tropical ecosystems that can sequester and store carbon (C) very efficiently. They play a substantial role in the global C cycle and provide significant opportunities for climate change mitigation and adaptation. Currently, mangrove ecosystems worldwide are under substantial pressure from anthropogenic degradation, land use change, sea level rise and climate change. In Colombia, an extensive area of mangrove forests is harbored in the Magdalena River delta. The Magdalena River, one of the largest rivers in the world, has been the most important waterway in Colombia for centuries. The presence and development of the city of Barranquilla on the Magdalena River mouth, has heavily impacted the river and mangrove forests on its delta. Sediment supply and freshwater inflow of the delta have also been modified by land-use change in the catchment and the building of dikes. However, there is limited understanding of how mangroves in the Magdalena River delta and their C storage capacity respond to environmental changes, both natural and anthropogenic. We study mangrove forest development and C accumulation capacity using sediment cores from Cienaga de Mallorquin, a highly-degraded deltaic lagoon neighbouring the city of Barranquilla. Sedimentary sequences have been analyzed for their biological and geochemical signatures. The results suggest how ecosystem changes have influenced C sequestration rates over the last centuries and control contemporary C stocks in an environment heavily impacted by human activities.

Coastal sediments record mid-Holocene dynamics of sea level, extreme events, and the human societal response in eastern China

Prof. Michael Meadows [1], *Prof. Zhanghua Wang* [2], *Dr. Tongtong Zheng* [2], *Dr. Yufeng Chen* [2]

1. University of Cape Town, 2. East China Normal University

Muddy coasts downdrift of large river mouths trap fine-grained sediments supplied from these rivers and have provided important settlement sites for prehistoric people, although the evolutionary history of such human-environment relationships has not been well described. In this overview of a number of well-dated sediment profiles and Neolithic sites from the northern and southern coasts of Hangzhou Bay, we deploy multiproxy evidence, including lithology, particle size, microfossils, organic and alkaline earth metal geochemistry, together with archaeological evidence, to reconstruct sea level changes and their associated societal impacts in the mid-Holocene. Neolithic occupation during ca. 8.0-4.0 ka occurred mainly during periods of stable sea level, while three major transgressions associated with sea-level rise interrupted the Neolithic cultures at ca. 7.6, 6.4, and 4.5 ka. Meanwhile, regional regression at ca. 5.6 ka favoured subsistence rice cultivation on the coastal plain. However, frequent storm events and saltwater intrusion at ca. 5.3-4.9 ka induced crop failure, possibly prompting the formation of a well-organized complex society i.e. the Liangzhu State theocracy. A further phase of sea-level rise at 4.5 ka, possibly in combination with climate change, triggered the collapse of the Liangzhu State, although a sea-salt industry emerged as an adaptive strategy of the coastal society in some localities. The integrated record casts light on the close linkage between environmental dynamics and the evolution of Neolithic cultures along the coast of eastern China.

Multi-centennial scale analysis of human-environment interactions in coastal areas: A multidisciplinary approach

Dr. Ekta Gupta [1]
1. Indian Institute of Technology Gandhinagar

Coastal areas are dynamic and keep changing across time and space. Coastal changes are studied using proxies of thousands or millions of years old geological records, biological indicators, archaeological evidence, data from the tidal gauges (consistently available from 50-60 years), and satellite images. Most of these methods require elaborate field and lab facilities and provide data of a few point locations; therefore, do not represent the entire area precisely. Geospatial data provided by satellites covers a short span of time (i.e. past few decades). Considering the dearth of direct evidence in coastal research, the study of early cartographic records available from the 16th century onwards become a critical source of information to visualise the regional geomorphology of the time for which we do not have other direct evidence and inform us about the sequence of physical changes. There is no doubt that these geographical records, especially the earliest ones, contain errors and are inaccurate in many ways. However, this inadequacy can be overcome by applying a combination of a quasi-quantitative spatial approach and a quantitative geospatial model, which allows the integration of geographical data of heterogeneous nature. The present study demonstrates the invaluable contribution of historical coastal maps and maritime charts in expanding our understanding of long-term (300-400 years) coastal dynamics and their interaction with humans by applying multiple-perspective geospatial approaches to evaluate, validate and analyse the early maps. The suggested approach opens up the possibilities to harness the untapped potential that these maps have in the study of coastal geomorphology and maritime heritage.

Morphostructural evolution of the Granada rocky coast (Southern Spain) and its influence on urban areas: example from La Herradura section

Mr. Davide Torre [1], *Mr. David Alfonso-Jorde* [2], *Prof. José Miguel Azañón* [2], *Prof. Marco Menichetti* [1], *Dr. Daniel Ballesteros* [2], *Prof. Daniela Piacentini* [3], *Prof. Francesco Troiani* [3], *Ms. Cristina Reyes-Carmona* [2], *Dr. Jorge Pedro Galve* [2]

1. *Department of Pure and Applied Sciences, University of Urbino "Carlo Bo"*, **2.** *Department of Geodinámica, University of Granada*, **3.** *Department of Earth Sciences, Sapienza University of Rome*

To support data acquisition and the field surveys, the use of remote sensing and GIS spatial analysis are necessary for coastal instability studies. In the Spanish Mediterranean coast, La Herradura section exhibits a clear example of the interrelation between geological structures and coastal landslides that affected populated areas. The coastal section of La Herradura is a 3 km-long bay constrained by two capes called Cerro Gordo (322 m altitude) and Punta La Mona (126 m elevation). The bedrock of both capes is part of the Alpujárride Complex, composed by Permian-Triassic marble, phyllite and schist, forming an Alpine S-vergent recumbent anticline affected by NW-SE and NE-SW normal faults since the middle Miocene. In this complex setting, the Cármenes del Mar and Marina del Este resorts were built just on the above-mentioned promontories, impacted by active slope movements almost since the beginning of the 21st century. Previous studies have already been conducted in these urbanised areas using photogrammetric and InSAR techniques, aimed at estimating the velocity of mass movements. Most are centimetres per year, but the displacements arrived at metric in specific sectors during highly rainy periods.

In our work, the analysis of the morphostructural framework revealed that the major tectonic structures have played a key role in the slope evolution of both study promontories, conditioning slope processes along faults, the bedding and tectonic foliations. First, by comparing the Cerro Gordo with the nearby Punta La Mona promontory, it was possible to give an assessment of the slope evolution of the promontories. In fact, both have similar lithology and geological structure, but they are morphologically different, due to an earlier evolution of the La Mona promontory. Second, the field survey supported by drone images and GIS spatial analyses have shown morphological features that suggest the existence of a large and ancient landslide in the eastern Cerro Gordo promontory. This implies that the active landslide affecting the Cármenes del Mar resort is only a nested body within a major mass movement involving the entire slope, entailing different implications regarding the interactions with the vulnerable elements therein.

Postglacial and Holocene environmental and sea-level change in northern Isle of Skye, western Scotland, and implications for human settlement.

Mr. Edward Taylor [1], *Dr. Natasha Barlow* [1], *Prof. Karen Hardy* [2], *Dr. Adam Booth* [1], *Dr. Graham Rush* [1], *Dr. Amy McGuire* [1], *Mr. Luis Rees-Hughes* [1]

1. School of Earth and Environment, University of Leeds, 2. Department of Archaeology, University of Glasgow, UK

Edward Taylor, Natasha Barlow, Karen Hardy, Adam Booth, Graham Rush, Amy McGuire, Luis Rees-Hughes

Lithic artefacts found in the modern intertidal and coastal environments of northern Skye indicate Late Upper Palaeolithic human settlement in the area (Hardy et al., 2021) prior to and during the Younger Dryas ice advance that covered the Cuillin hills, thereby restricting migration from mainland Scotland and potentially creating a northern Skye refugium. Some artefacts have been found in amongst raised beach deposits, while others have evidence of rolling, suggesting they have possibly been reworked by tidal or wave action and redeposited. In some cases, these artefacts may have been transported from locations that are today underwater. However, sea-level constraints for this area of Skye are insubstantial which limits understanding of the environment occupied by this community.

We undertake analysis on a core, taken from a basin behind the raised beach in which the archaeological remains are found, to reconstruct changes in relative sea level, and palaeoenvironments, during the postglacial and Holocene in northern Skye. The basal bedrock topography was mapped through a Ground-Penetrating-Radar (GPR) survey and utilised to identify suitable sites for sediment coring. The stratigraphy is typified by marine clays at the base, followed by reed-rich clastic sediments, which are overlain by a sphagnum peat. By conducting diatom analysis, we identify the transition between saline, brackish and freshwater conditions, and ^{14}C date the timing of these changes in marine influence. Additionally, pollen analysis provides further evidence of local vegetation and climatic variability at the site. We hypothesise that, due to lower than present sea levels, Late Upper Palaeolithic people were able to occupy the previously exposed foreshore as well as the area nearer the basin. Sea level then rose through the early and mid-Holocene, subsequently blocking the marine basin by the formation of a mid-Holocene highstand cobble beach. This work provides an important context for these unique Palaeolithic settlements on the islands of western Scotland.

A landscape-scale geoarchaeological approach to long-term human-environment dynamics and heritage management in metropolitan Vancouver

Dr. Christopher Ames [1], ***Mr. Andrew Mason*** [2]

1. *University of Victoria,* ***2.*** *University of British Columbia*

Metropolitan Vancouver in southwestern British Columbia, Canada, is situated along the coast of the Pacific Ocean, with a landscape characterized by rocky shorelines, large inlets, and the extensive Fraser River delta. Shoreline and nearshore environments are highly developed with residential, commercial, and industrial infrastructure, as well as large swathes of agricultural lands along the shores of the lower Fraser River. The region is also the traditional lands of multiple Central Coast Salish Indigenous Peoples and, despite the extensive development, it preserves a robust archaeological record documenting at minimum 9000 years of their cultural heritage. However, the landscape of metropolitan Vancouver that we know today is the result of Quaternary glaciations and a complex interplay of sea-level history, isostatic rebound, and the formation of the Fraser River delta following decay of the Cordilleran Ice Sheet (CIS) at the end of the Pleistocene. Ultimately, more than 300 km^2 of land emerged from beneath the sea during the Holocene due to the westward progradation of the Fraser River delta, and the archaeological record confirms that Coast Salish Peoples lived in the region alongside this immense reshaping and restructuring of the regional coastline. In this presentation, we draw on large datasets available through the BC Provincial Heritage Register and Canadian Archaeological Radiocarbon Database to integrate 9000 years of Indigenous occupation and use with the spatial and temporal patterns of landscape evolution to explore long-term human-environment dynamics in metropolitan Vancouver. We also demonstrate how a regional, landscape-focused approach to heritage management can provide evidence-based assessment tools within a highly urbanized context, helping to provide responsible solutions to address regulatory requirements and proponent obligations for project completion, while also balancing the interests of Indigenous communities and stakeholders, consistent with the principles and objectives of the United Nations Declaration on the Rights of Indigenous Peoples (UNDRIP) and the UN Sustainable Development Goals.

Ultra-high resolution analysis of inter-annual natural and anthropogenic variability over the past 600 years documented by a prodeltaic depocenter in the Gulf of Cadiz (Spain)

Ms. Christina Boyce [1], *Mr. Nicholas Turner* [1], *Dr. Isabel Mendes* [2], *Dr. Susanne Alfken* [3], *Dr. Marcus Elvert* [3], *Dr. Heidi Taubner* [3], *Dr. Till Hanebuth* [4]

1. Department of Marine Science, Coastal Carolina University, 2. Centro de Investigação Marinha e Ambiental, University of Algarve, 3. MARUM-Center for Marine Environmental Sciences, University of Bremen, 4. Coastal Carolina University

Due to low-resolution sediment deposition or discontinuous stratigraphy, investigating rapid environmental variability using sediment cores on continental shelves is challenging. Fine-grained fluvially sourced mud depocenters on continental shelves (MCDs), can provide an exceptional opportunity to examine such ultra-high resolution natural and anthropogenic processes. One such place to decipher the variability over the past centuries is the prodeltaic record of the Guadalquivir River in the eastern Gulf of Cadiz. This region is located between the Atlantic and Mediterranean climate systems and has a rich history of anthropogenic disturbances, particularly from the Industrial Revolution, affecting both the Guadalquivir River basin and regional coastal-marine system.

To analyze the timing and magnitude of changes and impacts, a 5-m long sediment core was taken at 23 m water depth from the Guadalquivir MDC spanning the past 645 ± 25 cal yrs CE. XRF core scanning at 1 cm resolution in conjunction with radiography imaging suggests three types of sedimentary facies within the core: hemipelagic (83%), flood event (15%), and storm layers (2%). High-resolution grain size, C/N isotope, and event-layer frequency analysis combined with elemental proxies and foraminifera assemblages are used to reconstruct climatic changes and environmental impacts on the river system, its estuarine mouth, and the offshore substrate during Little Ice Age to Anthropocene times.

Besides this classical approach, an ultra-high resolution preliminary study was performed on a flood layer using mass spectrometry imaging (MSI) *via* laser desorption ionization coupled to Fourier transform-ion cyclotron resonance-mass spectrometry for biomarker analysis along with micro-x-ray-fluorescence scanning (µXRF). Both MSI-based lipid biomarker analysis, targeting fluctuations of short- and long-chain fatty acids at 200-µm resolution, as well as 100-µm resolution elemental maps from µXRF measurements provide in-depth information on sediment source variations throughout a flood event.

Vegetation and arable farming in a Dutch Neolithic estuary landscape: first findings from the 'On Suitable Grounds' project in a wider context

Dr. Mans Schepers [1]***, Ms. Ana Smuk*** [1]***, Prof. Hans Huisman*** [2]***, Prof. Marco Madella*** [3]***, Dr. Kim M. Cohen*** [4]

***1.** Groningen Institute of Archaeology, University of Groningen, **2.** Groningen Institute of Archaeology, **3.** CaSEs – Department of Humanities, Universitat Pompeu Fabra, Spain; School of Geography, Archaeology and Environmental Studies, The University of the Witwatersrand, South Africa, **4.** Dept. of Physical Geography, Faculty of Geosciences, Utrecht University*

The interaction between people and the environment in the Early Neolithic in Dutch coastal wetlands has been studied extensively from the 1970's onwards. Settlements of the so-called Swifterbant Culture have been studied in detail, in particular those located in the polders of the present province of Flevoland, near the eponymous village of Swifterbant.
A recently started research project, 'Finding Suitable Grounds' studies the formation, age, and environmental properties of buried creek systems outside the polder area, buried under what is now the IJsselmeer. Using a combination of various geoarchaeologicaland palaeoecological proxies, we investigate the suitability for these landscape zones for early farming activities.
We will present the first findings from palaeoecological analyses on creek, levee, and floodplain deposits in this area, and place it in the context of the wider understanding of the interaction of the Swifterbant culture people with their environment. We will subsequently place this interaction in the broader discussion regarding arable farming in coastal wetlands in the Netherlands. This is a debate occurring in Neolithic, Bronze Age, and Iron Age research across the country. Finally, the degree to which this debate reflects the present perception of wetland landscapes, rather than past realities, will be discussed.

Shedding light on early embankments and associated landscape change on the Belgian coast using OSL profiling and dating

Dr. Soetkin Vervust [1]***, Ms. Zoë Vanbiervliet*** [1]***, Dr. Pieterjan Deckers*** [1]***, Dr. Víctor Cartelle*** [2]***, Dr. Ruth Plets*** [2]***, Dr. Tim Kinnaird*** [3]

1. *Multidisciplinary Archaeological Research Institute (MARI), Vrije Universiteit Brussel, Belgium,* ***2.*** *Flanders Marine Institute (VLIZ), InnovOcean Campus, Jacobsenstraat 1, 8400 Oostende, België,* ***3.*** *University of St. Andrews*

Water management is a key element in the history of the Belgian coast. Nowadays, hundreds of kilometres of manmade dikes and channels characterise the region's landscape and contribute to its unique historical value. This is a fairly recent development. For most of its Holocene history, the coastal plain was an unembanked tidal marshland. Studying how it was transformed into today's manmade embanked and drained polder landscape is the main aim of TESTEREP, an interdisciplinary research project looking into the evolution of the Belgian Middle Coast over the past 5000 years (https://testerep-project.be).

The project is named after the Testerep peninsula, once located here between the cities of Nieuwpoort and Oostende. Testerep was separated from the mainland by a broad tidal gully, which was embanked and drained, and consequently ceased to exist sometime during the Middle Ages. A relative chronology for the embankment process in the Testerep region had already been established, but absolute dating evidence was largely lacking. To address this shortcoming, two case study areas were chosen for detailed investigation: one where a presumed late medieval embankment is still preserved aboveground, another where subsurface remains of a peat-reinforced bank, perhaps of Roman age, had been excavated 20 years ago.

In both cases OSL dating in the lab was combined with OSL profiling in the field using a portable OSL reader. This allowed luminescence-depth profiles to be constructed for both the banks and their underlying and overlying sediments. As a result, detailed chronologies could be created of when the banks were in use, but also of the landscape phases preceding and following them. The study helps us better understand the long-term evolution of the Belgian coastal plain and how people adapted to life in this dynamic environment, modifying the landscape itself in the process.

The sensitivity of a coastal environment as documented by the Late Holocene record from Lake Butrint (Albania)

Dr. Alessia Masi [1]***, Prof. Laura Sadori*** [1]***, Prof. Adele Bertini*** [2]***, Dr. Marta Marchegiano*** [3]***, Prof. Flavio Anselmetti*** [4]***, Dr. Mario Morellon*** [5]***, Dr. Gaia Sinopoli*** [6]***, Prof. Daniel Ariztegui*** [7]

1. *University La Sapienza,* ***2.*** *Dipartimento di Scienze della Terra, Università degli Studi di Firenze, Via La Pira 4, I-50121 Firenze, Italy,* ***3.*** *VUB,* ***4.*** *Univ. of Bern,* ***5.*** *Instituto de Geociencias (CSIC, UCM), Facultad de Ciencias Geologicas, Univ. Lake Butrint (39°47 N, 20°1 E) is a coastal lagoon located in southwestern Albania along the Ionian Sea coast. Butrint is considered one of the most important Albanian archaeological sites with a considerable cultural, historical and natural value. It was declared a UNESCO World Heritage Site in 1992 and became a National Park in 2000. The lake's natural paleoarchive recovered as a 12 m long core composed of laminated sediments allows the high-resolution paleoenvironmental reconstruction of the last 4400 years. Permanent water stratification has led to the continuous deposition of varved sediments during the last millennia that, together with seven AMS radiocarbon dates and ^{137}Cs dating, contributed to the construction of a robust age depth model. The sedimentary succession has been widely investigated and sedimentological, geochemical, ostracod, dinocysts, pollen and microcharcoal data are available. These data document a coastal environment with marine influence that progressively became more terrestrial as evidenced by geochemical and ostracod patterns. Frequent earthquake shaking led to deposition of homogeneous turbidites that interrupt the laminated sedimentation. During the first part of the record in the Mid-Holocene, the present-day lagoon was a large embayment open to the sea. The progradation of the Pavllo River Delta caused the progressive isolation of the basin from the sea so that the Vivari Channel remained the only connection to the Ionian Sea since Roman times. Rather arid conditions occurred during warm periods such as the early Roman Warm Period (500 BC – 0AD), the Medieval Climate Anomaly (800-1400 AD) and after 19th century AD; fresher conditions occurred during cold intervals, i.e. the Late Roman-Early Middle Ages (0-800 AD) and LIA (1400-1800 AD). In summary, the Lake Butrint paleoenvironmental record is a combined result of climate variability, riverine processes, tectonic events and anthropogenic forcing, which all played together in shaping the region over the millennia.

Tracing a drowned medieval landscape –palaeoenvironmental reconstruction of the development of the Trendermarsch (North Frisia, Germany)

Ms. Antonia Reiß [1], ***Dr. Hanna Hadler*** [2], ***Dr. Dennis Wilken*** [3], ***Dr. Bente Sven Majchczack*** [4], ***Ms. Sarah Bäumler*** [3], ***Dr. Ruth Blankenfeldt*** [5], ***Prof. Claus von Carnap-Bornheim*** [5], ***Dr. Ulf Ickerodt*** [6], ***Dr. Stefanie Klooß*** [6], ***Prof. Wolfgang Rabbel*** [3], ***Dr. Timo Willershäuser*** [2], ***Prof. Andreas Vött*** [2]

1. *Johannes Gutenberg University Mainz, Institute for Geosciences, Mainz, Germany,* ***2.*** *Johannes Gutenberg University Mainz, Institute of Geography, Mainz, Germany,* ***3.*** *Christian-Albrechts-Universität zu Kiel, Institute of Geosciences, Kiel, Germany,* ***4.*** *Cluster of excellence ROOTS, Christian-Albrechts-Universität zu Kiel, Kiel,* ***5.*** *ZBSA,* ***6.*** *ALSH*

The UNESCO Wadden Sea World Heritage Site in North Frisia is a coastal landscape characterized by intensive cultivation and land reclamation against the background of rising sea level and intense storm impacts throughout the late Holocene.

In the high to late Middle Ages, the Trendermarschkoog belonged to the island of Alt-Nordstrand, which was largely destroyed during a major storm surge (the 2nd Grote Mandränke) in 1634 AD. Parts of the cultivated marshland were, therefore, presumed to be seawards of the modern sea dike, hidden under the recent tidal flat sediments. On the land side, parts of this medieval marshland are preserved in today's Trendermarschkoog.

Reconstructing this sunken landscape requires a broad methodological spectrum. Geophysical prospections in combination with vibracoring provided insights into the subsurface of the Wadden Sea directly in front of the modern dike of Nordstrand. Moreover, sedimentary, geochemical and microfaunal paleoenvironmental parameters helped to identify the surface of the medieval landscape. Radiocarbon dating, archaeological age determination of ceramic fragments and historical reports and maps were used to establish a geochronological framework.

As parts of the preserved medieval Trendermarsch, we identified dikes, ditches, dwelling mounds (terps) and cisterns and their individual signatures in the sedimentary record of the Wadden Sea. Moreover, we were able to reconstruct the palaeogeography of wide parts of the medieval Trendermarsch, partly drowned in the present-day North Sea. Finally, our findings provide a reliable basis for further (geo-)archaeological investigations in offshore near-coast areas of North Frisia.

Session 160: Geoheritage: role of scientists to keep earth scientific treasures for future generations

Quaternary Science-Based Geoheritage Evaluation: Constructing Effective Criteria for Arid Environments

Mr. Kenta Sayama [1]

1. School of Geograohy and Environment, University of Oxford

Since the establishment of the UNESCO Global Geoparks program in 2015, geoheritage conservation has developed considerably. An emerging issue amidst this rapid expansion is the geographical and typological imbalance of protected sites.

Quaternary geoheritage sites in arid environments, such as the Middle East and North Africa (MENA) region, form an under-protected type of geoheritage. These sites are important not only to understand the development of the regional landscape and for geohazard management, but also to understand the relationship between past climate change and human settlement/migration. Nevertheless, they remain largely unprotected, despite reports of their destruction from regions such as Southeast Arabia.

To protect these sites, robust criteria for their evaluation are essential. Although many methods have been proposed, evaluation of the scientific values of geoheritage sites has largely relied on the expert knowledge of a few researchers, without input from the broader scientific community. Moreover, there is geographical imbalance in expert opinions, which are largely based on European experience. Only a few studies have targeted arid environments or Quaternary geological/geomorphological sites.

Challenging this *status quo*, the present study created a new method to evaluate scientific values of Quaternary geoheritage sites in arid environments based on a survey of 43 interdisciplinary researchers (i.e. geoscientists, archaeologists, and evolutionary anthropologists) with interests in arid environments. The survey asked participants to assess the relative importance of 11 factors related to Quaternary sites and to rate the appropriateness of the types of proxies used to evaluate each factor.

Compared to previous studies, this method appoints a higher weighting to rarity, scientific knowledge, and archaeological relevance, and a lower weighting to site integrity and geological diversity. The importance of the archaeological connection is especially noteworthy, as it provides support for a “geocultural” approach to protecting Quaternary geoheritage sites in arid regions. Overall, this project demonstrates the necessity of involving the geosciences community to create environment- and type-specific criteria to identify scientifically valuable geoheritage sites.

Geoheritage and geoconservation in the sub-Antarctic: An illustration from the Prince Edward Islands from a South African perspective

Prof. Werner Nel [1]***, Dr. Elizabeth Rudolph*** [2]***, Prof. David Hedding*** [3]

1. *University of Fort Hare,* ***2.*** *University of the Free State,* ***3.*** *University of South Africa*

The Prince Edward Islands (Marion Island and Prince Edward Island) are the only South African territories in the sub-Antarctic and an important platform for South African led terrestrial science in the greater Southern Ocean. Using high-resolution satellite imagery and digital elevation data, more spatially accurate information of the surface geology of the Prince Edward Islands were recently presented. The islands enjoy the highest level of protection afforded to any natural area under South African law and are managed under the Prince Edward Islands Management Plan (PEIMP). Conservation efforts on the Prince Edward Islands have focussed on the protection of biological species, preservation of archeological artefacts, the management of pollution and waste and preventing the further introductions of alien species, but the conservation of geodiversity has received limited attention. This presentation shows how a standard geological and geomorphological mapping and ground surveying exercise was used to 1) highlight that certain geological features and specimen from the Prince Edward Islands are unique examples of geodiversity in a South African context; and 2) recommend a more comprehensive geoconservation strategy be incorporated into the PEIMP. Geological features that should be regarded as important elements of geodiversity include large landforms as well as removable specimens. For large feature such as lava tunnels, tubes and the modern-day lava flows and ash cones, we present the scientific reasoning and recommendations for a higher conservation designation to protect their structure. Whereas removable specimens such as pyroxene megacrysts and lava bombs associated with Pyroxene Kop on Marion Island and Kent Crater on Prince Edward Island, should be protected with more prescriptive collection restrictions. The Prince Edward Islands may not necessarily present international value in terms of UNESCO geoheritage standards, but they certainly contain geological features and specimens that are scientifically valuable and rare elements of geodiversity in a South African context and should be included in future assessments and policy of South Africa's geoheritage.

Geoheritage and Geological Mapping in Ireland

Mr. Michael Sheehy [1], *Dr. Clare Glanville* [1], *Dr. Sophie O'Connor* [1], *Ms. Trish Smullen* [1]

1. *Geological Survey Ireland*

The Geological Heritage programme of the Geological Survey Ireland (GSI) works to protect and promote the appreciation of geological heritage sites of national and international importance in Ireland. Ireland is well represented by its number of audited county geological heritage sites (CGS) that make up a national inventory of over 900 CGS which is likely to be completed by end of 2024. Furthermore, Ireland has three UNESCO Global Geoparks (UGGp) and one aspiring UGGp. This is a reflection of Ireland's rich geodiversity.

Despite CGS having no statutory protection in Ireland many counties have adopted CGS into their County Development Plans and also promote their public interest and preservation through Heritage Plans. This recognition, and de facto protection, of the national inventory of CGS is an appreciation of the significant contribution geological heritage makes to; our knowledge and understanding of past climate changes; documenting geodiversity which is linked to biodiversity and; our cultural heritage, tourism and education sectors.

The Irish landscape is dominated by glacial features of Quaternary age and correspondingly, almost half of Irish CGS have a direct link to themes associated with the Quaternary Period. Many other CGS have Quaternary features of note that are listed as part of the management and promotion strategy for these sites.

The Geological Mapping Programme in GSI supports the Geological Heritage programme by updating maps that depict the rocks and Quaternary deposits of the onshore area of Ireland. Quaternary geological mapping activities focus on areas of low confidence in the national Quaternary Sediments and Quaternary Geomorphology maps where stakeholder interest is high. CGS are always an important target for data acquisition when mapping an area as these sites often have a strong history of research activity. The synthesise of this existing research for the site often permits an updated understanding and an assessment of site specific preservation risks and allows the geologist to gather further information to deepen the store of knowledge of these sites.

Microbial and chemical characterisation from occupation contexts involved in the preservation of Roman writing tablets.

Dr. Caroline Orr [1]***, Dr. Rhys Williams*** [1]***, Dr. Rosie Everett*** [2]***, Dr. Gillian Taylor*** [1]

1. *Teesside University,* ***2.*** *Northumbria university*

Soil at the Roman site of Vindolanda (Northumberland, UK) provides excellent preservation of wooden artefacts including Roman writing tablets containing what is thought to be the oldest example of a women's handwriting. In this study we examined how chemical and microbial signatures change within varied occupation contexts of archaeological soil. Analysis included investigating elemental composition, bacterial diversity and community structure from excavation trenches at Vindolanda using pXRF and 16S rRNA gene amplicon sequencing. Samples were taken from varying depths starting at topsoil and working down through layers of Roman occupation including one cavalry stable floor, two infantry barracks and a cook house and layers which contained Roman writing tablets.

The chemical results indicate that areas where wooden artefacts were found had increased soil moisture which was also correlated with specific chemical conditions including shifts in iron, sulphur and phosphorous concentration. Sterols decomposing plant material were detectable from preservation layers only.

Microbial diversity was not correlated with depth but differed due to soil moisture and carbon availability. Overall microbial community structure was influenced by soil type (anaerobic, aerobic or waterlogged) and occupation context with layers showing best preservation of artefacts having different microbial communities to those without. Microbial community structure and putative function, as inferred by PICRUSt2, is linked to occupation usage rather than depth of samples with laminated floor layers differing from turf structures.

Understanding the complex processes within archaeological soil can help us to understand dynamics of decomposition and preservation. In addition, the apparent preservation of the environmental microbial community as well as the artefacts themselves allows expansion of this work allowing us to understand the microbial environments of the past, how they relate to the present and what this means for our changing environments in the future.

In this presentation we will show our data from the Vindolanda site and talk of our planned expansion of the work to cover the unexcavated peatlands found at the Roman site of Magna.

Applications of the Microbially Induced Calcium Carbonate Precipitation.

Microbial-induced calcium carbonate precipitation (MICCP) is a naturally occurring biological process in which bacteria promote the production of calcium carbonate, from microscopic crystals to large geological formations. This technology has been extensively explored in various environmentally friendly applications, such as the biorestoration of limestone monuments and can help to reduce the consequences of climate change through atmospheric fixation of CO_2, the main contributor of greenhouse gases. Thus, the application of this technology can counteract the ever-increasing concentration of CO_2 in the atmosphere and the extreme acceleration of the degradation of stone artworks due to global warming and increasing environmental pollution. However, while biomineralization is a common phenomenon among bacteria, not all microbes are suitable for such an application, due to their slow growth rate and low conversion efficiency and because many of them not only precipitate but also dissolve calcium carbonate. Consequently, we characterized a collection of bacteria isolated from several Cultural Heritage artworks, mainly from limestone highly degraded by atmospheric factors. We selected the most suitable bacterial strains by analyzing their ability to precipitate calcium carbonate crystals, studying the amount of precipitation in different media and conditions. In fact, biomineralized carbonate can also be useful in a wide range of applications such as sand consolidation, filling of pores and cracks by reducing water permeability in concrete, cement mortar restoration, increased strength of bricks. Our work is focused on carbonatogenic bacteria isolated from artworks to establish a *workflow* for *in situ* biorestoration applied on different calcareous materials, such as mortars and different limestones. This process involves the formation of crystals of calcium carbonate and has the potential to store large quantities of CO_2 and can be applied in different context using the MICCP for several applications, seeking also to counteract climate change effects.

Climate change and cultural heritage: a unique and fragile interaction

Archaeological sites and hypogeal tombs are considered the most exposed cultural heritage sites to climate changes. For thousands of years, these sites were preserved in specific, and sometimes extreme, natural environments, with which they have established a perfect equilibrium. The slightest variation of one of the environmental parameters could irreversibly modify the conservation of these archaeological sites. For example, in the hypogeal Etruscan tombs of Tarquinia, even a slightly variation of temperature and/or humidity could lead to the activation of microbial proliferation, irreversibly altering the mural paintings. In the Phoenician archaeological site of Mozia, the modelling of climate changes has predicted future floods, thus, a dramatic changes in salt content experienced by the microbial communities could accelerate the biodeterioration. There is a need to raise awareness, to draw up a future action plan to contain the damage caused by climate change at the most at-risk sites. The aims of this work are the following: firstly, to study the microbial community and its interaction with the different substrates in these sites of great historical and cultural interest, using molecular and analytical techniques to characterise the metabolic products of microorganisms. Then, changes in environmental parameters will be simulated in laboratory to assess the resilience of the microbial community to specific modifications, to design an action plan that could be applied in the future, if necessary. Finally, in line with the guidelines to reduce the impact on the environment, more sustainable alternatives for the removal of biological patina will be tested.

Session 162: Astronomical forcing and nonlinear climate feedbacks during the Pleistocene Epoch

Freshwater release from under an Arctic ice shelf triggering rapid climate oscillations

Dr. Walter Geibert [1], Dr. Jens Matthiessen [1], Dr. Jutta Wollenburg [1], Prof. Rüdiger Stein [1]

1. Helmholtz Centre Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany

At the seafloor of the Arctic Ocean and the Nordic Seas, traces of erosion by ice can be found down to surprising depths. For the Central Arctic Ocean, almost 1000 m are confirmed; in Fram Strait, which connects the Arctic Ocean to the Nordic Seas, up to 1200 m; south of Jan Mayen in the Nordic Seas at 850 m; and around the Greenland-Scotland Ridge, which connects the Nordic Seas to the North Atlantic with a depth of max. 900 m today, around 940 m below current sea-level. This ice thickness is best explained by extended ice shelves, which is also supported by model calculations. The observed differences in shelf ice thickness would have created under-ice cavities that can trap freshwater.
In periods of sea-level low stands, the outflow from the Arctic Ocean to the Pacific was blocked by land (Beringia), while rivers from East Siberia were still discharging freshwater into the shelf-ice covered Arctic Ocean- in addition to the freshwater input via glaciers. The combination of restricted outlets for freshwater from the entire Arctic drainage area, under-ice cavities due to different ice thickness in the basin, and a strong variability of local seafloor depths due to glacial erosion, isostatic change, and sea-level rise offer a mechanism to explain rapid climate oscillations.

A sudden release of freshwater from under the ice shelf must be accompanied by the penetration of large volumes of relatively warm, salty water into the Nordic Seas or the Arctic Ocean, leading to strong amplification of minor changes in sea-level, bathymetry or insolation by sudden heat transfer. This scenario is not only plausible when combining the available evidence, but it is also supported by strong proxy evidence. However, it also conflicts with several existing interpretations of Arctic and North Atlantic marine sediment records. This conflict has sparked considerable debate. Here, we give an overview of the state of the discussion and present more data in support of a temporary under-ice freshwater system in the Arctic Ocean and the Nordic Seas.

Meltwater-AMOC feedbacks at the centennial to millennial scale from speleothem records

Prof. Heather Stoll [1], ***Mr. Oliver Kost*** [2], ***Ms. Laura Endres*** [3], ***Prof. Hai Cheng*** [4], ***Prof. R. Lawrence Edwards*** [5], ***Dr. Carlos Pérez-Mejías*** [4], ***Prof. Isabel Cacho*** [6], ***Dr. Ana Moreno*** [7], ***Dr. Jakub Sliwinski*** [8], ***Dr. Judit Torner*** [9]

Department of Earth Sciences, University of Minnesota, 6. Universitat de Barcelona, 7. Pyrenean Institute of Ecology - CSIC, 8. University of St Andrews, 9. University of Barcelona

It has been difficult to empirically evaluate if meltwater was the trigger of most AMOC reductions during stadial events, or conversely if meltwater release was the consequence of subsurface warming and marine ice sheet destabilization during stadials? The decadal scale resolution of speleothem records provides a unique perspective on the leads and lags between freshening and cooling at the onset of D-O type events. The Northwest Iberian Speleothem Archive (NISA) from coastal caves is ideally situated since it records both meltwater events which decrease the d18O of the eastern North Atlantic ocean, as well as regional coolings resulting from AMOC reductions (via speleothem d13C). We present new perspectives on the interplay of meltwater and abrupt coolings during diverse periods of the last two glacial cycles, including MIS 5a, Termination II, and millennial variations within MIS 6. Over TII, freshwater forcing initiates AMOC weakenings early in the termination, and the short duration of the first AMOC reduction is consistent with a negative feedback between AMOC cooling and melt rate. In contrast, early in MIS 6, we find abrupt coolings which preceed by a century evidence for freshening. Such records should provide important constraints on model explorations of the sensitivity of AMOC to disruption under different boundary conditions.

Multiple mechanisms responsible for deep Atlantic oxygenation variations during MIS 4 with implications for oceanic respired carbon storage and atmospheric CO2

Ms. Svetlana Radionovskaya **[1]**, ***Prof. Julia Gottschalk*** **[2]**, ***Dr. Mervyn Greaves*** **[1]**, ***Dr. Oscar Branson*** **[1]**, ***Prof. Luke Skinner*** **[1]**

1. *University of Cambridge*, **2.** *Institute of Geosciences, Christian-Albrechts-Universität zu Kiel*

The deep ocean likely played a key role in modulating atmospheric CO_2 on millennial and astronomical timescales, through respired carbon inventory changes. Because the amount of seawater Corg broadly scales with the $[O_2]$ via Redfield ratio, we apply bottom water O_2 ($[O_2]_{bw}$) reconstructions to elucidate the oceanic mechanisms of CO_2 variability during MIS 4. MIS 4 is a key paleoclimatic interval of the last glacial inception, characterized by a rapid CO_2 drop of ~40 ppmv, and includes several millennial events, eg. Heinrich Stadial 6.
Here, we present multi-proxy $[O_2]_{bw}$ reconstructions from an Atlantic depth transect spanning the Iberian Margin to the sub-Antarctic South Atlantic, using redox-sensitive foraminiferal U/Ca and $\Delta d^{13}C$ between pore and bottom, supported by qualitative inferences from benthic foraminifer assemblages. We interpret the $[O_2]_{bw}$of a deep water mass as determined by: the amount of O_2 consumption (through respiration), and the amount of O_2 supply (influenced by concentrations at the sinking region(s), and ventilation changes).
Whilst the mid-depth North Atlantic (~2.6km) shows gradually decreasing $[O2]_{bw}$ into MIS 4, a minimum during HS 6, and subsequent recovery at the onset of MIS 3; in the abyssal North Atlantic (~4.6km), the U/Ca record maintains relatively constant and high $[O2]_{bw}$ throughout, supported by benthic foraminifera assemblages. The South Atlantic (~3.8km) differs from both: rapid reduction in $[O2]_{bw}$ into MIS 4 followed by clear increase during HS 6, reminiscent of the Antarctic CO_2 records. Our reconstructions suggest an accumulation of respired carbon in both the mid-depth and deep (~2-4km) North and South Atlantic Oceans at the onset of MIS 4, lowering atmospheric CO_2. However, during HS 6 continued North Atlantic $[O2]_{bw}$ draw-down and a large carbon release from the South Atlantic suggest significant ventilation impacts on oceanic respired carbon storage, mediated through the bipolar seesaw. Proxy records from abyssal depths are probably controlled by extremely low C_{org} (export) fluxes, preventing oxygen consumption.
Thus, our results highlight the differences between mechanisms of deep-water oxygen supply, versus oxygen consumption (ultimately local C_{org} and global atmospheric CO_2 variability), underlining the difficulty of disentangling their contributions to U and/or $d^{13}C$ cycling, on millennial versus orbital timescales.

An 800’000-year-old tag game: high-res viewpoints on CO2-Antarctic temperature phasing under different orbital frames

1. Climate and Environmental Physics and Oeschger Centre for Climate Change Research, University of Bern, Switzerland, 2. British Antarctic Survey, 3. Institut des Geosciences de l’Environnement (IGE), CNRS, 4. Université Grenoble Alpes, CNRS, IRD, Grenoble INP, IGE

Many novel atmospheric CO2 ice-core records have appeared since the last 800-thousand-year (800 ka) compilation in 2015, with several-fold improvements in resolution. Similarly, water isotope-based ice core reconstructions have also improved, allowing more precise phase studies between CO2 and Antarctic site and source temperatures. Alongside these developments, new well-constrained age scales have also spawned, reducing lead-lag uncertainties to sub-millennial scales. Here we draw from the most up-to-date ice-core datasets within the last 800 ka and study the phasing and rate evolution between CO2 and different Antarctic temperature reconstructions, in particular during glacial terminations and glacial inceptions. Our results evidence an overall pattern linking different CO2-Antarctic temperature pathways to specific orbital configurations, explaining some of the interglacial variability. Further, we propose that glacial inceptions may be induced via an obliquity threshold, after which cooling in Antarctica sets in. The timing between this cooling and the moment atmospheric CO2 concentrations fall toward glacial values can be to first order attributed to purely orbital features. In particular, the time elapsed between reaching the obliquity threshold and the next minimum in Northern Hemisphere Summer insolation seems to regulate any ensuing lag between CO2 and Antarctic temperature. Using a novel high-resolution atmospheric CO2 dataset covering the last interglacial (135–105 ka), we mechanistically ascribe the observed sharp CO2 drawdowns during glacial inceptions to abrupt weakening events of the Atlantic Meridional Overturning Circulation. We further suggest that these fast transitions were possibly triggered by a series of cascading events in the Northern Hemisphere that ultimately lead to the establishment of a deep ocean CO2 reservoir.

What do paleothermometers tell us about the mid-Pleistocene transition? The combination of Mg/Ca, clumped (Δ47) and conventional (18O) stable isotope in planktonic foraminifera

Dr. Marion Peral [1], ***Dr. Thibaut Caley*** [1], ***Dr. Bruno Malaizé*** [1], ***Prof. Erin McClymont*** [2], ***Dr. Thomas Extier*** [1], ***Dr. Dominique Blamart*** [3], ***Dr. Franck Bassinot*** [3], ***Dr. Mathieu Daëron*** [3]

1. *University of Bordeaux*, ***2.*** *Durham University*, ***3.*** *LSCE*

The Mid-Pleistocene transition (MPT - 1,2 Ma to 0.8 ka) allowed the establishment of the Late Pleistocene climate with the 100 ky orbital cycles. The orbital variations alone cannot explain the shifts in climatic periodicity of the MPT. The evolution of internal mechanisms and feedbacks have been called upon, in relation with the global cooling trend, the expansion of Ice Sheet and/or the decline in [CO_2]atm. A key point is therefore to accurately reconstruction of oceanic temperatures (SST) and to decipher the processes driving climate variations.

Here, we studied the marine sediment core MD96-2048 taken from south Indian Ocean in the source region of the Agulhas current. We compared 5 thermometers: alkenone, TEX86, foraminiferal transfer function (TF), Mg/Ca and clumped isotope (Δ_{47}). All thermometers have been measured at high resolution, except for Δ_{47} that focuses on the maximum of glacial (G) and interglacial (IG) periods over the last 1.2 Ma. Strong differences are observed between the 5 derived-SST: the alkenone and TEX86 recorded higher temperatures than the other proxies. Alkenone-SST do not show G-IG variations within the MPT. The Mg/Ca- and the TF-SST show a good agreement to each other, while the Δ_{47}-SST are systematically colder than the other SST proxies.

The $d^{18}O$ is dependent on SST and $d^{18}Osw$, which is regionally correlated with the salinity (SSS) in the present-day ocean. The Mg/Ca is controlled by SST and affected by SSS and pH, while the Δ_{47} is only SST-dependant. If the present-day $d^{18}O_{sw}$-SSS relation was the same during the MPT, we can separate changes in $d^{18}O_{sw}$ from SST effects and reconstruct past SSS. The $d^{18}O$, Mg/Ca and Δ_{47} combination may then allow the reconstruction of SST, SSS and pH. We used this new approach to estimate the long-term evolution of past SST, SSS and pH across the MPT. The SST (excepted for Δ_{47}), SSS and pH results show that amplitude of G-IG variations was insignificant between 1.2 and 0.8 Ma and increased after the MPT.

Nonlinear response to insolation in a context of low CO2 for triggering the onset of Greenland ice sheet during Pliocene/Pleistocene boundary

Dr. Gilles Ramstein [1]***, Dr. Ning Tan*** [2]***, Dr. Jean-Baptiste Ladant*** [3]***, Dr. Christophe Dumas*** [3]***, Dr. Paul Bachem*** [4]***, Dr. Eystein Jansen*** [5]

1. *Le Laboratoire des Sciences du Climat et de l'Environnement, LSCE,* ***2.*** *IGG Pékin,* ***3.*** *LSCE-IPSL, Laboratoire des Sciences du Climat et de l'Environnement (CEA-CNRS-UVSQ), Paris-Saclay,* ***4.*** *NORCE Norwegian Research Centre, and Bjerknes Centre for Climate Research,* ***5.*** *Department of Earth Science, University of Bergen and Bjerknes Centre for Climate Research*

The Plio-Pleistocene boundary, a milestone between Pliocene warm climate and cooler Quaternary is an important tipping point in the recent evolution of the climate at geologic time scale. From a largely asymmetric planet, with predominantly, one ice sheet located over the polar region of the Southern Hemisphere, and associated deep-water formation, the climate shifted to a more bipolar system.

To explore this large climatic change, it is necessary to investigate a long period (3-2.5 Ma), using climate and ice sheet models. The driver of such a transition has long been pointed out as the astronomical forcing with a large insolation decrease around 2.7 Ma, in a context of low CO_2 compared to Miocene values. However, no real transient experiment using an atmosphere ocean general circulation model (AOGCM) was able to prove this. To explore this issue, we developed a dedicated coupling between AOGCM and ice sheet model (ISM), based on a mapping of the phase space. Therefore, we constructed a tri-dimensional matrix based on 3 driving parameters: atmospheric CO_2, insolation and different configurations of Greenland ice sheet (GRIS), ranging from no ice sheet to an equivalent pre-industrial (PI) GRIS. Specifically, we used two values of insolation (maximum and minimum summer insolation occurring at 65°N for this period), four pCO_2 values spanning the reconstructions: 220, 280, 360 and 405 ppm, and seven GRIS configurations. In total, we performed 56 snapshot climate simulations.

Once the "mapping" is available, this allows us to quantify the threshold of pCO_2 necessary to trigger the GRIS, using variations of summer insolation at 65°N, and demonstrate that it has to overcome a threshold between 280 and 320 ppm. More interestingly, this method enables us to compute the GRIS evolution, using different sets of pCO_2 reconstructions for the period 3.0-2.5 Ma, accounting for insolation changes. We may compare our simulations to sea-surface temperature (SST) and ice rafted debris (IRDs) available for that period over Greenland and to diagnose which pCO_2 reconstructions is the most appropriate.

In summary, this approach demonstrates the nonlinear response of the cryosphere and climate system to orbital forcing when pCO2 reaches values around 300ppm.

Prospects of suborbital astronomical tuning in the field of geochronological and climate change research

Mr. Anguo Xiao [1], ***Prof. Chunju Huang*** [2]

1. *State Key Laboratory of Biogeology and Environmental Geology and Hubei Key Laboratory of Critical Zone Evolution, School of Earth Sciences, China University of Geosciences, Wuhan 430074, China,* ***2.*** *China University of Geosciences, Wuhan*

Accurate geological time is the key to reveal the Earth's evolutionary history and geological processes. Astronomical theory based on the paleoclimate changes has been successfully applied to the calibration of geology time scale. However, astronomical solution in suborbital scale has not been established due to the relatively poor understanding of the astronomical cycles and the driving mechanisms of climate change in suborbital scale. In this study, we set up a suborbital-scale climate database from published climate indicators of ice cores, stalagmites, tree rings and lake sediments. By spectral analysis, cross spectrum of wavelet transforms and amplitude modulation, we find that different deposition archives show strong and stable suborbital cycles about 500, 1000 and 2000 years. These cycle signals are significantly correlated with the interannual-millennial scale cycle of solar activity and may be the amplitude-modulated cycles of 11, ~88 and ~210 years solar activity cycle. This amplitude modulation relationship is similar to the eccentricity modulated precession cycle in orbital scale. This illustrates that the century and millennium cycles show a great potential for suborbital-scale chronological tuning, especially the 500-year cycles. In this study, we applied a stable 500-year solar activity cycle to build an age model for the stalagmite record in Dongge cave and surface eolian sediments record in northern Qilian Mountains. The results show that the duration derived by our suborbital astronomical tuning method is consistent with the high-precision U-Th dating results in stalagmite deposition and radiocarbon dating in eolian sediments. The difference is only 50 years in stalagmite and 100 years in eolian sediments. The successful use of suborbital cycle calibration the geological time scale demonstrates the operability and practical value of this dating method. Our results reveal the relationship between solar activity and Earth's climate change, which has a good application prospect in chronology research. This study helps to advance the study of Earth's climate evolution at suborbital scales, and also has important implications for predicting future climate change on short time scales that are closely related to human development.

Session 163: Quaternary palaeoenvironmental dynamics/variability: promoting multiple proxy records from West-Central Africa

Holocene vegetation and climatic changes in coastal tropical rainforests

Dr. Emuobosa Orijemie [1] ***, Prof. Marlon Franca*** [2] ***, Prof. M. Adebisi Sowunmi*** [3]

1. University of Ibadan, Nigeria, 2. Federal Institute of Espírito Santo, Brazil, 3. University of Ibadan

The Holocene vegetation and climatic history of the tropical rainforest (TRF) in coastal south-western Nigeria was investigated through the palynological study of sediment cores retrieved from four coastal localities, namely Ahanve, Ogudu, Otolu-Lekki and Ikorigho. In Ahanve and Ogudu, during the middle Holocene the TRF, comprising lowland rainforest (LRF), mangrove swamp forest (MSF) and freshwater swamp forest (FWSF), was abundant and extensive, indicative of the prevalence of a wet climate and high sea levels. In the late Holocene, with the onset of drier climatic conditions, there was a westward decline in the TRF along with a steady increase in charcoal particles. The LRF and MSF decreased significantly and the MSF eventually disappeared by 1440-1310 cal. yr BC (3109 ±26 BP) in Ahanve. The MSF and LRF were replaced by coastal savannas and secondary forests, respectively; there is archaeological evidence of the presence of humans and their impact on the environment in the area at this time. In Ogudu, the TRF also declined drastically at 2760-2730 cal. yr BP (2620 ± 30BP); it recovered subsequently but did not attain the previous level of diversity. In Ikorigho, the TRF declined at 1240-1200 cal. yr BP (1210 ±30 BP); it too recovered and diversified subsequently. At Otolu-Lekki, although still substantially diverse, the LRF and MSF experienced slight decreases which were accompanied by marked increases in charcoal particles and the appearance of the pollen grains of several exotic plants from Asia and South America. The palynological and anthracological evidence has shown that the decline of the TRF in the area during the middle and early late Holocene was initially climate driven while subsequent and recent decline has been exacerbated by anthropogenic factors.
Keywords: Tropical rainforest, palaeoenvironment, Holocene, human impact, coastal southwestern Nigeria

The diatomic lacustrine deposits in the Hassi Mouina of the Grand Erg Occidental, North Western Algerian Sahara, during the lower and middle Holocene

Dr. Bachiri Nourreddine [1]***, Prof. Bouhameur Mansour*** [2]***, Dr. Mennad Saci*** [1]***, Prof. Mahammed Mahboubi*** [1]

1. *Université Oran 2,* ***2.*** *Université d'Oran 2,*

One of the interdune depressions of the Grand Erg occidental with lacustrine sedimentation in the region of Hassi Mouina was the subject of a diatomic study.This paleolake is in the form of a control mound metric thick (3m maximum) and made up from bottom to top: blackish clays (5 cm) topped with diatomic limestone. The whole rests on fine yellowish sands.
The set of diatomic limestone shows two very distinct parts according to the presence of traces of plants which mark their appearance from the 9th level to the top.
The analysis of the diatomic microflora provided a total of 19 genera (18 pennal genera and a single centric genus) belonging to two ecological groups according to the way of life (habitat). The most dominant littoral taxa (epiphytic and epilithic) are: *Epithemia* Brébisson ex Kûtzing, 1838, *Mastogloia* Thwaites, 1856, *Nitzschia* Hassall, 1845, *Cymbella* Agardh, 1830, *Gomphonema* Ehrenberg, 1834, while the planktonic forms are not represented by *Cyclotella* Kutzing, 1834.
The quantitative and qualitative distribution of microflora makes it possible to distinguish 10 zones representing periods of water level change.
The paleoenvironmental analysis of these 10 identified zones makes it possible to identify three phases of sedimentation:
- a phase characterized by a shallow, mixed environment (freshwater-oligosaline water); strongly alkaline.
- a phase characterized by unstable hydrological conditions with rapid fluctuations in the level of the water body which reflects a very shallow environment, fresh water with a tendency towards olig-meso-polysaline waters, attested by the high frequencies of the taxon *Mastogloia smithii*.
- one phase bears witness to a slice of very alkaline shallow water, attested by the low frequencies of epiphytic taxa reflecting a mixed environment (olig-meso-polysaline water to fresh water).
Keywords: Grand Erg Occidental, Hassi Mouina, sedimentation, lacustrine, Holocene, diatoms, Paleoenvironment.

Palynological evidence for the rapid disappearance of Mangroves around the Lagos coastal environment (LCE) in the late Holocene

Dr. Linus Ajikah [1], ***Prof. Olusola Helen Adekanmbi*** [2], ***Dr. Emuobosa Orijemie*** [3], ***Prof. Marion Bamford*** [1], ***Prof. Oluwatoyin Ogundipe*** [2]

1. University of Witwatersrand, Johannesburg, 2. University of Lagos, 3. University of Ibadan, Nigeria

Coastal environments are regarded among the most threatened habitats in the world, often associated with anthropogenic activities whose impact range from ecosystem alteration to biodiversity and socio-economic loss. A multi-site palynological and sedimentology study of 60cm sediment cores from five locations a Universal peat corer from the coastal environment of Lagos, Southwestern Nigeria was conducted. These were subjected to standard palynological procedures, as well as lithological, pH and salinity analysis. Recovered and identified species of Mangroves *were* found to be disappearing in all the study sites. Also recovered were taxa from freshwater swamps, lowland rainforest, marine/freshwater, open coastal forest/savanna and fungal spores. The preponderance of mangrove, freshwater swamp and lowland rainforest species is suggestive of a generally humid climate. However, there were periods of dry climate indicated by open/secondary forests or savanna. Absolute AMS dates showed the sequence was deposited around the last 1480±30 BP. Furthermore, a series of lithological types were recognized suggesting overbank or floodplain settings of a low-energy regime. The pH and salinity values varied considerably across the cored depths and locations while the lithological analysis revealed a mosaic of sedimentary depositional environments in which the recovered palynomorphs were preserved. This multi-site palynological analysis across ecosystems revealed that the last 1480 yrs BP witnessed significant vegetation changes occurring in this area, transiting from a more mangrove and lowland rainforest vegetation to an open/secondary or savanna setting compounded by anthropogenically driven disturbances. It provides the first record of the rapid disappearance of mangroves in the late Holocene from the region.

Palynological and sedimentological studies were carried out on sixteen borehole samples drilled within the Benin Formation of the Benin Basin in Ota, Ogun State of Nigeria. This study was aimed at investigating the pollen records from the basin leading to perspectives on the vegetation and climate history with time. From the predominantly coastal plain sandy lithofacies, significant pollen such as those of *Rhizophora* spp., Poaceae, Cyperaceae, Amaranthaceae and *Elaeis guineensis* as well as freshwater pteridophytes spores with diverse fungal spores were recorded. Significant proportion of charred Poaceae cuticles were also recorded. The pollen vegetation indicated humid tropical conditions prevailing at deposition. The well established less representation of *Rhizophora* spp. and the sharp rise in the pollen of *E. guineensis* associated with the Late Quaternary suggested age in the range between ca 3000 yr. BP and ca. 2000 yr. BP.

Two pollen zones, a dry Pollen Zone I, typified by low records of freshwater swamp forest, lowland rainforest species with high Poaceae pollen and CPC, and a succeeding wet Pollen Zone II, associated with increase in wet climate floral components with reduction in dry climate elements, were recognized. The two zones were associated with the West African climates post-Noukchottian transgression of the Tafolian regression (4000-2000 yr. BP) and its succeeding Sea Transgression recorded between 2000-1700 yr. BP. This study depicts a typical humid tropical forest in climatic conditions alternating from a dry to a wet phase. Evidence of anthropogenic farming activities was inferred from the trends in the records of *E. guineensis* and charred Poaceae cuticles.

A model for reconstructing a sedimentary basin can be developed using sedimentological and micropaleontological analyses. Geomodelling can simultaneously represent the subsurface's geological structures and the geometry and properties of these geological formations. The example chosen in this work is the Pleistocene marine formations in the Achakkar area in the West of Tangier-Morocco. In this study we propose a new approach to reconstruct the history of the implementation of these formations based on sedimentological, micropaleontological analyses and to integrate these data, for the first time, in a mathematical model. These model allows a 3D distribution of sedimentary facies using Cellular Automata. Sedimentary modelling consists of predicting the architecture of sedimentary forms and the distribution of their facies.

During the Weichselian Early Glacial (MIS5d-a), rapid climatic changes occurred where global sea level varied tens of meters between the stadial (MIS 5d,b) and interstadial (MIS5c,a) periods. This was followed by a major sea level drop into the Early Pleniglacial (MIS4). Shallow, low-gradient shelf sea regions were significantly impacted by these shifts in sea level and the associated temperature variations, resulting in shifts in coastline configurations and changes in the vegetation characteristics of the surrounding landscapes.
The southern North Sea is an example of such a shallow shelf sea area, but the effects of Early Glacial climatic variations are poorly understood. Here, clay-rich Early Glacial sediments, referred to as the Brown Bank Formation (also known as Brown Bank Member), are known to occur in a vast region with a thickness varying between 2 and 20 m. In studies across the southern North Sea, shallow marine, lagoonal and lacustrine deposits have been described for the Brown Bank Formation, with ages linked to the period from MIS5d to MIS3. For this study, the Brown Bank sediment has been studied in unprecedented detail at its type area. Analyses of core material show shallow marine to pro-deltaic sediments deposited during the final phase of MIS5a and the transition into MIS4.
In order to place these sediments into a context of regional climatic, landscape and sea-level changes, and to better understand the sediment supply systems and processes, a solid land-sea correlation is needed. To achieve this, data from the Brown Bank Fm are compared with Early Glacial (i) deposits found onshore in the Saalian glacial Amersfoort basin and (ii) sediments cored offshore the Maasvlakte. Such long-distance correlations have been possible by combining core data with high-resolution seismic data. We will focus specifically on the comparisons of Early Weichselian deposits from these three locations by discussing the lithology, age and palaeo-environmental indicators. This will enable us to understand the evolution of this depositional systems in response to climatic changes during Late MIS5 and the MIS5-MIS4 transition in the North Sea basin.

Constraining MIS 5a and 5c highstand ages: New dates and stratigraphy from the Florida Keys Reef Tract

Ms. Scarlette Hsia [1], ***Dr. Lauren Toth*** [2], ***Dr. Richard Mortlock*** [3], ***Dr. Charles Kerans*** [4]

1. The University of Texas at Austin, 2. United States Geological Survey, 3. Department of Earth and Planetary Sciences, Rutgers University, NJ, USA., 4. Department of Geological Sciences, The University of Texas at Austin

Marine Isotope Stage (MIS) 5a and 5c represent sea-level highstands before the most recent marine regression and are useful records for building linkages between sea-level fluctuations, orbital forcing, and ice-sheet dynamics. However, Global Mean Sea Level (GMSL) estimates for these sub-stages, occurring after the well-constrained MIS 5e, contain meters of uncertainty and fewer data points due to several challenges. In the Western Atlantic, MIS 5a and 5c shoreline facies are mostly eroded or not deposited, while dateable in-situ coral facies in tectonically stable regions are submerged by MIS 1 sea level. More robust MIS 5a and 5c data with absolute age constraints and well-defined indicative ranges are needed to infer GMSL and correct for Glacio-Isostatic Adjustment and long-term deformation.

Twenty three cores from five sectors of Florida Keys Reef Tract (FKRT) taken by the United States Geological Survey were logged. Across the Dry Tortugas, Lower Keys, Middle Keys, Upper Keys, and Biscayne subregions, 34 coral samples were taken from below the Holocene-Pleistocene contact bounded by previously radiocarbon-dated Holocene-age corals. After passing XRD screening (≤2.7 % calcite), U-Th concentrations were measured by a Multi-Collector Inductively Coupled Plasma Mass Spectrometer (MC-ICP-MS) using a ThermoScientific NEPTUNE PLUS ICP-MS in the Department of Earth and Planetary Sciences at Rutgers University. U-Th dates generated for 20 coral samples, including *Pseudodiploria strigosa, Siderastraea siderea, Acropora palmata, Orbicella* spp., and *Porites astreoides*, yielded MIS 5a ages and 3 coral samples, consisting of *Pseudodiploria clivosa,* and *Orbicella,* yielded MIS 5c ages. Corals dated to 5a ages were 6.13-19.18 meters below present (uncorrected) sea level. *Acropora palmata* framework in the Lower Keys was found 12.6 m below present at 83,941 ± 143 years (2σ) and interpreted to represent 5a reef crest facies. The recorded depths will be cross-referenced with modern coral depth distributions to generate sea-level estimates within each time-step for 5a and 5c. Despite containing shorter transgressive intervals than 5e or the Holocene, MIS 5a and 5c-aged reef deposits exist extensively along the FKRT, suggesting larger coverage than in previously dated deeper outlier reefs of South Florida.

MIS 5d-a terrestrial equivalents from western to eastern Ukraine: chronology, and palaeoclimate derived from palaeosol and pollen successions

Prof. Natalia Gerasimenko [1]

1. Taras Shevchenko National University of Kyiv

The most complete Early Glacial sequences were formed in palaeogullies cut during MIS 5e. Detailed studies of such sites (including palaeosol catenas) in the forelands of the Carpathians, the Poltava Plain and the Donetsk Upland allowed long distance correlation of climatic events and environments. The A horizon of the upper soils of MIS 5e (TL 110 ka, 108 ka) is the lower limit of the MIS 5d-a sequence, whereas the loess (TL-dated 60 ka, 67.5 ka and 70 ka) delimits it at the top. During MIS 5d and MIS 5b, thin silt beds formed in the west under a tundra-like environment; there was intensive development of ground wedges and cryolamination. These, sand wedges and involutions were formed in the tundra-steppe of central Ukraine (particularly abundantly during MIS 5b). In MIS 5d, sediment re-deposition and cryogenic channeling were common. In the east, during both stadials, thin loesses accumulated in boreal grassland, and desiccation fissures occurred frequently. Involutions and cryolamination did not develop because of lack of ground moisture.

During MIS 5c, pedocomplexes included lower grey forest soils formed under birch and broad-leaved woodland (TL 98 ka, 95 ka) in the central region, and Cambisols under forest-steppe in the east. The upper soils were Chernozems, formed in mesophytic steppe, in the east - grassland (TL 90 ka). The MIS 5a soil successions consisted of lower forest-steppe Cambisols (85 ka, 82 ka) in the central region and Calcaric Cambisols in the east, both followed by upper Chernozems, formed under grassland (78 ka). In the west, Luvic Cambisols of MIS 5c and 5a, with Middle Palaeolithic layers, developed under mixed forest. The proportion of broad-leaved trees was small, particularly during MIS 5a.The climate was transitional from temperate to boreal in MIS 5c, and south-boreal during MIS 5a. Aridification progressed from the beginning to the end of both MIS 5c and 5a. Short cool and dry events, identified only by pollen data, mark the time between the formation of the lower and upper soils of both pedocomplexes. Reduction of woodlands occurred and broad-leaved trees disappeared. Continentality increased eastwards during all sub-stages.

The Pleistocene Sardinian composite marine terraces. Insight on sea level and tectonic interplay to reconstruct the recent geodynamic evolution of Western Mediterranean.

Dr. Daniele Sechi [1], ***Dr. Fabrizio Cocco*** [2], ***Prof. Stefano Andreucci*** [3], ***Prof. Vincenzo Pascucci*** [1]

1. University of Sassari, 2. University of Cagliari, 3. Università degli Studi di Cagliari

Despite Sardinia Island being located in the centre of an active geodynamic puzzle, the western Mediterranean region, it has been considered tectonically stable since the Early Pleistocene. However, a light tectonic instability of the Island, possibly related to the isostatic disequilibrium of its lithosphere, has been recognized and testified by low-magnitude earthquakes, vertical movements and displaced geomorphic features associated with an ongoing uplift.

The Sardinia coast hosts several Pleistocene shallow marine deposits mostly related to the Marine Isotopic Stage (MIS) 5e highstand (116-126 ka) and placed at +5/9 m above the present sea level. However, chrono-stratigraphic reviews of Pleistocene marine successions have recently highlighted the superimposition of two o more sea highstands, particularly the stratigraphic superimposition of MIS 5c (~100 ka) on MIS 5e, both placed above the present sea level. However, this conflicts with the globally accepted sea-level curve, which described the MIS 5c at around -22 m below the present. Thus, the composite nature of marine terraces suggests the possible interplay between regional tectonic and sea level changes.

The evidence raises different questions: i) Is the highstand of MIS 5c substage well constrained in amplitude and elevation respect to present sea-level positions for the Mediterranean area? ii) Is the Quaternary Relative Sea Level curve of the Mediterranean characterised by unrecognised high-frequency sea-level oscillations below the sensitivity of presently available dating methods? iii) Has the western Mediterranean area been characterised by undetected regional versus local tectonic activity during the Pleistocene?

Answering these questions will open new scenarios on the Quaternary geodynamic evolution of the western Mediterranean during the last 300 ka.

Early Weichselian deposits in the Amersfoort Basin (NL): understanding sedimentary environments, paleogeography and paleoclimate during MIS 5d-a

Dr. Jeroen Schokker [1], ***Ms. Caroline Goossens*** [2], ***Dr. Kees Kasse*** [2], ***Dr. Nathalie Van der Putten*** [2], ***Dr. John van der Woude*** [2], ***Ms. Irene Waajen*** [3], ***Dr. Freek Busschers*** [1], ***Dr. Frank Wesselingh*** [4]

1. *TNO - Geological Survey of the Netherlands,* ***2.*** *Vrije Universiteit Amsterdam,* ***3.*** *Utrecht University & TNO - Geological Survey of the Netherlands,* ***4.*** *Naturalis Biodiversity Center & TNO - Geological Survey of the Netherlands*

Eemian and Early Weichselian (MIS 5) deposits are exceptionally well preserved in the up to 200 m deep glacial basins that were formed in the southern North Sea Basin during the Saalian Drenthe substage glaciation (MIS 6). As such, these basins provide an excellent opportunity to study the sedimentary record from this time interval at the boundary between the marine and terrestrial realm. Internationally renowned research by prof. W.H. Zagwijn focused on the Eemian marine deposits and turned the Amersfoort Basin (central Netherlands) into the informal stratotype of the Last Interglacial (MIS 5e) in North-Western Europe. The overlying Early Weichselian sedimentary succession (MIS 5d-a), however, received less attention, although this 10 m-thick stack of alternating clastic and organic deposits reflects dramatic environmental and climatic changes. As part of a marine-terrestrial correlation project, we present new multi-proxy results from two recent high-quality sediment cores in the Amersfoort Basin, focusing on the Early Weichselian record.

The undisturbed sediment cores extend down to the base of the glacial basin and were analysed in detail. Granulometric and geochemical data were obtained, selected intervals were studied with biostratigraphic methods and optical dating was performed. There is generally a good agreement between the new cores and classic research. However, new analysis techniques and high-quality core material enable a much better insight in the sedimentary properties of the deposits.

Our results show that Eemian marine highstand deposits grade into coastal peat deposits, reflecting relative sea-level lowering, the onset of colder conditions and associated floral change. The next cold phase (MIS 5d) is characterised by sandy and loess-like deposits with frost cracks. Further upward two organic layers with arboreal pollen testify to the temporary return of mild conditions. These two organic intervals are separated by a thick loam layer (MIS 5b) and are correlated to Brørup (MIS 5c) and Odderade (MIS 5a), respectively. The sequence is capped by fluvio-aeolian deposits with ice-wedge casts (MIS 4).

Ultimately, this multi-proxy research gives better insights in the interaction of climate, landscape and ecosystems in the transitional period between the warm-temperate Last Interglacial and the severe cold of the Last Ice Age.

Identification of the Los Chocoyos supereruption in polar ice and marine sediment cores: climate and stratigraphic implications.

***Ms. Helen Innes* [1], Dr. William Hutchison [2], Ms. Laura Crick [2], Prof. Siwan Davies [3], Dr. Steffen Kutterolf [4], Dr. James Rae [2], Dr. Mirko Severi [5], Prof. Michael Sigl [6], Prof. Stephen Sparks [7], Prof. Anders Svensson [8], Prof. Eric Wolff [9], Dr. Andrea Burke [1]**

Physics of Ice, Climate and Earth, Niels Bohr Institute, University of Copenhagen, 9. University of Cambridge

The Los Chocoyos supereruption (LCY) of Atitlán Caldera, Guatemala is one of the largest volcanic events of the last 100,000 years, depositing one of the most widespread Quaternary tephra marker horizons in the Eastern Equatorial Pacific (EEP) and Central American regions. A recent zircon-rim radiometric age estimate of 75 ± 2 ka (1σ) suggests LCY is several thousand years younger than the previously adopted sediment stratigraphy age of 84 ka. This new age is also within error of the Younger Toba Tuff supereruption (YTT; 73.7± 0.3 ka (1σ)), and transition to Greenland Stadial 20 (GS-20; 74.1 ka), bringing into question the role of supereruptions in global climate shifts.

Identification of tephra shards associated with volcanic aerosol peaks in polar ice cores can robustly tie the deposit to an eruptive source, providing an independent, well resolved eruption age estimate. Here, we perform major oxide analysis of tephra found in both Greenland and Antarctic ice cores associated with a large volcanic sulfate deposit at 79.5 ± 1.7 ka (AICC12; Antarctic Ice Core Chronology 2012). We found 6 tephra shards (2 in Antarctica and 4 in Greenland) which are consistent with LCY geochemistry. In addition, we identify LCY ash at 80.5 ± 0.9 (2σ) in EEP marine sediment core V19-30, one of the best resolved stratigraphic $\delta^{18}O$ records in the region.

The agreement between our ice and sediment core ages provides a new, robust age for this key chronostratigraphic marker. Based on this finding, we can rule out back-to-back YTT-LCY supereruptions at the onset of GS-20, indicating LCY is not a driver of sustained (longer than decadal) global climate perturbations.

Climatic record of the Upper Pleistocene (MIS6-MIS2) in terrestrial sediments at the Parchliny site, central Poland against the bentic isotope records

Prof. Lucyna Wachecka-Kotkowska [1]***, Dr. Aleksandra Majecka*** [2]***, Prof. Malgorzata Malkiewicz*** [3]***, Prof. Dariusz Krzyszkowski*** [4]***, Mr. Dariusz Wieczorek*** [5]

1. *University of Lodz, Department of Geology and Geomorphology,* ***2.*** *Faculty of Geology, University of Warsaw, Poland,* ***3.*** *University of Wrocław, Institute of Geological Sciences,* ***4.*** *University of Wrocław, Institute of Geography and Regional Development,* ***5.*** *Polish Geological Institute – National Research Institute, Holy Cross Branch*

The upper Pleistocene stratigraphy has been well documented in numerous terrestrial profiles in Poland. Unfortunately, most of the positions contain fragmentary record, therefore it is difficult to find a model position for the stratigraphy of this period. Documented profiles "Parchliny 2012", "2014" and "2016" profiles in the Bełchatów Lignite Opencast Mine are the record of overlapping but continuous sedimentation within the same palaeolake. On their basis, we traced the rhythm of palaeoenvironmental changes from the Late Saalian across the Eemian interglacial to Pleniglacial (MIS6-MIS2). Three phases of changes have been distinguished within the Late Saalian (MIS6). The first phase was related to the rapid melting of a block of dead ice buried in the tills and the formation of a lake reservoir with no traces of vegetation cover. The second phase was gradual, with a mosaic of tundra correlated with Stadial 1. The third phase indicate improvement of climatic conditions, with sparse pine-birch boreal forest communities correlated with the Zeifen interstadial and subsequently Kattegat stadial, expressed by coexistence of forest communities and open park tundra. Eemian interglacial has been documented in complete with a well-marked climatic optimum – oak and hazel phase and a clearly marked phase of hornbeam-lime and spruce-fir forests. Stadial and interstadial phases have been captured within the Early Weichselian (MIS5e-d) and Pleniglacial (MIS4-MIS2). They indicate the transitions from sub-arctic tundra vegetation and grassland to boreal forest communities.

Palynologically documented climatic oscillations of different rank are confirmed by the LR04 bentic stack (Lisiecki and Raymo, 2005).

Majecka, A., et al., 2022. Environmental changes during the MIS 6a–MIS 5e transition: Example of the "Parchliny 2016" profile, central Poland. Geological Quarterly, 66, 31: 1-27, doi: 10.7306/gq.1663.

Session 166: Quaternary palaeohydrology: from the reconstruction of spatial impact of extreme events to long-term changes in catchments and landscapes

Rapid laminated clastic alluviation associated with increased Little Ice Age flooding co-driven by climate variability and historic land-use.

Dr. Ben Pears [1], ***Prof. Antony Brown*** [2], ***Dr. Phillip Toms*** [3], ***Dr. Jamie Wood*** [3], ***Dr. Benjamin Pennington*** [1], ***Dr. Richard Jones*** [4]

1. University of Southampton, 2. Arctic University of Tromso, 3. University of Gloucestershire, 4. University of Leicester

The discovery of exceptionally well-preserved visible clastic laminations in deep alluvial sediments at Kempsey, Worcestershire (UK), provides the opportunity to analyse and understand localised micro-depositionary conditions in the River Severn. At the sample site over 4.5m of sandy silt alluvium has accumulated on the floodplain, and Optically Stimulated Luminescence (OSL) dating of the upper 2.25m demonstrates accretion from the late 14th century AD onwards. High resolution multi-proxy sediment analysis using Loss on Ignition (LOI), magnetic susceptibility, particle size, ITRAX and portable XRF (pXRF) demonstrate clear variations in depositional history. Between AD 1380-1550 overbank alluviation was driven by small-scale flood events, with negligible effect from climatic conditions during the Spörer Minimum (AD 1460-1550). After AD 1550 the magnitude of flooding events increased and by AD 1610, the start of the visible sub-centimetre laminations, the accumulation rate regularly exceeded 3mm yr-1, which subsequently increased to 4.5mm yr-1 between AD 1690-1710, and 3-3.5mm yr-1 between AD 1790-1840 before alluviation was altered by the construction of a major embankment. The greatest extent of coarse alluvial deposition and increased accumulation rate occur concurrently with periods of climatic instability associated with the Maunder (AD 1645-1715) and Dalton (AD 1790-1820) Minima, the periods of largest historical floods and during the intensification of arable cultivation across the middle Severn catchment. Together these suggest that climate variability and land-use intensification were fundamental in driving the character and behaviour of the River Severn, and may have played a causal role in the development of settlement within the historic core of Kempsey.

Towards the Map Application Putting the Historical Floods into Context

Dr. Libor Elleder [1]

1. Czech Hydrometeorological Institute

The aim of this contribution is to present the recently created "Map of Extreme Floods" (MEF) ESRI application, as an extremely useful tool for numerous purposes related to historical hydrology. In contrast to usually applied flood extreme databases, undoubtedly very useful for fast searching and selection of information based on simple classification, but lacking geographical instruments, the MEF places the above into spatial and temporal frameworks. Actually, the MEF application enables to put the fundamental information on European historical floods, i.e. the exact location and datum, into broader spatial and temporal context. The maps created by this tool form the reliable fundament for detailed exploration and including of additional data. The principal MEF application aims are: (i) archiving, (ii) verification, (iii) corrections, (iv) addition of further data and information, and (v) providing information for both scientists and public. The performance of the MEF application is documented by selected historical extreme flood events, analogical to these of 1997, 2002, and 2013.

Decoding of Alpine flood types since 1480 based on the temporal-spatial integration of natural, documentary and instrumental data series

Prof. Lothar Schulte [1]***, Dr. Juan Carlos Peña*** [2]***, Dr. Oliver Wetter*** [3]***, Dr. Filipe Carvalho*** [1]***, Dr. Stefanie B. Wirth*** [4]***, Prof. Antonio Gómez-Bolea*** [5]***, Dr. Alexandre Badoux*** [6]

1. *Department of Geography, University of Barcelona. FluvAlps-PaleoRisks Research Group, Barcelona, Spain.,* ***2.*** *Meteorological Service of Catalonia, Barcelona, Spain,* ***3.*** *Section of Economic-, Social- and Environmental History & Oeschger Centre for Climate Change Research, University of Bern, Switzerland,* ***4.*** *Geotest Ltd, Zollikhofen, Switzerland,* ***5.*** *Department of Evolutionary Biology, Ecology and Environmental Sciences, University of Barcelona, Spain,* ***6.*** *Swiss Federal Institute for Forest, Snow and Landscape Research, Birmensdorf, Switzerland*

Under the umbrella of Work package 2 of the PAGES Flood Working Group an innovative multidisciplinary methodology was designed that integrates multi-archive datasets from floodplain and lake sediments, tree rings, lichens, historical documentary evidence, hydraulic infrastructure, and archaeological sites to perform robust centennial-long reference flood records for the Bernese Swiss Alps (Schulte et al., 2019). In the present paper we show how to investigate systematically the temporal-spatial pattern of floods and atmospheric dynamics from 1480 to 2011 CE in order to obtain a 4D flood model which provide holistic insights into flood generation in high mountains.

The paleoflood maps of the Bernese Alps show the following spatial patterns: i) all catchments (1480, 1831, 1851, 1977, 2005, and 2011) ii) western catchments (1575, 1651, 1711, and 1852); iii) northern catchments (1511 and 1566), iv) eastern catchments (1762) and v) local catchment flooding (1678, 1791, 1873 and 1933). According to the sequences of atmospheric dynamics generated from reconstructions (20th Century Reanalysis Project, 1836-2011) and paleoclimatic models (Last Millennium Ensemble Project, 1480-1836), different climatic patterns of flood episodes were classified: i) atlantic Mediterranean (aM; 1480), ii) Mediterranean (M; 1511, 1575, 1651, 1762, 1791, 1933, 2005), iii) Mediterranean winter (wM; -NAO; 1678, 1711), iv) Central European (CE; 1566), v) mediterranean Atlantic (mA; 1831, 1852, 1873 2011) and vi) Atlantic-Mediterranean (AM; 1851, 1977).

Subsequently twenty-two data series of flood intensities, local atmospheric and environmental conditions and climate proxies were normalized and Multivariable Analyses were performed to define flood patterns. These patterns were compared with maps of paleoflood incidence and composite Sea Level Pressure to investigate regional flood forcing, and types and changes through time since 1480 CE. From 1500 to 1762, for almost three centuries of the Little Ice Age, prevailed the Zonal flow type, followed by the Atlantic type from 1811 to 1852 during late cool pulse of the Little Ice Age. During the moderate climate pulses 1791 and since 1873 (20th-21st century warming trend) the Mediterranean type dominates. The timing and opposite pattern of the 1480 and 1977 flood episodes of the Atlantic Blocking type needs further investigation.

Combining multiproxy records and hydrological modeling to improve the reconstruction of past flood events in south-eastern Spain

Dr. Filipe Carvalho [1]***, Prof. Lothar Schulte*** [1]***, Dr. Carlos Sánchez-García*** [1]***, Prof. Antonio Gómez-Bolea*** [2]***, Dr. Juan Carlos Peña*** [3]

1. *Department of Geography, University of Barcelona. FluvAlps-PaleoRisks Research Group, Barcelona, Spain.,* ***2.*** *Department of Evolutionary Biology, Ecology and Environmental Sciences, University of Barcelona, Spain,* ***3.*** *Meteorological Service of Catalonia, Barcelona, Spain*

The analysis of the extent and magnitude of past floods and the identification of the main triggers that cause large floods are essential to understand the impacts of climate change and the effects of human intervention in the fluvial systems. Our study carries out a reconstruction of flood events in the Almanzora catchment, located in the southeast of Spain. We analyze the major large floods from the last 120 years, that have affected various settlements and caused the loss of human lives and/or significant damage to buildings and infrastructures.

For the reconstructions, we included instrumental data, flood marks on buildings and bridges, description of flood areas and water levels in historical documents and biomarkers of flood levels based on lichenometric analyzes of rocky surfaces exposed to water flow. These multiproxy records allowed the estimation of the maximum flow heights in various settlements along the main river course and in some important tributaries (such as: Huitar, Albox and Almajalejo).

The results show that over the last 120 years, this region has experienced some extreme precipitation events, usually related with blocking atmospheric circulation patterns, that produced very high peak discharges. For the reconstruction of the maximum flood discharges we ran a 1D hydrological model and 2D models in specific key areas where a detailed characterization of the hydraulic behavior of the flow was necessary. The most catastrophic event of the last 120 years occurred in October 1973, where we estimate a peak discharge higher than 5000 $m^3 s^{-1}$ on the Almanzora River. This extremely high discharge correlates with the devastating consequences of the event in the main settlements and in infrastructures along the Almanzora river and major tributaries. Other important floods occurred in 1900, 1924, 1977 and 2012, but with a lower magnitude than 1973 flood event.

This study shows that the integration of different flood proxies can generate detailed reconstructions of past floods and thus improve current estimates of flood risk, particularly in areas where vulnerability to flooding is high. These reconstructions also provide new insights into the frequency of large-scale flooding in the Mediterranean region over the past 120 years.

Increased hydrological droughts in the Irrawaddy River and Upper Yangtze River since the 1850s inferred from tree-ring oxygen isotope records

Prof. Chenxi Xu [1], ***Dr. Wenling An*** [1], ***Ms. Yaru Zhao*** [2], ***Mr. Yucheng Liu*** [2], ***Prof. Zhengtang Guo*** [1]

1. *Institute of Geology and Geophysics, Chinese Academy of Sciences, Key Laboratory of Cenozoic Geology and Environment,* ***2.*** *Institute of Geology and Geophysics, Chinese Academy of Sciences*

Ongoing global warming has a strong influence on regional hydrological cycles. The Irrawaddy River and upper reaches of the Yangtze River which are affected by Indian summer monsoon are highly vulnerable to extreme hydrological droughts and floods, but a lack of long-term streamflow observations has limited our understanding on global warming influences. Here, we establish two annually resolved and absolutely dated tree-ring oxygen isotope records, and use them to reconstruct the summer streamflow history of the Irrawaddy River and upper reaches of the Yangtze River during the period of 1617-2017 and 1260-2017, respectively. We found a trend toward dry conditions in the region with tendencies for an increased drought probability since around 1850s. Especially, the frequency of hydrological droughts in recent decades has been outside the envelope of natural variability of extreme hydrological droughts. The recent increase in the frequency of hydrological droughts is consistent with the observed trend toward a weaker Indian summer monsoon and increasing temperatures. Weaker transport of low-level moisture and greater evaporation caused by global warming have contributed to the increase in extreme hydrological droughts. Our results thus provide a long-term context for observed hydrological changes and suggest that the Irrawaddy River and upper reaches of the Yangtze River will experience more frequent and severe extreme events as a consequence of increasing greenhouse gas emissions.

Birth and death of the alpine Lake Tschingel. A 50 year-long multi-archive flood reconstruction in the Swiss Alps

Mr. Miguel Angel Calero Tomas [1], *Prof. Lothar Schulte* [1], *Dr. Filipe Carvalho* [1]

1. Department of Geography, University of Barcelona. FluvAlps-PaleoRisks Research Group, Barcelona, Spain.

Linking paleoflood-records (e.g. fluvial deposits, lake sediments, etc.) with instrumental data (precipitation, temperature and discharges) and historical information (reports, maps and photographs) is frequently applied in paleohydrology. However, one of the main challenges is to integrate time series of different temporal resolution and involved physical process. Furthermore, the precision of geochronological models of the last 150 years can be a critical issue.

In this work, we present the sedimentary and geochemical records obtained from the Tschingelsee Lake located in the Berner Oberland (1150 m.a.s.l.; 46° 33.170 'N; 7°44.661' E). The lake was formed by the damming of the Chiene River by a debris flow that occurred during the night of August 18th 1972. Since 1972, the Chine delta grew rapidly and today the accommodation space is almost filled with sediments. The short distance between the lake and the Kiental meteorological station as well as the high-resolution lake sediments allow us to analyze the relation between rainfall events, catchment hydrology and sedimentary flood records.

The 3m-long sedimentary core shows different textural facies covering the last 50 years. The geochronological model since 1972 was performed by the attribution of sedimentary facies to known extreme weather episodes, flood events or geomorphological changes. The changes in the lacustrine and fluvial-deltaic depositional system were inferred from aerial images, photographs, reports and witness testimony.

Subsequently, the sedimentary flood data series (Ca/Ti and Zr/Ti ratios) were cross-correlated with the precipitation data (mm/24h) obtained from the Kiental (930 m a.s.l.) and Kandersteg (1178 m a.s.l.) meteorological stations, and the discharges (m3/s) of the Kander river at the Kander-Hondrich (650 m a.s.l.) gauging station.

This work contributes knowledge about the effects of global warming on mountain hydrology, climatic forcing of sediment yield and precipitation-sedimentation thresholds in small alpine catchments. Finally, the approach highlights the possible limitations of the accuracy of centennial or millennia-long paleoflood records from lake sediments.

Flood Meteorology, Hydrology and Geomorphology of the Upper Godavari River: Western India

Dr. Archana Patil [1] ***, Prof. Pramodkumar Hire*** [2]

1. Department of Geography, RNC Arts, JDB Commerce and NSC Science College, Nashik Road, Nashik – 422101 (India), 2. Department of Geography, HPT Arts and RYK Science College, Nashik – 422005 (India)

High magnitude floods during monsoon are considered to be India's recurring and leading natural disaster. Such floods are extremely significant events in terms of human impact and geomorphic effectiveness. The Godavari River in Peninsular India is characterized by one of the most intense flood regimes. The river has experienced largest peak on record in India of 100000 m^3s^{-1} in 1986. In the present paper an attempt has been made to understand flood meteorology, hydrology and geomorphology of the Upper Godavari River (UGR), of western India. To understand flood hydrometeorological situations associated with floods on the UGR, analyses of synoptic conditions of large floods were carried out. This encompasses analysis of rainfall variability and floods and analysis of storm-tracks. Annual rainfall data were obtained for 142 years. The results signify that the interannual variability was characterized by increased frequency and magnitude of floods primarily after 1930s and majority of large floods were connected with low pressure systems. In order evaluate flood potential of the UGR, unit discharges (Q_u) and flash flood magnitude index (FFMI) were computed. The annual maximum series data were procured for six gauging sites. The values of Q_u range from 0.88 to 6.16 $m^3s^{-1}km^{-2}$ indicating potential of large floods on the UGR. The FFMI values range between 0.27 and 0.46 which show flashy and variable nature of floods and possibility of noteworthy geomorphic work during large floods. To find out effect of infrequent and large magnitude floods, parameters of flood hydraulics and hydrodynamics such as unit stream power (ω), bed shear stress (τ), Froude number (Fr), Reynolds number (Re) and critical velocity for inception of cavitation (Vc) were computed. The highest values for ω and τ are 8273.5 Wm^{-2} and 609 Nm^{-2} respectively. These values reveal unusually high ability to erode and transport sediments. The Fr <1 and >1, indicating subcritical and supercritical flows. High values of Re reveals extremely turbulent flood discharges.

Palaeoflood records of Bharathapuzha river, Kerala, South India and its implications to climate

Dr. Linto Alappat [1], ***Ms. Amala Varghese*** [2], ***Ms. Malika Singhal*** [3], ***Dr. Naveen Chauhan*** [4]

__1.__ Department of Geology and Environmental Science, Christ College (Autonomous), Irinjalakuda Thrissur, Kerala, 680 125, India, __2.__ Christ College (Autonomous), Kerala, India, __3.__ Atomic Molecular and Optical Physics (AMOPH) Division, Physical Research Laboratory, Navrangpura, Ahmedabad – 380 009; Indian Institute of Technology, Gandhinagar – 382 355., __4.__ AMOPH Division, Physical Research Laboratory, Ahmedabad, Gujarat, India; cIndian Institute of Technology, Gandhinagar, Gujarat, India

River Bharathapuzha is the second-largest perennial river in Kerala. The study focuses on the middle to late Holocene fluvial processes and flood-climate relationships utilizing the fine-grained (sand-silt-clay) stratigraphic sequence of slack water deposits (SWD) as palaeostage indicators on a bedrock river system. These stratigraphic indicators are important physical evidence of past floods that occurred in the region and their relation with climate, and land-use needs to be analyzed. Understanding the threshold levels of the largest floods in the past is crucial for assessing recurrence intervals of major floods, their geomorphic response, planning large-scale engineering structures, and obtaining a long-term perspective of major floods in the catchment. Five sections were excavated at different morphological units of the river system, which include over-bank, point-bar, natural levees, river terraces, flood benches, etc. Optically stimulated luminescence (OSL) dating was used to establish the chronology, while the granulometric studies and primary sedimentary structures were used to determine the characteristic stratigraphic indicators of SWD. The channel morphology was assessed and geometry and valley cross-section was studied using a close-interval total-station survey. The boundary between non-flood sediments and flood sediments was established based on the stratigraphic signatures of distinct clay-silt litho-unit formed during the waning stage of the flood, macro-debris, and palaeosols. The results of OSL dating of SWD show large-scale floods during 1830- 1882 AD. It is the period that coincides with the end of the Little Ice Age (LIA). The proxy records had shown weakened summer monsoon during LIA due to cool and dry climatic conditions. The OSL ages of samples from a flood bench at the banks of the palaeochannel have shown the age of deposition during 1956 AD. The upper terrace of this channel gave a depositional age of 1555 AD. The palaeofluvial terrace of 3.0 m thick adjacent to the present-day river course shows an age of deposition during 5.1 ka, implying a lateral migration of channels by progressive abandonment since the middle Holocene. The SLW and fluvial terraces show varying hydrological conditions and enhanced flooding of rivers in south peninsular India during the last two centuries.

Calibration of the high-resolution archive for past extreme events recorded in Lake Hallstatt with instrumental and historical data over the last 50 years

Lake Hallstatt is an inner-alpine clastic lake with a high-resolution sedimentary archive with mm-to-sub-mm-scale laminated background sediment with “sub-annual” resolution (sedimentation rates of ~0.5 cm/yr) spanning the entire Holocene. The area is well known for its Alpine landscape and well-documented human settlement history within the UNESCO World Heritage Cultural Landscape Hallstatt-Dachstein/Salzkammergut, Austria. Towards reconstructing impacts and understanding trigger-consequence relationships of extreme events on long timescales, detailed multi-proxy datasets of the Lake Hallstatt sedimentary sequence need to be “calibrated”. This is accomplished by robustly linking the lake-sediment stratigraphy to documented instrumental and historical data points to evaluate trigger processes of extreme events, their consequences for the landscape and society on prehistoric time-scales.
Here, we present a calibration study of the sedimentary archive of the last 50 years. The sediment cores are studied through visual core description, multi-sensor-core-logger data, X-ray computed tomography, elemental data (micro-X-ray fluorescence (XRF) mapping and XRF scanning) and grain-size measurements. These proxies are used to fingerprint event deposits (e.g. floods and debris flows). In combination with an age model based on radionuclides, this allows to link identified event deposits to instrumental and historical data of the last 50 years. To reduce human bias in data evaluation, multivariate statistics (e.g. principal components analysis and clustering) and time series analysis are pursued to help discriminate event deposits and their underlying trigger mechanisms. As a result, we identify and link flood deposits to documented floods occurring in 2013, 2002, 1997, 1991 and 1981 and to instrumental data such as daily precipitation, river discharge, flood height, and lake level. Furthermore, monthly lake geochemistry data allows for tracking the potential sedimentary fingerprint of two brine spills (related to salt mine activity) that occurred within the Lake Hallstatt catchment area and were reported to affect the limnological system. Biogeochemistry data of the sediment cores, including total carbon, total nitrogen, bulk carbon isotope, and biomarker, are investigated to identify salt-intrusion proxies for meromixis and low-oxygen bottom waters. This may shed new light to further explore the salt mine activities of the Hallstatt region in prehistorical times.

Developing flood histories using centennial to millennial floodplain sediment archives in contrasting New Zealand catchments

Ms. Imogen Doyle [1]***, Prof. Sean Fitzsimons*** [2]***, Prof. Ian Fuller*** [1]***, Prof. Mark Macklin*** [3]***, Dr. Samuel McColl*** [4]***, Dr. Simon Vale*** [5]***, Prof. Georg Zellmer*** [1]

1. *Massey University,* ***2.*** *University of Otago,* ***3.*** *Lincoln University,* ***4.*** *GNS Science,* ***5.*** *Manaaki Whenua-Landcare Research*

Recent extreme flood events in New Zealand have demonstrated the impacts and risks posed by high-magnitude, low-frequency flooding, the likes of which have not been previously recorded, emphasising the urgent need for further research to extend flood series to contextualise these events and improve prediction. Floodplain environments offer an ideal archive for flood series extension by acting as sediment sinks during flood events, directly recording episodes of flooding and catchment erosion as well as the influence of recent human induced landscape change. This research seeks to understand the timing, magnitude, origin and drivers of flooding and erosion events in two contrasting catchments. The Whanganui, North Island, is confined by steep, narrow valleys for much of its western and lower catchment, underlain by weakly lithified sandstone, siltstone and mudstone of the Whanganui Basin; while the north-eastern part of the catchment drains the central volcanic plateau. The Whanganui sediment archive is located in a valley cutoff (Atene) in the lower catchment. The Ōreti, by contrast rises in the foothills of the Southern Alps in the South Island and drains less erodible greywackes and schists in a largely unconfined valley setting. Infilled meander cutoffs provide the sediment archive in the lower Ōreti valley. Particle size analysis (PSA), geochemical analysis (XRF ITRAX core scanning), computed tomography scanning (CT) and magnetic susceptibility identify and distinguish flood units. Magnetic susceptibility and geochemical analysis also distinguish erosion sources. Initial basal radiocarbon dating indicates the ~12 m cores recovered from Whanganui date from 4458 ± 24 cal yr BP and the 2.5 m cores from Ōreti from 149 ± 20 cal yr BP. Spanning approximately ~4.5 ka years, the Whanganui archive tracks the impacts on erosion and flooding of late Holocene climate change, landscape response to the 232 ± 5 AD Taupō eruption and human arrival and settlement within the catchment. The Ōreti floodplain captures a more recent high-resolution record of flooding and erosion, particularly the influence of human settlement and agriculture within the catchment. This research contextualises contemporary flooding and erosion problems within a longer, pre-historical timeframe, helping to support better management of rivers and their catchments.

Pleistocene megafloods in the Altai-Mountains – recent challenges for reconstruction

Prof. Juergen Herget [1], ***Prof. Julian Klaus*** [1]

1. *Dept. of Geography, Bonn University*

In Pleistocene times, the Russian Altai Mountains located in southern Siberia experienced a typical valley glaciation. In the headwaters of the River Ob, the valley glaciers blocked the course of rivers and generated ice-dammed lakes with repeated outburst floods. Field evidence is frequently described and interpreted following different, partly controversial concepts.

Due to a continuously increasing amount of new contradictory dating results, the chronology of the outburst floods recently became confused. By combining different locations with varying age estimations, the potential number of floods of different origin and pathway increased while obvious field indicators for plausibility are occasionally left out of consideration. In addition, a closer look for mineralogical sample quality in combination with a critical view on methodological challenges of applied dating techniques might help for the judgement of the quality and reliability of the controversy results.

Another challenge is the water balance of the glacial lake. The recent climate of interglacial conditions within the catchment is semi- to full-arid with mean annual temperatures below zero degrees, but short hot summer times. From Pleistocene times, climate indicators are missing due to environmental conditions in the glaciated high mountain environment. Despite that in Pleistocene times the climate might have been even harsher, the conditions must have allowed the repeated refill of the lake within the time span between the outburst floods. First modelling approaches are presented for further discussion.

The structure of the Moksha River floodplain as a key to the Late Pleistocene history of the valley development

Dr. Ekaterina Matlakhova [1], *Prof. Andrey Panin* [1]

1. Individual researcher

The noticeable geomorphic feature of the Moksha River valley (middle Oka River basin) is the occurrence of numerous large palaeomeanders that evidence a several fold rise of river discharges. Such large meandering palaeochannels (macromeanders) are typical for the river valleys of the East European Plain. To establish the history of the Moksha River valley development, we studied the key site in the lower part of the valley. Using the results of mechanical coring, geomorphological and lithological analysis, and radiocarbon AMS-dating we reconstructed few stages of the Moksha River valley development in the end of the Late Pleistocene. About 40-30 ka ago the increase of the river runoff associated with climatic changes led to the river incision deeper than the present level. After that the drying up of the climate and a lowering of the river runoff led to the filling of the valley (the strongest drying was in LGM time, about 23-20 ka ago). Then 18.5-12 ka ago the river runoff increased again and caused macromeanders formation and widening of the valley bottom. Modern wide high floodplain was formed at that time. In the Holocene runoff decreased and the channel parameters became close to the modern ones and the meandering belt of the river narrowed.

Magnitude and frequency of floods in the Judean Desert streams, Israel, using palaeoflood hydrology: Understanding the past to prepare for the future

Dr. Rami Zituni [1]***, Prof. Noam Greenabum*** [1]***, Dr. Naomi Porat*** [2]***, Dr. Gerardo Benito*** [3]

1. *University of Haifa,* ***2.*** *Geological Survey of Israel,* ***3.*** *Department of Geology, National Museum of Natural Sciences (MNCN)*

The Judea Desert constitutes a distinctive hydrological region characterized by steep bedrock ephemeral streams draining eastward to the Dead Sea Valley. The hydrological data for these streams are partial and scarce, leading to poor estimation of magnitude and frequency of floods. The lack of data is particularly significant when it comes to risk assessment for infrastructure. The current study is based on Palaeoflood Hydrology which uses geomorphological evidence for past real floods that accumulate in typical natural traps, along the course of the streams for hundreds and thousands of years. Those evidences indicate on the minimum water elevation of the flood enabling discharge calculations using HECRAS hydraulic engineering software. The ages of the floods are determined by radiocarbon and OSL dating of the flood deposits. These hydrological palaeoflood data enables to reconstruct the history of the floods in the streams including the largest event that occurred in the stream during the last hundreds to thousands years. By combining these data with measured and historical data (if any), a long, solid database can be reconstructed. The largest flood that occurred in the stream can serve as a control on regional envelope curves and rainfall runoff models such as PMP-PMF.

The streams in this study are: Darga (71 km^2), Arugot (217 km^2), Ze'elim (250 km^2) and Rahaf (55 km^2), along with Heimar (450 km^2) and Ashalim (35 km^2) from previous study. The duration of the reconstructed palaeoflood records are 210, 410, 250, 700, 300 and 7600, respectively. The maximum reconstructed palaeodischarges were 300, 830, 900, 1250, 1100 and 400 m^3s^{-1}, respectively in relation to the maximum measured peak discharges of about 140, 530, 680, 525, 540 and 100 m^3s^{-1}, respectively.

Frequency analyses using Max and FLDFRQ3 programs with the integrated data (systematic and palaeo) shows is some cases a significant decrease in the discharge values for low probabilities, while in others, the opposite trend was obtained. In all streams, the values for the integrated data are significantly more reliable as indicated by the value of the standard error.

Late-Quaternary paleohydrological changes in the alluvial system of Isonzo River (Northern Adriatic)

Prof. Alessandro Fontana [1]***, Dr. Livio Ronchi*** [1]***, Mr. Marco Bagalini*** [1]***, Mrs. Federica Vanzani*** [1]***, Dr. Ana Novak*** [2]***, Dr. Veronica Chiarini*** [1]

1. University of Padova - Department of Geosciences, 2. Geological Survey of Slovenia, Ljubljana

In the last decades important progress has been done in understanding the evolution of the depositional systems forming the alluvial plains of NE Italy by the main rivers draining the south-eastern Alps. Anyhow, very little is known about the Isonzo, a river with a catchment extending for 3400 km^2 in the Julian Alps, mainly in Slovenia, but forming the eastern-most sector of the alluvial plain of Northern Italy.

Thanks to the analysis of Lidar-derived DEMs, remote-sensed images, stratigraphic cores and geophysical soundings, both in the mainland and in the seabed of the Gulf of Trieste, our work reconstructed the different channel belts activated by the stream during the last 20 ka cal BP. In particular, we documented and characterized the dramatic palaeohydrologic changes experienced by the river in response to climate changes and sedimentary connectivity with the mountain catchment.

During the final part of LGM the river formed an alluvial megafan extending in the whole Gulf of Trieste and the very last channel belt of that phase was strongly constrained by the setting of the bedrock and flowed the present coastal boundary of the Karst from Monfalcone to Trieste, Koper and Piran. The mountain basin was occupied by a glacier at the LGM peak and, since the beginning of the deglaciation and glacial withdrawal, most part of the sediment was trapped within the valley because of landslide damming. In the starved alluvial plain a single incision formed from Gorizia, confined by 40 m high scarps that were progressively decreasing, until disappearing 20 km downstream. Incised filled valleys are documented through boreholes in the present coastal plain. The largest one reached a depth of 20 m and a width of 2 km and was filled at the bottom by sands and gravels, but estuarine environments occupied those alluvial depressions since early Holocene. Along the coast the incised valleys have been filled especially in the last millennia, when the sedimentary flux from the mountain was reconnected to the plain. This setting allowed the Isonzo to form several fluvial ridges in its distal sector, characterizing a new aggradational phase.

Paleo-drainage network identification of Central Kerala using remote sensing and machine learning techniques: implications on palaeogeography

***Mr. Ayyappadas C S* [1], Mr. Aneesh Sebastian [1], Dr. Hector A. Orengo [2], Dr. Linto Alappat [1]**

1. Department of Geology and Environmental Science, Christ College (Autonomous), Irinjalakuda Thrissur, Kerala, 680 125, India, 2. Catalan Institute of Classical Archaeology

Fluvial depositional systems are complex transient sedimentary bodies originated from the erosion of catchment over a time period. They consist of multiscale landforms and displays variety of sedimentary architectures. Paleo-drainage networks are such important fluvial landforms that evolved as a result of the fluvial system's response to natural/anthropogenic forcing. Further, the ancient river channels act as conduits of flood waters during extreme weather events. Mapping the palaeo-channels in the area have thus become a prerequisite in hazard management to mitigate large scale floods. Conventional remote sensing techniques based on multi-temporal satellite data sets of a specific location were found to be useful in identifying ancient hydrological systems globally. However, due to the difficulties in processing large datasets, conventionally a single satellite image captured in a particular time period was used for the purpose thereby limiting their ability to identify features in complex and dynamic landscape scenarios. In this study paleo-drainage networks of Periyar-Chalakudy River basin of central Kerala in South India were studied using vegetation indices and image enhancement techniques of a multi-spectral and multi-temporal dataset. Landsat 5 data of twenty-five years were compiled and processed for identifying paleo drainage systems using a Java Script code in the Google Earth Engine Platform. The landward extension of South Kerala Sedimentary Basin (SKSB) in Central Kerala of South India had experienced episodes of fluctuating sea-level and climate throughout the Quaternary. The present alignment of Kerala coast and coastal landforms are consequences of the Holocene land-sea interactions. The study has allowed identification of paleo-drainage networks associated with Periyar and Chalakudy River systems which is the largest river network in Kerala. Most of the identified channels presently occur as misfit streams with wider valleys possibly implying their genesis in a distinct hydrologic and climatic condition than present.

Subaqueous geomorphology of Lake Whakatipu, New Zealand, and geomorphic hazard implications

Mrs. Steph Coursey **[1]*****, Dr. Joshu Mountjoy*** **[2]*****, Dr. Katherine L. Maier*** **[3]*****, Dr. Samuel McColl*** **[4]*****, Prof. Sean Fitzsimons*** **[5]*****, Prof. Andrew Gorman*** **[5]*****, Dr. Emily Lane*** **[2]*****, Prof. Ian Fuller*** **[1]**

1. *Massey University,* **2.** *National Institute of Water and Atmospheric Research,* **3.** *NIWA,* **4.** *GNS Science,* **5.** *University of Otago*

Alpine lakes are dynamic environments with a range of geomorphic hazards. These hazards are typically facilitated by steep slopes, high seismicity, and extreme climate, which create high sediment loads and rapid post-glacial evolution. Alpine lakes also attract development, often being the most densely populated parts of alpine landscapes. Few studies have evaluated the full range of subaqueous and lake margin geomorphic hazards of alpine lakes. The growing availability of high-resolution bathymetric data, particularly for the little-explored Southern Hemisphere lakes, has made such evaluation possible.

High-resolution bathymetric data for an 80-km long glacial trough lake (Lake Whakatipu, New Zealand) was acquired in 2019, which we used to map the subaqueous geomorphology. This mapping guided landslide-triggered tsunami modelling and repeat bathymetric and seismic refraction surveys in 2021. We mapped a 2-km wide lake-head delta that connects to a 39-km long sinuous subaqueous canyon incised into lake sediments. Crescentic-shaped bedforms dominate the subaqueous delta and canyon, with wavelengths of up to 150 m. There is evidence of active canyon erosion and deposition, and canyon wall collapse within the past 2 years. The lake margins consist of sediment-draped subaqueous slopes which are extensively gullied, and gully growth could potentially undermine the lake shore. Bedrock scars mapped along the lake margin and features buried within the lake sediments, provide evidence of past rock-slope failures. Scarps on bedrock slopes are evidence of ongoing instability and potential failure. Tsunami modelling for three mapped landslides suggested maximum wave heights could have exceeded 5-m at the shoreline.

The availability of high-resolution bathymetric data has provided new insights into the potential geomorphic hazards of dynamic alpine lakes. Identification of these geomorphic hazards is critical in order to reconcile the ongoing population growth and investment in alpine lake settlements with the high hazard exposure within these dynamic environments.

Glacial lake outburst floods in southern Norway during the Early Holocene

Mr. Fredrik Høgaas [1], _Dr. Katherine Aurand_ [2], _Dr. Ivar Berthling_ [3], _Dr. Louise Hansen_ [1], _Dr. Oddvar Longva_ [1], _Dr. Anders Romundset_ [1], _Dr. Thomas Vikhamar Schuler_ [4]

1. Geological Survey of Norway, 2. Norconsult, 3. Norwegian Water Resources and Energy Directorate, 4. Department of Geosciences, University of Oslo, Oslo

Landform mapping using high-resolution LiDAR data has confirmed the presence of a suite of glacier-dammed lakes that existed along the retreating Scandinavian Ice Sheet in southern Norway at the end of the last Ice Age. Some of the lakes drained catastrophically along or beneath the remnant ice sheet during deglaciation. In this talk we present the geomorphological imprints of the outburst floods from two large glacial lakes – Store Dølasjø (A: 480 km^2, V: 80 km^3) and Nedre Glomsjø (A: 1300 km^2, V: 140 km^3) – that existed in southern Norway during the Early Holocene. The landform record related to the Store Dølasjø outburst flood comprises for instance clusters of large dune-like bedforms and longitudinal bars. Similar dunes seem to have formed not only south of the remnant ice sheet, but also within the glacial lake itself during the outburst flood. The landform record related to the Nedre Glomsjø outburst flood is more varied and comprises different kinds of large-scale bedforms, palaeochannels and obstacle marks found over a large region. Sections through some of the bedforms reveal coarse-grained, unsorted and consolidated sediments that locally show steeply dipping large-scale foresets. The outburst flood deposits indicate high sediment transport capability and rapid deposition. We also present the results of hydrodynamic simulations of the outburst flood from glacial lake Nedre Glomsjø, where approximately 100 km^3
of the lake drained in one event. Mapped high-water marks in the flooded region provide excellent constraints for the simulations, which suggest peak outburst flood discharges of 1.5-2 million m^3/s. Separate simulations of channelized drainage through an expanding ice-walled tunnel support the feasibility of this peak discharge estimate.

Pulling the plug – the role of ice-dammed lakes on the final demise of the Scandinavian Ice Sheet

Dr. Carl Regnéll [1], ***Dr. Sarah L. Greenwood*** [2], ***Dr. Richard Gyllencreutz*** [1], ***Dr. Gustaf Peterson Becher*** [3]

1. *Department of Geological Sciences, Stockholm University, Sweden,* ***2.*** *Department of Geological Sciences, Stockholm University, 10691 Stockholm, Sweden,* ***3.*** *Geological Survey of Sweden*

In northern Scandinavia, geological evidence pertaining unequivocally to the final deglaciation of the ice sheet is sparse due to largely cold-based decay. Furthermore, absolute dating constraints are woefully few, leaving the timing and location of final ice sheet decay still elusive. In the late stages of the deglaciation, however, extensive glacial lakes were dammed between the easterly retreating Scandinavian Ice Sheet (SIS) and the Scandinavian mountains to the west. Using LiDAR-data, we have discovered shorelines and other landforms relating to ice-dammed lakes over larger areas and in greater numbers than previously known, opening a treasure trove of palaeoglaciological information for reconstructing the final demise of the SIS.

With examples from all along the mountain range, we show how ice-dammed lakes were an intricate part of the deglacial dynamics, and how mapping and dating them offer a solution to these problems. We have reconstructed the full suite of ice-dammed lakes (n >400) along the length (>1000 km) of the mountain range. Starting as a multitude of smaller ice-dammed lakes, following ice-margin retreat they successively coalesced to form progressively larger lakes up to >3500 km^2 and 100s m deep. In many of these lake systems, we depict multiple stages of lake lowering, corresponding ice margin evolution and shifts in drainage, while cored sediments that capture glacial- to nonglacial lake transitions offer a chronology for these events.

With these reconstructions, we explore the impacts of lake filling and drainage on rates of ice margin retreat and positions of (in)stability. We find that catastrophic lake drainage events were coupled to ice-sheet partitioning, arising from a complex interplay between the rapidly retreating ice sheet and sub- and pro-glacial topography. Initial emergence of nunataqs following ice-sheet thinning funnelled ice flow into lower ground where enhanced ablation by calving in ice-dammed lakes effectively dissected the decaying ice sheet. Often depicted as one coherent ice mass, we now see evidence of recurring unzipping and partitioning of the ice sheet along the mountain range.

The evolution of glacial lakes Barlow and Ojibway was controlled by a single outlet throughout the last deglaciation: evidence from new lake-level reconstructions

Prof. Martin Roy [1]***, Mr. David Turcot*** [1]***, Dr. Etienne Brouard*** [2]***, Dr. Pierre-Marc Godbout*** [2]***, Dr. Jean J. Veillette*** [2]

1. *Geotop-Université du Québec à Montréal, Montréal, Canada,* ***2.*** *Geological Survey of Canada, Natural Resources Canada*

The retreat of the Laurentide Ice Sheet across northern Ontario and Quebec (Canada) was accompanied by a succession of glacial lakes that culminated with Lake Ojibway – a large ice-dammed lake that coalesced with Lake Agassiz late in the last deglaciation. The glaciolacustrine episode began with Lake Barlow that flooded the upper Ottawa River watershed and continued ice retreat led to the northward expansion of the lake and the development of Lake Ojibway north of the St. Lawrence River–Hudson Bay drainage divide. The history of Lake Barlow and its relationship with Lake Ojibway remain poorly known, notably regarding its temporal changes in elevation and extent. Previous work reported distinct lake stages, with lake levels controlled by a series of uplift-driven topographic (bedrock) outlets whose locations remain arbitrary. Mapping and elevation measurements of raised shorelines and deltas using LiDAR Digital Terrain Models (DTMs) covering the Barlow basin yielded an inventory of >5000 shoreline segments. Strandline elevations were corrected for the effects of post-glacial uplift using a DTM integrating the basin paleotopography (at 10.5 ka) to facilitate the reconstruction of lake levels. The new lake-level reconstruction indicates a regular lowering of the lake surface below the maximum limit of submergence, with no evidence for distinct lake-level stages (i.e., stability phases). Projection of tilt-corrected (sub-horizontal) lake levels suggests that the Lake McConnell Moraine in the south of the Barlow basin was the single outlet that regulated meltwater overflow towards the St. Lawrence River throughout nearly the whole glaciolacustrine episode. Comparison of Lake Barlow shoreline sequence with that of Lake Ojibway shows that the two lakes shared a common surface for most of the deglaciation – a connection that lasted until the first major lake-surface drawdown that led to the drainage of Lake Agassiz-Ojibway. These results eliminate the need for a succession of outlets to explain the evolution of Lake Barlow-Ojibway, in addition to bring new considerations on the connection between Lake Agassiz and Lake Ojibway in the late deglaciation, with attendant implications for the modeling of the meltwater volumes associated with the main lake stages that led to the final drainage.

Glacial Lake Outburst Flood from the Central Alps (N-Italy): from the Last Glacial Maximum to the deglaciation

Andrea Pezzotta [1]***, Dr. Guido Stefano Mariani*** [2]***, Dr. Mattia Marini*** [1]***, Prof. Mauro Cremaschi*** [3]***, Prof. Andrea Zerboni*** [1]

Desio", Università degli Studi di Milano,* ***2.** Dipartimento di Scienze della Terra, Università degli Studi di Torino,* ***3.** Dipartimento di Scienze della Terra "A. Desio", Università degli Studi di Milano, via L. Mangiagalli 34, I-20133 Milano Italy*

In glacial amphitheatres, proglacial lakes formed between moraine ridges, small fluvioglacial plains, and glacier fronts, represent potential sensitive sedimentary archives of environmental variations, especially recording the evolution of glaciers during the Last Glacial Maximum (LGM). Shifts in facies associations in glaciolacustrine deposits are a useful tool to disentangle advance and retreat phases of glaciers and their effects on the landscape. The sedimentary record of the LGM deglaciation at the southern foothills of the Alps, regionally dated between 24 and 17 ka, suggests the transition to the Late Glacial was accompanied by dramatic events, including landslides, ice calving, and glacial lake outburst floods. The investigation of glaciolacustrine deposits from the Adige River Glacial Amphitheatre (ARGA), a LGM multi-moraine ridges system located at the end of the Adige Valley (N-Italy), revealed specific glacier dynamics in the deglaciation. Inside the ARGA innermost moraine arcs, the glacial topography acted as a dam originating two separated ice-contact lakes, collecting meltwaters. Analysis of facies associations suggests deposition of sands and gravelly sands in proximal settings (close to the glacier fronts), and thinly bedded mud-prone facies in distal settings. The proglacial lakes were likely enclosed by the glacier fronts, moraine ridges, and older glacial deposits that obstructed the pre-existent Adige River canyon; the two separated lakes eventually coalesced together during the last phase of retreat. The available stratigraphic framework suggests that the boulders cropping out in the Venetian Plain deposits to the South of ARGA, coeval to the deglaciation phase, may represent megaclasts transported by a glacial lake outburst flood formed after the catastrophic 'unclogging' of the Adige River canyon from the glacial deposit occluding it. Results presented in this contribution add to understanding of the ARGA deglaciation phases and to the wider picture of the LGM-Late Glacial transition in the South-Central Alps.

Sole survivor? Holocene lacustrine evidence suggests Svalbard's most resilient ice cap survived warmer-than-present past conditions

Ms. Andreea Auer [1]***, Dr. Willem van-der-Bilt*** [1]***, Prof. Anders Schomacker*** [2]

1. *Department of Earth Science and Bjerknes Centre for Climate Research, University of Bergen, Bergen, Norway,* ***2.*** *Department of Geosciences, UiT The Arctic University of Norway, N-9037, Tromsø, Norway*

Record breaking warming and hydrological intensification throughout the Arctic stand as evidence that the region is experiencing extreme environmental change, yet future developments remain poorly constrained by models. Gaining more insight into these changes can help clarify their highly uncertain and counteracting impacts on glaciers, dominant drivers of sea-level change. The Quaternary sedimentary record of environmental responses to climate change during warmer-than-present intervals offers an opportunity to better constrain models and can provide context for future warming. We explore the potential of these records in a key area of the Arctic - northern Svalbard, where throughout the Holocene and beyond, the interactions between climate and the Åsgardfonna ice cap are recorded in the sediment archives of down-stream glacier-fed lakes.

The characteristics of the sediments accumulated in two of these lakes are analysed using a tested multi-proxy toolbox (i.e. CT scanning, XRF, XRD, grain size analysis, seismic data) that provides independent lines of evidence for the fine-grained and minerogenic sediment fingerprint of glacial sediment input. We seek to link relative changes in glacigenic input to past ice margin positions, using remote sensing constraints on bedrock transitions or sub-glacial topographic divides and basins. We find evidence of a glacial lake outburst flood observed in both records at ~10 ka BP, seemingly marking the onset of deglaciation and highlighting the swift response of the ice cap to Early Holocene warming. In light of rapid on-going and predicted warming, similar events may occur in the near future. However, grain size and geochemical data also reveal a weakened yet present glacial signal throughout the Early and Mid-Holocene. We note that the ice cap appears to have reached its Late Holocene maximum long before the Little Ice Age. By the Late Holocene, the progressing intensity of the glacial signal is accompanied by regular mm-scale micro-laminations thus recording glacier-climate change on human-relevant (decadal-centennial) timescales.

Reconstructing Retreat Dynamics of the Last Irish Ice Sheet Using Proglacial Lake Sediments

Mr. Matthew Carney [1], ***Dr. Kathryn Adamson*** [1], ***Dr. Cathy Delaney*** [1], ***Prof. PHILIP HUGHES*** [2]

1. Manchester Metropolitan University, 2. The University of Manchester

Understanding the rate and pattern of current ice sheet deglaciation relies on long-term records of Quaternary ice sheet behaviour. This study investigates such a record in the form of glaciolacustrine sediments preserved from the retreat and breakup of the Irish Ice Sheet (IIS) during the Last Glacial Termination (LGT, c.21-14 ka) within the Irish Midlands.

Existing reconstructions of the IIS are based on geomorphological mapping of landforms, which are inherently discontinuous in their distribution and preservation. A more continuous archive can be found in proglacial lake sediment records. These lakes are sinks for glacially-derived meltwater and sediment, and enable continuous, spatially-integrated reconstructions of glacial and foreland environmental change, including annually or seasonally-resolved (varved) records. Sequences of laminated, varved, proglacial lake sediments from Palaeo-lake Riada are well-preserved in the Irish Midlands and provide valuable insights into IIS behaviour and lake sedimentation.

We present a new high-resolution analysis of laminated glacial lake sediments from Co. Offaly, close to IIS marginal landforms (moraines and eskers). A suite of physical and chemical analyses (including ITRAX μ-XRF, grain size, and thin section micromorphology) is used to reconstruct sediment and meltwater inputs and implications for ice sheet dynamics of the IIS during the LGT. The results and methodologies of this approach are explored here, with a focus on high resolution micromorphological assessment of laminations and how these facilitate palaeo-environmental reconstruction. These reconstructions are then used to provide context and relative chronologies to existing models of IIS retreat across the Irish Midlands.

This study demonstrates the value of lacustrine sediments to enhance and provide chronological context to existing ice sheet retreat models. Additionally, we demonstrate the utility of glaciolacustrine sediments to provide insights how into retreat patterns and behaviour of ice sheets during periods of climate amelioration, applicable to current and future dynamics of existing ice sheets.

Clasts in a subaquatic debrite – unifying results based on different methods

Prof. Piotr Woźniak [1]***, Mr. Lukasz Elwirski*** [2]

1. *Faculty of Oceanography and Geography,University of Gdańsk,* ***2.*** *Faculty of Oceanography and Geography, University of Gdańsk*

The properties of clasts contained in debrites (debris-flow deposits) provide information on the sedimentological history of a sediment. These include: clast lithology, morphology (form, roundness), clast fabric, and in the case of soft-sediment clasts (SSC) – their internal structure. Here we concern on clasts in subaqueous debris flows. The study site is located at a coastal bluff of the Baltic Sea in the northern Poland, at Rzucewo village. Analyzed debrites were resulted from cohesive flows on a subaqueous fan, in a glaciolacustrine basin, probably during the decay of MIS 3 ice-sheet. The debrites contain both lithic clasts and SSC. The cross-section of the fan along the palaeotransport direction is exposed in the site, what with the richness of sedimentary record gives the possibility of research using various methods. Previous works enabled: (1) the reconstruction of triggers responsible for debris-flow generating, (2) the recognition of the diversity of SSC, (3) tracing the types of deformations formed as a result of debrite deposition, (4) the reconstruction of debris-flow directions. Recently, the morphology evolution of lithic clasts transported in a debris flow has been studied. The aim of the latest research is to investigate the features of debrites using computed microtomography (μCT) and thin sections (TS) analysis. Use of μCT enables 3D analysis of SSC and millimetre-size lithic clasts, while TS analysis gives insights into properties of debrite matrix. Combining traditional methods, mainly based on field works, with μCT and TS analysis led to a comprehensive recognition of debrite features and inference about the processes occurring in a debris flow.

Session 170: Biotic markers and measures of biodiversity of Holocene environmental change

Early Holocene vegetation development on islands of proglacial Lake Ojibway in northwestern Québec

Ms. Marianne Vogel [1], ***Prof. Hugo Asselin*** [2], ***Prof. Adam A. Ali*** [3], ***Ms. Cécile Latapy*** [4], ***Ms. Sabrina Leclercq*** [5], ***Prof. Yves Bergeron*** [6], ***Dr. Sébastien Joannin*** [7]

1. *Université du québec en Abitibi-Témiscamingue & Université de Montpellier,* ***2.*** *Université du Québec en Abitibi-Témiscamingue,* ***3.*** *CNRS, Universite Montpellier,* ***4.*** *Université de Montpellier,* ***5.*** *Université de Sherbrooke,* ***6.*** *Université du Québec en Abitibi-Témiscamingue & Université du Québec à Montréal,* ***7.*** *Institut des Sciences de l'Évolution de Montpellier, University of Montpellier, CNRS, EPHE, IRD*

At the beginning of the Holocene, the Laurentide Ice Sheet was progressively melting and liberating eastern Canadian landscapes. Meltwater accumulated at the glacier front, forming the proglacial Lake Ojibway, which covered western Québec and eastern Ontario for approximately 2,000 years before flushing into James Bay around 8,200 years ago. Paleoecological vegetation dynamics reconstructions of sites covered by Lake Ojibway showed that spruce forests were established from the onset, whereas sites south of the southern extent of Lake Ojibway first went through a steppe period before being afforested. One possible explanation for this rapid postglacial forest establishment in western Québec is that islands present on Lake Ojibway (paleo-islands) were colonized by forests before the drainage of the proglacial lake, hence acting as migration outposts. However, this hypothesis had not yet been tested with empirical data. We studied sediments from two small lakes located on paleo-islands (current hilltops) of Lake Ojibway to reconstruct vegetation development and diversity at the local (macro-remains) and regional (pollen) scales. Afforestation occurred between 9,900 and 9,600 years before present on the paleo-islands and was followed by a transition from open woodlands to denser forests around 9,200 years ago. *Pinus banksiana*, *Picea mariana* and *Betula papyrifera* were thus established on the islands almost 1,000 years before the drainage of Lake Ojibway. We also used diversity indicators and charcoal particles counting to better understand and characterize the vegetation and fire dynamics. Diversity indicators showed opposite trends for macro-remains and pollen, indicating local diversification and regional homogenization of the vegetation, supporting the boreal-mixed wood establishment around 9,200 years ago. Charcoal particles combined with the Charcoal Size Distribution (CSD) method reveal that local fires occurred on the paleo-islands and seemed to trigger the vegetation diversification and densification observed. Our results suggested a high magnitude local fire could trigger the vegetation diversification during the colonization process. We also provided strong empirical evidence for boreal mixed wood forest early establishment on paleo-islands outposts, which likely fostered lowlands plant colonization following Lake Ojibway drainage.

Patterns and drivers of abrupt changes in mesic tree populations at Story Lake Indiana

Ms. Nora Schlenker [1], ***Mr. Jonathan Johnson*** [2], ***Ms. Tessa Ray-Cozzens*** [3], ***Dr. David Nelson*** [2], ***Dr. Bryan Shuman*** [3], ***Dr. Jack Williams*** [1]

1. University of Wisconsin Madison, 2. University of Maryland Center for Environmental Science, 3. University of Wyoming

Over the last 8,000 years, populations of mesic tree species in the Great Lakes region have experienced large fluctuations in abundance, with taxa such as *Fagus grandifolia* (American beech) and *Tsuga canadensis* (eastern hemlock) often undergoing multiple collapses. These declines are well documented by fossil pollen records, but their synchronicity and drivers are not well understood, with hypothesized causes including drought, fire, density-dependent interspecific competition, or some combination of these extrinsic and intrinsic processes. For the Holocene-ACES project (Abrupt Change in Ecological Systems), we are collecting a series of new lake sediment records with multi-proxy indicators of past vegetation (pollen), drought (lake levels and delta C 13 from pollen grains), and fire (charcoal) records to understand the spatiotemporal patterns and drivers of tree population fluctuations. Here we show results from a 9 ka-to-present lake sediment record from Story Lake in northern Indiana, anchored by 15 radiocarbon dates, that shows at least two abrupt expansions of beech. The initial expansion of beech occurred at 6.9 ka, immediately after a dry period based on the lake level reconstruction of nearby Lake Lavine, MI. The second rapid rise of beech at 2.6 ka is associated with low plant water stress (low delta C 13 of pollen grains) and declining intensity of fire regime (decreased charcoal accumulation rates). The pattern and timing of beech variations at Story Lake differs substantially from other nearby well-dated records of beech declines, suggesting that collapses of beech may have been highly localized. These localized dynamics may indicate that the past ecotone between mesic beech forests and oak savanna in northern Indiana and southern Michigan was highly patchy and subject to locally governed rapid shifts in ecosystem state.

Temporal dynamics of invertebrate community assembly in modern Lake Victoria

Preserved assemblages of invertebrate remains in the sediments of large lakes reveal centennial to millennial scale variations of community composition and environmental conditions. Such long-term records are rarely available from tropical lakes, including the largest tropical lake in the world, Lake Victoria. Here, we examine chitinous remains of larval Dipterans (Chironomidae and Chaoboridae) and Cladocera found in a new sediment core of Lake Victoria to quantify changes in the invertebrate assemblage from the Lateglacial period throughout the Holocene to the present (~13,700 cal yr BP to present). Lake Victoria has been a dynamic ecosystem with significant environmental variations, such as water level changes, biogeochemistry, and fish community composition, since the lake refilled ~15,000 cal yr BP. We detected three major changes in the assemblage of invertebrate taxa throughout the lake ontogeny. First, prior to the occurrence of cladocerans in the community, Chaoboridae and Chironomidae increased in abundance and sustained higher values from ~6,000-3,000 cal yr BP, which coincided with proxy data indicative of high diatom production towards the end of the African Humid Period. Second, starting ~5,000 cal yr BP, *Alona* spp., a predominantly littoral cladoceran, became established in the invertebrate community and persisted throughout the late Holocene to the present. Third, following the arrival of both *Chydorus* spp. and *Bosmina longirostris* around 2,000 cal yr BP, the community gradually shifted toward an increasing dominance of *B. longirostris*, typically a more pelagic cladoceran. This study provides the first multi-millennial record of sedimentary invertebrate remains in Lake Victoria and contributes valuable insight into the temporal sequence and dynamics of past invertebrate communities in response to ecosystem changes and climate variability.

Reconstructing the long-term dynamics and functioning of floodplain ecosystems through a multi-proxy and multi-site analysis

Ms. Renske Hoevers [1], ***Dr. Nils Broothaerts*** [2], ***Prof. Gert Verstraeten*** [1]

1. KU Leuven, Department of Earth and Environmental Sciences, Division of Geography and Tourism, 2. Thomas More University of Applied Science

Rivers and alluvial floodplains are dynamic environments, shaped by millennia of natural and anthropogenic induced changes. During the Early and Middle Holocene, most Northwestern European floodplains were stable environments, mainly influenced by natural forces, resulting in low-energy multichannel rivers in swampy floodplains. During the Late Holocene, forest clearances for agricultural purposes resulted in increased soil erosion rates and the burial of the Early- and Middle Holocene peat deposits under thick layers of sediment, transforming these environments into single channel meandering rivers with overbank deposits. While the general framework of this transformation is well-established, many uncertainties still exist given the strong spatiotemporal variability of this change in geoecohydrology. In this study, we reconstruct the Holocene geoecohydrological changes for five river catchments in northeastern Belgium through a multi-proxy approach. A combination of cluster analysis, ordination and Ellenberg indicator values (EIVs) is applied to a large palaeobotanical dataset to enable an objective identification and explanation of patterns.

The vegetation history of the studied floodplains is marked by an alternation between *Alnus* and Cyperaceae domination, which seems strongly controlled by moisture. While *Alnus* is locally present from at least ca. 11,200 cal. BP in northeastern Belgium – supporting the hypothesis of a western European refugium – its expansion happens in most cases several millennia later. The Early Holocene regional forest expansion resulted in a gradual decrease of water and sediment to the valleys, and *Alnus* started to dominate the local floodplain vegetation once the peat became sufficiently dry. The opposite can be observed in the Late Holocene, when the relatively dry *Alnus*-dominated floodplains transform back to more open and wet environments, linked to regional deforestation and the consequent renewed increase in water and sediment delivery from hillslopes to river valleys. These transformations are, however, highly heterogeneous in timing between and within (sub)catchments, suggesting that local factors including soil type and topography play an important role in the sensitivity to these changes in land cover. Such insights into the long-term dynamics of floodplain ecosystems, and their responses and sensitivity to changes in driving forces are of great importance in the development of sustainable management plans.

Climate change and human activity drive vegetation change during the last eight millennia in the Xistral Mountains of NW Iberia

Dr. Tim Mighall [1]***, Prof. Antonio Martínez Cortizas*** [2]***, Dr. Noemi Silva-Sánchez*** [3]***, Dr. Olalla López-Costas*** [2]***, Dr. Lourdes Lopez-Merino*** [4]

1. *University of Aberdeen,* ***2.*** *University of Santiago de Compostela,* ***3.*** *INCIPIT-CSIC,* ***4.*** *Universidad Complutense de Madrid*

An 8500-year record of high-resolution pollen, non-pollen palynomorph, microscopic charcoal and selected geochemical data (Ti, Zr and Pb) are presented from an ombrotrophic mire from the Serra do Xistral, Galicia, North-West Iberia. The results suggest that vegetation changes over the last eight millennia are primarily the result of human disturbance, fire and climate change. Climate and fire were the main factors influencing vegetation development during the early to mid-Holocene, including a short-lived decline in forest cover c. 8.2 ka. Changes associated with the 4.2 and 2.8 cal. BP events are less well defined. Human impact on vegetation became more pronounced by the late Holocene with major periods of forest disturbance from c. 3100 cal BP onwards: during the end of Metal Ages, Roman period and culminating in the permanent decline of deciduous forests in the post-Roman period, as agriculture and metallurgy intensified, leading to the creation of a cultural landscape. Climate change appears to become less influential during the Late Holocene as human activity dominates.

Holocene interactions between paleoecology and fishing practices in sub-Antarctic South America

Concerns about the conservation and management of marine ecosystems are currently growing. The Patagonian coastal ecosystems are one of the least intervened environmental regions worldwide, representing a real "hotspot" of biodiversity of great value and importance for its sustainability. In this paper, past fishery resources in the Strait of Magellan (MS) and Beagle Channel (BC) are evaluated by temporal and spatial variations in fish diversity and productivity based on archaeological, ichthyoarchaeological, and paleoecological data. Both regions present 7500 years of human history, and they are located in different insular and continental coastal environments, representing the environmental heterogeneity.
The ichthyoarchaeological assemblages of 14 from MS sites and of 17 from BC sites are analyzed in this paper. Results reveal spatial and temporal variations in fishing practices, which are closely related to the mobility of canoe groups, the development of fishing technologies, and the use of the diverse microenvironments. The ichthyoarchaeological assemblages from the mid to late Holocene and the encompassed space between MS and BC show that fishing patterns are period- and location-dependent. Between 7500 - 5000 years BP S. australis and M. magellanicus predominate in BC, while a slightly more diversified pattern of exploitation was observed in MS, including demersal fishes and shore environments. During 4000 - 2500 years BP there is a significant change in fishing preference MS, with both regions registering an exploitation focused of resources from environments located deeper and further offshore (demersal benthic), such as Salilota australis. There is less archaeological information available in the BC for this period, but the ichthyoarchaeological assemblages show a similar pattern in the exploitation of deep-sea species from an increase in the representation of Merluccius australis. Finally between –2500-100 years BP both the MS and BP there is a significant change, the rockfish and pelagic fish dominate the assemblages.
Together with regional paleoecological data, our results indicate that environmental changes during the late and mid Holocene affected fish taxa representations in the archaeological assemblages, and therefore the fishing practices used by the marine hunter-gatherer groups that inhabited the region for more than 7500 years.

Palynological determinations of species richness and spread from southern Greenland around the time of the Norse landnám

Dr. James Schofield [1], *Prof. Kevin J. Edwards* [1]

1. Geography & Environment, School of Geosciences, University of Aberdeen AB24 3UF

The Norse colonisation of the North Atlantic islands, beginning c. AD 800, resulted in the dispersal of a suite of 'alien' flora and fauna (anthropochores) to remote high-latitude environments with relatively simple biogeographies. Equally important were the opportunities created by human settlement for the expansion of a wider range of native species (apophytes). In many instances, the locations that were settled by the Norse may been viewed as 'natural laboratories' in which to study the impacts of anthropogenic activity on ecosystems and environments, given the western North Atlantic islands (i.e. Faroe Islands, Iceland and Greenland) were largely unoccupied prior to the arrival of the Norse. This paper will demonstrate the value of palynological evidence in investigating changes in the diversity and complexity of vegetation in Greenland as a result of the Norse landnám (Old Norse: 'land-taking', c. AD 1000), an event which phytogeographers have speculated could have resulted in the introduction of up to 5% of the region's modern flora. With a focus upon the area of southern Greenland known as the Eastern Settlement (Eystribyggð), this analysis is made possible through synthesis of data from a network of pollen sites, each typically featuring high-temporal resolution sampling, supported by precise age-depth models and estimates of species richness (rarefaction) and spread. We will also consider the 'legacy effects' of land abandonment – from c. AD 1400 forwards – on the region's vegetation. The period leading into, through, and after settlement in Greenland is of added interest and importance to studies of biodiversity given its broad temporal correspondence with the shift from the warmer conditions associated with the 'Medieval Climatic Optimum' (MCO) to the colder 'Little Ice Age' (LIA).

Hitchhikers, maritime routes and biogeographic change

Dr. Eva Panagiotakopulu [1], ***Dr. Ana Catarina Garcia*** [2]

1. *University of Edinburgh,* **2.** *Centre for the Humanities, Faculdade de Ciências Sociais e Humanas, Universidade NOVA de Lisboa, Portugal*

Movement of people and the spread of farming has also to do with the spread of insects and biogeographic change. This process involved different pathways including both maritime and riverine transport, with insects passively ferried in cargo, dunnage and ballast. Some, as human lice and other ectoparasites of humans and domestic animals, also travelled on their hosts, while others, as wood borers, pests of crops and dung beetles would hitch a ride. This paper will provide an overview of introductions of insects using evidence from shipwrecks and key ports, examining change overtime in terms of range and number of species, differing maritime routes and change over time. The data go back at least 2600 years ago and provide us with some understanding of pathways for invasive species. Most of the insect data come from the medieval and post medieval period, when ships became larger and less likely to be thoroughly cleared out between voyages, allowing beetles and flies to become residents in ballast and dunnage. At that point, various species, taking advantage of the foul conditions in ships' holds, started spreading geographically, following the routes of colonisers and traders and providing interesting information about itineraries, goods traded and conditions on board. A number of post-medieval references provide some information, from mentions of cockroaches on a galleon off the Azores, to the complaints of weevil-infested bread from James Cook's crew in the late eighteenth century. Our insect data from two shipwrecks from the Azores include the first and early records of now cosmopolitan species of flies and cockroaches and the work sheds light on their spread through maritime trade and the importance of ports of call. The fossil insect record from wrecks and other assemblages from ports and relevant contexts, show the process of accidental imports, which are often strongly associated with exchange networks and give an alternative record for ecological imperialism through maritime trade.

Session 173: Palaeoclimate records from the Southern Hemisphere

Long-distance transported pollen record from sub-Antarctic Kerguelen shows Southern Hemisphere Westerly Wind dynamics during the Holocene

Ms. Maaike Zwier [1], ***Dr. Willem van-der-Bilt*** [1], ***Prof. Jostein Bakke*** [2], ***Dr. Nathalie Van der Putten*** [3], ***Dr. Tobias Schneider*** [4], ***Prof. William D'Andrea*** [5], ***Prof. Anne Bjune*** [1]

1. University of Bergen, 2. Department of Geography, University of Bergen, Bergen, 3. Vrije Universiteit, 4. Lamont-Doherty Earth Observatory Columbia University, 5. Lamont-Doherty Earth Observatory, Columbia University, Palisades, NY

The Southern Hemisphere Westerly Winds (SHW) play a major role in the regulation of the global climate. Through wind driven upwelling, the SHW affect sequestration of atmospheric CO_2 and heat uptake by the Southern Ocean. Changes in the position and strength of the SHW core belt can greatly affect the intensity of these processes through invigoration of the Antarctic Circumpolar Current. Understanding the SHW's natural variability is crucial to comprehend the wind driven component of the carbon cycle. Recent intensification and southward movement of the SHW core belt has been inferred, but long-term changes in its behavior remain largely unconstrained. We reconstruct changes in the SHW through a tested method with unique application: using the accumulation rate of long-distance transported (LDT) pollen grains and charcoal from the main continental landmass of southern Africa to the sub-Antarctic island of Kerguelen. Unlike the vast majority of previous LDT pollen studies where pollen fluxes are interpreted as a measure of SHW strength, the position of Kerguelen relative to Africa allows us to use our data to infer changes in zonal position of the SHW core belt. In addition, a combination of palynological and stratigraphic evidence is used to reconstruct local Holocene climate. Our results show that there have been substantial changes in local and regional climate variability during the Holocene. We infer a dynamic Early Holocene and relatively stable climatic conditions over Kerguelen during the Mid- to Late Holocene, coinciding with a tipping point in the SHW's latitudinal position: from a more southward to equatorward position around 8,5 ka BP. These results are supported by other paleorecords from the region and suggest large-scale changes in SHW behavior on millennial to centennial timescales.

The ITCZ variability during the last three millennia in Northeastern Brazil and related impacts on human population

***Dr. Giselle Utida* [1], *Dr. Francisco Cruz* [2], *Dr. Mathias Vuille* [3], *Dr. Valdir Novello* [4], *Ms. Angela Ampuero* [5], *Prof. Hai Cheng* [6], *Prof. R. Lawrence Edwards* [7]**

Changes in tropical precipitation over the last millennia have usually been associated with latitudinal displacements of the Intertropical Convergence Zone (ITCZ), but recent studies provided evidence that contraction/expansion of the rainbelt have contributed to precipitation variability. In South America, the scarcity of paleoclimate records in the northern portion of the continent prevents a clear understanding of ITCZ changes in the region. In order to fill this gap, our study presents a reconstruction of paleo-precipitation for the last 3000 years from Northeast Brazil (NEB) based on oxygen isotopes in speleothems. NEB receives most of its precipitation from the ITCZ when the core of convection is located in its southernmost position. The association between our oxygen isotopes record with paleo-precipitation records located at northern position of ITCZ indicates that the range of seasonal migration and contraction/expansion of the ITCZ was not symmetrical over the equator. During the period corresponding to the Medieval Climate Anomaly (MCA), our record shows an abrupt transition from wet to dry conditions, which persisted until the onset of the period corresponding to the Little Ice Age (LIA), This interval is characterized as the longest dry period in the last 3000 years in NEB. Our stalagmite documents abrupt and strong drought events occurring during the LIA (~1500 – 1850 CE) that correspond with historical droughts documented by the Portuguese colonialists. These droughts recorded by the NEB stalagmite indicate that these events were able to affect the population, karst system and environment of NEB. The correspondence of geological and historical records demonstrates how important speleothem science is for this region to document past climate and occurrence of extreme events that have the potential to affect human life.

Large-scale reorganisation of atmospheric circulation for the late Holocene derived from a 7.2 ka Altiplano peatland record (Cerro Tuzgle, NW Argentina)

Dr. Karsten Schittek [1], ***Dr. Sebastian Kock*** [2], ***Mr. Holger Wissel*** [3], ***Dr. Julio Kulemeyer*** [4], ***Dr. Liliana Lupo*** [5], ***Prof. Frank Schaebitz*** [1], ***Dr. Andreas Lücke*** [3]

Jujuy*

High-elevation cushion peatlands are promising archives for paleoenvironmental studies in their extreme habitat of the Central Andean highlands between 4000 and 4800 m a.s.l. We present the environmental and climatic history for the last 7200 years of Cerro Tuzgle peatland (CTP), located in the dry Puna of NW Argentina.
The stable isotope composition of bulk material and cellulose ($\delta^{18}O$, $\delta^{13}C$, $\delta^{15}N$) of the dominant cushion-forming species *Oxychloe andina* (Juncaceae) and *Zameioscirpus muticus* (Cyperaceae) were investigated. We further applied a multiproxy approach with XRF scanning and bulk geochemistry. Pollen assemblages give an insight into substantial environmental changes on a regional scale.
The results reflect prominent late Holocene climate anomalies and provide evidence that in situ moisture changes were consistently coupled to temporal changes in the match to South American Summer Monsoon (SASM) reconstructions during the last 2900 cal yr BP.
The prominent feature of the entire record is a distinct and lasting transition centred around 3100 cal yr BP characterized by declining minerogenic content, increasing organic carbon content, rising stable carbon isotope values of organic matter and cellulose, and increasing stable oxygen isotope values of cellulose. We interpret this specific proxy pattern as a hydroclimatic transition towards less arid conditions at the CTP after 3100 cal yr BP. Moisture supply during a more arid middle Holocene was provided by isotopically depleted precipitation, while moisture supply after the transition originated from isotopically enriched SASM summer precipitation. Concurrent hydroclimatic changes in the SHW winter precipitation regime south of the South American subtropical dry zone (SASDZ) are documented in a distinct lake level rise of Laguna Aculeo (33˚50´S) around 3200 cal yr BP. These coinciding hydrological changes of the SASM and the Southern Hemisphere Westerlies precipitation regimes indicate larger scale reorganisations of atmospheric circulation components, potentially connected to major modulations of the SASDZ. Thus, our CTP record sheds light on the middle to late Holocene development of the SASM at its southern limit and corroborates connections between the tropical and extratropical hydroclimate of South America.

Interaction of tributary alluvial fan and fluvial sediments during the Late Pleistocene - Holocene transition in the arid southern Central Andes.

Dr. Jose Luis Antinao [1]***, Dr. Antonio Maldonado*** [2]***, Dr. Eric McDonald*** [3]***, Ms. Laura Díaz-McAdoo*** [4]***, Dr. Robert Negrini*** [5]***, Mrs. Rachel Tiner*** [6]

New mapping and luminescence geochronology of fluvial and alluvial fan deposits from the arid southern Central Andes of Chile were used to infer Pleistocene-Holocene paleoclimate for this high relief region. During this period, alluvial fans descending from tributary catchments into major river valleys encroached on fluvial deposition, creating a record of interbedded fluvial-alluvial fan deposition. In many places, alluvial fans obstructed river flow and generated extensive river damming, with associated lacustrine deposition. In addition to geochronology, the sedimentology and pedology of several sets of alluvial fan deposits were also characterized. The oldest sequence of fan deposition (~40 ka) appears as isolated deposits on hillslopes and is highly eroded. Two regionally distributed, massive (25-100 m thick) fan sequences are dated to 14-9 ka and post ~5 ka. Deposition of the 14-9 ka fans in catchments sourced from both high and intermediate elevations suggests a common factor in generating these fans, which we interpret as linked to a regional precipitation increase derived from Pacific moisture sources. An intermediate sequence of fan deposition occurred ~8.2 ka in some outlets sourced from high elevation catchments. The occurrence of these fans during the most arid period of the Holocene in the southern Central Andes suggests an easterly moisture source for the precipitation events that generated the fans. The post-5 ka fans can be associated with a relative increase in precipitation during the late Holocene, previously documented at these latitudes in the southern Central Andes. The largest fans associated with a Late Pleistocene precipitation increase were probably driven by a northward excursion of the Westerlies. The 8.2 ka event is relevant to hazards analysis today and in the near future with predominance of arid conditions.

Developing a hydrological transfer function for montane peatlands in the tropical South Pacific

Dr. Michelle Marie Mckeown [1], ***Dr. David Beilman*** [2], ***Dr. Matiu Prebble*** [3], ***Dr. Marika Tuiwawa*** [4], ***Dr. Jean-Yves Meyer*** [5]

Background: The South Pacific Convergence Zone (SPCZ) exerts a strong influence on precipitation patterns across the central South Pacific. A small displacement in the position of the SPCZ causes drastic changes to the hydroclimate conditions and the frequency of extreme weather events (such as prolonged droughts, floods, tropical cyclones), experienced by vulnerable tropical island nations in the region. Palaeoclimate reconstructions of ocean temperature, salinity and rainfall derived from speleothem, coral, lake and swamp archives have advanced our long-term understanding of the SPCZ in the southwest Pacific. However, palaeohydrological records spanning the full Holocene are rare. This is due to a lack of conventional sites typically used for millennial-scale proxy reconstructions, which has limited efforts to extend observational rainfall and tropical cyclone data sets. While longer-term changes in tropical vegetation and human activity have been recorded in sediment archives, proxies specifically targeting centennial-scale hydrological shifts are needed to further hone of understanding of precipitation fluctuations governed by the SPCZ in the tropical southwest South Pacific.

Our project: Montane peatlands in the humid highlands of Taveuni (Fiji) and Futuna (Wallis and Futuna) offer rare palaeoclimate archives in the southwest Pacific region. We investigate the potential of testate amoebae (a group of single celled free-living protozoa) to infer a Holocene hydrological signal from the two peatland complexes. Over the last two decades, testate amoebae have been mainly used to reconstruct changes in hydrological conditions in peatlands, typically expressed as water table depth. In 2022, surface soil and vegetation samples were collected, and abiotic (depth to water table, pH and conductivity) variables were recorded, from distinct habitats in the Lake Tagimaucia peatland in Fiji, and a peatland on Mt Puke in Futuna. Micro-topographical gradients (pools to hummocks) were targeted to capture a hydrological range. In the first phase of this study, we examine the ecology of contemporary testate amoebae and their relationship with key abiotic variables and test the hypothesis that their distribution is primarily controlled by hydrological conditions. We will then build two separate transfer functions to reconstruct the dominant controls on testate amoebae assemblages from each peatland complex.

Temperature and hydroclimate reconstructions over the past 16 kyr from Lake Llaviucu, Ecuador

Dr. Boyang Zhao [1], ***Prof. James Russell*** [1], ***Dr. Ansis Blaus*** [2], ***Dr. Mark Bush*** [2]

1. Department of Earth, Environmental, and Planetary Sciences, Brown University, 2. Institute for Global Ecology, Florida Institute of Technology, Melbourne, Fl, USA

Decades of research have produced a coherent picture of global temperature change since the Last Glacial Maximum, with global warming during the last glacial termination punctuated by millennial-scale cool intervals such as the Younger Dryas (YD) and Antarctic Cold Reversal (ACR). However, quantitative reconstructions of temperature are geographically biased toward the oceans and northern latitudes, limiting our understanding of global climate processes and the global footprint of millennial-scale cool events such as the YD and ACR. To better understand the impacts of 'northern' vs. 'southern' modes of temperature changes in the southern tropics, we examine branched glycerol dialkyl glycerol tetraether and leaf wax hydrogen isotopes in a 12 m sediment core from Lake Llaviucu, Ecuador, to develop high-resolution temperature and hydroclimate records for the past ~16000 years. Our δ^2H record suggests the tropical Andes experienced a transition from a relatively wet to a dry climate from ~16 to 12 ka, a dry early Holocene, and a long-term trend toward wetter conditions in the late Holocene, consistent with seasonal insolation forcing of the South American Summer Monsoon. This hydroclimate variability agrees with the stalagmite oxygen isotope records from a nearby cave, validating the age model of our lake sediment core. Our reconstruction indicates ~4 °C warming during the glacial termination, punctuated by a ~1.5 °C cold interval that is concurrent with the ACR. This points to an important influence of meltwater forcing and sea surface temperatures over the South Hemisphere on tropical Andean temperatures during the deglaciation. During the Holocene, our temperature reconstruction is very stable, then shows a gradual warming trend since ~6000 yr BP, which was likely controlled by increasing atmospheric CO_2. Unlike other parts of the tropics, we do not observe an early to mid-Holocene thermal maximum, suggesting a limited influence of feedbacks amplifying northern hemisphere summer insolation in our study region. Our results highlight the complexity of this region and the need to acquire more quantitative temperature records from the southern tropics.

Middle to Late Holocene environmental dynamics of the subtropical Andes (32°-36°S)

***Dr. Maria Eugenia de Porras* [1], *Mrs. Eleonora Ines Cavagna* [1], *Dr. Juana Alejandra Martel-Cea* [2], *Dr. Antonio Maldonado* [2]**

***1.** Instituto Argentino de Nivología, Glaciología y Ciencias Ambientales (IANIGLA-CONICET), Mendoza, ARGENTINA., **2.** Centro de Estudios Avanzados en Zonas Áridas (CEAZA)*

The subtropical Andes (32°-36°S) are one of those areas in the world that has been experimenting a strong trend to more arid conditions as the result of increased temperatures and a reduction in (winter) precipitation due to the ongoing climate change. Precipitation in the high Andes, related to the Southern Westerlies, is the source of water for central Chile and Argentina becoming therefore a key resource in socio-environmental terms. The scarce long-term records in the Andes located in the western lowlands point out that this region experimented widespread and extreme arid conditions during the Middle Holocene. Hence, studying the high Andean environments response to such conditions in the past would provide some clues to face the future scenarios in this region. Thus, this work aims to reconstruct the paleoenvironmental dynamics of the subtropical Andes (32°-36°S) at centennial/sub-centennial scale by presenting the pollen record of Laguna Corazón (LCO; 35,14°S-70,21°W) and other high Andean records spanning the Middle to Late Holocene. Naked-eye description, RX radiographs, Loss on Ignition, and pollen analysis were performed on the 2.4-meter long sediment core of LCO dating back 5400 yrs BP. The sedimentary record is mostly composed of dark-brown laminated silts and presents a volcanic ash layer at 21-24cm depth that according to the chronological control could be attributed to the 1932 Quizapu eruption. The LCO record reflects the development of a grass steppe with a millennial scale drier-than-present phase between 5400-3000 yrs BP, more humid conditions than present between 2700-1100 cal yrs BP followed by a decrease in moisture up to 300 cal yrs BP when similar than present conditions established but under a high environmental variability. Other high Andean lake records at 32°, 33° and 36°S point out drier-than-present conditions during the Middle Holocene even the peak/amelioration of such conditions is asynchronous probably related to their latitudinal/longitudinal position regarding the precipitation source.

The Late Quaternary environmental history of the Kalkkop palaeolake: a unique terrestrial record from the Nama-Karoo Desert, South Africa

Dr. Kelly Kirsten [1], ***Prof. Torsten Haberzettl*** [2], ***Dr. Tara Edwards*** [3], ***Dr. Alexander Blackwood*** [4], ***Mr. Paul Strobel*** [5], ***Dr. Marcel Bliedtner*** [5], ***Dr. Robyn Pickering*** [6]

1. *Department of Geological Sciences, University of Cape Town,* **2.** *Physical Geography, Institute for Geography and Geology, University of Greifswald,* **3.** *Department of Geological Sciences & Human Evolution Research Institute, University of Cape Town,* **4.** *Department of Archaeology and History, La Trobe University,* **5.** *Physical Geography, Institute of Geography, Friedrich Schiller University Jena,* **6.** *University of Cape Town*

The contemporary Nama-Karoo region is defined by its semi-arid environment which hosts a desert and xeric shrubland matrix. However, a meteorite impact in the Eastern Cape of South Africa led to the formation of a deep lake system during the Quaternary. A core extracted from the profundal zone penetrated 89 m of lacustrine deposits, achieving ~80% sediment recoverability. A basal sample from the lacustrine sediments date the lake's origins to ~250 ± 50 ka based on U–Th, while a near surface sample suggests lake extinction occurred at ~18 cal. ka. The core is dominated by fine laminations, with some massive deposits. The grey scale index revealed several major cycles within the data potentially alluding to key climatic shifts. A multiproxy approach, which included spectrophotometry, magnetic susceptibility, CNS elemental analysis, grain size analysis and diatom analysis, was undertaken at an approximately 16 cm resolution. Based on these analyses, three main phases of development could be ascertained, namely Z1: 8735 –7938, Z2: 7904 –1881, Z3: 1866 –0 cm. The I-band index, which isolates the [660, 670 nm] reflectance trough values as produced by Chlorophyll-a and its diagenetic products, revealed low, high, and moderate periods of primary productivity, respectively. Diatom preservation potential is greatest in the lower 30 m of the core and is dominated by a high representation of pioneer species, suggesting some degree of environmental variability but with permanent, close to neutral to slightly alkaline, open water conditions. Future research will focus on lipid biomarkers and trace elemental analyses but primarily on a more detailed U-Th chronology, annual layer counting and the generation of a detailed age model. The implications of this new palaeoclimate archive presented here, plus its future age model, are significant given the site's depositional period and its proximity to the rich archaeological record of early modern human behaviour on the adjacent southern Cape coast.

A comparison of pollen and macrofossil-based reconstructions of vegetation and climate: Case studies from Southeastern Australia

Ms. Kia Matley [1], ***Dr. Kale Sniderman*** [2], ***Dr. Andrew Drinnan*** [1], ***Dr. Nick Porch*** [3], ***Dr. Quan Hua*** [4], ***Dr. Jan-Henrik May*** [5]

1. School of BioSciences, The University of Melbourne, 2. School of Geography, Earth and Atmospheric Sciences, The University of Melbourne, Australia, 3. Deakin University, 4. ANSTO, 5. School of Geography, Earth and Atmospheric Sciences, The University of Melbourne

Despite its widespread use in palaeoecology, pollen-based reconstructions are limited by coarse taxonomic resolution. Pollen of narrow-range species that might be used as ecological indicators, for example, can be difficult or impossible to distinguish from the pollen of geographically widespread, and therefore less informative, taxa. Plant macrofossils, by contrast, are routinely identified to species level, and a majority of the species present in Southeast Australia during the late Quaternary still exist today. These improvements to the taxonomic precision of palaeobotanical records allow for the use of bioclimatic niche models to quantitatively reconstruct palaeoclimate, based on fossil species' modern day climatic niches. Combining these two proxies, we are able to produce a more nuanced interpretation of late-Quaternary vegetation and climate.

We sampled for pollen, plant and insect macrofossils at multiple sites across Southeast Australia. For each, we produced detailed pollen records which indicate regional-scale vegetation change. In addition, select macrofossils were identified to higher taxonomic resolution, and based on those species' modern-day bioclimatic profiles, we are able to quantitatively reconstruct the climate at the time of deposition. Radiocarbon and Optically-Stimulated Luminescence dating confirm that these sites fall within the last glacial period; one of which is a continuous record from the Last Glacial Maximum (LGM) to present, and which represents a rare mainland Australian refugium of the cool-temperate rainforest tree *Nothofagus cunninghamii*.

By examining both pollen and macrofossils, we are able to provide precise new insights into the composition of Southeast Australian communities and climate. These data will also illuminate the historical biogeography of individual species and provide crucial insights into the degree of sensitivity of Australian plant taxa to changes in climate in general.

Late glacial climate evolution in the Patagonian Andes from glacier modelling

***Ms. Ruby Muir* [1], *Dr. Shaun Eaves* [1], *Dr. Lauren Vargo* [1], *Dr. Brian Anderson* [1], *Prof. Andrew Mackintosh* [2], *Dr. Esteban Sagredo* [3], *Dr. Rodrigo Soteres* [4]**

1. Victoria University of Wellington, 2. Monash University, 3. Pontificia Universidad Católica de Chile, 4. Universidad de Magallanes

Numerical glacier models applied to moraine chronologies provide an opportunity to quantify past climate change. Here we apply a two-dimensional coupled mass balance – ice flow model to well-dated moraine sequences of two Patagonian glaciers at 44 and 47°S to reconstruct the local temperatures during both the Antarctic Cold Reversal (14.7–13 ka) and the Younger Dryas (12.9–11 ka). Modelled temperature anomalies during the Antarctic Cold Reversal are 2.6 ± 0.4 °C at 44°S, and 2.9 ± 0.6 °C at 47°S. At both locations this cold event is followed by temperature increases of +0.6 – 0.7 °C or precipitation reductions of c. 20% to drive glacier retreat to moraines deposited during Younger Dryas time. The consistent climatic anomalies between these two latitudes suggest this region of Patagonia was responding to a common climatic event. Further, the late-glacial temperature anomalies found here compare well to those determined by similar glacier modelling techniques in New Zealand, at 43–44° S. These results support a trans-Pacific response throughout the southern mid to high latitudes (43–47° S) during the ACR that is best explained by a northward expansion of the south westerly winds.

Flipping the wet-dry dichotomy: moist glacial and dry interglacial climates across the Southern Hemisphere subtropics

Dr. Rieneke Weij [1]***, Dr. Kale Sniderman*** [2]***, Prof. Jon Woodhead*** [3]***, Dr. John Hellstrom*** [4]***, Dr. Josephine Brown*** [5]***, Prof. Russell Drysdale*** [3]***, Dr. Elizabeth Reed*** [6]***, Mr. Steven Bourne*** [7]

1. *Department of Geological Sciences & Human Evolution Research Institute, University of Cape Town,* ***2.*** *School of Geography, Earth and Atmospheric Sciences, The University of Melbourne, Australia,* ***3.*** *School of Geography, Earth and Atmospheric Sciences, The University of Melbourne,* ***4.*** *School of Geography, Earth and Atmospheric Sciences, University of Melbourne, Melbourne,* ***5.*** *School of Geography, Earth and Atmospheric Sciences, University of Melbourne, Victoria, Australia,* ***6.*** *University of Adelaide & South Australian Museum,* ***7.*** *Limestone Coast Landscape Board, Mount Gambier*

Late Pleistocene glacial periods have been widely characterised by low vegetation biomass, and routinely interpreted as indicating climates drier than today, ignoring the effects of low atmospheric CO_2 on plant growth. Here, we measure the timing of speleothem growth in the southern hemisphere subtropics, which today mostly has a negative annual moisture balance, in order to develop a record of climatic moisture availability that is independent of vegetation. Our records from caves in southern South and Western Australia reveal that, over the past ~350 ka, high moisture availability was largely confined to glacial periods, while warm interglacial periods supported little speleothem growth. This moist-glacial response is consistent across the Southern Hemisphere, implying that high subtropical moisture availability is primarily driven by reduced evaporation under cool glacial temperatures. Our findings suggest that widespread interpretation of Southern Hemisphere subtropical glacial climates as environmentally difficult times for plant, animals and people, should be reconsidered.

Tracking an anomaly: a MIS 6 warming event in Tasmania, Australia.

Ms. Louisa Sheridan [1]

1. School of Geography, Earth and Atmospheric Sciences, The University of Melbourne

The Earth system is rapidly changing in response to anthropogenic climate change. Reliable modelling and climate predictions, which depend upon high-resolution and continuous paleoclimatic reconstructions, are crucial for future environmental management. In Australia, and indeed the southern hemisphere, continuous terrestrial records that stretch into the Pleistocene are extremely rare. The Darwin Crater of western Tasmania is an exception, offering ~70m of lacustrine sediment and ~800,000 years of paleoclimatic history. Darwin Crater therefore provides a unique opportunity to analyse deep-time southern hemisphere climate dynamics.

Numerous marine cores surrounding Tasmania suggest an anomalous oceanic warming during Marine Isotope Stage (MIS) 6, yet the limited data makes it difficult to draw conclusions. Analysis of the Darwin Crater core for this project has revealed a decoupling of Tasmanian and Antarctic climate during the same period (MIS 6). This anomaly raises questions about ocean-atmosphere teleconnections in this regionclimate change, as Tasmanian climate is generally very faithful to trends in Antarctic climate.

This project investigated the pollen record from across MIS 6 in the Darwin Crater terrestrial record and the FR1/94-GC3 marine record (offshore Eastern Tasmania), identifying the anomaly of interest. The spatial extent of this anomaly was then explored, after which a potential mechanism influencing this anomalous warming period in the marine and terrestrial records across Tasmania was suggested. By investigating both the marine and terrestrial records during MIS 6, this research has added critical information to the under-documented southern hemisphere palaeoclimate record and the globally-significant southern ocean.

The Mid-Pleistocene Transition in the Southwest Pacific

Dr. Helen Bostock [1], ***Mr. Ben Houseman*** [1], ***Prof. Patrick Moss*** [2], ***Dr. Joel Pedro*** [3], ***Dr. Gavin Dunbar*** [4]

1. *The University of Queensland,* ***2.*** *University of Queensland,* ***3.*** *Australian Antarctic Division,* ***4.*** *Victoria University of Wellington*

The Mid-Pleistocene Transition (MPT) in global climate is evident from a shift in the frequency and characteristics of glacial-interglacial cycles, from small amplitude symmetrical 41 kyr cycles to large amplitude asymmetrical 100 kyr cycles starting around 1.2 Ma. The reason for this shift is highly debated as there is no change in the long-term pattern of insolation at this time. There are several hypotheses for this transition including (and not mutually exclusive); enhanced CO_2 removal from the atmosphere; coeval timing of ice sheet expanse in the northern and southern hemisphere, deep ocean cooling and reduced ventilation in the Southern Ocean; and intensification of the tropical Pacific Ocean/atmosphere circulation.

In this study we compiled existing data covering the last 1.2 Myrs with several new stable isotope records from marine cores from the Southwest Pacific Ocean. Previous work largely focussed on sea surface temperature (SST) changes as the MPT evolved. These studies found a large increase in the glacial/interglacial SST amplitude across the subtropical front. We have developed two new Tasman Sea marine stable isotope records from Lord Howe Rise (DSDP591A) and east of Tasmania (ODP1172). These data suggest there were broader changes in circulation in the Southwest Pacific across the MPT transition. These oceanographic circulation changes had an impact on the climate of the region as indicated by pollen evidence from the marine cores and other coastal and terrestrial evidence for climate change.

The marine data provides context for the Million Year Ice Core (MYIC) and Beyond EPICA Ice Core (BEIC) projects that is being drilled at Little Dome C in East Antarctica over the next few years to target the MPT transition.

South Pacific Antarctic Intermediate Water variability during the last deglacial atmospheric CO2 increases

Dr. Cyrus Karas [1]***, Prof. Dirk Nürnberg*** [2]***, Dr. Fabrice Lambert*** [3]***, Prof. Jaime Pizarro*** [1]

1. *Universidad de Santiago de Chile, Avenida Libertador Bernardo O'Higgins nº 3363. Estación Central, Santiago, Chile,* ***2.*** *GEOMAR Helmholtz Centre for Ocean Research Kiel, Kiel, Germany,* ***3.*** *Pontificia Universidad Católica de Chile*

Antarctic Intermediate Water (AAIW) forms in the Southern Ocean and is currently one of the main sinks of atmospheric CO_2. During the last deglaciation (21,000-10,000 years before present), atmospheric CO_2 levels increased significantly during two specific time periods, the Early Deglaciation (~17.5-14.7 ka BP) and the Younger Dryas (~12 ka BP). Model simulations and data studies suggest that processes in the Southern Ocean were crucial in explaining these changes. Deep mixing and upwelling occurred during the deglaciation in the Southern Ocean, close to where AAIW is formed, leading to degassing of CO_2 formerly stored in the deep ocean. These processes may have influenced the composition of the newly formed AAIW, and hence its role in atmospheric CO_2 changes, but its variability and properties in the Pacific Ocean are still unclear. To fill this gap, we show over the last 30,000 years benthic foraminiferal carbon and oxygen isotopes, benthic Mg/Ca bottom water temperatures, salinity reconstructions and grain size analyses from deep sea Ocean Drilling Program (ODP) Site 1233 in the Southeast Pacific Ocean off Chile. Our bottom water temperatures show a ~4°C warming during deglaciation and salinity reconstructions indicate a freshening during the Early Deglaciation, however, there is no long-term trend from the Last Glacial until the Holocene. Benthic carbon isotopes show a clear negative anomaly (of ~1 ‰) during the Early Deglaciation and the Younger Dryas, synchronously with evidence of major upwelling in the Southern Ocean, major increase in atmospheric CO_2, and negative atmospheric carbon isotope values in Antarctic ice cores. We interpret these low $\delta^{13}C$ values as first direct evidence for the entrainment of low $\delta^{13}C$ into AAIW that most likely stem from upwelling of deep and old ocean water masses in the Southern Ocean. Our results hence support existing hypotheses that Circumpolar Deep Waters with low $\delta^{13}C$ formerly isolated from the atmosphere entrained into AAIW during the deglaciation with consequences for low latitude primary productivity and atmospheric CO_2 and contrast with previous studies from AAIW depths in the West Pacific or deeper water depths from the Southeast Pacific that described higher benthic $\delta^{13}C$ values.

The Southern Ocean's role in the global carbon cycle over the last 800 kyr constrained using reconstructions of the CO2 system

Mr. Chen Xu [1], ***Dr. Jessica Crumpton-Banks*** [1], ***Dr. Andrea Burke*** [1], ***Dr. Hana Jurikova*** [1], ***Dr. Claus-Dieter Hillenbrand*** [2], ***Dr. Bradley Opdyke*** [3], ***Dr. James Rae*** [1]

***1.** University of St Andrews, **2.** British Antarctic Survey, **3.** The Australian National University*

The critical role of the Southern Ocean in controlling the Pleistocene atmospheric CO_2 oscillations is widely acknowledged. However, hindered by sampling difficulties surrounding Antarctica, the underlying mechanism and associated pathway of ocean-atmosphere CO_2 exchange in the Antarctic zone of the Southern Ocean remains mysterious. CO_2 exchange between the ocean and atmosphere is closely coupled with the pH and partial pressure of CO_2 (pCO_2) of surface seawater. Here, we present a new $\delta^{11}B$ record of *Neogloboquadrina pachyderma* from sediment core PS1506 (68.73°S, 5.85°W) that tracks the pH and surface pCO_2 of the Antarctic zone of the Southern Ocean over the last 8 glacial cycles. These data are complemented by benthic B/Ca and carbonate preservation indices; due to the location of this core on the continental margin of the eastern Weddell Sea, these data allow us to track the source CO_2 chemistry of the dense Antarctic waters that feed the ocean's lower overturing cell. From these data, we discover a tight relationship between seawater CO_2 chemistry and atmospheric CO_2, thereby highlighting the Southern Ocean's key control on glacial-interglacial CO_2 change. Considering the changes in carbonate preservation seen at this site, we also investigate the potential influence of dissolution on the shell chemistry of *N. pachyderma*. Together, our records provide direct geochemical evidence of changes in the Air-Sea CO_2 exchange of the Antarctic Zone of the Southern Ocean over multiple glacial cycles, and also contribute insights into the applications of foraminiferal $\delta^{11}B$ in paleoceanography.

Session 174: Tracing the impact of palaeoenvironmental changes in ancient DNA

Successful isolation of endogenous ancient DNA from subfossil Dryas octopetala leaves preserved in an ice cave

Analysis of ancient DNA (aDNA) preserved in subfossil plant remains can provide deep insights into the evolutionary history and processes involved in the current genetic diversity of organisms. However, DNA preservation in ancient soft tissues is influenced by an array of biological, chemical, and physical processes, typically leading to very low amounts of DNA, which is invariably degraded to short fragments. Permafrost and ice caves often contain ancient plant remains and due to frozen conditions, which are optimal for DNA preservation, such fossils might be a rich source of aDNA.

Here, we focus on exceptionally well-preserved *Dryas octopetala* leaves (5,600–2,200 years old) stored in the Armeña A294 ice cave (Central Pyrenees, Spain). As a cold-adapted arctic-alpine dwarf shrub, *D. octopetala* expanded around the ice cave during the Neoglacial cooling period (ca. 4,600 years ago), where it still occurs. However, human-induced climate warming can reduce its occupancy range, leading to a decrease of genetic diversity. As a starting point to track genetic variation at high temporal resolution, we aimed to authenticate the endogenous DNA potentially preserved in the subfossil leaf remains.

DNA isolated from the subfossil *D. octopetala* leaves was incorporated into single-stranded libraries and sequenced on an Illumina platform. The results strongly indicate that the DNA we isolated contains endogenous ancient *D. octopetala* DNA. Assembled chloroplast sequences were nearly identical (99.91%) to a partial *D. octopetala* reference chloroplast genome sequence, and the chloroplast sequence reads showed all the key characteristics of aDNA: very short fragment size (mean read length between 54 and 70 bp); increased occurrence of purines before strand breaks; and increased frequency of cytosine-to-thymine misincorporations close to the ends of the DNA fragments. The endogenous DNA content of the samples was very low (≤ 1%). Thus, for a deep analysis of genetic variation, we will use a capture-based method to enrich the endogenous DNA component of the libraries, particularly functional nuclear genes. The sequence data will provide a baseline of genetic diversity before the onset of the human-induced climate change.

New insights into early human impact, animal domestication and landscape transformation in the Central Pyrenees (Spain) through sedaDNA analysis

Current Global Change (GC) is proving to be unprecedented, showing nature’s vulnerability to both climate and environmental changes, particularly in key sensitive areas such as high mountain regions. To adapt and mitigate the impact of GC in the mountains, the compound effects of climate variability and human activities in these regions have to be disentangled. In this sense, tracing early human impacts in mountain environments is key to understand climate-human interactions and inform future climate scenarios.

This work is focused on the identification and characterization of anthropogenic indicators in the Central Pyrenees, an Iberian region highly sensitive to past climate changes and with a long record of human occupation. Despite numerous paleoenvironmental studies of this region, data are insufficient and lack consensus among interpretations to define the timing and role that humans played in shaping early Pyrenean landscapes.

Through the re-study of a new sediment core from Tramacastilla Lake (42°43’35“N, 0°22’04”W, 1682 m.a.s.l.), we aim to test two long-debated questions: 1) the timing of arrival and history of animal domestication in the Pyrenees; and 2) the impact that animal husbandry may have had on plant communities in the subalpine belt. In this contribution, we present innovative paleocological results, through the analysis of plant and animal sedimentary ancient DNA (*sed*aDNA) from 46 samples, that inform about the past ecological dynamics of plant and animal taxa.

Our results identify domestic animals (cows, sheep, goats) in the surroundings of Tramacastilla since ca. 6 ka BP, and a concurrent expansion of open vegetation landscapes that progressively increased from ca. 4 ka BP, consistent with pastoralism. In addition, our results show the existence of bovines since the onset of domesticate presence in the region, challenging the long-time assumed idea of ovines and caprines being the dominant domesticates in the Pyrenees. Our findings allow us to reconstruct not only human land-use through an abrupt landscape opening since the Early Neolithic in the southern Central Pyrenees, but also provide data to design current day conservation strategies that integrate the traditional management of landscapes in the mountains.

Lake sedimentary ancient DNA reveals ecosystem response to fire and climate on Kangaroo Island (Karti), Australia

Increasingly hotter and drier climate combined with post-colonial changes in land management have led to more catastrophic fires across southern Australia in recent decades - threatening people and the environment. However, there is still a lot we don't understand about the complex interplay between climate, fire, ecosystems, and people - especially on longer timescales that pre-date British colonisation. Our study focuses on Kangaroo Island, where devastating bushfires decimated the island's unique ecosystems in 2019-2020. We used shotgun metagenomics of sedimentary ancient DNA (*sed*aDNA) to reconstruct the aquatic and terrestrial biodiversity within the green plants group (Viridiplantae) over the last ~ 7,000 years from the sediments of Lashmars Lagoon. We compared our *sed*aDNA record to a pollen record, charcoal-inferred fire history and geochemical proxies for catchment and climate processes to provide new insights into plant community responses to climate and fire. We found compositional changes statistically linked to fire history and climate change. Specifically, sediment calcite content (linked to drier climates) significantly explained changes in composition within the Viridiplantae. Statistical analysis further revealed that the major compositional change within the Viridiplantae, including a decrease in the Fabaceae family (which includes the genus *Acacia*), coincided with an inferred increase in fire activity at ~3.3 ka. Interestingly, we also found evidence for increased amounts of plant DNA during this period of increased biomass burning and or more frequent fires, alluding to the role of fuel loads and vegetation density in controlling fire regimes. Overall, our study sheds new light on the way climate and fire have shaped past biodiversity on Kangaroo Island, providing insights relevant to future fire management and further contextualising the complex human history of Kangaroo Island. Finally, this study demonstrates the potential for the preservation of *sed*aDNA dating back to at least ~ 7,000 years in an Australian lake and encourages the application of this novel proxy in the region.

Paleoenvironmental reconstruction of the last 14,000 years in the Bransfield Strait (Antarctica) using sedimentary ancient DNA

The Southern Ocean is of critical importance to the world's carbon budget and global climate. Therefore, it is necessary to understand how the ecosystem will respond to future climate changes. Coastal regions such as the Bransfield Strait, Antarctic Peninsula, are particularly exposed to global warming. Using a genetic approach, like shotgun sequencing and diatom metabarcoding to sediment cores, past changes in the photoautotrophic community composition can be determined to derive information on the ecosystem's response to climate change. However, community changes in the Southern Ocean's past have rarely been studied using genetic methods. Here we show that *Phaeocystis antarctica* (haptophyte) was the dominant taxa during the remainder of the Antarctic Cold Reversal (14 - 13 ka BP) and that there was a shift toward generalists such as *Chaetoceros* (diatom) since 13 ka BP. This study shows a strong correlation between sea ice cover, water temperatures, and the photoautotrophic community in different climate periods. Furthermore, the results evidently demonstrate the dominance of *P. antarctica* during iron-replete times supporting its key functional role in the past Southern Ocean ecosystem. This study highlights the importance of surveying biodiversity by using shotgun sequencing to retrieve a comprehensive picture of the photoautotrophic community turnover and its consequences on carbon sequestration and cycling in the past.

Evolutionary populations genomics of Baltic Sea phytoplankton across the Holocene

Ms. Alexandra Schmidt [1], ***Ms. Juliane Romahn*** [2], ***Dr. Sarah Bolius*** [3], ***Dr. Anke Kremp*** [3], ***Prof. Miklos Balint*** [2], ***Prof. Laura Epp*** [1]

1. *University of Konstanz,* ***2.*** *Senckenberg Research Institute Frankfurt,* ***3.*** *Leibniz Institute for Baltic Sea Research Warnemünde*

The Baltic Sea is currently challenged and under profound stress. Climate change, overfishing and eutrophication (mainly through fertilizers in agricultural waste water) are three of the main impacts that endanger the stability of the ecosystem nowadays. Additionally, the low biodiversity of the Baltic Sea increases the risk of destabilization. Since its formation after the last glaciation, the Baltic Sea has faced multiple periods of intense ecological changes. These changes were related to climate and anthropogenic factors, such as salinity and temperature shifts as well as increased nutrient loads. In the PhytoArk project, conducted jointly by researchers from the Leibniz Institute for Baltic Sea Research Warnemünde, the University of Konstanz, the Senckenberg Research Institute Frankfurt and the University of Hamburg, we are investigating phytoplankton changes during the Holocene of the Baltic Sea and integrating community and population dynamics into phytoplankton models. At the population level, we are tracing intraspecific genomic changes and potential evolutionary adaptions within and among the diatom *Skeletonema marinoi* and the dinoflagellate *Apocalathium malmogiense*. For this, we are using ancient DNA from sediment cores as well as genomic DNA extracted from resurrected cultures. These cultures are germinated from resting stages contained in the sediment. With this we aim to decode population dynamics and evolutionary changes related to ecological shifts to collect information to better understand current and future responses of these abundant phytoplankton species.

A high-resolution metagenomic exploration of Upper Lake Constance sediment over the past 14000 years

The perialpine Lake Constance has experienced significant changes since the end of the Last Glacial, influenced by varying climatic and anthropogenic impact. Its large, deep Upper Lake, the basin of which formed during the Last Glacial Maximum, was influenced mainly by natural environmental changes through most of its history. Postglacial colonisation and climatic perturbations of the Holocene, for example, are among the processes that affected the ecosystem of the lake and its surrounding area. To characterise these changes, we utilise the archiving property of lake sediments and extracted multiple sedimentary DNA data series from a 24-meter-long core. Among them, a shotgun sequencing data series consisting of 34 samples spanning the last 14000 years was created and is presented here as a comprehensive representation of biological community over time. A significant vegetation change after the Younger-Dryas Boundary is recognised in the dataset. Subsequently throughout the Holocene, we observe a general increase in bacterial diversity in the lake, as well as an increase followed by a decline in vegetation and megafauna diversity at ~1300 years BP (AD 650). Through integrating time series of taxa from all trophic levels, we are aiming to reconstruct ecological changes and processes such as turnover in genetic diversity of key species, an endeavour to reveal the evolution of lake ecosystems under the ever-changing environment.

Phylogeny of Late Pleistocene and Holocene Bison from the south-eastern Alpine region and the Carpathian basin

***Dr. Lars Zver* [1], Dr. Borut Toškan [1], Dr. Urška Gerič [2], Dr. Elena Bužan [2]**

***1.** Research Centre of the Slovenian Academy of Sciences and Arts, Institute of Archaeology, **2.** University of Primorska, Faculty of Mathematics, Natural Sciences and Information Technologies, Department of Biodiversity*

During the last 130,000 years, two species of *Bison* were traditionally acknowledged to be present in Europe: the steppe bison (*Bison priscus*), which appeared as early as the Middle Pleistocene and became globally extinct in the Middle Holocene, while the morphologically distinct osteological remains of the extant European bison or wisent (*Bison bonasus*) first appear in the fossil record around the start of the Holocene. Phylogenetic inferences based on mitochondrial DNA prove the existence of three clades in the last 50,000 years: Bp, which includes the steppe bison, and Bb1 and Bb2, which are related to the European bison.

Although several dozen Late Pleistocene and Holocene bison remains have been discovered in Slovenia and Hungary, genetic analysis has been mostly performed on (sub)fossils from Western Europe, Poland, the Caucasus and Siberia. Therefore, the aim of our study was to analyse the ancient DNA (aDNA) from teeth/bones found in these two regions in order to assign the specimens to the existing clades. For this purpose, we extracted the DNA from fossil remains, morphologically attributed to *Bison sp.*, in a specialised aDNA laboratory. By using an amplicon-based approach with a maximum amplicon length of 198 base pairs, targeting the 12S, 16S, ND2, COI, ND4 and cytochrome b regions of the mitochondrial DNA, we sequenced the amplicons on the Ion Torrent S5 next-generation sequencing system. We processed the sequencing results using an in-house developed bioinformatics pipeline, and constructed phylogenetic trees using the BEAST software.

We successfully amplified and sequenced aDNA from several samples, followed by the assembly of 2,195 bp long concatenated consensus sequences of the mitochondrial DNA. Our results show that Late Pleistocene *Bison* from the studied areas belong to the Bp clade, while the Late Glacial and Holocene specimens belong to the Bb2 clade. We did not detect the presence of the extinct Bb1 clade. Our research can therefore contribute new insights into the paleogeography of Late Pleistocene and Holocene bison in Central Europe.

Identification and engineering of woolly mammoth regulatory elements

Dr. Emil Karpinski [1], *Dr. Ramiro Perrotta* [1], *Dr. Ana Queiroz* [1], *Dr. George Church* [1]

1. Harvard University

Changes in gene expression have been implicated in adaptation to many types of environmental stress, such as between high/low altitude and nutrient rich/poor environments, and even in speciation. However, most palaeogenomics have focused on changes in protein coding genes alone, due to the difficulty in recovering RNA from ancient samples and the quantitative biases associated with it, as well as the generally poorly understood role of regulatory changes in adaptation. Here we combine two complementary computational approaches to predict cis-regulatory elements in woolly mammoths and identify those that may be impacted by structural changes across different mammoth populations. We couple this with preliminary experiments on the functional impact these predicted changes have on gene expression, and the possible roles these changes may have on arctic adaptation. Given the increasingly important role gene expression changes are believed to play in adaptation, being able to accurately predict and engineering regulatory changes will be instrumental to current and future de-extinction and conservation projects.

Session 176: Tectonic and Climate-driven Landscape Evolution a never-ending challenge for modern society (Thoughts from LEMON project, INQUA - AIQUA)

Quantitative models in slow deforming, low-relief landscapes: example from the Central Po Plain (Italy)

Dr. Chiara Zuffetti [1], ***Dr. Francesco Maesano*** [2], ***Prof. Riccardo Bersezio*** [1], ***Dr. Chiara D'Ambrogi*** [3], ***Ms. Alice Abbate*** [4]

1. Department of Earth Sciences - University of Milan, Milan, 2. National Institute of Geophysics and Volcanology - INGV, Rome, 3. Geological Survey of Italy - ISPRA, Rome, 4. Department of Mathematics and Geosciences - University of Trieste, Trieste

Landscape-changing events help constraining sedimentary basins' evolution during syn-tectonic orogenic belt growth. In low-relief and slow-deforming areas, as in many Quaternary foreland basins of the world, landscape evolution markers and tectonic rates are difficult to unravel and represent a topic for ongoing research related to seismogenic potential of active faults and related seismic hazards.

In this research, we describe and quantify the Quaternary tectonic modulation of the landscape during its response to glacial cycles along a buried thrust front of the Northern Apennines (San Colombano and Casale-Zorlesco thrusts). We focus on three subdued hills, which elevate above the latest Pleistocene-Holocene terraces of the central Po plain.

This study integrates multi-scale methods including geomorphological, sedimentological, stratigraphic, geo-pedological, and structural field surveys, constrained by C^{14} and OSL age determinations, borehole logs, and seismic images analysis for the deepest unconformities and fault surfaces reconstruction. We identified five Quaternary high-rank unconformities and intermediate-rank unconformities that were correlated from surface to subsurface. The architectural and chronological reconstruction gave the constraints to compute the 3D subsurface geological model. The deformation observed on the unconformities was restored, considering the sediment compaction and the tectonic component, by computing the slip on the buried faults with a trishear inversion. The resulting tectonic component of the deformation is presented as probabilistic slip rates accounting for the sources of uncertainty in the computation.

The investigated ramp anticlines underwent thrusting during the last 1.8 Myr with variable rates. Since the Middle Pleistocene, the San Colombano thrust moved faster than the Casale-Zorlesco one. The San Colombano hill registered the anticlinal collapse from the LGM. A post-glacial outwards propagation of the Apennine thrusts was buttressed by the opponent Alpine thrust-belt front and induced the entrenchment of the river network. The quantification of slip rates highlights how the climate-controlled sediment flux from the Alpine side of the basin was accommodated during the Apennine N-wards thrusting. Surface markers of this evolution are landforms such as relicts of uplifted planation surfaces covered by the latest Pleistocene weathered loess units, mildly tilted alluvial terraces and diversions of extinct meandering river traces on the latest Pleistocene plain.

Complex erosional response to uplift and rock strength contrasts in transient river systems revealed by 10Be and 26Al cosmogenic nuclide analyses

Dr. Sarah Boulton [1], ***Dr. Angel Rodes*** [2], ***Dr. Derek Fabel*** [2], ***Dr. M. Cihat Alçiçek*** [3], ***Dr. Alex Whittaker*** [4]

***1.** University of Plymouth, **2.** Scottish Universities Environmental Research Centre, **3.** Pamukkale University, **4.** Imperial College London*

Understanding the influence of bedrock lithology on the catchment average erosion rates of transient river systems crossing the strike of an active normal fault, and effect that different intrinsic and extrinsic factors have on the evolution of transient fluvial geomorphology remain major challenges for the tectonic geomorphology community. To investigate this problem we collected 18 samples for ^{10}Be and ^{26}Al cosmogenic nuclide analysis to determine catchment averaged erosion rates along the well-constrained Gediz Fault system in western Turkey, which is experiencing fault-driven river incision owing to a linkage event ~ 0.7 Ma. Combined with existing cosmogenic data we show that the background rate of erosion of the pre-incision landscape is 46 ± 46 mMyr^{-1} and erosion rates within the transient reach vary from 30 – 1330 mMyr^{-1}. Erosion rates weakly scale with unit stream power, steepness index and slip rate on the bounding fault, although erosion rates are an order of magnitude lower than fault slip rates. Conversely, there are no clear relationships between erosion rate and relief or catchment slope. Bedrock strength is assessed using Schmidt hammer rebound and Selby Rock Mass Strength Assessments, despite a 30-fold difference in erodibility there is no difference in the erosion rate at the reach scale between strong and weak rocks. We argue that for the Gediz Graben the strong lithological contrast effects the ability of the river to erode the bed resulting in a complex erosional response to uplift along the graben boundary fault, while weak co-variant trends between erosion rates and various topographic factors potential resulting from incomplete sediment mixing or pre-existing topographic inheritance.

Evidence of past tsunamis from mega and large earthquakes in Indian Ocean: Records from the last 8000 years, Andaman Islands India

Prof. Javed Malik [1], ***Prof. Kenji Satake*** [2]

1. *Department of Earth Sciences, Indian Institute of Technology Kanpur,* ***2.*** *Earthquake Research Institute, the University of Tokyo*

We report evidence of tsunamis from South Andaman Island obtained from a stratigraphic records of last 8000 years. In total seven tsunamis were identified in form of sand sheets resting over buried wetland soils. The youngest of these deposits represents the 2004 Sumatra-Andaman tsunami, whereas the older are likely correspond to historical tsunamis of 1881, 1762, and 1679 CE, and prehistoric tsunamis those occurred during 1300-1400 CE, 2000-3000 and 3020-1780 BCE, and before 5600-5300 BCE. The tsunami event of 1300-1400 was a mega event, had a wider effects in the Indian Ocean and is comparable to the 2004 tsunami. Based on grain size and thickness, the tsunamis assigned to 1679, 1762, and 1881 were confined to the northeast Indian Ocean. Sources have not been determined for the three earliest of the inferred tsunamis. Considering the OSL and AMS ages, distribution of tsunami deposits reported from countries adjoining Indian Ocean and correlation, we suggest a recurrence of 420-750 years for mega-earthquakes with different source, and a shorter interval of 80-120 years for large magnitude earthquakes.

Paleoseismological inferences and characteristics of medieval earthquakes along the Himalayan Frontal Thrust (HFT) from the Kumaun region of the Central Himalaya

Mr. Mitthu Dhali [1]***, Prof. Javed Malik*** [1]***, Mr. Eshaan Srivastava*** [1]***, Mr. Nayan Sharma*** [1]***, Dr. Mahendrasinh Gadhavi*** [2]***, Mr. Gurvinder Singh*** [3]

1. *Department of Earth Sciences, Indian Institute of Technology Kanpur,* ***2.*** *L. D. College of Engineering,* ***3.*** *Department of Geology Panjab University*

The Himalayan orogenic belt is one of the world's most seismically active mountain belts, accumulating strain during the interseismic period and releasing it as earthquakes. In the last century only, it has been the locus of some of the largest continental earthquakes in the world. The recent 2015 Gorkha earthquake shade on our understanding of the Himalayan earthquakes. Paleoseismological, investigations of the last two decades all along the Himalayan arc have suggested that greater Himalayan earthquakes have ruptured the frontal part in recent as well as in medieval times. With the recorded history of earthquakes, the Central Himalaya experienced several large and great earthquakes in medieval times. There exist large uncertainties in determining the most recent surface rupturing event in the Central Himalaya. Recently we excavated a trench on a 15-20 m uplifted alluvial fan surface along the Himalayan Frontal Thrust (HFT) in Haldwani, Kumaun (Central) Himalaya. We collected 27 samples from different lithounits for Optically Stimulated Luminescence (OSL) dating and 16 Charcoal samples for Radiocarbon dating. The dating of these samples will help to bound the events which deformed these surfaces. Furthermore, we have collected samples for OSL dating from the older alluvial fan surfaces, River Terraces, and Fault Scarps of the region. The great earthquake of CE 1505 and the most recent one, which occurred in CE 1803, significantly impacted the region. However, there is a debate among the scientific community over the surface rupture of the CE 1803 earthquake and the spatial extent of the great CE 1505 earthquake in the kumaun region. This study mainly focuses on understanding past earthquake activity and the uncertainty associated with them in the Kumaun region of Central Himalaya.

Geomorphologic analysis along the Palomares Fault (SE Iberian Peninsula): Evidence of tectonic activity in low deformation rate regions.

***Ms. Júlia Molins Vigatà* [1], Dr. Raquel Martín Banda [2], Prof. María Ortuño [1], Prof. Juan Miguel Insua Arévalo [3], Dr. Julián García Mayordomo [2], Dr. Octavi Gómez-Novell [4], Prof. Eulàlia Masana Closa [1]**

***1.** (1) RISKNAT Group. GEOMODELS. Earth and Ocean dynamics, Earth Sciences faculty, Universitat de Barcelona, c/ Martí i Franquès, s/n, 08028 Barcelona, Spain, **2.** (2) Instituto Geológico y Minero de España, CSIC, 28760 Madrid, Spain, **3.** (3) Dpto. de Geodinámica, Facultad de Ciencias Geológicas, Universidad Complutense de Madrid. 28040 Madrid, **4.** (4) INGV, Pescara, Italy INGEO, Università degli Studi "Gabriele d'Annunzio" Chieti-Pescara, 66013 Chieti, Italy*

The Palomares Fault (PF) is a main N-S oriented strike-slip fault in the Eastern Betics Shear Zone (EBSZ), a crustal-scale transpressive fault system that absorbs a significant part of the current shortening between the Eurasian and the Nubian plates. The system also has generated several damaging earthquakes since historical times, which demonstrate its catastrophic potential. Despite this, the EBSZ faults are considered moderate to slow-active faults as their slip rates do not exceed 2 mm/yr. In the case of the PF, slip rate estimates from different geologic markers are between 0.01 to 0.42 mm/yr. These values are about one or two orders of magnitude lower than the other faults in the system, where paleoseismic studies have been done providing more reliable data. The expression of the PF is also not as clear as the others; its deformation is distributed in several fault strands forming a very wide fault zone (1 to 4 km approximately) and its vertical deformation is also lower, showing mainly left lateral movement. Consequently, and especially in its northern termination where the fault trace has a more E-W orientation, the area does not present a prominent relief nor extensive alluvial deposits, which makes it difficult to determine and characterize its recent activity. Therefore, a new study has been proposed with the aim of well characterizing the fault, and obtaining new paleoseismic data, the first stage of this study is the geomorphological exploration of the area. A neotectonic and geomorphologic mapping of the entire fault zone has been carried out, recognizing the main tectonics structures affecting Quaternary alluvial fans and identifying their generations. Also, different geomorphologic analyses have been performed using several methodologies and visualization approaches of digital elevation models, such as Red Relief image maps or Swath Profiles. From these analyses, new sites for paleoseismologic trenches have been selected that will likely provide new data of the fault and improve the reliability of the slip rate estimates.

Late Quaternary coastal uplift of southwestern Sicily, central Mediterranean Sea

Prof. Luigi Ferranti [1]***, Dr. Pierfrancesco Burrato*** [2]***, Dr. Daniele Sechi*** [3]***, Prof. Stefano Andreucci*** [4]***, Prof. Fabrizio Pepe*** [5]***, Prof. Vincenzo Pascucci*** [3]

1. *DiSTAR - Dipartimento di Scienze della Terra, dell'Ambiente e delle Risorse Università di Napoli "Federico II",* **2.** *Istituto Nazionale di Geofisica e Vulcanologia, Rome (Italy),* **3.** *University of Sassari,* **4.** *Università degli Studi di Cagliari,* **5.** *Dipartimento di Scienze della Terra e del Mare, Università degli Studi di Palermo*

Mapping and luminescence aging of raised marine terraces and aeolian ridges along an ~90 km coastal stretch in southwestern Sicily provide the first quantitative assessment of vertical tectonic deformation in this region, which spans the frontal part of an active thrust belt. We recognized a staircase of eleven terraces and nine related aeolian ridges. The elevation profile of terraces parallel to the coast shows a >90 km long bell-shaped pattern, onto which shorter-wavelength (~10 km long) undulations are superimposed. Luminescence ages from terraced beach deposits and aeolian sediments constrain the position of paleoshorelines formed during MIS 5e, 7a and 7c, with a maximum uplift rate of ~0.75 mm/a, and indicate a late Middle-Late Pleistocene (80-400 ka) age for the sequence of terraces. The elevation of Lower Pleistocene morpho-depositional markers points that uplift may have occurred at similar rates at the beginning of the Early Pleistocene, but almost zeroed between ~1.5 and 0.4 Ma before the recent renewal. The uneven elevation of Middle-Upper Pleistocene paleoshorelines observed moving along the coast documents that uplift embeds both a regional and a local component. The regional, symmetric bell-shaped uplift is related to involvement in the thrust belt of thicker crustal portions of the northern African continental margin. The short-wavelength undulations represent the local component and correspond to actively growing bedrock folds. The present study contributes to unravel the different spatial and temporal scales of deformation processes at a collisional margin.

3D modelling for the reconstruction of the pre-anthropic landscape, the case study of the plain of Palermo (Italy)

Dr. Alessandro Canzoneri **[1]*, Prof. Mauro Agate* [1]*, Prof. Raffaele Martorana* [1]*, Prof. Attilio Sulli* [1]*, Dr. Maurizio Gasparo Morticelli* [1]*, Dr. Patrizia Capizzi* [1]*, Dr. Salvatore Pierini* [2]**

1. Dipartimento di Scienze della Terra e del Mare, Università degli Studi di Palermo, 2. Dipartimento di Scienze della Terra e del Mare, Università di Palermo

The reconstruction of the geological model of the subsoil in urban areas is a very topical problem. Defining the geometry and extension of the lithotypes is useful for the definition and implementation of urbanistic plans but, almost in highly populated areas, it is not always possible to carry out direct surveys that provide information on the subsoil. Therefore it appears extremely helpful constructing geological models defined based on available subsoil information. In this respect the Palermo plain can be consider as an effective case study.

A worthwhile support for the geological model definition comes from a massive data collection managed by the University of Palermo. Since about twenty years, the Department of Earth and Marine Sciences has been involved in the creation of a database where there are currently collected data such as boreholes, geological section and geotechnical parameters. The database was created by collecting the stratigraphies provided by public bodies, research institutes and private companies. The surveys are geo-localized and lithologies nomenclature has been homogenized and standardized. This work of analysis, description and re-nomenclature of the stratigraphies has led to the identification, definition and partial mapping of the anthropogenic covers that are widely present. This database is the basic tool for creating a 3D model of the Palermo plain. The development of this latter gives several advantages among which the reconstructing of geological surfaces through the stratigraphies boreholes interpolations. Applying this work on the available stratigraphies is possible to reconstruct the paleo-morphological and paleo-topographic features of the land surface in a pre-anthropic age and to define the continuous and constant transition from the ancient natural to the urbanized landscape through the classification and placement of anthropic deposits.

This reconstruction is handy to identify the original natural constraints, such as presence of watercourses, which influenced the primary anthropized landscape evolution and to understand how several neighborhoods built inside constrained areas are nowadays subjected to geological hazards.The achieved model can be verified, corrected and validated comparing it with the different historical and cartographic representations of the Palermo plain that describing the evolution in time of the urbanized landscape.

Time series of remotely sensed shoreline variability: possible implication for climate change analysis?

Mr. Francesco Caldareri [1], ***Dr. Nicolò Parrino*** [1], ***Dr. Antonino Maltese*** [2], ***Prof. Gino Dardanelli*** [2], ***Dr. Simona Todaro*** [3], ***Prof. Attilio Sulli*** [3]

1. Dipartimento di Scienze della Terra e del Mare, Università di Palermo, Italy, 2. Dipartimento di Ingegneria, Università degli Studi di Palermo, 3. Dipartimento di Scienze della Terra e del Mare, Università degli Studi di Palermo

The recent development of the remotely-sensed shoreline extraction technique improved investigations about Shoreline Change Analysis. Such analyses base on time series to quantify the recent coastal landscape evolution that could be driven by climate changes, tectonics, and anthropic processes. Improving our understanding of the past evolution could provide critical information for forecasting future coastal landscape scenarios for better coastal management and mitigating the natural hazard linked to coastal erosion processes.

In this work, we use an in-house developed semi-automatic geospatial model to quantify the shoreline evolution using a dataset ranging from a single month up to 40 years with a sub-pixel resolution. Shorelines were extracted from a dataset of satellite images with various geometric, radiometric, and temporal resolutions into sandy coasts of Sicily (central Mediterranean) affected by similar daily tide excursions ranging from 15 to 35 cm. Obtained results demonstrate the high potential of satellite observations to quantify both the rate of beach accretion and retreatment over roughly 40 years and the variations in the sedimentary budget using monthly observations.

A periodicity of 3.5 years in the shoreline oscillations highlights the potential of considering the shoreline evolution as a proxy for understanding climate changes linked to the atmospheric circulation pattern in the Mediterranean basin.

Session 177: Factors influencing the diversity of loess sedimentary environments and the resulting variability of palaeoclimatic and palaeoenvironmental signals

Differentiation of loess records and landscapes based on a European Loess map

Prof. Frank Lehmkuhl [1]***, Dr. Ulrich Hambach*** [2]***, Dr. Philipp Schulte*** [1]***, Prof. Zdzisław Jary*** [3]***, Dr. Stephan Pötter*** [1]***, Dr. Daniel Veres*** [4]***, Dr. Janina Nett*** [1]

Here we present a conceptual model of loess landscapes based on the spatial analysis of loess and loess facies in Europe. Our model conceptualizes loess formation in a ‘loess-triangle’, which corners represent the three extreme eco-zones of nival, humid, and arid environments. ‘Typical’, continuous and silt-sized dominated loess is placed in the triangle’s center. We identify three modes of loess formation that are controlled by climatic factors, namely humidity and temperature, which in turn constrain the prevailing vegetation. Mode 1: Periglacial and tundra loess, Mode 2: Temperate and subtropical loess, Mode 3: Desert margin loess. Our model is based on a new European loessmap which distinguishes six main genetic domains and 17 subdomains. For the subdivision we used the following criteria: (1) role of silt production areas, (2) link to sub-catchments, as rivers are very important regional silt transport agents, (3) occurrence of past periglacial activity. Additionally, the sediment distribution is combined with elevation data to investigate the loess distribution statistically as well as visually. Whereas periglacial and tundra loess were deposited in the northern European loess belt north of the Alpine Mountain Belt, typically desert margin loess occurred especially in dry steppe environments in southeastern Europe and in semi-desert environments in Spain. The temperate and subtropical loess and the related paleosols formed mainly in regions with a distinct dry season (summer or winter, e.g. towards the Mediterranean regions with winter rainfall or in monsoonal regions with summer rainfall). The conceptual model also has relevance if used vertically. For example, at higher elevations in semi-arid regions of central-eastern Europe humidity-controlled forest belts do not contain any loess deposits. The uppermost boundary of loess in mountainous areas is periglacial loess of Mode 1, whereas the lowermost one in the adjacent lowlands can be typical steppe to desert margin loess of Mode 3, especially south of the Alps and Carpathians. For the latter regions, there are still debates on the role of glaciers and deserts on loess formation. We conclude that the semi-arid drylands are one of the main regions for “typical” loess formation.

Holocene Arctic loess deposits around Kangerlussuaq, Greenland

Dr. Thomas Stevens [1], *Mr. Petter Hällberg* [2], *Dr. Daniele Sechi* [3], *Dr. Jan Pieter Buylaert* [4], *Dr. Mihály Molnár* [5], *Dr. Rienk H. Smittenberg* [2], *Ms. Ramona Schneider* [1], *Prof. Vincenzo Pascucci* [3]

1. Department of Earth Sciences, Uppsala University, 2. Bert Bolin Centre for Climate Research, Stockholm University, Stockholm. Department of Geological Sciences, Stockholm University, Stockholm, 3. University of Sassari, 4. Technical University of Denmark, 5. Isotoptech Zrt - ATOMKI, Debrecen

The current pace of Arctic climate change is unprecedented in instrumental records. This change is of wide significance because many Arctic-specific climate feedbacks have global impacts. It is therefore crucial to examine geological archives of past Arctic environments in order to understand abrupt Arctic change. Loess deposits are preserved around the ice-free area of Kangerlussuaq, western Greenland, and potentially provide a means for understanding climate change on Greenland during the Holocene. However, to date there are no detailed depositional chronologies or climate proxy records for these sediments, limiting their use in understanding past Arctic change. Here we sample loess and combined peat-loess sections around Kangerlussuaq for detailed luminescence and radiocarbon dating, as well as testing of possible climate proxies. Preliminary sampling yielded few organic macrofossils, meaning that initial radiocarbon dates were obtained on bulk organic matter. While the results are stratigraphically consistent, this approach is susceptible to carbon contamination during soil formation. Luminescence dating via standard quartz optically stimulated luminescence methods was not possible due to weak quartz signals, but the post IR infrared stimulated luminescence (IR50; pIR IRSL180) signal yielded reproducible and stratigraphically consistent ages. However, Holocene pIR IRSL ages are susceptible to overestimates due to 'partial bleaching', where solar exposure is insufficient to completely zero the signal. Comparison of bulk organic matter ^{14}C and pIR IRSL ages from one test site close to Russell Glacier shows that these two independent methods are offset from each other by c. 2 thousand years. We present further results of tests for the causes of these offsets between different age-dating techniques. We also present results from initial climate proxy analyses, including mineral magnetic, particle size, geochemistry, and bacterial brGDGT approaches, revealing fluctuations in environment since initial loess formation, at c. 4-6 ka.

A Classic Loess Transportation Surface in the Great Lakes Region, USA

Dr. Randall Schaetzl [1]

1. *Michigan State University*

Loess transport is often initiated or assisted by saltating sand. As long as sand remains available on devegetated surfaces, silt deflation may continue to be active, and deposition of loess may be difficult to accomplish. These types of loess generation-transport systems, first described by Joe Mason and colleagues in 1999 (Geomorphology 28:223-236), epitomize loess transportation surfaces. On a loess transportation surface, sand is widely available, winds are strong, and vegetaive cover is minimal. Loess transport will continue until a topographic barrier such as a deep valley or an abrupt upland impedes the saltating sand. Thick, sand-poor loess deposits typically accumulate downwind from the barrier. In this talk, I describe a classic loess transportation surface/system in western Wisconsin, USA. Across the transportation surface, loess is absent, or exists only a thin sandy-loamy-silty eolian mantle. The transportation surface has two main sand sources: glacial outwash and isolated hills of friable sandstone. Most of these sand sources occur in the western (upwind) parts of the transportation surface. Eastward, eolian deposits remain thin and loamy, with bimodal (sand and silt) grain size distributions. Thick loess deposits occur downwind of two types of locations: (1) high, isolated sandstone hills, and (2) the valley of the north-to-south flowing Black River. Maps of loess grain size and distribution, relative to these two types of topographic barriers, comprise the bulk of this talk. These data clearly illustrate how loess texture, thickness, and distribution are related to topography, in areas where sand is available. This work may help others explain small- to medium-scale loess patterns on the modern-day landscape.

Environmental characterisation of Greenland Interstadial 2 by combining high resolution molluscan records and radiocarbon dating of earthworm calcite granules and mollusc shells

In Upper Weichselian loess sequences pedogenic horizons (mostly gleysols) are typical features documented in many profiles across the European Plain. Their site-to-site correlation was long precluded owing to uncertainties of luminescence dating techniques exceeding their temporal spacing. In western and central Europe, the use of earthworm calcite granules (ECG) overcomes the scarceness of charcoals and bones in loess sequences. Furthermore, their recent correlation with global Dansgaard-Oeschger climate events demonstrates that they can be correlated over long distances.

The youngest of these pedogenic units, named Nagelbeek Complex, constitutes an interesting study case owing to its more complex structure made of at least one gley horizon and one more or less gleyified humic horizon in the area of the eponym site, whereas it is farther mostly represented by a single pedogenic horizon of variable nature. Moreover, its age often lacks of precision and it is poorly documented from a molluscan point of view. Closer from the surface it is often degraded by subsequent Lateglacial-Holocene pedogenetic processes. Otherwise, its carbonate content ensures as for older pedogenic horizons the good preservation of ECGs and mollusc shells, which allows for radiocarbon dating and palaeoenvironmental reconstructions respectively.

New ECG-based radiocarbon ages around 23-22 ka obtained in several west-European sites, one of which close to the Nagelbeek quarry, strengthen its correlation with Belmen and Elfgen soils of the Eben Zone and with Erbenheim soil 4 in Germany, as well as with Greenland Interstadial 2. This agrees with the age of 24.3-24.4 ka estimated for the directly underlying Eltville tephra. Molluscan records help depicting environmental changes associated with its deposition dynamics and with the spatial variability of its facies. Contrary to older pedogenic horizons, the most striking point is the absence of strong molluscan abundance increases in the most northern sites, which matches with the absence of LGM human settlements.

Overall, this first attempt of mapping GI 2 molluscan fauna in western and central Europe provides new information about the spatial heterogeneity of periglacial loess environments but also raises questions about the specificities (duration, magnitude…) of the triggering climate oscillation.

Geochemistry and source characterization of late Pleistocene aeolian deposits in Dolni Vestonice, Central Europe (Czech Republic)

***Dr. Galina Faerhstein* [1], *Dr. Denis Didier Rousseau* [2], *Dr. Pierre Antoine* [3], *Dr. Yael Kiro* [1]**

1. Weizmann Institute of Science, 2. CNRS, Universite Montpellier, 3. CNRS, Universite Paris1

Dust deposits hold an important record of present and past climate and environmental changes. Hence, identifying dust sources and spatial distribution is useful in reconstructing past climate conditions and atmospheric circulation. Dust provenance can be traced by its chemical composition and changes in radiogenic isotopes such as Sr, Nd, and Pb. During Marine Isotope Stage (MIS) 5, two types of peculiar aeolian deposits were identified in central Europe: so-called “eolian silts” (ES) and “marker silts” (MS) sharply situated on top of soil units and are correlated with climate records that represent abrupt cooling such as cold stadials in the $\delta^{18}O$ Greenland record. The formation of these silts and their source is unclear yet and should be further investigated. This study aims to characterize their provenance and trace possible atmospheric circulations responsible for their deposition.

We investigated the chemical (major and trace element) and radiogenic isotope (Pb, Nd, Sr) composition of a continuous sedimentary succession in Dolni Vestonice (DV), Czech Republic, which spans the last 110 ka and contains the silt units of interest. The different geochemical analyses were performed on different grain fractions (<5, 5-20, 20-63, >63 μm) in order to distinguish between proximal and distal material sources.

The distribution of the trace elements in the DV sediments generally agrees with the known values from various loess sites throughout Europe. The fine sediment fractions are depleted for most elements with respect to the coarse fractions suggesting a difference in sedimentary protoliths. According to the radiogenic isotopes, it seems that during MS deposition, the local source is more significant, probably coming from the east. While, during the ES deposition, there was moisture contribution from the North Atlantic.

Model of loess sedimentation in south-west Poland

Mr. Marcin Krawczyk [1], ***Prof. Zdzisław Jary*** [1], ***Prof. Ludwig Zoeller*** [2], ***Prof. Piotr Moska*** [3]

1. *University of Wrocław,* ***2.*** *University of Bayreuth,* ***3.*** *Silesian University of Technology*

Characteristics of the depositional environment on the basis of studies of loess-soil sequences in a selected region require a reliable paleogeographic database. Moreover, to be able to create deposition models it is not enough to analyze only one sequence but at least two, located in the most characteristic places of the region. Convenient conditions are found in southwestern Poland, where archival results from many sequences are available. These studies have contributed an unusually large important information on loess sedimentation. The paleoenvironmental interpretation was extended to include the results of multidisciplinary studies of loess-soil sequences in Zaprężyn and Biały Kościół, which, i.e. detailed grain size analysis, spectrophotometric color testing, and OSL dating results in two independent laboratories were used. These two profiles are located less than 60 km apart on a north-south line. They represent two main loess areas in Lower Silesia: Trzebnica Hills and the Niemczańsko-Strzelińskie Hills. The obtained chronostratigraphic results were related to the basic Weichselian division, taking into the isotope-oxygen stages, which made it possible to create a model of the sedimentation conditions of the loess of southwestern Poland.

The results of the present studies lead to the following conclusions.:

- The occurrence of several morphoclimatic zones directly related to the migration of the Fennoscandian Ice Sheet was distinguished. Moreover, the study indicates that these zones clearly changed their boundaries. The meridional location of the two studied loess-soil sequences was helpful in capturing this phenomenon. The information recorded in the sequences allows concluding that the conditions of the depositional environment were slightly different despite their fairly close location relative to each other.
- Despite the apparent differences, it is possible to find features that indicate some commonalities. In particular, in loess from earlier stages of dust sedimentation during MIS4. These common features act as stratigraphic markers of a trans-regional nature.
- The best-preserved loess was deposited during the last “cold” isotope-oxygen stage of MIS2. Studies of these units indicate a rapid rate of dust accumulation, from local sources.

Paleocryogenic phenomena in the periglacial loess-paleosol sequence of Ukraine

Dr. Olena Tomeniuk [1] ***, Prof. Andriy Bogucki*** [1]

1. *Ivan Franko National University of Lviv*

Aeolian-deluvial loess sediments, which form a thick loess-paleosol sequence (LPS), are the most common type of continental Quaternary sediments in Ukraine. They cover about 70% of the territory of Ukraine. Loess is not widespread in the Ukrainian Polissia, only isolated loess islands are located here, and it does not occur in the Ukrainian Carpathians and Crimean Mountains. The total thickness of the Quaternary loess-paleosol cover reaches a maximum of 40-50 m, and it does not exceed 20-30 m on average. The Quaternary LPS is divided into separate loess, paleo-soil, and paleocryogenic horizons. Evidence of permafrost development is recorded in the form of various paleocryogenic phenomena that are unambiguous witnesses of the loess formation in cold periglacial conditions.

We present the materials of a comprehensive study of the LPS of the Right Bank of Ukraine (Volhyn-Podolian Upland, Forecarpathian). Many reference sections were studied using modern methods of Quaternary research. Paleocryogenic phenomena were also widely analysed. In the Middle and Upper Pleistocene, it was detected at least eight paleocryogenic stages occurred in the studied LPS. The oldest one (Boyanychi stage) is dated to the beginning of MIS 8. Older paleocryogenic horizons have not been discovered yet. Therefore, there is every reason to claim that periglacial conditions were established in the west of Right Bank Ukraine at least eight times, in which permafrost developed.

Evidence of various paleocryogenic phenomena was found in the Pleistocene LPS. Among them are soil movements resulting from solifluction processes, viscous plastic deformations within former active layers, small and large-polygonal frost cracking, cryogenic texture formation, etc. All these phenomena have been studied in detail.

The performed studies unequivocally indicate that Pleistocene paleocryogenesis played a significant role in the formation of the composition and physical and mechanical properties of sediments of the LPS of Ukraine, and the Krasyliv (Final Pleistocene, MIS 2) paleocryogenic stage in addition significantly influenced the modern relief.

Problems from periglacial environments for luminescence dating of loess

Prof. Ludwig Zoeller [1]

1. *University of Bayreuth*

Luminescence ages obtained from last glacial–interglacial Polish loess palaeosol sequences (LPSs) by several established current protocols are presented. 38 new optically stimulated luminescence (OSL) ages from fine-grained (4–11 µm) quartz separates extracted from four LPSs, measured in the Bayreuth Luminescence Laboratory, Germany, are reported. The investigated sections are situated in Lower Silesia, the Sandomierz Upland in central Poland, and the Volhynian Upland in the east. From one Silesian section (Biały Kosciół) 12 new post-infrared infrared stimulated luminescence (pIRIR) ages are presented in addition to the quartz ages of identical sample material. The obtained ages are compared to already published independently elaborated middle-grain (45–63 µm) and coarse-grain (90–125 µm) quartz ages and pIRIR ages from fine grains produced in the Gliwice Luminescence Laboratory (Poland). This comparison shows that in many cases the middle- and coarse-grain quartz ages underestimate the fine-grain quartz ages, but a general rule has not been able to be established so far, likely due to different geological origin of the quartz grains. Even fine-grain quartz ages ≥ 50 ka may be underestimated with respect to lithostratigraphic expectations. For pIRIR ages, however, no evidence for age underestimates has been found in the studied sections, but they are more easily prone to age overestimates due to unknown residual doses at deposition in a periglacial environment. Basic agreement between the luminescence-based chronologies elaborated in the two involved laboratories can be stated for the first time in contrast to other previous studies. The observed age differences are, however, critical for the accurate time bracketing of geomorphologic and pedostratigraphic features and for their attribution to marine isotope stages. Alternative interpretations are discussed including possible periglacial mirroring of pre-LGM ice advances (Ristinge and Klintholm advances) in the southwestern Baltic Sea area. In order not to leave the users alone with the decision about the most credible dating, the suggested way forwards is to simultaneously apply various luminescence dating protocols including different quartz grain sizes and pIRIR from fine polymineral grains, as an honest approach to reliable time bracketing of geomorphological processes and stratigraphic events under debate.

Session 179: From coastal geomorphology to earthquake hazard (F-Coast2EHZ): new perspectives and multidisciplinary approaches

"The time when Bali shook" : geomorphological and geohistorical approach of the complex natural hazards cascade in the north Bali in November 1815

Ms. Audrey Faral [1]***, Prof. Franck Lavigne*** [1]***, Mr. Atmaja Dewa Made*** [2]***, Dr. Made Pageh*** [2]***, Mr. I Gede Putu Eka Suryana*** [2]***, Mr. A Sediyo Adi Nugraha*** [2]***, Dr. Made Windu Antara Kesiman*** [2]***, Dr. Malawani Mukhamad Ngainul*** [3]***, Dr. Danang Sri Hadmoko*** [3]

1. *CNRS-Laboratoire de géographie physique: environnements quaternaires et actuels (UMR 8591 Université Paris 1 Panthéon-Sorbonne, UPEC),* ***2.*** *Undiksha - Universitas Pendidikan Ganesha,* ***3.*** *Environmental Geography Department, Faculty of Geography, Universitas Gadjah Mada*

Seven months after the Tambora eruption, whose ash fallout covered Bali to a thickness of 20-30 cm, a series of natural disasters occurred in November 1815 in north Bali. An earthquake (Ms 7), whose epicenter was located along the Flores Fault, caused a tsunami and the collapse of a mountain slope, which evolved into a gigantic debris flow that engulfed Singaraja city. These cascading hazards have killed nearly 12,000 people. Current knowledge of this series of disasters, rooted in Balinese memory, is based solely on written sources, but has never been scientifically studied.

The aim is carrying out an in-depth analysis of the cascading disasters that struck Bali in 1815, from the root causes and the chronology of the natural hazards to their environmental and societal effects at different geographical scales. Indeed, the hazards involved are poorly understood: the tsunami described in the historical sources is unknown or confused with a flood, and the deposits have never been identified. The cause of this possible tsunami is also uncertain (earthquake or arrival of the mass landslide into the sea). The origin(s) of the debris flow looks complex: based on local belief, it was triggered by the emptying of the lake due to a breach of the caldera rim, which remains doubtful considering the geomorphological setting. It is likely due to a deep earthquake-induced landslide(s), to which was added a multitude of volcanic debris flows (lahars) due to the remobilization of Tambora deposits. The trajectory of the debris flow remains vague, the delimitation of the coastal areas impacted by the tsunami is unknown, as well as the magnitude of the different phenomena (volume of the debris flow, height of the tsunami) and their chronology.

To solve these issues, we combine transdisciplinary approach with geomorphological field surveys, sedimentological analyses, and geohistorical studies through the exegesis of local (Balinese) and colonial narrative sources (English and Dutch colonizers). These approaches allow characterizing the precise sequence of the hazards and their mechanisms; reconstructing the post-disaster landscape of the ancient kingdom of Buleleng, to improve our understanding of past, present, and future coastal geohazard risk in Bali.

Emerged Coral Terraces and Beachrocks in Southwest Panay, Philippines: Clues to Holocene Relative Sea-Level Changes and Coastal Deformation Along the Northern Negros Trench Forearc

Mr. Lyndon Jr Nawanao [1], ***Dr. Noelynna Ramos*** [1], ***Mrs. Robelyn Mangahas*** [2], ***Ms. Jelian Reyes*** [2], ***Ms. Chrizenda Carl Del Rosario*** [2]

1. *Geomorphology and Active Tectonics Research Laboratory, National Institute of Geological Sciences, University of the Philippines Diliman, Quezon City, Philippines,* ***2.*** *Philippine Institute of Volcanology and Seismology, Diliman, Quezon City, Philippines*

The Negros Trench is one of the active subduction zones in the Philippines located in the marginal Sulu Sea. Despite its potential to generate strong to great earthquakes, the seismogenesis of the Negros Trench remains poorly understood. In this study, emergent coastal features have been investigated in southwestern Panay, facing the trench, to elucidate clues of prehistoric coastal deformation and relative sea-level changes. Real-time kinematic (RTK) GNSS and drone surveys were conducted to determine the elevations relative to the tide datum and the extent of emergent beachrocks and coral terraces. In a small island off southwestern Panay, emergent coral terraces were present only on the western side facing the trench at elevations ranging 1.52–1.95 m amllw with double notches indicating abrupt relative sea-level change. In other coastlines of southwestern Panay, emergent fossil corals were also mapped at elevations ranging 1.25–3.45 m mllw. Two parallel but discontinuous strips of emerged beachrocks, about 100–200 m long, were also mapped in southwestern Panay. Petrographic analysis and $\delta18O$ and $\delta13C$ ratios (Z) of beachrock cements reveal isopachous prismatic cement and marine origin (Z = 126.74–130.47), respectively, indicating subtidal beachrock development. The NE segments of both strips have lower maximum elevations (1.46 and 1.47 m amllw) than the SW segments (2.45 and 3.61 m amllw). These differences in maximum elevations are attributed to variations in depth of formation, where the NE segments are presumed to have formed at deeper portions than those in the SW. Radiocarbon dates of subtidal beachrock cements indicate that the first beachrock strip development occurred around 5855–4508 cal BP, whereas the second strip formed around 3128–1825 cal BP. Both ages range by about 1400 years of beachrock development and are attributed to a period of relative sea-level stability. Disruptions in subtidal beachrock development are linked to abrupt relative sea-level fall that could be tectonically induced. U-Th dating of emerged fossil corals and their correlations with the emerged beachrock strips may support this inferred coseismic uplift.

Mid-Holocene Paleo Sea Level and Uplift History Deduced from Emerged Sea-Level Indicators in Poro Island, Luzon, Philippines

Ms. Mari Shylla Joaquin [1], ***Dr. Noelynna Ramos*** [1], ***Mr. Lanze Allen Magalona*** [1], ***Dr. Hiroyuki Tsutsumi*** [2]

1. Geomorphology and Active Tectonics Research Laboratory, National Institute of Geological Sciences, University of the Philippines Diliman, Quezon City, Philippines, 2. Doshisha University

Past sea levels are deduced from sea-level proxies which give insights into the relative sea level at the time of their formation. In northwestern Philippines, at least three sea-level highstands were reported, having higher elevations than the highstands in central Philippines. Proxies such as marine terraces and coastal notches are present in Poro Island, Luzon, a 1.21 sq km landmass located 80 km east of the Manila Trench where the Eurasian plate subducts eastward beneath the Philippine Mobile Belt. These geomorphic features were characterized and correlated with other sea-level proxies in the area to constrain the sea-level history in the area. The marine terraces were delineated through surface classification modeling, using slope and roughness values from DEMs, and were validated through topographic profiles from Real-Time Kinematic (RTK) surveys using a GNSS receiver instrument. Two to nine terrace steps, with elevations ranging from 1.4 to 25 meters above mean sea level (m amsl), were validated during fieldwork. Terraces in the western section of the island occur ~20 cm higher than those in the eastern and southern sections indicating an eastern tilt for the island. Terrace widths range from 0.3 to 7 m and are composed of coral reef and beachrock with the older terraces being overlain by sand and terrestrial debris. Coastal notches have widths of 0.2 to 0.9 m and heights of 2 to 6 m amsl. Radiocarbon dating of fossil corals collected from the lower terraces (1.3 to 3.0 m) reveals ages of 6070 ± 30 BP to 6790 ± 30 BP, indicating emergence after the mid-Holocene highstand. Correlating these results with the nearby proxies in the region revealed that the estimated average uplift rate in Poro Island, which is 0.35 mm/year, is similar to those observed in Badoc Island, a landmass approximately 20 km north of the study site. These uplift rates in Poro and Badoc islands are lower than those measured in other tectonically active sites such as Papua New Guinea, New Zealand, and Japan. Studying sea-level proxies is important in reconstructing paleo sea levels and determining uplift activity in tectonically active regions such as northwestern Luzon.

Quantifying Quaternary uplift of southern Sumatra using marine terraces

Dr. Jennifer Quye-Sawyer [1], *Prof. Aron J. Meltzner* [2], *Dr. Kyle Bradley* [1]

1. *Earth Observatory of Singapore,* **2.** *Earth Observatory of Singapore, Nanyang Technological University*

Marine terraces are exposed paleoshorelines that form in response to land uplift and changing sea level. These landforms are found in many tectonically active regions, and dated terraces are commonly used to quantify coastal uplift rates over timescales of 10^4–10^5 yr. However, sea-level highstand elevation remains poorly constrained for many interglacial periods, and numerous terrace sequences—particularly in tropical regions—have not yet been surveyed or dated. Along the west coast of southern Sumatra, Indonesia, approximately 250 km from the Sunda Trench, we have identified previously unmapped flights of terrace landforms up to 300 m above present sea level. To estimate the age of this currently undated landscape, we have developed an inverse approach that calculates probable uplift rates while encompassing uncertainties in observed terrace elevation, depth of terrace formation, and the timing and magnitude of sea-level highstands. Swath profiles from digital terrain models were used to measure apparent terrace shoreline angles, and preliminary inversion results suggest local uplift rates of less than 0.5 mm yr−1 since uplift began during, or before, MIS 7e. We infer that these terraces formed in response to long-term Pleistocene−Holocene uplift of the coastal environment and discuss whether mapped (or unmapped) onshore or offshore faults could generate the observed surface deformation.

The impact of lithological variations in the evolution of recent drainage systems: the study case of the peri-Adriatic belt

Dr. Simone Racano [1]***, Dr. Maxime Bernard*** [1]***, Prof. Peter van der Beek*** [1]

1. *University of Potsdam, Institute of Geosciences, Potsdam, Germany*

Studying Quaternary landscape evolution is key for the understanding of active tectonics. In coastal areas, marine terraces, notches, and abrasion platforms are commonly used to infer active tectonics, but when outcropping lithologies (such as clays and sands) are too weak to allow good preservation of these landforms, the study of the drainage system can help the understanding of recent and active tectonics. However, river metrics are sensitive to many factors besides tectonics, such as climate and lithological variations, that can complicate the interpretation of the data. On the east coast of the Italian peninsula, the Quaternary (<900 ka) uplifted peri-Adriatic belt is a type example of a coastal area where drainage features are widely used to infer recent tectonics. In this area, metrics like river steepness and changes in stream directions appear to suggest the recent activity of blind thrusts, interpreted as resulting from eastward propagation of Apennine compression. However, there are no indications of active surface deformation, such as faults or tilted stratification. The geology of the peri-Adriatic belt reflects the evolution of a marine basin progressively transitioning to a coastal system with widespread fluvial deltas. These deltas are now uplifted and form resistant conglomeratic bodies superimposed on and surrounded by marine clays of the peri-Adriatic bedrock. In this study, we explore how the morpho-stratigraphic features of a recently uplifted coastal system may condition the formation of the drainage network and generate features similar to those indicative of active tectonics. By combining field observations, morphometric analysis, and landscape-evolution modeling, we demonstrate how a young landscape such as the peri-Adriatic belt is strongly influenced by the morpho-stratigraphic characteristics of the eroded bedrock, which can trigger changes in river directions and channel steepness that resemble features developed by the activity of blind thrusts. Our interpretation does not exclude active tectonics in the peri-Adriatic belt, but focuses attention on the impact that lithological variations may have on the drainage network development and on the inference of the recent tectonic regime.

Anfeh Peninsula in coastal Lebanon: evidence for past coastal geo-hazards.

Dr. Ata Elias [1]

1. Lebanese University

Located over the coast of northern Lebanon, Anfeh promontory is at the intersection between land and sea, recording the imprints of various coastal processes over the tectonically growing Mount-Lebanon range. The area holds important archeological and cultural sites from prehistoric periods to modern times. The most prominent morphological feature in the area is a narrow 70 to 100 meter and ~ 480-meter-long peninsula oriented almost E-W at right angle to the general direction of the coastline. The top of the peninsula stands at around 14 masl and drops regularly from North, West and South over a wave-cut platform rimmed with vermetid bioconstructions. The peninsula is occupied by the mainly medieval site of Anfeh Castle, invested since more recent times by artificial salt pans that covered and preserved most of the initial landscape and remains. The detailed survey of the area reveals the rich potential of the site, where evidence of relative sea-level changes, tsunami deposits and fault rupture are documented. The site is also actively shaped by the coastal erosion and karstification processes. Focusing on the tectonic signal, inspecting the remains of the Anfeh Castle revealed evidence of surface rupture and destruction along a previously unknown NW-SE oriented fault system. Foundation structures and geomorphic features are offset, mostly right-laterally, by few centimetres to few decimetres. However, the wealth of available data on the medieval historical seismicity in Lebanon, has no mention of an earthquake in this area. The surface rupturing event at Anfeh may relate to the large AD 1202 earthquake and seismic crisis that essentially ruptured the Yammouneh Fault segment of the Levant Fault System. The newly identified fault at Anfeh Castle can also be traced in the near offshore morphology and could be responsible for the tsunami waves associated with the AD 1202 events. Thus, Anfeh Castle is the first documented archaeological site in Lebanon showing evidence of direct seismic rupture. The newly identified active fault and earthquake event will add to the resolution of the seismic hazard assessment in this part of the Mediterranean.

Landscape Evolution and Paleo Seismicity at central part of the Shimabara Bay, Kyusyu Island, Southwestern Japan

Dr. Takashi Ogami [1], ***Dr. Tadashi Maruyama*** [1], ***Mr. Takashi Hosoya*** [2], ***Mr. Takahiro Kubo*** [3], ***Mr. Oshie Tazawa*** [3], ***Dr. Kenji Tara*** [3], ***Dr. Kenjiro Mukaiyama*** [3]

1. Geological Survey of Japan, AIST, 2. Chuo Kaihatsu Corporation, 3. Kawasaki Geological Engineering Co. Ltd.

The Shimabara Bay is an elongated bay of 85 km-long with maximum width of 20 km, locating at central part of Kyushu Island, southwestern Japan. At the central part of the bay, the Unzen Fault Group (UFG) and the Futagawa Fault Zone (FFZ) develop a graben structure which comprises the Beppu-Shimabara Graben. UFG is composed of active normal faults and FFZ should be composed of active dextral and normal faults. As a part of active faults survey consigned by MEXT, we conducted high-resolution MCS and offshore drilling survey at central part of the Shimabara Bay. At the both side of UFG, we obtained 40.0 m long sedimentary core at the subsiding side (46.7 m BSL) and 35.3 m long core at the upthrown side (33.1 m BSL) by offshore drilling survey. At the subsiding side, the core is composed of muddy sediment of LGM and subaerial and submarine sediment of the post-glacial period. At the upthrown side, the core is composed of muddy sediment of MIS 5, pyroclastic sediment of Aso-4 eruption (89 ka) and post-glacial sediment. We determined sedimentary age model based on radiocarbon ages from 20 horizons and identification of volcanic deposits. The submarine geology of the Shimabara Bay was clarified owing to high-resolution seismic sections and sedimentary cores obtained by this study. We found a fluvial surface of erosion is displaced 33-38 m vertically by UFG. Assuming the surface was formed during 21.0-16.5 ka, the averaged vertical slip rate of UFG should have been 1.6-2.3 m/ky. At subsiding side of UFG, post-glacial succession is about 30 m thick and cumulatively displaced by associated faults of UFG. According to sedimentary ages determined by drilling survey, 3 or 4 earthquakes have occurred at UFG since 16.5 ka, at least. We demonstrated combination of offshore drilling survey and high-resolution MCS may provide convincing and detailed imagery of landscape evolution and elucidate paleo seismicity of active faults.

Drifting pumice on the Okinawa Main Island and Ishigaki Island: 2021 November and December and later changes in occurrence

Prof. Mitsuru Okuno [1], *Dr. Masayuki Torii* [2]
1. Osaka Metropolitan University, 2. Kumamoto University

A large amount of pumice was erupted by a large-scale eruption of submarine volcano of Fukutoku-Okanoba on August 13, 2021. Since early October, it has gradually drifted to the Daito Islands, the Okinawa, Amami Islands and the Sakishima Islands. This drifting pumice derived from Fukutoku-Okanoba is the first time in 35 years since 1986 in these areas. Okinawa Main Island has aligned more than 100 km from northeast to southwest, and is convenient to consider the distribution characteristics of drifting pumice, so we conducted a field survey on drifting pumice in November 2021. After that, in order to verify the process of which drifting pumice is recorded as geological information, a field survey was conducted in Ishigaki Island in addition to the Main Island in December, 2021. In this presentation, we will report typical occurrence on both islands.
On the Main Island, we will compare the survey results for November and December 2021. First of all, in Sashiki in Nanjo City, the entire surface was covered at the time of the November survey, but the drifting pumice is almost half in December. Yamada in Onna Village, Nakijin Village, Hedona and Oku in Kunigami Village, the loss of pumice is progressing. In this way, in many places on the Main Island, the pumice erosion and decrease are continuing, but in the Haneji Inland Sea located on the east coast of the Motobu Peninsula, many drifting pumice still occupies the sea surface even in December. This is probably due to the direction of the prevailing wind or coastal morphology. In the eastern edge of Inamine in Nago City, which is adjacent to the east of the Haneji Sea, a large amount of pumice was about 2 meters behind the breakwater of about 3 meters in a hight. Here, there is a pum of pumice with a width of 2 m just below the breakwater, but drifting pumice is no longer found in the coastal area. This is thought to have been lifted by waves or strong winds, but at this stage, the detailed transport mechanism is unknown.

Session 180: Sedimentary record of past catastrophic coastal flooding (tsunami, storms)

New insights from organic geochemistry into paleo-tsunamis – Maita River Valley, Noda (Japan)

Dr. Piero Bellanova [1], *Prof. Yuichi Nishimura* [2], *Prof. Jan Schwarzbauer* [3], *Prof. Klaus Reicherter* [1]

1. Institute of Neotectonics and Natural Hazards, RWTH Aachen University, 2. Institute of Seismology and Volcanology, Hokkaido University, 3. Institute of Geology and Geochemistry of Petroleum and Coal, RWTH Aachen University

Organic geochemical indicators have proven suitable to identify and characterize deposits of modern tsunamis, such as the 2011 Tohoku-oki tsunami. For instance, provide anthropogenic organic proxies, such as polycyclic aromatic hydrocarbons, linear alkylbenzenes or pesticides, indications on the destructive potential of tsunamis (e.g., release or remobilization of anthropogenic pollutants). Further do organic anthropogenic and natural compound markers allow insights into processes during a tsunami, such as the erosion and distribution of marine and terrestrial sediment inland (inundation) and offshore (backwash).

However, the organic geochemical approach has been rarely adopted to historic and paleo-tsunami studies. We present a concept study for the application of different biological and anthropogenic organic markers to study past tsunami deposits from the Maita River Valley, Noda, Japan. At this site in northern Japan, at least 4 tsunami deposits covering the past 2700 years have been documented by different publications. This study focuses on a sediment core containing three sand layers related to paleo-tsunami events that precede the 869 CE Jogan tsunami. For the analysis of the obtained sediment core, a set of organic natural compounds including *n*-aldehydes, *n*-alkanes, terpenoids, leaf wax esters, fatty acids and fatty acid methyl esters, have been applied to differentiate between marine intrusions by historic and paleo-tsunamis from the fluvial/terrestrial background sedimentation (e.g., higher land-plant material). Aside from a characteristic natural organic signature, the tsunami deposits have been analyzed for their historic anthropogenic impact by non-industrial compounds, such as polycyclic aromatic hydrocarbons, hopanes, and fecal steroids.

For the study of historic and paleo-tsunami deposits in the sedimentary record natural organic compounds show great potential based on their high preservation potential and the insights into event-related environmental changes and processes (e.g., inundation of marine events, erosion, etc.) they allow.

Sedimentary Evidence for Paleotsunami South of the 2004 Indian Ocean Tsunami Inundation Zone

Dr. Jędrzej Majewski [1]***, Dr. Patrick Daly*** [1]***, Dr. Geoff Richards*** [1]***, Prof. Adam Switzer*** [1]***, Dr. Nazli Ismail*** [2]***, Mr. Tomi Afrizal*** [2]***, Dr. Jessica Pilarczyk*** [3]***, Prof. Margaret Christie*** [4]***, Ms. Lillian Pearson*** [5]***, Prof. Benjamin Horton*** [1]

1. *Earth Observatory of Singapore, Nanyang Technological University Singapore,* ***2.*** *Department of Geophysics, Syiah Kuala University,* ***3.*** *Department of Earth Sciences, Simon Fraser University,* ***4.*** *McDaniel College, Westminster, USA,* ***5.*** *University of Southern Mississippi*

Paleotsunami research has established that the 2004 Indian Ocean Tsunami was the most recent of at least a dozen tsunamis dating back over the past 7,400 years. It is now clear that areas devastated by the 2004 tsunami are vulnerable to future destructive events. However, there is currently no geological evidence of tsunami occurrence along the west coast of Sumatra, Indonesia south of the 2004 inundation zone. To address this, we conducted an extensive program of paleotsunami research between the city of Banda Aceh at the northern tip of Sumatra, to the city of Padang in central Sumatra. Given travel restrictions and public health concerns during the COVID-19 pandemic, we developed an innovative workflow so that researchers from multiple countries could remotely participate in field work, analysis, and local capacity building. This allowed us to core over 20 wetland sites identified as having the potential to contain buried tsunami sands. Here we present results from a wetland site approximately 40km south of the 2004 impact zone. The stratigraphy shows a sequence of sediments lain down in a brackish lagoon, which gradually became a constrained, freshwater environment. The muds are interrupted by four sandy pulses, identified by stratigraphic and grain size analysis. Foraminiferal analysis indicates an offshore marine source for the sands. These results support our interpretation of the sands as tsunami deposits. Radiocarbon dating of a peat layer below the lowest possible tsunami sand sheet dates to c. 1850 cal. yrs BP, suggesting this stretch of coast has been hit by up to four tsunamis over the past 2,000 years. These data are the first convincing evidence for paleotsunami originating from ruptures of the Sunda Megathrust south of the 2004 rupture patch, and strongly suggest that large parts of the west coast of Sumatra might be vulnerable to future tsunami.

Linking coastal boulder deposits to extreme events: Recent advances and the need for more field based datasets

Prof. Adam Switzer [1], ***Dr. Masashi Watanabe*** [1]

1. *Earth Observatory of Singapore, Nanyang Technological University Singapore*

Coastal boulders and boulder fields potentially provide useful information for examining the hydraulic characteristics of tsunamis or storm waves that have struck a particular coast in the past. Boulder transport models are commonly used to reconstruct the hydraulic characteristics needed for boulder transport. Since the 1990s a suite of inverse and forward models have been applied to examine coastal boulders and boulder fields globally. The aim of such modelling commonly aims to attribute a depositional mechanism with one particular focus of modelling studies focussed on efforts to attribute tsunami or storm waves to the deposits. Inverse models can estimate the minimum wave height and velocity necessary to slide, rotate, or saltate the boulder. In contrast, forward models are used to estimate hydraulic parameters such as the maximum wave velocity or wave runup height as this is a product of the boulder transport distance. Boulder transport models commonly contain relatively few parameters because they have been developed by simplification of the overwash process. As such boulder transport models contain large errors and considerable uncertainty. Emerging fields like structure from motion (SfM) and LIDAR provide new opportunities for data collection expanding much needed data sets and increasing efficiency in the field. Current efforts to homogenise the reporting of boulder datasets are also to be applauded but there remains a clear need for field studies on boulder fields of known tsunami or storm origin. Such datasets provide validation for models and are vital for advancing efforts to better link boulder deposits with the hydrodynamic processes of storms and tsunamis.

Major controls on storm surge flooding: sea-level rise, climate or coastal landforms? Insights from the coastal sedimentary record of southern Baltic Sea

Dr. Karolina Leszczyńska [1], Prof. Karl Stattegger [2], Dr. Damian Moskalewicz [3], Dr. Robert Jagodziński [2], Prof. Mikołaj Kokociński [4], Prof. Przemysław NIedzielski [5], Prof. Piotr Oliński [6]

1. Geohazards Research Unit, Institute of Geology, Adam Mickiewicz University, 2. Geohazards Research Unit, Institute of Geology, Adam Mickiewicz University, Poznań, Poland, 3. Faculty of Chemistry, Adam Mickiewicz University, 6. Institute of History and Archives, Faculty of History, Nicolaus Copernicus University in Toruń

The southern Baltic Sea coast presents an ideal target for the research on the frequency and intensity of catastrophic storm surge flooding as it is nontidal/microtidal sea, where major water level fluctuations are related to well-documented past sea-level changes and storm surge floodings. It is located in the area highly sensitive to latitudinal shifts in North Atlantic Oscillation and changes of the westerly storm tracks. Furthermore, the southern Baltic coast has recently been identified as the region where the storm surge flooding overtopping coastal barriers is one of the highest in the world and is expected to increase in the near future together with the climate change.

We document the longest to date, high-resolution sedimentary succession from the Polish coastal wetland located at Mechelinki, Puck Bay within the Gulf of Gdańsk at the southern Baltic sea coast. There, high-resolution records of extreme storm surge flooding of inundation regime within two periods: 3.6-2.9 ka BP and from ca. 0.7 ka BP until present, are preserved. The results indicate that both periods were characterized by high-frequency storm surge flooding in order of 1.3 – 4.2 events per century. They are correlated to widely recognized enhanced storminess periods in NW Europe and took place during both rising and fluctuating sea levels. Our results show that the storm surge driven coastal inundation frequency and extent largely depend on the development of coastal barriers (e.g., beach ridges).

Current research is extended to the first systematic throughout survey of locations prone/susceptible to past coastal flooding at the southern Baltic Sea in search of deposits associated with storm floods. Catastrophic historical events did not yield with substantial sedimentary record. The locations where the depositional archive of storm flooding was identified, had specific topographical, coastal and offshore bathymetric conditions, which resulted in extensive archive of multiple events.

The research project CatFlood is funded by National Science Centre, Poland, OPUS grant nr: 2018/29/B/ST10/00042

Cyanobacteria as potential new proxy for marine inundation events

Dr. Michaela Spiske [1]***, Dr. Michaela Spiske*** [2]***, Ms. Julia Hasler*** [2]***, Dr. Jakob Zopfi*** [2]

1. *State Museum of Natural History Karlsruhe,* ***2.*** *Universität Basel*

Storm surges and tsunamis cause temporary inundation of coastal areas, with seawater covering them for a few minutes to hours or even a few days. As a consequence, saltwater penetrates the substrate and brings moisture to otherwise dry settings.

Moreover, storm surges, storm waves and tsunami waves transport marine organic material ashore. Seaweed or seagrass may be concentrated in wrack lines, but also cover the entire flooded area. Once this organic material decomposes, nutrients are released into the environment.

Thus, marine inundation events temporarily induce increased moisture and nutrient concentrations in otherwise dry and nutrient-deprived habitats. This allows for the intermittent growth of cyanobacteria in the weeks to months after an event.

Hurricane Irma´s storm surge caused coastal flooding in the northern Caribbean in September 2017. During a post-hurricane survey on the island of Anegada (British Virgin Islands), a conspicuous bright green layer was detected in the uppermost 1-2 mm of the storm surge deposits. Morphologic and molecular analysis identified 7 different genera of cyanobacteria that colonized the fine-grained light-exposed top of the event layer. Both filamentous and coccoid forms were identified, with *Nodosilinea*, *Nostoc*, *Leptolyngbya*, *Chlorogloeopsis* and *Desikacharya* being most abundant.

During a second survey, 18 months after the hurricane, a change in color of the uppermost millimeters of the event unit was observed. The formerly green layer faded to light to medium gray. Even though less distinctive, remains of cyanobacteria were still visible under fluorescent light and under the microscope. Clearly, the conditions changed, i.e. decreased moisture and nutrient concentrations in combination with covering by wind-blown sand and thus shielding from sunlight, so that cyanobacterial growth was no longer possible.

The growth and potential conservation of cyanobacteria in the uppermost millimeters of marine inundation deposits in onshore settings may be a promising biological indicator of recent and past inundation events, and allowing for the detection of an event unit and the localization of the top of the unit.

Multi-site lacustrine sedimentary record of extreme marine inundations during the last four centuries in the southern Burin Peninsula (Newfoundland, Canada)

Dr. Krzysztof Pleskot [1], ***Prof. Les C. Cwynar*** [2], ***Mr. Cyprian Kowalczyk*** [3], ***Prof. Mikołaj Kokociński*** [3], ***Prof. Witold Szczuciński*** [1]

1. Geohazards Research Unit, Institute of Geology, Adam Mickiewicz University, Poznań, Poland, 2. Department of Biology, University of New Brunswick, Fredericton, Canada, 3. Department of Hydrobiology, Adam Mickiewicz University, Poznań, Poland

The Western North Atlantic seaboard experiences various types of events causing extreme marine inundations (EMIs), including winter storms, tsunamis, and hurricanes. This study aims to provide the first lake-sediment-based reconstruction of recent EMI history (past ~350 years) of the southern Burin Peninsula (Newfoundland, Canada). We investigated short sediment cores collected from four shallow coastal lakes. The identification of EMIs relied mainly on sand grain counts supported by the analyzes of diatoms, dry bulk density, and loss-on-ignition. The age-depth models of the cores were based on ^{210}Pb and ^{137}Cs dating. Correlation of our records with historical events confirmed that statistically significant sand count peaks serve as a useful proxy for EMIs in the case of three of the sites. Diatom composition did not reveal noticeable turnover at depths corresponding to EMIs at any of the four sites, likely because diatom communities in the lakes are adapted to salinity fluctuations due to the frequent minor marine water overtopping events. Combined, the four records indicated that at least seven EMIs occurred over the last ~350 years, four of which could be likely correlated with historically documented events, namely the 1755 Lisbon tsunami, the 1775 Great Independence Hurricane, the 1929 Newfoundland tsunami and the 1983 winter storm. The observed recurrence of EMIs resembles the coastal flooding frequency along the subtropical western North Atlantic seaboard. However, the criteria to identify the cause of particular EMI events still need to be established. The study was financed through a grant from the National Science Centre (NCN), Grant No. 2020/37/N/ST10/02614.

Portuguese offshore tsunami deposits - high-resolution X-ray CT-scans as an innovative analytical tool

Ms. Lisa Feist [1], *Prof. Pedro JM Costa* [2], *Dr. Simon Falvard* [3], *Mr. Tobias Ganther* [1], *Dr. Raphael Paris* [4], *Dr. Juan I. Santisteban* [5], *Dr. Piero Bellanova* [1], *Prof. César Andrade* [2], *Prof. Klaus Reicherter* [1]

1. *Institute of Neotectonics and Natural Hazards, RWTH Aachen University,* **2.** *IDL – Instituto Dom Luíz, Faculdade de Ciências da Universidade de Lisboa,* **3.** *UCA-LMV,* **4.** *CNRS-LMV,* **5.** *Dpt. Geodynamics, Stratigraphy and Paleontology, Complutense University of Madrid*

X-ray Computed Tomography (XCT) is a powerful tool for sedimentological studies. It is a non-destructive imaging technique that allows the characterization of sediments and the identification of sedimentary structures. Microstructures and sedimentary fabric can be analysed in 3D. High-resolution XCT-scans unequivocally contribute to raising the understanding of tsunami deposits and their micromorphological imprints, and establishing their relationship with flow dynamics of both the inundation and backwash phases.
We present high-resolution XCT-scans of shallow offshore sediment cores collected from the southwestern Portuguese Algarve shelf, focussing on sedimentary signatures of two tsunami deposits, related to the 1755 CE Lisbon event and an older event dated to ca. 3400 years BP. XCT-scans of both offshore tsunami deposits were performed in 50 µm and 20 µm per voxel resolution. Selected sections were sub-sampled to achieve a higher resolution of up to 14 µm per voxel. The 1755 CE tsunami deposits consist of shell fragments and sand-sized quartz grains mixed with fine-grained particles (mean grain-size of silt to very fine sand) representing the present-day permanent sedimentation regime of this shelf region. The ca. 3400 years BP tsunami deposits are much more complex with peculiar characteristics in different sub-units. An erosive base is followed upwards by a thin lamina enriched in shell fragments and an inversely graded sand lamina. Further up-section, the deposit consists of well-sorted quartz-rich medium sand that is affected atop by another erosive surface. The latter is followed by fine-grained background sediments mixed with shell fragments and sand-sized quartz grains. The characteristics of the uppermost sub-unit and the 1755 CE tsunami deposit are quite comparable. We present the results of semi-automated image analysis for the characterisation of the samples in 2D and 3D. The 2D analysis determined grain-size parameters. The 3D analysis revealed the properties of the sedimentary fabric. Both provide clues to infer flow characteristics, such as flow regime, current strength and sediment concentration.

Session 181: Transferring scientific knowledge on Quaternary geological processes and geohazards into disaster risk reduction activities

Palaeo-activity of large, deep-seated landslides in the Whanganui-Rangitikei Hill Country, New Zealand

Ms. Ella Nisbet [1], ***Dr. Katherine Holt*** [1], ***Dr. Samuel McColl*** [2], ***Prof. Ian Fuller*** [1], ***Prof. Alan Palmer*** [1], ***Dr. Andrew Neverman*** [3]

1. Massey University, 2. GNS Science, 3. Manaaki Whenua - Landcare Research, New Zealand

Large, deep-seated landslides are a prominent geomorphological feature of Quaternary landscapes globally, and in New Zealand, with >7000 such landslides mapped to date. Many of these are situated within Neogene-aged marine sedimentary soft rocks that cover ~15% of the country. These large (>2 ha) landslides can be hazardous; while typically slow-moving (mm – m per year), cumulative displacements can damage land and infrastructure, but they can also fail rapidly. They are a key agent of hillslope erosion and source of sediments to river systems. Few of the known landslides have been dated, limiting our ability to assess failure patterns and changes in sediment delivery over time. Our current research aims to narrow this knowledge gap by dating soft-rock landslides in the Whanganui/ Rangitikei Hill Country. In particular, our objective is to assess the long-term patterns of failure, and rates of sediment delivery within soft-rock terrain, to help contextualize modern day patterns and sediment delivery rates.

Our primary method of absolute age dating is radiocarbon analysis of organic matter accumulated within landslide deposit depressions, with samples recovered by coring. We date 10-15 landslides and use these ages to calibrate a morphometric dating tool we are developing, which quantifies landslide age (i.e., youthfulness of the morphological expression) from high-resolution elevation data. The first step in tool development involves statistical modelling of the relationship between multiple morphometric variables and the ages of several dated landslides. In the second step, we test the model's performance against landslides independent of the model training set. In the final step, we apply the tool to landslides across the whole study region.

Herein we present preliminary results of the morphometric dating tool development, and absolute age data for several landslides within the Mangawhero catchment in the central North Island of New Zealand. We use the data from our study to investigate links between landslide age and activity in relation to external factors, which can be used to guide land and hazard management decisions and inform erosion control.

Pockmark Assessment on the Mediterranean Continental Margins

***Dr. Daniele Spatola* [1], *Prof. Daniele Casalbore* [2], *Dr. Martin Hovland* [3], *Dr. Marco Bianchini* [1], *Prof. Francesco Chiocci* [4], *Mr. Ashok Dahal* [5], *Dr. Stephanie Dupré* [6], *Dr. Gemma Ercilla* [7], *Prof. Christian Gorini* [8], *Prof. Luigi Lombardo* [9], *Mr. Simone Napoli* [1], *Dr. Marzia Rovere* [10], *Prof. Attilio Sulli* [11], *Dr. Juan-Tomás Vázquez* [12]**

***1.** Department of Earth Sciences, Sapienza University, Rome, Italy, **2.** Department of Earth Sciences, Sapienza University of Rome, **3.** Magma Chem Research Institute, Sola, Norway, **4.** Department of Earth Sciences, Sapienza University, Italy, **5.** University of Twente, Faculty of Geo-Information Science and Earth Observation (ITC), Netherlands., **6.** Ifremer, Geo-Ocean, Plouzané, France, **7.** Institut de Ciències del Mar (ICM CSIC), Barcelona, **8.** Sorbonne Universitè, CNRS-INSU, Institut des Sciences de la terre de Paris, **9.** University of Twente, Faculty of Geo-Information Science and Earth Observation (ITC), Netherlands, **10.** CNR-ISMAR Bologna, **11.** Dipartimento di Scienze della Terra e del Mare, Università degli Studi di Palermo, **12.** Instituto Español de Oceanografía (IEO, CSIC), Centro Oceanográfico de Málaga*

Fluids (gas and liquids) trapped within sedimentary strata being lighter than the solids, move upwards driven by buoyancy. The seafloor “fluid flow” is widely recognised in different geodynamic contexts (e.g., active and rifted continental margins, compression zones -subductions-, highly sedimented areas -deltas), and gives rise to different morphologies. Pockmarks (known since the ‘70s) are the most common features linked to fluid escaping from the seafloor and are characterised by a negative relief. They can have diameters and depths of up to a few kms and >100m respectively, with circular to elongate planforms, and flat bottom to conical vertical profiles. The general mechanisms for pockmark formation and growth are still not completely understood even though geological and geophysical data provide valuable insights on factors controlling their genesis and development. Several hypotheses and conceptual models have been proposed to explain the formation and maintenance of pockmarks (e.g., by near-bottom currents), which involve either continuous processes (seeps) or rapid and sudden events of episodic releases and blowout (vents) of fluids. Pockmarks are often found associated with fluid-driven sedimentary failures. Their occurrence can be considered as an important revealing geohazard factor that suggests the presence of fluid migration, excess pore pressure and their potential relationship for the triggering of landslides. Therefore, their study is important for geohazard assessment and to setup any submarine infrastructure. Several studies also suggest pockmarks are important earthquake precursors, as it has been noted increase of seeping water temperature before the seismic event and still venting of gas bubbles afterward. The correlation between fluids and seismic activity is rather reasonable since fluids tend to act as a lubricant in faults. Many Mediterranean regions, from the Alboran Sea to the Levantine Basin host large pockmark fields. In this study we selected more than ~7,500 pockmarks to evaluate (i) their relationship with all the potential factors driving their formation based on morphological, sedimentological, and geochemical evidences (e.g., seafloor features, active faults, hydrocarbon regions, gas hydrates), and (ii) their likelihood of occurrence across the whole Mediterranean Continental Margins on a GIS-based and data-driven approaches.

Geomorphological education to students and citizens for disaster risk reduction

Prof. Takashi Oguchi [1], _Mr. Hiroyuki Yamauchi_ [1], _Dr. Jiali Song_ [2], _Dr. Takuro Ogura_ [3]

1. The University of Tokyo, 2. Shandong University, 3. University of Tsukuba

Reducing the risks of natural disasters is crucial for the sustainable development of nations and societies. Island arcs are prone to various types of natural disasters due to their tectonic settings and maritime environments. For example, intense rainfall, heavy snow, earthquakes, tsunamis, and volcanic eruptions often affect Japan, resulting in casualties and economic losses. In such places, practical education on natural disasters for ordinary people, based on scientific knowledge, is an essential task of relevant scientists such as physical geographers and earth scientists.

Therefore, we have developed educational materials and modules on geomorphology and natural disasters. We have used them in classes and social events for high-school students, university undergraduates, and citizens in Japan and China. The materials are in digital format utilizing GIS, Internet technology, and augmented reality. The developed materials include 1) online resources for learning GIS operations, including geomorphometric analysis; 2) Web-based online GIS for a better understanding of flood hazard maps in relation to landforms; and 3) explanatory materials of typical landforms in Japan based on photographs and topographic data obtained by drones, along with original text and illustrations.

This presentation introduces the main points of our educational activities, discusses their implications, and provides future perspectives. The questionnaire surveys on the attendees of classes and social events allowed us to understand the effectiveness of our education. We have found that the developed digital educational materials with functions of changing map layers and 3D topographic representation are more effective than traditional analog materials, such as paper hazard maps. For example, young high-school students effectively operated the digital system to identify possible flood-inundation areas and correctly select evacuation routes. In contrast, understanding some geomorphological issues, such as recognizing disaster-prone landform types on a map or photograph, was challenging for them. We will update the educational materials and modules considering the limitations of the current version and evaluate the effectiveness of new versions through applications in classes and events.

GIS based Regional Approach on Landslide Hazard Assessment in Karewa Basin, Jammu and Kashmir, India

Mr. Ankit Singh [1], *Dr. tarun Singh* [1], *Dr. K. S. Rao* [1]

1. *Department of Civil Engineering, Indian institute of technology delhi*

Landslides are one of the biggest natural disasters occurring in every part of the world. In India, land sliding is the second largest catastrophe, affecting thousands of people annually. This disaster is often connected with heavy rainfall events and active tectonics of the Himalayas. Considering the mountainous region, the events are aided by the steeper slope morphometry, undercutting by rivers, and numerous mega infrastructure projects being sanctioned in the Himalayas. A lot of studies have been carried out on landslides and several attempts have been made in predicting them. Landslide forecasting with certainty is still a challenge in the Himalayas. The present study focuses on remote sensing and GIS-based regional approach on Landslide Hazard Assessment in Karewa Basin, Jammu and Kashmir, India. The intermontane Karewa basin covering an area of 11717.86 square kilometers lies between the Great Himalayan Range to the northeast and Pir-Panjal Range to the southwest. The basin is tectonically active with Panjal and Main Boundary thrust running across the length of the basin in the Southwest and Zanskar thrust in the North East. The goal of the current study is to determine and characterize the crucial topographical parameters that influence the frequency of landslides in the area. Topographic maps, on-site observations, and available published data are used, and the corresponding thematic data layers are created in the GIS domain. Also, the satellite data, HRDEM, and Landsat series 8 OLI/TIRS level 2 atmospheric corrected data are utilized for the Landslide Hazard assessment of the area using weighed overlay approach. The result of the study is presented in the form of Hazard maps and the study area is divided into five different hazard zones based on their potential of land sliding in the future. The resulting maps can be used as a primary source of comprehensive evaluation of landslide hazards in the area with certain modifications as per the requirements.

Holocene Drought processes, community risk perception, and preparedness in Wyoming headwaters

Ms. Michelle Kim [1], *Dr. Jacqueline Shinker* [1]
1. Department of Geology and Geophysics, University of Wyoming

Holocene climate change has and will continue to increase environmental hazards (e.g. droughts), with impacts on vulnerable, rural and minoritized populations. In the Western U.S., impacts to water resources exemplify an environmental hazard enhanced by climate change during the Holocene. Within the region, Wyoming has a unique geographic backdrop that includes headwaters of three major river basins (Snake/Columbia, Green/Colorado, and Platte/Mississippi), with associated rural communities. Anthropogenic warming during the Holocene has led to early spring melt, reduced runoff, and diminished late-season flow. This research focuses on the spatial and temporal variability of atmospheric processes associated with recent droughts impacting Wyoming's headwater regions. We identified recent anomalous dry years from precipitation time series and used data from the ERA5 project to analyze climate variables associated with precipitation processes during selected dry years. Seasonal composite anomalies were calculated for precipitation rate; specific humidity at 850hPa; geopotential height at 500hPa; and omega at 500hPa. The composite-anomaly values represent the selected cases (e.g. drought years) compared to long-term means (e.g. average conditions) to provide information on atmospheric processes associated with persistent drought conditions in the region. Preliminary results indicate that anomalous dry conditions are supported by persistent sinking motions (omega at 500hPa), lower-than-normal moisture availability (indicated by specific humidity at 850hPa) combined with anomalous higher-than-normal pressure regionally. Our results use modern climate data to understand drought processes that can be applied to paleo-environmental, present, and future hazards. We use our results from our climate analysis of recent drought, as well as future temperatures from CMIP5 data, to develop graphics for use in community-based focus groups to assess community members' perception of past and future drought risk. Holocene climate change (e.g. enhanced drought) both recent and future will impact communities regionally. Through coding responses from community-member focus groups, we use analysis of variance; and cluster analysis for individual basins and between basins to identify community perception of drought risk. Our research provides a bridge between Holocene climate processes and perceived risk within rural communities to assist in the development of community preparedness to extreme events like drought.

Exploiting inventories of submarine geohazard-related features as a tool for a first assessment of coastal susceptibility to marine geohazard: examples from Calabro-Tyrrhenian margin, Messina Strait and Aeolian islands.

Prof. Daniele Casalbore [1], ***Prof. Francesco Chiocci*** [2], ***Dr. Angelo Corazza*** [3], ***Dr. Chiara Cristiani*** [3], ***Dr. Antonio Ricciardi*** [3]

1. *Department of Earth Sciences, Sapienza University of Rome,* ***2.*** *university of Rome Sapienza,* ***3.*** *Dipartimento della Protezione Civile Presidenza del Consiglio dei Ministri*

In the last few decades, a large effort in mapping continental margins and submarine flanks of coastal/insular volcanoes was performed at worldwide scale through the ongoing advances in seafloor imagery systems (especially using vessel- and/or AUV/ROV-mounted multibeam systems). These data have drastically changed our vision of the geological processes shaping the seafloor, also evidencing a large suite of possible geohazard-related features, including submarine landslides and canyons, pockmarks, active fault scarps, migrating bedforms, volcanic cones. In Italy, the Department of Civil Protection (DPC) funded a large-scale project (2007-2013 MaGIC Project) devoted to collect multibeam data along most of the Italian margins, through which mapping the main geohazard-related features here present. Just as an example, more than 8,000 landslide scars were mapped together with hundreds of submarine canyons, some of them deeply indenting the continental shelf up to arrive to the coast.

In order to let the study became an operational instrument, this large dataset was re-classified and partially re-analysed to provide a useful tool for civil protection purposes. The hazard zoning of coastline according to susceptibility to geological processes able to potentially generate marine geohazards was realised, including submarine eruption, fluid seepage, retrogressive erosion at canyon's head, mass wasting processes with the generation of local tsunami waves.

In this work, we briefly show a first and general approach based on the presence/absence of geohazard-related features for a preliminary zoning at regional scale. Then, we illustrate a more advanced approach, based on the re-analysis of morpho-bathymetric data integrated with simple tsunami modelling on specific areas, such as part of the Calabro-Tyrrhenian margin, the Messina Strait and some volcanic edifices of the Aeolian Arc.

Session 182: From Cores to Code: Data-Model Integration to Improve Reconstructions and Forecasts of Coastal Change

Onshore deposit sedimentology and source mechanism of the 1994 Mindoro tsunami in the Philippines

Mr. Alec Benjamin Ramirez [1], ***Dr. Noelynna Ramos*** [1], ***Ms. Sheinna May Claro*** [1], ***Mr. Lyndon Jr Nawanao*** [1], ***Mrs. Robelyn Mangahas-Flores*** [2], ***Dr. Toshitaka Baba*** [3], ***Dr. Naotaka Chikasada*** [4], ***Dr. Daisuke Ishimura*** [5], ***Prof. Kenji Satake*** [6]

The 1994 Mindoro tsunami is the most recent of destructive tsunamis in the Philippines, producing wave heights at shore exceeding 7 m and resulting in 41 deaths. The tsunami hit the coasts surrounding the Verde Island Passage (VIP) following a Mw 7.1 earthquake along the right-lateral Aglubang River Fault. While local in scale, the 1994 tsunami holds global significance as one of the few known examples of tsunamis occurring after strike-slip earthquakes, similar to the 2018 Sulawesi tsunami in Indonesia.
Submarine geomorphological mapping of the VIP resulted in the discovery of the San Andres submarine mass failure (SASMF). The SASMF, located <1 km north of San Andres, has an estimated volume of 0.0483 km^3. Analysis of pre-1956 depth soundings and post-1997 submarine surveys constrains its possible occurrence between 1956 and 1997. Assuming that the SASMF was triggered by the Mw 7.1 earthquake, numerical modeling of the 1994 tsunami based on a combined earthquake and SMF source (EQ+SMF) mechanism approximates actual wave height measurements better than an earthquake-only source mechanism (EQ-only). Compared with observed wave heights at shore, root mean square errors of modeled median wave heights for the EQ-only and EQ+SMF models are 3.21 m and 1.6 m, respectively.
Two facies of the onshore 1994 tsunami deposit were also identified from geoslicer sampling in northern Oriental Mindoro in February 2019. The tsunami deposit in San Teodoro, 6 km WSW of SASMF and 20 m inland, occurs as >80 cm-thick channel-fill sediments composed of normally-graded, medium-to-coarse lithic sand with a basal pebble-rich layer. At least 2 wave incursions are recognized based on the occurrence of an intermediary, □1 cm-thick mud cap. In Baco, <1 km S of SASMF, the tsunami deposit is characterized by a □25 cm-thick layer of mud clast-rich, muddy, medium-to-coarse lithic sand with a basal erosional contact over mangrove swamp sediments. Radiocarbon dating of the mud clast yielded an age between 843 and 790 BC. Modeled wave velocities at the Baco sampling site exceed 3 m/s, which could explain the inclusion of old mud layers within the tsunami deposit.

End-member mixing analysis (EMMA) as a novel tool for the detection of paleo-storms in far inland lake sediment records

Major tropical cyclones and other large storm events cause extensive damage in coastal regions throughout the western North Atlantic Basin. The short instrumental record leaves significant gaps in understanding long-term trends in TC recurrence and intensity, creating uncertainty about modeling future storm trends. Analysis of a >500-year core record from Harvey Lake, located >80 km from the Atlantic coast in southwestern New Brunswick, Canada was carried out using: 1) End Member Mixing Analysis (EMMA) of lake sediment grain size data to identify storm-linked sedimentological processes; and 2) ITRAX XRF derived element/ratios (Fe, Ti, Ca/Sr, Zr/Rb, K/Rb, Br+Cl/Al) associated with precipitation, weathering, catchment runoff and air masses. Three derived end members were correlated to heavy rainfall events (EM01), spring freshet (EM02), and large storm events (EM03). CONISS analysis of the EMMA and XRF core data resulted in recognition of four unique climatic zones distinguished by distinct distributions of storm records and rainfall, weathering, runoff, and air masses. Numerous, major (EM01) rainfall events and (EM03) large storm events characterized the basal core record during the early Little Ice Age (LIAa; Zone 1) phase, terminating at ~1645. A near cessation of heavy rainfall and major events differentiated the subsequent colder LIAb (~1645-1825; Zone 2) and subsequent Little Ice Age Transition (~1825-1895; Zone 3) . A resurgence of major rainfall and large storm events occurred during recovery from the LIA starting in ~1895 (Zone 4). EMMA provides a robust tool for recognition of large stormu and major rainfall events, and greatly expands the potential for paleo-storm activity research well inland from coastal regions.

The past, present, and future of barrier-system dynamics: New insights from the Virginia Barrier Islands (USA)

Dr. Chris Hein [1], ***Dr. Justin Shawler*** [2], ***Dr. Giulio Mariotti*** [3], ***Ms. Mahinaokalani Robbins*** [4]

1. Virginia Institute of Marine Science, William & Mary, 2. U.S. Army Engineer Research and Development Center, Coastal and Hydraulics Laboratory, 3. College of the Coast and Environment, Louisiana State University, 4. Department of Geology, Western Washington University

Among the most dynamic coastal landforms, barrier islands play central roles in ecosystem processes, habitat resilience, and mainland storm protection. Though over centennial and longer periods barriers simply migrate landward in near-direct proportion to the rate of sea-level rise (SLR), mesoscale barrier morphodynamics are far more complex. Focusing on the 13 largely undeveloped barrier islands of Virginia's Eastern Shore (USA), we combine new insights from the late Holocene geologic record, historical data, and numerical modeling to explore multidecadal to centennial barrier-system behavior. Specifically, we document shifts between phases of island erosion, migration, and progradation in response to changing rates of SLR, storminess, interactions with antecedent substrate, and long- and cross-shore sand exchanges. Overall, we find that the Virginia Barrier Islands have modestly (<5%) decreased in volume over historical time, with average shoreline transgression rates (due to island narrowing or landward migration) accelerating by ~45% in the last ~100 years. Given that the local SLR rate has increased by ≥200% over this same period, we infer multidecadal lag dynamics in barrier behavior with respect to SLR. Using a novel coastal evolution model, we reveal that observed shoreline retreat at the barrier-chain scale is not controlled by SLR over the last decades, but rather by the baseline SLR rate of the past centuries. As such, we predict a "committed" coastal response: the rate of retreat of undeveloped barriers will increase by ~50% within the next century, even if SLR remains at present rates. At the island scale, these dynamics play out in a far more complex manner: the potential for retreat is first realized through removal of 'geomorphic capital' (sand reservoirs associated with island stratigraphy, dune systems, tidal deltas, etc.), which can accelerate sand delivery to downdrift islands. Initiation of net migration once the eroding island becomes overwash-dominated, leads to an acceleration in shoreline migration and in the erosion of the downdrift islands, which are now experiencing a decreased (or net negative) longshore sand flux. Together, these findings help elucidate and better predict barrier behaviors, including those active through inter-island sand exchanges, over long coastal reaches, and with significant lag dynamics.

Reconstructing the Extent of the 1964 Alaska Tsunami at Port Alberni and Ucluelet, British Columbia, Canada: Implications for the Salinization of Groundwater Resources in Northern Cascadia

Mr. Stephen Bartlett [1], ***Dr. Jessica Pilarczyk*** [1], ***Dr. Diana Allen*** [1], ***Dr. Michaela Spiske*** [2], ***Dr. Robert Weiss*** [3], ***Dr. Davin Wallace*** [4], ***Dr. David Huntley*** [5], ***Mr. Roger Macleod*** [5]

1. *Department of Earth Sciences, Simon Fraser University,* ***2.*** *Universität Basel,* ***3.*** *Department of Geosciences, Virginia Tech, Blacksburg, Virginia 24061, USA.,* ***4.*** *University of Southern Mississippi,* ***5.*** *Geological Survey of Canada, Natural Resources Canada*

An important, but often underestimated, consequence of tsunami inundation on a coastline is the salinization of groundwater-bearing geologic formations known as aquifers. Tsunami-related salinization may yield groundwater unusable for up to 15 years. Key variables of uncertainty related to the effects of tsunamis on groundwater include tsunami flow depth and the rate at which water can pass through site-specific geologic material. Thus, this problem requires methodologies from both the paleoseismological and hydrogeological disciplines. We seek to improve our understanding of the impacts of far-field tsunamis on northern Cascadia, and to quantify the risk they pose to groundwater resources in the coastal communities of Port Alberni and Ucluelet, located on western Vancouver Island, British Columbia, Canada. We focus on the most recent far-field tsunami in the region known to have inundated both locations – the 1964 Alaska tsunami. A framework for assessing the risk of tsunami-groundwater contamination is developed using sedimentological analysis (stratigraphic mapping, grain size analysis, short-lived isotope dating) and groundwater modeling. To accomplish this goal, we use sedimentary evidence and grain-size distributions associated with the 1964 tsunami deposit to reconstruct the wave characteristics. Using a Russian peat corer, 50 cm-long cores were collected from two marsh locations in Port Alberni (19 cores) and Ucluelet (4 cores). Laser diffraction grain-size analysis on each core reveals that the 1964 tsunami sand deposit consists of 1 to 5 cm-thick layers of very fine to medium grained (ranging 4.87 to 2.20 ϕ), normally graded sand varying in depth from 5 to 18 cm below ground surface. Combined Cs-137 and Pb-210 dating confirm that sampled sands likely derive from 1964. These data and a high-resolution digital surface model derived from LiDAR are combined in an inverse sediment transport model (TSUFLIND) to resolve geologically-constrained inundation maps. Impacts of the 1964 tsunami inundation on groundwater resources are assessed using a hydrogeological model that can account for saturated-unsaturated and variable-density flow (SUTRA). Aquifer risk maps for each community will combine groundwater and tsunami inundation modelling results to provide vital information for at-risk communities in the region seeking to protect their groundwater supply.

Sedimentary records of high-energy events in the coastal lake of Arenella (South-eastern Sicily, Italy)

Prof. Giovanni Scicchitano [1], ***Dr. Giovanni Scardino*** [1], ***Prof. Matteo Vacchi*** [2], ***Prof. Nick Marriner*** [3], ***Dr. Vincenzo De Santis*** [1], ***Prof. Massimo Caldara*** [1], ***Dr. Sebastiano Tarascio*** [4]

Past occurrences of tsunami and storm events can leave imprints in the sedimentary records located along the coasts of Mediterranean coast. Storm and tsunami impacts determine the sedimentation of high-energy deposits in coastal areas. In particular, lagoons and backdune areas constitute long-term Holocene records. South-eastern Sicily is one of the most seismically active areas of the Mediterranean Sea, characterized by a high level of crustal seismicity, causing major earthquakes (up to Mw ~7). As a consequence, this area is prone to earthquake-generated tsunamis, which affected the Ionian coast of Sicily in historical times. These tsunamis left geomorphic and sedimentary imprints, such as large boulders or high-energy deposits, along the coasts. In this study, we describe several sediment cores sampled in a costal lake sited 30 km southward the town of Siracusa. This lake is located about 100m from the coastline and, as described in ancient charts and chronicles, it has never been connected with the sea. In 2014 and 2018 two different Mediterranean Hurricanes (Quendresa and Zorbas respectively) flooded the coastal area reaching the lake and depositing thick layers of coarse sand. Several cores have been from the lake, sediments result mainly represented by silty peat deposits interbedded with various sandy marine layers. Marine layers are overlaid by wood fragments, which were dated through radiocarbon method to provide temporal constraints on the high-energy deposits. Radiocarbon dating show that the upper marine layer can be temporally assigned to the 1908 tsunami event while the lower marine layer can be attributed to the 1693 tsunami event. These two events were particularly destructive and led to coastal flooding along the coast of South-eastern Sicily. Several analyses have been performed in order to better define the characteristics of the 1908 and 1693 tsunami events and to identify other marine extreme events that reached the lake in historical times, with particular focus on events that have occurred since 1908.

Session 183: Frontiers in drylands research

Najaf Sea palaeoshorelines, western Iraq

Dr. Becky Briant [1], *Dr. Jaafar Jotheri* [2], *Prof. Mark Bateman* [3], *Dr. Stefan Engels* [1], *Prof. Eduardo Garzanti* [4], *Dr. Ismael AlAmeri* [1]

1. Department of Geography, Birkbeck, University of London, 2. Department of Archaeology, University of Al-Qadisiyah, Diwaniyah, Iraq, 3. Department of Geography, University of Sheffield, 4. Dipartimento di Scienze dell' Ambiente e della Terra, Universita di Milano-Bicocca

Investigation of palaeolake deposits in arid and semi-arid regions is important for determining the palaeohydrological conditions that imposed controls on human communities throughout antiquity. This is particularly important in Iraq where many early civilisations were located. Resolving this debate is critical because freshwater availability would have been vital for local populations and the development of agriculture in the early to mid Holocene. Ephemeral lakes in Iraq have the potential to make a useful contribution to these debates by providing data for the north of the Arabian Peninsula. They also provide a useful background context for current climate changes.

Between the Mesopotamian floodplain in the centre of Iraq and the western desert on the western border are a series of north-west to south-east aligned depositional basins which currently contain ephemeral lakes of varying sizes (Habaniyah, Razazza, Najaf, Sawa). These follow the line of the Abu-Jir-Euphrates fault zone and are fed by a series of wadis aligned across the desert from the southwest. Prior to the tectonic uplift that created these depressions, these wadis fed large fans. Whilst there is evidence of prehistoric cave dwelling in the natural caves formed in the Injana Formation that underlies the fan deposits, there is no direct age control on the fan deposits or the initial formation of these basins. It is therefore not known when these depressions began to fill with water and whether lake volumes have been greater in the past. The Najaf Sea has in recent memory been completely dry (1980s, satellite images). To the east of Najaf Sea, detailed investigation and radiocarbon dating of palaeochannels of the Euphrates has shown that the Euphrates river flowed close to this depression from 125 BC to 1258 AD (Jotheri et al., 2016).

In this project we date previous extents of the Najaf Sea, shown in palaeoshorelines. This paper will present the context and importance of the Najaf Sea and OSL and radiocarbon dated sequences including heavy mineral and fossil shell data from both palaeoshorelines and boreholes drilled in a former channel that connected the Najaf Sea to the Euphrates. Regional palaeogeographies will be reconstructed.

Implications for Late Quaternary climate, weathering, and soil formation at Atacama's hyperarid coast drawn from trapped charge- and cosmogenic nuclide-dated alluvial fans

Dr. Janek Walk [1], Dr. Melanie Kranz (née Bartz) [2], Dr. Ariane Binnie [3], Dr. Martin Kehl [4], Dr. Ramona Mörchen [5], Dr. Philipp Schulte [6], Ms. Xiaolei Sun [7], Dr. Georg Stauch [6], Mr. Christopher Tittmann [6], Prof. Roland Bol [7], Prof. Helmut Brückner [4], Prof. Frank Lehmkuhl [6]

Department of Geography, RWTH Aachen University, 7. Institute of Bio- and Geosciences, Agrosphere (IBG-3), Forschungszentrum Jülich GmbH

The limited availability of water in the hyperarid Atacama Desert governs the occurrence and magnitude of hydromorphodynamic events, subsequent formation of fluvial and alluvial landforms, biotic activity, weathering, and soil formation. While those aspects have received considerable attention by geoscientists in the core of the desert, they are as yet not well understood especially in the coastal environment. In contrast to the interior, the coast receives much larger amounts of moisture – partly due to slightly higher precipitation but mainly as a result of orographic blocking of advective fog by the Coastal Cordillera between ~500 and ~1,200 m above sea level.

We present a synthesis of six years of research on the coastal alluvial fans of the Atacama Desert (20.5–25.5°S), conducted within the framework of the CRC 1211 "Earth – Evolution at the dry limit", and provide new insights into the processes and timing of their primary aggradation as well as secondary, post-depositional alteration by weathering and pedogenesis. Therefore, we established a regional geochronological framework based on both trapped charge dating (K-feldspar luminescence and electron spin resonance) and cosmogenic ^{10}Be exposure dating. The latter was additionally applied for chronosequence studies on two specific multi-stage alluvial fans. Combining the morphochronologies with a morphostratigraphy (spectral, textural, and gravelometric surface characteristics) on the one hand, and a pedostratigraphy (physicochemical soil properties) on the other, allowed to deduce the types and rates of weathering and soil formation, respectively.

Our results indicate that increased fan aggradation occurred throughout Late Pleistocene and Holocene periods of higher pluvial activity nourished by the Pacific, while fan generations older than the last interglacial period are absent or only preserved in form of small remnants. Post-depositional formation of weathering rinds, clast breakdown due to salt weathering, and denudation results over timescales of 10^4 years in mature desert pavements. The weathering intensity during the Late Quaternary is found to be related to sea surface temperature variability and sea level variations jointly driving the oceanic moisture supply. Towards the south, higher (palaeo)precipitation resulted in more advanced soil formation characterized by initial humification, decalcification closely coupled with acidification, rubification, and loamification.

Age and origin of gravel spreads in the Thar Desert, India

Inter-University Accelerator Centre (IUAC), New Delhi, India, 6. Deutsches GeoForschungsZentrum GFZ, Telegrafenberg, 14473 Potsdam, Germany., 7. College of Science and Engineering, James Cook University, Cairns, 4232, Australia; Fenner School of Environment and Society, Australian National University, Canberra, 0200, Australia, 8. Central Arid Zone Research Institute, Pal Road, Jodhpur (deceased)

The presence of fluvial gravels in the core of the Thar desert has been enigmatic and their origin has been widely debated. The gravels form a lag - a layer of gravel with little or no matrix. They are poorly sorted, subrounded to rounded pebbles of 1-80 cm in size. Conjectures about the origin of the gravels include fluvial transport during the early Quaternary or weathering of conglomerate in Mesozoic rocks. The age of lag formation is unknown. To resolve the origin of the gravels and the timing of the lag formation, we (a) used high resolution satellite images to re-map gravel occurrences and their contexts, (b) sampled major gravel occurrences at Bhojka, Hamira, Jayal, and Solanki sites along with their source rocks and, (c) measured in-situ produced cosmogenic nuclides to establish when the lag appeared. A major occurrence of gravel of > 50 km^2 is at the Bhojka site near Jaisalmer. Field evidence buttresses the suggestion that the gravels are the weathered products of underlying conglomeratic bedrock near Jaisalmer, Bikaner-Nagaur and Barmer in basins of Mesozoic age.
Initial ^{10}Be measurements suggest exposure ages of 0.7 to 1.7 Ma for gravels at Bhojka, Hamira Jayal, and Solanki. These ages are consistent with the archaeological evidence of a pre-Acheulian age. Depth profile of ^{10}Be at Bhojka suggests that the landscape was stable during most of the mid-late Quaternary and perhaps even longer. Currently ^{26}Al measurements are underway on quartzite pebbles and these together with other measures will inform complexities (if any) about putative overburden on the lag gravel. Owing to the fact that ^{21}Ne is a stable nuclide, its concentration together with appropriate modelling should provide an upper bound to the age and potentially help resolve the debate about the origin of these gravels.
This work was supported through a DST-SERB-YOCP grant, India.

A mechanistic approach for interpreting hydroclimate from halite-bearing sediments during abrupt climatic transitions

Dr. Ido Sirota [1]

1. *Institute of Earth Sciences, The Hebrew University of Jerusalem, 919040 Jerusalem, Israel*

Establishing accurate paleo-hydroclimatic reconstructions from lacustrine and marine archives is a long-standing challenge in paleoenvironment studies. Closed-basin evaporites and especially halite record episodes of extremely arid conditions during rapid climate change. However, the complex limnologic behavior of deep hypersaline water bodies and the stochastic hydroclimatic regime and its variations limit detailed paleo-hydroclimatic interpretations from such records. Therefore, we developed a mass-balance model to explore hydrology-limnology-sedimentology relationships in hypersaline environments under both deterministic and stochastic approaches that generate synthetic halite-mud sequences. Applying the model to the Holocene Dead Sea halites yields novel insights on paleoenvironmental conditions in the Levant, a hydroclimatically sensitive region, on the boarder between the mid-latitude and the arid climate zones. The deterministic framework indicates that (i) under a series of similar hydroclimatic cycles, the thickness of each subsequent halite interval decreases, due to the depletion of dissolved ions storage in the brine. (ii) Halite deposition requires lake levels drop to below the minimal lake level of the preceding cycle. (iii) The time interval between halite deposition and the hydrologic minimum is increasingly delayed in subsequent cycles. Thus, counter-intuitively, halite deposition mostly takes place as water discharge increases, providing that the water balance is still negative. The stochastic approach produced random sequences comparable to the observed Dead Sea sedimentary record. It demonstrates that some hydrologic minima are not represented by halite deposition at all. Furthermore, the thickness and number of halite beds at each hydrologic cycle vary substantially, depending on the specific hydrologic conditions realized. Finally, our results imply that the major deglaciation, pre-Holocene (~14 ka BP) Dead Sea level drop, previously assumed to be a record minimum, could not have been as pronounced as suggested, and must have been milder than the subsequent drop at the early Holocene (~11–10 ka BP).

The challenges of dating (and interpreting) dunes in topographically-complex regions – a case study from the Mojave Desert

Dr. Andrew Carr [1]***, Dr. Alex Hay*** [1]***, Prof. Mark Bateman*** [2]***, Dr. Mark Powell*** [1]***, Prof. Ian Livingstone*** [3]

1. *School of Geography, Geology and the Environment, University of Leicester,* **2.** *Sheffield University,* **3.** *The Graduate School, University of Northampton, Northampton, UK*

The dunes of the Mojave River catchment have been studied in some detail over the last three decades, particularly in terms of their relationship to the region's basin and range topography ("sand-transport corridors"), and sediment supply variability linked to the evolution of the Mojave River. There are however, reasons to suggest existing luminescence chronologies for these deposits need to be re-assessed. In particular, quartz may regularly exhibit malign luminescence properties, while low temperature K-feldspar IRSL suffers from relatively high anomalous fading rates. We applied post-IR IRSL methods to a suite of new luminescence samples from a range of Mojave aeolian deposits. We specifically considered sands associated with complex topography (The Cady Mountains) abutting the Mojave River and (palaeo) Lake Manix. The goal was to interrogate the proposition that topographically complex environments strongly mediate the (local) potential to store sand. Such control will greatly complicate interpretations of any "aeolian record" obtained from (e.g.) a multi-site programme of OSL dating. Sand deposits in the Cady Mountains were analysed using the Landserf morphometric classification GIS, and were shown to be represented by four accommodation space types: Slopes (mountain front sand ramps), Valley-Fills, Sandsheets and Slope-Valley-Fill composites. Luminescence samples were obtained from exemplars of each.

K-feldspar post-IR IRSL dating protocols perform very well, although incomplete bleaching remains a hazard where aeolian and slope-derived sediments mix (e.g. within some sand ramps). Our new ages span ~90 ka and differ with accommodation space type. Sand ramps consistently represent the oldest deposits (~40-80 ka), while (early-mid) Holocene dune accumulation is particularly associated with Sandsheets and Valley-Fills, both on the margins and within the interior of the mountain block. The results suggest topography significantly mediates the preserved aeolian sedimentary history, due to varied trapping potential, distances to sediment source and preservation potential (e.g. potential overland flow). The ages differ from previously compiled (mostly sand ramp) data, but this need not only reflect age inaccuracy. The preserved record at any locale is likely to be highly contingent on its meso-scale topographic setting. This renders the climatic / environmental interpretation of OSL ages/phases compiled across multiple sites questionable.

New constraints on the glacial–interglacial paleohydrology of southwestern North America from lake and wetland deposits at Playa San Bartolo, northwest Mexico

Mr. Brendan Fenerty [1]

1. The University of Arizona

During the last glacial–interglacial transition (ca. 18–11 ka), millennial-scale shifts in global atmospheric-oceanic circulation resulted in highly variable hydrologic responses across southwestern North America. Regional paleohydrologic records are critical to resolving these spatial and temporal shifts in patterns of moisture transport and for understanding the dominant mechanisms driving past changes in the magnitude, seasonality, and timing of precipitation. Here, we present new constraints on the paleohydrology of southwestern North America from Playa San Bartolo, a 42-km^2 intermittently flooded shallow basin in Sonora, northwest Mexico. As one of the most southerly lake systems in southwestern North America, in a region influenced by both winter westerly and summer monsoon precipitation, Playa San Bartolo is an important archive for understanding the regional response of the arid Southwest to late Quaternary climate change. We reconstruct the expansion and contraction of lake and wetland environments based on the sedimentology and stratigraphy as well as the fossil and stable isotope composition of lacustrine and groundwater discharge deposits exposed in outcrop. Radiocarbon determinations on fossil gastropod shells and sediment total organic carbon suggest that elevated lake levels coincided with the Last Glacial Maximum (~20 ka) and Heinrich Event 1 (~16 ka). From ~18–16 ka, an interval of decreased effective moisture throughout the southwestern US, a shallow lake and wetlands persisted at Playa San Bartolo, perhaps due to intensification of the North American monsoon. A shift from lacustrine to groundwater-discharge-dominated deposition and playa-like conditions characterizes the early–middle Holocene. By ca. 6 ka, desiccation and wind erosion of the basin floor resulted in the emplacement of a large source-bordering dune. The Playa San Bartolo record is broadly consistent with the southernmost pluvial lakes in the southwestern US, which, together, indicate that the dominant factor affecting moisture availability are shifts in Northern Hemisphere subtropical and midlatitude circulation systems influenced by the extent of the Laurentide Ice Sheet and abrupt freshwater input into the North Atlantic during Heinrich Events.

Extreme pluvials over the last two millennia detected using ephemeral lakes

The Australian continent is characterised by thousands of ephemeral lakes that only fill after extreme (daily or seasonal maxima) rainfall conditions. Many have little to no contributing/catchment area, while others drain up to one seventh of the continent (e.g. Kati Thanda-Lake Eyre [KT-LE], draining 1.14 M km^2). Here we use ephemeral lakes from diverse moisture sources across the Australian continent and with catchment areas varying over three orders of magnitude to reconstruct past pluvial phases over the last two millennia. We present chrono-stratigraphic data of beaches/palaeoshorelines that are all at or above the modern maximum (e.g. ≥ 1% annual exceedance probability), therefore representing extreme runoff conditions. Such landforms represent unambiguous evidence of pluvials that have occurred over the last 2000 years. Data from Lake Woods (Northern Territory), Kati Thanda-Lake Eyre, Lake George (NSW) and Lake Buchanan (Queensland) are discussed with the aim of assessing recurrence intervals for such wet extremes. These sedimentary archives, whilst discontinuous, add to the capacity to evaluate late Holocene climate change and extreme rainfall event occurrence within context of the observational record.

Windows of opportunity: the role of Arabia as a biogeographic crossroad over the Plio-Pleistocene

Dr. Monika Markowska [1]***, Dr. Hubert Vonhof*** [2]***, Dr. Huw Groucutt*** [3]***, Prof. Michael Petraglia*** [4]***, Prof. Denis Scholz*** [5]***, Dr. Michael Weber*** [6]***, Dr. Axel Gerdes*** [7]***, Dr. Ashley Martin*** [8]***, Prof. Gerald Haug*** [1]

Arabia is part of the largest near-continuous chain of drylands stretching from the Sahara to the Gobi Desert. This harsh and often hyper-arid belt acts as a barrier between two major biogeographic realms: the Palearctic and the Afrotropics, creating unique geographic endemism between Africa and Eurasia. However, late Mid- to Late Pleistocene hydroclimate records in Arabia suggest significant humid periods evidenced by paleolakes in the Nefud Desert and the Empty Quarter (the largest sand desert on Earth) associated with vertebrate fossils and stone tool assemblages. In coastal southern Arabia speleothem evidence also suggests the occurrences of humid periods in conjunction with insolation-driven interglacial phases. However, there are no direct hydroclimate records from the hyper-arid interior, particularly before the mid-Pleistocene, leaving the terrestrial hydroclimate and the role of Arabia as a biogeographic crossroads, largely unknown.
We use desert speleothems preserved in northern Arabian caves to identify past humid phases. These are particularly useful terrestrial climate archives as they act as underground rain gauges, requiring a minimum of ~300 mm a^{-1} precipitation, pedogenesis and vegetation cover to form. Moreover, they can be accurately and precisely dated and are subsequently a valuable tool in identifying past large-scale hydrological and vegetation changes in ancient drylands. Here, we show evidence for multiple 'windows of opportunity' over the Plio-Pleistocene which contain multiple episodes of climate amelioration, allowing biogeographic exchange and dispersals to occur across the Arabian hyper-arid zone. Further, the isotopic composition ($d^{18}O$ and $d^{2}H$) of speleothem fluid inclusion waters, representing 'fossil rainwater', reveal the changing influence of tropical rain-belt precipitation in Arabia across Earth's transition from a largely 'ice-free' northern hemisphere to an 'ice-age' world. These results have significant implications for understanding the drivers of dryland aridity in non-polar deserts globally.

Session 184: Seismic hazard assessment in populated areas of Latin America: incorporating seismogenic faults

Potential seismogenic structures in populated areas of NW Argentina: the Medeiros anticline and the growing capital of Salta province

Historical and instrumental seismicity records from the Central Andes of north-western Argentina spanning the last 350 years has been the primary data source to characterize this region’s exposure to seismic hazard as “moderate” to “high” (0.18-0.25 PGA). The lack of detailed studies regarding widespread evidence of Quaternary seismogenic deformation has prevented a more accurate seismic hazard assessment (SHA) in the vicinity of the metropolitan regions of San Salvador de Jujuy, Salta, and San Miguel de Tucumán, which together total almost 2 million inhabitants and host important infrastructure.

In order to improve the neotectonic characterization of potential seismogenic sources in this region we have employed a multidisciplinary and multimethodological research approach that includes remote sensing analysis, detailed structural and geomorphic mapping and topographic surveying, interpretation of seismic reflection lines and near-surface geophysical surveys, structural modeling, the deployment of temporary local seismic networks, as well as geochronology. The geochronological methods include terrestrial cosmogenic nuclide (TCN) dating and U-Pb dating of volcanic ashes to establish the age of abandoned fluvial terraces (10^4 to 10^5 yrs), and optically stimulated luminescence and AMS^{14}C dating to constrain the depositional ages of sedimentary sequences on centennial to multi-millennial timescales.

In this context, the Medeiros anticline has been already characterized as an N-S oriented, 16 km-long, fault-propagation fold deforming the entire sedimentary cover through a blind 30°W dipping ramp and a sub-horizontal detachment located in the contact with the metamorphic basement. Syntectonic unconformities in the synorogenic deposits allowed to establish the onset of the fold growth by upper Pliocene times. The Medeiros anticline is the southern termination of the La Caldera-Vaqueros ranges, representing as a whole a more than 60 km-long structural block.

Recently obtained TCN ages from two (T3 and T5) of the six (T1-T6 from oldest to youngest) folded fluvial strata terraces of the Vaqueros River, which cross the Medeiros anticline in an E-W direction, allow us to calculate average slip rates of 2.8 mm/a for the last ca. 45 ky implying a much higher potential seismic risk for the capital of Salta province that has rapidly expanded over the Medeiros anticline in the previous decades.

Seismotectonic and paleo-seismology insights of the Fortuna Fault and the Venado Transtensive System, Costa Rica.

Mr. Alejandro Arguello [1]***, Dr. Andres Ulloa Carmiol*** [2]***, Mr. Walter Montero*** [2]

1. Universidad de Costa Rica, 2. Centro de Investigacion en Ciencias Geológicas, Universidad de Costa Rica

Costa Rica's northern back-arc region is crossed by a dextral strike-slip system called the Haciendas-Chiripa-Fortuna fault system (HCFS). The Fortuna Fault is a northwest dextral strike-slip structure that causes the Venado Transtensive System (VTS) due to a right bend along the fault. The Fortuna Fault marks a limit of the Guanacaste Volcanic Sliver, that is moving NW about 11mm/year. The study area is near Arenal volcano, which maintained a decades-long eruption between 1968-2010, and close to two important active-fault systems. The Venado region is located within a back-arc Miocene Sedimentary basin with Limestones and karstic elements covered by Plio-Quaternary volcano units. The zone has a predominant transtensive stress with a dominant morphological-structural control on NNW-SSE and a smaller one on E-W direction. This zone shows active tectonics evidence and karstic elements such as deflected drainages, linear valleys, shutter ridges, sag ponds, and a relevant variety of recent structural information on the caves and karst. The shallow seismicity is low and varies between Mw 1.5 - 4.5. Using drone photogrammetry, karstic and cave geology, geological mapping, structural geology, seismotectonics, and geomorphology, this work contributes to the Fortuna fault characterization and provides a better definition of the HCFS to improve the seismic hazard assessment, risk management and contribute to the characterization of the tectonic sliver of northern Costa Rica.

Palaeoseismic record in Pyrenean lakes.

Mrs. Tamara Briceño-Sarmiento [1]**, *Prof. María Ortuño*** [2]**, *Dr. Ana Moreno*** [3]**, *Dr. Blas Valero-Garcés*** [4]**,**

Universidad Regional Amazónica Ikiam*

Lacustrine sediments are useful as a source of paleoseismic information, mainly due to their ability to record the shaking produced by an earthquake and their great temporal resolution in cases of continuous sedimentation. The Pyrenees are one of the main active seismic zones in the Iberian Peninsula and understanding the behavior of their seismogenetic structures is extremely important to generate adequate seismic risk models. The low recurrence of moderate to large seismic events makes it difficult to have a robust historical and instrumental record and, therefore, paleoseismology is an optimal tool for studying the seismicity of the area. Contrasting with the scarcity of palaeoseismic studies on active faults in the Pyrenees, there is considerable information on the sedimentation recorded in Pyrenean lakes. Thus, in this study, the existing lacustrine records of the Pyrenean lakes are used to identify deformation structures resulting from seismic events and correlate them with historical seismic events such as the Ribagorza earthquake of 1373, whose seismogenetic source is presumably the North Maladeta Fault system.

In the records obtained from lakes near the North Maladeta Fault system, such as Cregüeña, Barrancs and Estaña, the presence of seismic-type deformation structures of various dimensions has been evidenced that may be related to the 1373 Ribagorza earthquake, since that match the age pattern of the lakes. The Ribagorza earthquake is the most relevant historical seismic event that has occurred in the Central Pyrenees. Previous studies detail the connotation that the earthquake had on the inhabitants of Catalonia in the Middle Ages. This event had an estimated magnitude around Mw 6.2 and a maximum intensity of VIII-IX in the epicentral zone.

Morphotectonics of the “Depressão Periférica Paulista” and basaltic cuestas, at the areas of São Carlos, Rio Claro, São Pedro and Piracicaba (São Paulo-Brazil)

Dr. Edna Facincani **[1], *Prof. Pedro Cunha*** **[2], *Dr. Norberto Morales*** **[3]**

***1.** Universidade Federal de Mato Grosso do Sul, **2.** University of Coimbra, MARE & ARNET, Dep. Earth Sciences, **3.** Universidade Estadual Paulista UNESP*

Neotectonic structures were investigated within the “Depressão Periférica Paulista” and basaltic cuestas, two major geomorphological units in the areas of São Carlos, Rio Claro, São Pedro and Piracicaba (São Paulo, Brazil). The research was based on geological and geomorphological data, with emphasis on drainage pattern and anomalies, lineaments and digital terrain modeling, in order to define the overall morphostructural and morphotectonic characteristics of the region. The main structural features identified are two faults systems. The older one is represented by normal faults, oriented preferentially NE-SW, that mark the oldest limits of the Cenozoic infill. They represent an extensional stress regime with $\sigma 1$ vertical, $\sigma 2$ NE-SW and $\sigma 3$ NW-SE. The younger group is characterized by strike-slip faults oriented preferentially E-W. The stress field is marked by $\sigma 2$ vertical, σ 1 NW-SE and $\sigma 3$ NE-SW. Other faults, oriented NE-SW and N-S, are also associated with a strike-slip regime. In this region, upper Cenozoic deposits are characterized by a basal conglomerate and an upper sandy-clayish unit, the later also intercalated with debris flow deposits. The Cenozoic is distributed in a discontinuously pattern, expressed by structural and lithologic steps, controlled by the main lineaments NW-SE, NE-SW, E-W and N-S. These lineaments impose tectonics landforms by tilting, which created escarpments, with triangular or trapezoidal facets, abandoned meanders, river captures, shutter ridges, offsets, lateral migrations, arches and elbows. These features are related to the neotectonic activity, due to rotation of the South American Plate, interpreted as dextral.

Active faults of the Andean Active Orogenic front (32° 30´S)

Dr. Stella Moreiras [1], ***Dr. Rafael Toural Dapoza*** [2]

1. *Instituto Argentino de Nivología, Glaciología y Ciencias Ambientales (IANIGLA), Centro Científico Tecnologico CONICET, Mendoza, Argentina,* ***2.*** *Departamento de Geodinámica, Estratigrafía y Paleontología, Universidad Complutense de Madrid (UCM), 28760 Madrid, Spain*

The Andean active orogenic front, located in the Precordillera foothill at 32º 50'S, gathers the largest Quaternary deformation of Argentina. This region is related to intra-plate seismicity linked to the Pampean Flat Slab segment, the subduction of Juan Fernandez Ridge, a volcanism absence, and the particular morphostructural style of the morphotectonic unit of Precordillera (Southern Precordillera) that culminates at this latitude (32°S). Besides, a change in the style deformation of Quaternary structures is determined at this latitude, where folds limited by active faults and N-S reverse faults offsetting Late Pleistocene alluvial levels, predominate. In this study, the main Quaternary faults were studied. The maximum probable earthquake magnitude associated with these structures was established (~Ms=6.4) based on parameters measured along fault planes. The result was compared with values obtained indirectly by fault long. According to morphometric indices, the greatest current deformation area was located in the southern portion of the Andean piedmont. This zone shows as well the greater deformation detected by interferometry (DINSAR technique). Optically Stimulated Luminescence datings on sag ponds related to active faults allow to infer a regional slip rate during the Late Pleistocene.

Session 185: Active faults evolution: revelations from different timescales

Temporal variations in deformation rates from structural modeling, Quaternary dating, and geodetic measurements: Zagros Mountain Front Fault, Kurdistan Region of Iraq

Dr. Mjahid Zebari [1], ***Dr. Christoph Grützner*** [2], ***Prof. Kamil Ustaszewski*** [2]

1. *University of Munich*, ***2.*** *University of Jena*

Constraining a responsible temporal record of active faults is usually associated with considerable complications. However, this record may provide hints toward the predicted trend of its activities. Here, we evaluate the temporal variations in the deformation rates on the Zagros Mountain Front Fault since its initiation in the Late Miocene. The Mountain Front Fault makes a prominent morpho-tectonic boundary along-strike of the entire Zagros Belt, and it is seismically active (e. g. 2017 Mw 7.3 earthquake in the Iraq-Iran border). The long-term (geological) deformation rates were measured from balanced cross-sections and structural forward modeling. The Late Pleistocene-Holocene slip rates were calculated from fault-related fold modeling and differential uplift rates of associated river terraces on both hanging wall and footwall. The results were then compared to the present-day geodetically derived deformation rates in that region. The total displacement on the fault since its formation in the Late Miocene, derived from the balanced cross-sections, was used to calculate slip rates of about one millimeter per year. In contrast, the Late Pleistocene-Holocene calculated slip rates are 1.9±0.7 millimeter per year. Interestingly, the geodetically-derived deformation rates for that area are much (3-5 times) higher than both previous rates. This study shows that combining multiple approaches allows for better constraints on the temporal behavior of active faults. Discrepancies in estimates obtained via these three approaches might thus allow to identify locked fault strands that pose an increased seismic hazard.

New multidisciplinary investigations on the tectonic and sedimentary evolution of the southern sector of Sulmona basin (Central Italy).

1. *Dipartimento di Ingegneria e Geologia, University "G. d'Annunzio" of Chieti-Pescara,* **2.** *Dipartimento di Scienze della Terra, University of Pisa, Pisa, Italy,* **3.** *Istituto di Geologia Ambientale e Geoingegneria, CNR, Roma,* **4.** *Consiglio Nazionale delle Ricerche, Istituto di Geologia Ambientale e Geoingegneria (IGAG)*

The Sulmona intermontane plain is a tectonic basin filled by Quaternary fluvio-lacustrine deposits, driven by the recent activity of the Mt. Morrone fault system during the post-orogenic extension of the Central Apennines. Detailed multidisciplinary investigations were carried out in the southern sector of the basin, in the Santa Rufina (SR) borehole. SR was drilled down to a depth of ca. 200 m in the western section of the basin and compared with a ca. 435-m-depth water-well (Medibev Well: MW) in the depocentral portion of the basin, characterized by a lacustrine succession.

Although recent studies have explored in detail the stratigraphy of the Sulmona Basin, these are generally limited to the northern sector of the basin, leaving open numerous issues, such as: the overall geometry and stratigraphy of the basin infill, the depth of bedrock/sediment interface, the onset age of the basin formation, and the relations between the basin subsidence rate vs. Mt Morrone fault slip-rate. In both SR and MW sediment cores the lacustrine clayey-silty deposits dominated with respect the coarse grained alluvial-fluvial deposits.

The magnetic susceptibility of SR, measured both on the core and on discrete samples, shows higher values corresponding to tephra layers. The paleomagnetic analysis, performed by alternating field demagnetization on 156 samples, identifies the Brunhes/Matuyama boundary (773 ka) at 194 m depth.

Tephrochonological analysis in SR core allowed the recognition of several chronologically well-constrained tephra markers, either of regional (e.g., Vico a, ca. 415 ka, White Trachitic Tuff, ca. 320 ka, and Villa Senni, ca. 366 ka) or basinal scale, which constrain the whole succession between ca. 300 and 800 ka.

The comparison of the coarse grained alluvial and tephra layers in the two boreholes constrained a geological section crossing the basin, which allowed new insights into its tectonic, sedimentary and paleoenvironmental evolution. Preliminary results from the correlation confirmed an asymmetric half-graben type geometry of the basin, highlighting the Mt. Morrone fault system as a leading factor responsible for the opening of the basin and its Quaternary tectonic-sedimentary evolution.

Long-term evolution of the Mt Pettino seismogenic fault zone (central Apennines): structural, isotopic, and geochronological constraints

Dr. Giorgio Arriga [1]***, Prof. Federico Rossetti*** [1]***, Prof. Domenico Cosentino*** [1]***, Dr. Mauro Brilli*** [2]***, Prof. Chuan-Chou Shen*** [3]***, Dr. Hu Hsun Ming*** [4]***, Dr. Michele Soligo*** [5]

1. *Roma tre University,* **2.** *CNR-IGAG,* **3.** *High-Precision Mass Spectrometry and Environment Change Laboratory (HISPEC), Department of Geosciences, National Taiwan University, Taipei 10617, Taiwan, ROC,* **4.** *National Taiwan University,* **5.** *Università Roma Tre*

The central Apennines are a Cenozoic fold-and-thrust belt that is undergoing post-orogenic collapse in its axial region since the Pliocene. Post-orogenic extension resulted in the formation of several intermontane basins bordered by high-angle extensional faults, striking subparallel to the backbone of the chain. The Monte Pettino seismogenic fault (MPF) is the NE boundary fault of the Quaternary L'Aquila intermontane basin. Its fault zone is characterized by a complex structural architecture that documents a polyphase tectonic history. To study the long-term evolution of the MPF, we integrated fieldwork, geochemical (C-O stable isotopes), and geochronological (U-Th) analyses. Our study highlights two main tectonic phases. The first phase corresponds to the development of a major cataclastic zone, defined by an 8-meter-thick SW-dipping (65-70°) fault core exposed at the piedmont of the Monte Pettino. This cataclastic zone is sealed by the L'Aquila Breccias (Middle Pleistocene, ca. 250-350 ka). The stable isotope systematics of the cataclastic matrix and of the associated calcite slickenfibers, which are in the range of the carbonate bedrock, indicates a "closed" system behaviour during fault zone nucleation and development. The second phase, is recorded both in the L'Aquila Breccias and in discontinuous volcanic deposits, interpreted as pyroclastic products of the Albani Hills, which unconformably cover the bedrock at the SE termination of the MPF. It consists of anastomosed, high-angle WNW-ESE striking fault strands, spaced m to hm apart and with cm to m displacements, associated with carbonate veining and travertine formation. Stable isotopes measured from the fault slickenfibers show a progressive re-equilibration with meteoric fluids, as evidenced by a decreasing trend in $\delta^{13}C$ and $\delta^{18}O$ values. The carbonate veins and travertines systematically show negative $\delta^{13}C$ and $\delta^{18}O$ values, showing a dominant supply of meteoric fluid ("open" system) with important contribution of organic carbon. The U-Th ages of the veins and travertines are in the range of 182-331 ka, in accordance with the temporal constraints from stratigraphic data. Structural and isotopic results have supplied no evidence of tectonic reactivation of the cataclastic core of the MPF during the Middle-Upper Pleistocene, suggesting that it was already exhumed at that time.

Quaternary activity of the Viar and Medina Azahara faults in a strongly strain partitioned, tectonic scenario: new constraints from geomorphic analysis and 10Be-derived denudation rates

Dr. Michele Delchiaro [1]***, Dr. Alejandro Jiménez-Bonilla*** [2]***, Prof. Inmaculada Expósito*** [2]***, Prof. Marta Della Seta*** [1]***, Prof. Juan Carlos Balanyá*** [2]***, Prof. Manuel Díaz-Azpiroz*** [2]***, Dr. Dmitry Tikhomirov*** [3]***, Prof. Markus Egli*** [3]***, Dr. Marcus Christl*** [4]

1. *Department of Earth Sciences, Sapienza University of Rome,* ***2.*** *Department of Physical, Chemical and Natural Systems. University Pablo de Olavide,* ***3.*** *Department of Geography, University of Zurich, Zurich, Switzerland,* ***4.*** *Geological Institute, ETH Zürich*

Relief rejuvenation of geologically ancient areas often occurs in response to intraplate deformation. In these long-lived areas, the reactivation of pre-existing structures is a common mechanism for strain accommodation, which is often favored over the generation of new structures. Thus, previous discontinuities can be expected to localize the relief rejuvenation associated with recent or active tectonics, which can therefore be analyzed to delve into the kinematics of recent deformation.

In this regard, we explored the relationship between the relief rejuvenation pattern and the distribution, geometry, and kinematics of Viar and Medina Azahara faults in a wide segment of the Betic foreland (Sierra Morena, southern Spain). Specifically, we focused on the forebulge, a WSW–ENE flexural relief that formed, paired to the Betic foreland basin, in response to orogenic load, where little work has been done to address the geomorphological imprint of the tectonic rejuvenation in the Sierra Morena.

For this purpose, we applied both qualitative and quantitative geomorphological tools, including geomorphic indices and knickpoint pattern modeling in order to detect transient signals along the river profiles linked to the fault activities. Moreover, to investigate how the denudation rates vary in relation with the fault activity, we measured the content of in situ-produced cosmogenic ^{10}Be of river-borne quartz from sands samples collected in active channels of 8 sub-catchments of Viar basin upstream to the Viar fault and 7 sub-catchments of Guadiato basin upstream to the Medina Azahara fault.

We found that the sampled sub-catchments are in disequilibrium conditions with non-lithological knickpoints delimiting a relict landscape with lower denudation rates from rejuvenated and active landscape with higher rates.

Multi-scale definition of the activity rates of segmented faults: the case of the Mt. Marine Fault (Central Apennines, Italy)

Dr. Francesco Iezzi [1], Dr. Marco Francescone [2], Prof. Alberto Pizzi [2], Dr. Anna Maria Blumetti [3], Prof. Paolo Boncio [2], Dr. Pio Di Manna [4], Prof. Bruno Pace [5], Prof. Tommaso Piacentini [6], Dr. Felicia Papasodaro [7], Dr. Francesco Morelli [2], Dr. Marco Caciagli [8], Dr. Massimo Chiappini [9], Dr. Francesco D'Ajello Caracciolo [9], Dr. Valerio Materni [9], Dr. Iacopo Nicolosi [9], Dr. Vincenzo Sapia [9], Dr. Stefano Urbini [8]

Geological Survey of Italy – ISPRA, 5. Università degli Studi "Gabriele d'Annunzio" Chieti-Pescara, 6. INGEO - Dipartimento di Ingegneria e Geologia, Università degli Studi "G. d'Annunzio" Chieti-Pescara, 7. Italian Geological Survey ISPRA, Rome, 8. INGV, Bologna, 9. INGV, Roma

The understanding of the dynamics of highly segmented faults is made difficult by the lack of information on whether the 3D shallow deformation is equally spread over multiple fault splays or the activity tends to localise on specific splays. This problem is enhanced when these faults are located within urban areas, and therefore their surface expression is altered by intense anthropic activity.

Within the framework of a work on the mitigation of the fault displacement hazard associated with the Mt. Marine active normal fault (Central Italy), we have performed two paleoseismological surveys within the town of Pizzoli (about 10 km NW of L'Aquila), where the fault is expressed with several splays arranged both along and across-strike. The trenches were planned in order to explore (i) potential fault scarps altered by human activity, identified through aerial photographs, LiDAR and fieldwork analysis, and (ii) discontinuities in the stratigraphic record highlighted by geophysical investigations (ERT, GPR) and borehole data. The first survey is characterised by a continuous trench about 156 m long and it intercepts two synthetic and one antithetic faults arranged across-strike. The three faults show evidence of multiple Holocene surface-rupturing seismic events, marked by colluvial wedges and infilled fractures, with observable coseismic displacement up to 80 cm. The second paleoseismological survey is located about 720 m SE of the previous site, and it is composed by two adjacent smaller trenches, with length about 20 m and 10 m each. These trenches intercept two faults arranged across-strike, both providing evidence of repeated Holocene surface-rupturing earthquakes.

Moreover, we constrained the Late Pleistocene slip-rate of the Mt. Marine fault by dating and correlating Late Pleistocene paleosols found (1) outcropping in the footwall of one of the inner fault splays and (2) in a borehole located just at the hangingwall of the outermost splay.

Our results show that multiple fault splays are active with different rates through time, suggesting that the activity is localised on specific splays. The comparison between the Late Pleistocene slip-rate and the paleo-seismological results allows us to understand how single fault splays contribute to the overall behaviour of segmented active faults.

Active tectonics of the Cordillera de la Sal fold-and-thrust belt, Salar de Atacama, Chile. Evidences from deformed fluvial features

Mr. Pedro Guzmán-Marín [1]***, Dr. Vincenzo Picotti*** [1]***, Dr. Christoph Schmidt*** [2]***, Prof. Georgina King*** [2]

1. *Geological Institute, ETH Zürich, 8092 Zurich, Switzerland,* ***2.*** *Institute of Earth Surface Dynamics, University of Lausanne, 1015 Lausanne, Switzerland*

The Salar de Atacama basin is a low topographic anomaly located in the proximal forearc of the Central Andes (~23°S, Chile). Within the Salar de Atacama depression, we focus on the Cordillera de la Sal (CdS), a ridge that emerges on its western margin and extends to the northeast for more than 100 km towards the volcanic arc, where the Salar de Atacama basin closes. The core of the CdS ridge is formed by a fold-and-thrust belt affecting the Oligocene-Miocene continental sedimentary successions of the San Pedro Formation. Towards the volcanic arc, these units are unconformably overlain by Upper Miocene-Pleistocene tuffs and sediments with varying intensities of deformation. At this latitude, the Andean active crustal tectonics is characterised by extension in the external part of the forearc, whereas by compression in the retroarc. Nevertheless, there is discussion about the recent Pliocene to Late Pleistocene tectonics affecting the Salar de Atacama area.

Our objective is to contribute to the understanding of the Neogene to recent tectonics of the proximal forearc of the Central Andes by constraining the variable spatial patterns of deformation affecting the CdS. Our methods combine a detailed geological mapping of the northern segment of CdS and the construction of cross-sections with geochronology and structural modelling.

In this work, we provide field evidences of Late Pleistocene to Holocene active tectonics, which is deforming fluvial features that cross the frontal structures of the CdS, such as deformed fluvial strath terraces and Holocene salt cave conduits. Moreover, we present novel geochronological data for the deformed strath terraces, which we are currently dating using Infra-Red Stimulated Luminescence methods. This new geochronological data will allow us to constrain the variability of the incision rates associated with the streams that cut the deformation front of the Cordillera de la Sal and to model the slip rates of the thrust structures at different time scales.

Evidence of Late Cenozoic reactivation of an inherited strike-slip fault system in the Longitudinal Valley of Northernmost Chile

Mr. Ambrosio Vega [1], ***Dr. Pia Victor*** [1], ***Ms. Sara Pena Castellnou*** [2], ***Prof. Klaus Reicherter*** [2]

1. *Deutsches GeoForschungsZentrum GFZ, Telegrafenberg, 14473 Potsdam, Germany.,* ***2.*** *Institute of Neotectonics and Natural Hazards, RWTH Aachen University*

The Longitudinal Valley in Northernmost Chile is the main depocenter of widespread fluvial-alluvial systems active through the Neogene until exoreic drainages developed between Arica and Pisagua ca. 3 Ma ago. The top surfaces of the continental deposits form a regional scale pediplain (Pacific Paleosurface), where present-day perennial streams drain to the Pacific Ocean trough deep incised quebradas. Some geomorphic and climatic constrains exists regarding how uplift of the Coastal Cordillera and western Andes influence the shift in drainage regimes. However, little is known how tectonic activity across this region affected landscape evolution since the structural architecture is difficult to unravel in this area of high sedimentation but low displacement rate.
To address this, we combined a reprocessed ENAP (Empresa Nacional del Petróleo) seismic section comprising the forearc at ~19°20'S with detailed structural mapping and geomorphic evidence in key areas to unveil deep to surface geometry, kinematics and timing of tectonic structures across the Longitudinal Valley. Our first observations led to strong evidence of the existence of a complex Mesozoic inherited strike-slip system across the Longitudinal Valley which reactivation deformed Oligocene to Late Miocene strata. Local growth strata, angular unconformities, and flower structures within Late Miocene to Early Pliocene lacustrine deposits suggest syn-sedimentary and later dextral transpressional faulting along the boundary in between the Longitudinal Valley and Coastal Cordillera during this period. Surface expression of these structures consist in gentle bulging with normal faulting across folds. Importantly, timing of faulting matches with the major draining event of the paleolake. Then, these structures localize later large landslides events inside the deep quebradas. Progressive abandonment and deformed terraces of low incised rivers crossing compressive structures suggest that these are active during the Quaternary. New dating of deformed marker horizons will bring further insights regarding key parameters of fault activity for the Late Cenozoic and Quaternary. One important result of this study is that we observe large drainage reorganization patterns triggered by only little displacement along the often blind fault structures, that create nevertheless enough topography that cannot be surpassed by drainage incision in this hyperarid setting.

Session 186: The Long Walk to the Anthropocene: Exploration within Quaternary contexts

Timing of the anthropogenic carbon invasion in the Southern California Current surface waters

Ms. Yéssica Vanessa Contreras Pacheco [1]***, Mr. Jose Luis Abella Gutiérrez*** [2]***, Mr. Gerardo Vallejo Espinosa*** [3]***, Mr. Juan Carlos Herguera*** [1]

1. *Center for Scientific Research and Higher Education of Ensenada,* ***2.*** *The University of Texas at Austin,* ***3.*** *Center University of Los Altos, University of Guadalajara*

High resolution carbon isotopic records from organic and carbonate carbon show an unprecedented several decades long decreasing trend in their stable isotopic compositions for the past millennium. These time series were obtained from laminated cores collected from a semi-closed basin off Baja California Peninsula, San Lázaro basin (SLB), bathed by suboxic waters at depth, and located below the southern dynamic boundary of the California Current System. The carbon isotopic compositions of two planktic foraminifera *N. dutertrei* and *G. ruber* show a decreasing trend toward lighter isotopic compositions during the past 8 decades, further reflected in the organic carbon isotopic composition. These trends are similar to the widely observed trend toward lighter carbon isotopic values in the atmospheric CO_2 although with slightly lower slopes. These trends most likely result from the invasion of anthropogenic carbon dioxide in the surface waters of the California Current, another expression of the Suess effect in the upper ocean waters. Their different slopes are most likely due to the combined effects of vertical mixing of subsurface nutrient driven by the dominant NW winds along the western North American margin bringing nutrient and dissolved inorganic carbon rich waters characteristic for their relatively heavier carbon isotopic values, and the equatorial advection of northern waters carrying anthropogenic carbon dioxide in this highly productive eastern boundary current.

Lead legacy of preindustrial activities in lake sediments: the case study of the Lake Accesa (Southern Tuscany)

Ms. Francesca Pasquetti [1], _Prof. Giovanni Zanchetta_ [2], _Dr. Benoît Caron_ [3], _Prof. Monica Bini_ [4], _Prof. Boris Vannière_ [5], _Prof. Marc Desmet_ [6], _Dr. Michel Magny_ [7], _Dr. Ilaria Baneschi_ [8]

1. *Department of Earth Science, University of Pisa, Italy,* ***2.*** *University of Pisa,* ***3.*** *Institut des Sciences de la Terre de Paris ISTeP UMR 7193, Sorbonne Université,* ***4.*** *DST, Department for Earth Sciences, University of Pisa (Italy).,* ***5.*** *Laboratoire Chrono-Environnement, UMR 6249 CNRS, Université de Bourgogne Franche-Comté, Besançon, France,* ***6.*** *Laboratoire GéHCO, Université de Tours,* ***7.*** *Laboratoire Chrono-Environment, Université Bourgogne Franche-Comté,* ***8.*** *Istituto di Geoscienze e Georisorse, Consiglio Nazionale delle Ricerche, (IGG-CNR), Via G. Moruzzi 1, 56124, Pisa, Italy*

Geochemical analyses of long-time series provided by lacustrine sediments can give new insights into the possible contribution of preindustrial activities to the trace metal dispersion in the environment at different scales (e.g., local and regional scales), and into the natural background conditions of selected areas. The Mediterranean basin, and especially Italy, has a long history of civilization and anthropic modifications and hosts some of the largest metal mines in the world, therefore is perfectly suitable for a wider study on this matter.

For this project, we selected five different lacustrine cores from lakes mainly located in Italy (Lake Ledro, Lake Accesa, Lake Lungo, Ganzirri salt-marsh and Lake Volvi) and dating back to the second half of the Holocene to trace local-to-regional Pb pollution for a preliminary resolution of ca. 200-300 yr.

Data for lead indicates that most lakes recorded an increase in lead concentrations moving toward the uppermost part of the cores. However, among the lakes, the Lake Accesa is the only one that shows incredibly high concentrations of lead, with values up to ~1600 ppm starting from the Middle Age. The Lake Accesa is a small karstic lake (~0.15 km²) located on the southern border of the Colline Metallifere mining district, which is characterized by widespread hydrothermal mineralization. The catchment area of the lake (about 5 km²) is also surrounded by sulfide polymetallic deposits exploited in the last centuries. The high values detected in the Lake Accesa could be thus related to the growth of human activities during the Middle Age that favored soil and sediment erosion of different areas of the catchment such as mining and agricultural activities. This means, for example, that preindustrial activities in southern Tuscany may have left an important legacy of potential toxic elements in the environment, even higher of the recent pollution.

The politics of plants: socio-political contexts as drivers of upland cultural land-use change, impacts on landscape and ecosystem. The Cabreira Mountain, northwest Portugal.

Dr. Carla Ferreira [1]***, Dr. Gill Plunkett*** [2]***, Dr. Luis Fontes*** [3]

1. Queen's University Belfast, 2. Archaeology & Palaeoecology, School of Natural and Built Environment, Queen's University Belfast, 3. Universidade do Minho

In many regions today, mountain landscapes are under threat from climate change, degrading ecosystems and rural exodus, despite a long history of human settlement and exploitation. The present study aims to reconstruct human activity in the Cabreira Mountain, in northwestern Portugal, to investigate the degree to which human interaction with the mountain environment has contributed to shifting landscapes and ecosystem demise throughout the last millennium. This study offers a long-term perspective on the evolution of cultural land-use in the context of ongoing social and economic change through the examination of three palaeoenvironmental sequences interpreted in the light of available archaeological, historical and documentary records. Social-political factors and population pressure were fundamental in the utilisation of upland spaces and in defining the economic structure of the uplands.

We conclude that long-term occupation of the uplands was sustained by low-intensity land-use throughout the Medieval to post-Medieval periods, and that the present landscape has assumed a very different character following depopulation of the mountain areas and a shift towards commercial forestry. The analysed palynological sequences have addressed gaps in the archaeological and historical evidence, such as the nature of land-use in the uplands of northern Portugal, the impact political crises had on upland economy and the role of mountain regions within the wider economic setting. This study has also highlighted the importance of traditional management systems in maintaining landscapes and healthy ecosystems: the demise of the traditional land-management practices led to landscape degradation, increased fire vulnerability, changes to the water cycle and increasing aridity.

Back to the Grind: A Study of Grinding Stones in the Southern Indian Neolithic

Ms. Sutonuka Bhattacharya [1], ***Prof. Katragadda Paddayya*** [2], ***Prof. Ravi Korisettar*** [3], ***Prof. Naama Goren-Inbar*** [4], ***Prof. Gideon Shelach-Lavi*** [4], ***Prof. Shanti Pappu*** [5]

1. Hebrew University, Jerusalem and Sharma Centre for Heritage Education, 2. Deccan College Post-Graduate and Research Institute, Poona, 3. ICHR Senior Research Fellow, 4. Hebrew University, Jerusalem, 5. Sharma Centre for Heritage Education & Krea University

This paper discusses grinding stones from the Indian Neolithic seeking to examine issues related to subsistence, social organisation and degrees of sedentism. The study moves beyond typological lists of grinding stones, commonly noted in Indian archaeological literature, towards an interpretation of their reduction sequences, use, reuse and discard. This research focuses on the southern Indian Neolithic complex (c. 2500-1400 BCE) particularly reviewing the context and nature of grinding stones present at the site with issues related to subsistence, mobility and intra- and inter-site spatial organisation. In this study, we analysed a total of 109 grinding stones from the sites of Sangankallu, Budihal and Tekkalakota. These sites have a long history of research with evidence of the transition from hunting-gathering to agro-pastoralism, the evolution of the Neolithic and transitions to the subsequent 'Iron Age', marked by cultural changes reflecting adaptation to differing ecological 'niches.' In addition to metrical and qualitative variables, 3D Photogrammetry was attempted to further interpret variability in surfaces utilised. We evaluated the context where each grinding stone was found alongside its morphology and potential strategies for manufacture, use and discard, in order to reconstruct its life history. Results indicate some degree of commonality amongst different types of grinding stones found at these sites, with the presence of both portable and non-portable grinding stones. The artefacts reflect complex life histories culminating in breakage, rejuvenation, reuse and discard. Our research suggests that grinding stones, which are essential elements of food processing in agro-pastoral communities both in the past and today, are important indicators for activities such as plant processing and non-subsistence-related activities. They can help us better understand important issues such as seasonality and degrees of sedentism amongst Neolithic communities in southern India. Grinding stones form a key element in multiple aspects of the lives of agricultural communities in India, not only in the past but also in the traditional lifeways of modern India. The significance of this study lies in analysing these artefacts from multiple perspectives and how they are instrumental in understanding changing human interactions with the 'wild' and 'domesticated' landscapes through time.

Pollen based reconstruction of vegetation dynamics in the urban fabric of an Ancient lost capital - Angkor Thom, Cambodia

Dr. Anupama Krishnamurthy [1], ***Mr. Srinivasan Prasad*** [1], ***Dr. Phillipe HUSI*** [2], ***Dr. Jacques GAUCHER*** [3], ***Ms. Kannitha LIM*** [4], ***Mr. Lazar J.*** [1]

1. *French Institute of Pondicherry,* **2.** *UMR Citeres, CNRS / University of Tours,* **3.** *EFEO, Paris,* **4.** *EFEO, Siem Reap*

This paper presents the first results from a palynological study of cores recovered from an organically rich deposit at the bottom of the Srah Srei, a tank that was built on the grounds of the Royal Palace in Angkor Thom. The sediments date back to at least the mid 13th century. The vegetation in the vicinity of the tank was very different in the past from the one we find currently both in terms of the overall tree cover and in the possible assemblages making up this tree cover. We present the vegetation succession from the time of the initiation of the tank in these palace grounds to the abandonment of this urban space in the overall context of a new explanatory model of the Urban fabric of Angkor Thom developed by combining long term archeological studies with recent excavations and other interdisciplinary approaches to the archeological study of this site.

What and whom is the category of the 'Anthropocene' good for?

Dr. Kyle Nichols [1], ***Dr. Bina Gogineni*** [2]

1. *Skidmore College,* ***2.*** *Independent Scholar*

The Anthropocene debates are rooted in epistemological differences. Geologists seek temporal markers of spatially-even anthropogenic impact. Thus, they favor geologic data that fit this category. Humanists and social scientists, on the other hand, tend to focus on the negative effects of spatial unevenness. Without linking the Anthropocene's temporal and spatial components, the official designation, ultimately determined by geologists, will be a futile exercise that will not make good on the Anthropocene Working Group's intention for it to be useful for wider segments of society. However, if the Anthropocene is divided into an Early, Middle, and Late Anthropocene, each defined by geologic evidence, the uneven spatial distributions of anthropogenic damage can be traced to specific events in human history, thus actualizing the predictive value of geology. Further, this diachronic scheme, unlike the synchronic ones thus far proposed, makes more legible two fundamental dynamics between human and natural trajectories: the intensification of global inequity coterminous with the intensification of natural damage; and humanity's ever more audacious attempts to control the environment. This ethos, wielded as the prime justification for taking over that which belonged to cultures not espousing it, has resulted in anthropogenic damage disproportionately affecting the most economically and historically vulnerable peoples. However, their alternative modes of coping with the damages—an ineluctable responsiveness to, rather than control over, environment—enables them to survive. As such, they could lead the way through the Anthropocene, modeling adaptation and mitigation strategies, and obviating the global North's unsound hope for a technological solution. By expanding the data beyond the stratigraphic, coordinated interdisciplinary research can measure variegated effects of—-and responses to—-the Anthropocene, thus better equipping humanity to adapt to and/or mitigate climate change and to eschew unsustainable practices.

Session 187: Equity, Diversity and Inclusion Initiatives in the Quaternary Sciences

Enabling equitable cultures of knowledge and practice in physical geography and environmental sciences.

Dr. Naomi Holmes [1]***, Dr. Gavin Brown*** [2]***, Dr. Catherine Souch*** [3]***, Prof. Nicola Thomas*** [4]

1. *Department of Natural and Built Environment, Sheffield Hallam University,* ***2.*** *Department of Geography, University of Sheffield,* ***3.*** *Royal Geographical Society,* ***4.*** *Geography, Faculty of Environment, Science and Economy, University of Exeter, UK*

Studying geography and / or environmental science are two of the pathways into the Quaternary Sciences. There is significant under representation within these disciplines with respect to gender, race, class, sexual and gender identity, disability, those with caring responsibilities, social class, and their intersectionalities. The subjects are rooted in colonial cultures of scientific knowledge production and practices, and the relationship between decolonising knowledge production and equality, diversity and inclusion (EDI) challenges is entangled.
Our 'Enabling equitable cultures' project aimed to find out about the EDI challenges UK-based physical geographers and environmental scientists faced through different stages of their career. We focussed on finding out about:

- The lived experience of individuals and allies
- The EDI needs and gaps across institutions
- The positive work in the community (to develop and share good practice)

We worked with an advisory group of geographers from 10 UK higher education institutions to map current EDI work, with EDI consultants, and held focus groups with individuals from 23 institutions in the UK. The areas for discussion in the focus groups arose from a review of the current literature and data, and conversations with the advisory group. The focus groups:

- Examined the experiences of specific groups of staff and students within Geography departments (undergraduates, postgraduate researchers and postdocs, and technicians)
- Explored areas we knew that positive EDI work was happening (decolonising the curriculum, and accessible fieldwork)
- Discussed emerging and overlooked issues (support around neurodiversity, trans and non-binary, and socio-economic class).

Together with a specialist EDI consultant we developed an 'Enabling Equitable Outcomes' maturity matrix for our community to use, alongside a set of online resources, to support departments to reflect on progress and take actions that contribute to greater diversity within the discipline, help to deepen the community's commitment to systemic change, and which will help to build communities of practice around EDI work in Geography and Environmental Sciences.

Communicating geoarchaeology and paleopedology: Experiences with the young Latino community

Mr. Axel Cerón González [1], ***Ms. Thania Garcia*** [1], ***Dr. Elizabeth Solleiro-Rebolledo*** [1], ***Prof. Sergey Sedov*** [2], ***Mr. Jesús Aceves Romero*** [1]

1. *National Autonomous University of Mexico,* ***2.*** *Instituto de Geología, Universidad Nacional Autónoma de México, Mexico City*

The soils serve several functions in the ecosystems and have played as scenarios for human development. Right on, soil scientists and archaeologists have noticed this fact and started interdisciplinary approaches through geoarchaeology and paleopedology. Nevertheless, it implies a certain degree of academic specialization which complicates its dissemination to a wider people. In this way, the Institute of Geology (National Autonomous University of Mexico, UNAM) and Proyecto Suelox have developed infographics, workshops, and podcasts to communicate this knowledge with the Spanish-speaking community. The *Edafografías* project (infographics on soil science) was launched in 2020 as an element of marketing for the Proyecto Suelox educational projects on social media (@psuelox). For 2021, there was a season dedicated to the *Ibero-American Workshop on Paleopedology and Geoarchaeology*. While the online workshop offered lectures on *Soil memory*, *Applied Micromorphology and Micromorphometry, Pre-Quaternary and Pleistocene Paleosols, or Dating techniques in Geoarchaeology*, the infographics were focused on more specific and complementary topics like *Karstic environments, Paleo-fires, or Erosion in archaeological sites*. Both the infographics and workshop impacted 17 countries in the Americas and Europe including non-Spanish-speaking countries such as Brazil, France, and Serbia. Particularly, the main participants of the workshop were young bachelor's students. On the other hand, *Suelófono: the very first podcast on soils in Spanish* is a project supported by the International Union of Soil Sciences with short interviews with senior soil scientists. So far, two seasons have been launched, being episodes like "What is soil?" with Sergey Sedov and "The ancient soils" with Elizabeth Solleiro two of the most listened episodes in more than 20 countries including non-Spanish-speaking regions in Central Europe and the Middle East. We have detected a Hispanic community interested in geoarchaeology and paleopedology in Latin America and beyond, between 23 and 34 years old, with equity conditions in masculine and feminine and minorities of non-defined and non-binary gender identities.

Decolonisation and the Geosciences: challenges and opportunities

Prof. Peter Langdon [1], ***Dr. Chris Prior*** [1], ***Dr. Joe Higgins*** [1], ***Prof. David Sear*** [2], ***Ms. Kimberley James*** [3], ***Ms. Fiona Oakley*** [3], ***Mr. Kiatapu Lopati*** [4], ***Mr. Roger Malcolm*** [5]

1. *University of Southampton,* ***2.*** *School of Geography and Environmental Science, University of Southampton,* ***3.*** *Gilbert Whites Museum,* ***4.*** *Nanumea Island Council,* ***5.*** *The Island Council, Atiu*

Decolonisation is often a difficult term, but one we need to confront within Quaternary Science (and the wider Geosciences), if we want to develop our science to be fully inclusive, and to recognise that indigenous people have agency. At its simplest, decolonisation could be described as looking at things from different perspectives, and then working outwards. In terms of Quaternary science, this could relate to working with indigenous people and involving them in the research, especially as many communities may have oral traditions and/or histories which will likely provide an alternative viewpoint. Many of us may work on sites that are sacred to the local communities, and we should consider carefully how we could incorporate those communities into the research, from first principles to undertaking and reporting the work.

Here we draw on work from two very different projects. The first is work with colleagues from history, focused on trying to uncover the hidden histories within historical texts – to consider how we can read against the grain, and how these alternative views may inform us more broadly. The context is around 'the scramble for Africa' in the mid to late 19th

century, and we will consider how we can apply our learning to elements of Quaternary science, notably around biodiversity and conservation. The second project is focused on reconstructing past climate change from remote Pacific islands using lake or swamp archives. In these islands we have been working with indigenous communities to consider ways to co-produce the research effectively for all concerned. In one low lying Atoll threatened by rising sea levels and droughts, we are remotely supporting local people to undertake the lake coring work to reduce the emissions we make during traditional field work visits. In the second we illustrate how engaging with local communities enriches both the interpretation of the data, but also raises the awareness of the heritage and cultural value of their lake sediment archives.

Broadening Brown v. Board of Education's Impact: Toward Inclusive Pedagogies in Archaeological Research

Dr. Laura Murphy [1]

1. Washburn University

In June 2022, as part of a five-week field school, Washburn University students conducted archaeological field and laboratory work at Brown v. Board of Education National Historical Park in Topeka, Kansas, USA, in collaboration with the Kansas Historical Society and Kansas Anthropological Association. The National Park includes the Monroe Elementary School building - a once segregated African American school attended by Linda Brown who was denied enrollment in the all-white but nearby Sumner School because of her race. In 1951, Linda's father, Oliver Brown, filed a lawsuit against the Topeka Board of Education to end segregation in public schools. On May 17, 1954, the US Supreme Court unanimously declared that "separate educational facilities are inherently unequal." Because of the importance of the Monroe School in the national story about the Civil Rights movement and Black history, excavations sought to answer research questions about the neighborhood prior to the construction of the school and during the school's operation. However, because archaeological research in the US is inherently colonial and predominately white, I sought new strategies to imbed diversity and inclusion into the field school course. As educators we must create anti-colonial and anti-racist curriculum in archaeology in order to break away from traditional work that excludes descendant communities and underrepresented students. Current archaeological pedagogy largely focuses on training students for jobs in cultural resources management or to prepare them for research in graduate school. I will discuss inclusive pedagogies and changes that I made to my field school course design, which included multi-vocal assigned readings, written reflections and discussion prior to fieldwork, daily reflections during fieldwork, and a final project that could be tailored to the needs and interests of each student from their own diverse backgrounds. One learning objective was to have students connect their field findings to both the longer history of the site and to modern concerns in our local Black communities. I will share examples of student work and their feedback on these initiatives. I will also provide strategies for continued community engagement and the importance of BIPOC and Queer voices in archaeological fieldwork and interpretation.

Session 190: Paleosol memory of environmental change and man-landscape interactions: from soil profile to geosystem

The enigmatic fills of Palenque constructions: how they can help to decipher the development of the city

Dr. Elizabeth Solleiro-Rebolledo [1]

1. *National Autonomous University of Mexico*

Palenque, an ancient Maya city (250-900 CE), was constructed on a karstic landscape, derived from folded limestones and sandstones. Some scholars have argued that only the civic-ceremonial core of the city was carefully designed, while the residential areas were lacking planning. We did a geoarchaeological survey to evaluate the differences among the construction materials used during the several phases of the development of the city. We worked in a building of the Group IV and accomplished the work with an off-site sampling. In the building, we recognized several infills corresponding to different construction stages, which are associated to burials. Soils around the city are yellowish sandy, derived from the Cretaceous sandstones. This soil cover has been also found under the building. The common elements observed in the infillings are: high amounts of silt, clay, and organic carbon, ceramic fragments, bones, charcoal, mollusks, and limestone fragments. One remarkable finding was the presence of travertine, extracted from the nearby river. Although these elements were present in all infills, they were in different amounts. Additionally, we observed that infills close to the burials showed pH values higher than 9 and only one (corresponding to the last construction stage) showed a positive reaction to HCl. We considered that these differences and similarities are related to changes in the political and economic conditions which could influence the availability of the construction's materials.

Changes of the environmental conditions of primitive societies in the center of the East European Plain over the last 20 thousand years

Dr. Fatima Kurbanova [1]***, Dr. Evgeniy Konstantinov*** [1]

1. *Institute of Geography, Russian Academy of Sciences*

On the right bank of the Middle Don, near the villages of Kostenki and Borshchevo, there is the largest complex of Upper Paleolithic monuments in Eastern Europe. Active geoarchaeological work aimed at reconstructing the habitat of ancient man has been carried out since the middle of the 20th century. Despite of the large number of paleosol studies of the Kostenki sites, the question of the genesis and evolution of paleosols and the conditions of their formation has not yet been resolved. Soil-sedimentary sequences containing cultural layers are not characterized analytically in sufficient detail, and a wider range of lithological-soil methods should be used.

The purpose of this study is to reconstruct the local natural environment on the territory of the Kostenki-17 archaeological site, from the late Pleistocene to the present. For the first time, for the sediment sequence at the Kostenki-17 site, lithological and soil analyzes were performed with high detailing: samples were taken from the wall of the excavation (with a total depth of 6 m) with a step of 5 cm without interruptions. The following types of analyzes were performed in sampled sediments: elemental composition, C:N ratio, magnetic susceptibility, spectrophotometric characteristics in CIE-L*a*b* system, particle size distribution, radiocarbon dating and hierarchical morphological description. Conducted analysis made it possible to divide the sequence according to the mechanisms of sedimentation, to reveal the participation of slope cryogenic, fluvial, soil biogenic and eolian processes. It was found that in the period earlier ~40 ka formation of sediments mainly occurred due to the filling of small channels of temporary water courses, which formed an alluvial fan. In the period from ~40 to ~20 ka processes of soil formation and solifluction alternated. Starting from ~20 ka the intensity of slope processes decreased, sedimentation occurred to a large extent, due to the eolian dust input. In the Holocene, the surface stabilized, and a full Chernozem profile was formed.

Mineralogical and geochemical records of environmental change in the Takatokwane Saline Pan, Southern Botswana.

Dr. Peter Eze [1], ***Ms. Yvette Matshameko*** [1]

1. *Department of Earth & Environmental Science, Botswana International University of Science and Technology, Private Bag 16, Palapye, Botswana*

Soil-sedimentary sequences were exposed through local clay mining at the Takatokwane saline pan in the Kalahari Basin, southern Botswana. A combination of pedological, geochemical and mineralogical approaches were applied to study the pedosediments with the objective of providing insights into regional environmental change. Standard pedological parameters, such as structure, colour, bulk density, porosity, pH, electrical conductivity, organic matter content, carbonate contents and magnetic properties were determined using routine laboratory procedures. The total elemental composition and clay mineralogy analysis were done using the x-ray fluorescence spectroscopy and x-ray diffractometry respectively. Chemical index of alteration (CIA), chemical index of weathering (CIW) and index of compositional variability (ICV) were used to assess chemical weathering intensities. Molecular pedogenic ratios were used to quantify pedogenesis in the soils. An interplay of both pedological and geological processes shaped the pedostratigraphy of the Pan. The soil colour spanned grey to greenish. Electrical conductivity ranged from 1.92 and 6.45 dS/m. The soil pH ranged from 7.0 to 9.6 with high CEC (< 20 Cmol kg^{-1}). Elemental abundance followed SiO_2

$> Al_2O_3 > Fe_2O_3 > TiO_2$

pattern in two profiles. The clay mineral assemblages are smectite, sepiolite, vermiculite, kaolinite, montmorillonite and illite. Ground water had strong influence on pedogenesis. The degree of weathering of the soils are generally incipient as they had ICV >1 and CIA values < 60. The dominant pedogenic processes in the soils include hydrolysis, lessivage, leaching, eluviation, illuviation and gleization. Given the scares and discontinuous nature of archives for paleoenvironmental reconstruction in the region, finding of this study could be a valuable addition.

Understanding past environmental change in pedo-sedimentary sequences of coastal Sardinia (Italy)

Dr. Guido Stefano Mariani [1] ***, Prof. Kathleen Nicoll*** [2] ***, Prof. Rita Melis*** [3]

1. *Dipartimento di Scienze della Terra, Università degli Studi di Torino, Torino, Italy,* ***2.*** *University of Utah, Salt Lake City, Utah,* ***3.*** *Dipartimento di Scienze Chimiche e Geologiche, Università degli Studi di Cagliari, Cagliari, Italy*

Along the Sardinian coast many sedimentary archives preserve the Quaternary history of this area of the Mediterranean. Sea level change dynamics during the last glacial cycles influenced the geomorphic processes, with a resulting variety of depositional environments and distinct phases of stability and soil formation. We present the preliminary results of an integrated approach focused on descriptive stratigraphic and geoarchaeological investigations and landscape survey on the Southwestern coast of Sardinia. We describe pedo-sedimentary sequences related to stratal architectures that date back to the Late Pleistocene, in order to understand the effect of the main geomorphic processes and of human presence in the evolution of the landscape.

Pleistocene-to-Recent coastal sequences lie on bedrock outcrops of Variscan basement composed of volcaniclastics, metasediments and schists. Locally, these appear intensely weathered and form saprolites, over which Late Neogene sediments have been deposited. Across the region, the basement metamorphic rocks weather quickly into heavy minerals as well as smectites and mixed-layer clays that impart popcorn textures and other shrink-swell attributes to the sediments. Granitic clasts composed of quartz monzonite break down into gruus, and the feldspars slowly degrade into kaolinite. Variously weathered Quaternary deposits attest mainly fluvial and colluvial processes during periods of marine regression. The Quaternary strata include marine beach clastics and carbonate-cemented fossiliferous beachrock as well as terrestrial fluvial, colluvial and aeolian facies. These sequences display various amounts of salt weathering, oxidation, bioturbation and pedogenesis. Rubified debris flow sediments and colluvial deposits are also likely anthropogenic in origin. These sediments preserve included artifacts – modern trash with plastics as well as artifacts from deeper time frames, including pottery, building materials and metal objects.

Soils in this region of Sardinia were originally mapped as Andisols. Careful re-examination of sediments comprising the coastal sequences suggests this is an oversimplification. Work is ongoing to better characterize the variables that influence the styles and rates of erosion and pedogenesis at different locales.

A re-evaluation of the MIS 3 palaeosol record at the Brno-Bohunice site (Czech Republic)

Dr. Katarína Adameková [1], ***Dr. Jan Petřík*** [1]

1. *Masaryk University*

Several important loess sections containing marine isotope stage 3 palaeosols have been discovered in the area of the Czech Republic. Most of them were previously examined mainly from an archaeological point of view in relation to the Middle/Upper Palaeolithic transition, and their palaeopedological records were not studied in detail. The crucial Middle/Upper Palaeolithic transition site has been discovered in Brno-Bohunice. A newly exposed loess section (Brno-Bohunice 2018) and a preserved section from the last archaeological research (Brno-Bohunice 2002) provide an opportunity to revise the Brno-Bohunice palaeosol record. We present a comprehensive multiproxy evaluation of soil development over the period of 60–30 ka BP, based on a combination of soil micromorphology and physical and geochemical proxies. Our study has shown that palaeosol development in the Brno-Bohunice area is more complex than previously assumed. Studied sections include three individual palaeosols, more specifically Cambisol, Tundra gley and Regosol. Cambisol developed most likely in GI 11, the Tundra gley probably in GI 9 and/or GI 8 and the Regosol developed from GI 7 onwards. Palaeosol or palaeosols developed during GI 13 and GI 12 are missing. Microscopic and macroscopic evidence indicates that records were strongly influenced by frost processes. Palaeolithic artefacts from the transition between the Cambisol and Tundra gley were probably lifted by freezing-thawing processes from an earlier position It is likely that even in the first excavated contexts were not necessarily found in their original position.

Calcretes and paleosols on Cozumel Island, Mexico; paleoenvironments implications for the Quaternary

Dr. Daisy Valera-Fernández [1]***, Dr. Elizabeth Solleiro-Rebolledo*** [2]***, Prof. Sergey Sedov*** [3]***, Dr. Rafael López Martínez*** [3]***, Dr. Héctor Víctor Cabadas Báez*** [4]

1. *Instituto de Geofísica, UNAM,* ***2.*** *National Autonomous University of Mexico,* ***3.*** *Instituto de Geología, Universidad Nacional Autónoma de México, Mexico City,* ***4.*** *Facultad de Geografía, Universidad Autónoma del Estado de México*

The calcarenite deposits, red clayey paleosols, and calcrete layers in outcrops of the Island of Cozumel is a record of terrestrial paleoenvironments that provides complementary information to the records studied so far in this region of the Caribbean Sea. Two outcrops were studied, Catera Payo Quarry and Cantera Transversal, and two soil profiles, Aerolito and Chempite, overlie calcrete layers. Micromorphological, physicochemical and mineralogical analyzes of soils and calcretes were carried out. A stable isotope analysis of C and O in calcretes was also performed. The chronological framework was obtained through the correlation of dated calcretes and coral samples from the Yucatán Peninsula, with ages ranging from Marine Isotope Stage (MIS) 7 to MIS 1. The red paleosols exhibited abundant redoximorphic features. The mineralogy of clays in paleosols and modern soils is similar, with vermiculite and minerals from the kaolinite group. We interpret them as the result of moderate weathering under a seasonal tropical climate like present conditions. The level where we find the soils is crowned by a layer of calcrete, whose age probably corresponds to Marine Isotopes Stage (MIS) 6 (164 to 135 ka). This calcrete's stable carbon isotope composition has a mean δ^{13}C value of −10.40 ‰, suggesting the presence of a C3 vegetation cover. During MIS 5, poorly cemented calcarenites accumulated on the island related to sea level rise during this interglacial stage. In the previously mentioned sections, formed in MIS 5 and the transition to MIS 4, there is another laminar calcrete with root traces and an alveolar septal structure. Its δ^{13}C value oscillates between −9.40 ‰ and −10.27 ‰, also related to a C3 vegetation cover. In the period between MIS 4 and MIS 1, karst development and pedogenesis are observed on the island, evidenced by the formation of caves and reddish-brown soils.

Session 193: Indo-Asian Monsoon on decadal to centennial-millennial scale and their link to the Indo- Pacific past climate variability

Impact of Ganga-Brahmaputra-Meghna runoff to the tropical Indian Ocean mixed-layer during the past 42 ka: foraminiferal Mg/Ca and B/Ca ratios and biomarkers (TEX86) approach

Dr. Harunur Rashid [1], ***Mr. Yang Wang*** [1], ***Dr. Min Luo*** [1], ***Prof. CK Shum*** [2]

1. *Shanghai Ocean University,* ***2.*** *The Ohio State University*

Past studies reconstructed the Indian summer monsoon strength using marine and lake sediments, speleothems, etc., mainly focusing either on the upwelling region of the Arabian Sea or Ganga-Brahmaputra-Meghna (GBM) discharge, proximal to the continental margin inundated by the vast seasonal sediment discharge. A few studies reconstructed the Bay of Bengal (BoB) surface hydrology using a single foraminiferal species limiting profiling of the entire mixed-layer. Here, we present seawater oxygen isotopes ($\delta^{18}O_{SW}$) by making paired $\delta^{18}O$ and Mg/Ca measurements in *Trilobatus sacculifer* from a Bay of Bengal core CJ23-02 for the past 42 ka. Concurrently measured Ba/Ca ratios in the same samples were used with the $\delta^{18}O_{SW}$ to assess the GBM runoff. Further, the organic biomarker GDGTs was determined to estimate the water column temperature from the same samples. Our data show a striking temperature difference (ΔT) between the organic and inorganic proxies in which an inverse relationship between the paleo-proxy temperatures from 42.07-33.89 ka and 32.37-20.38 ka was observed. It is hypothesized that the ΔT may have been caused by either seasonality or depth habitats of the temperature recorder reflecting a variation in temperature between the shallow mixed versus deep mixed-layer. The $\delta^{18}O_{SW}$ and Ba/Ca ratios suggest a decrease in the GBM runoff, which might be caused by the weakening of the ISM during late MIS3-MIS2. Two dry HS1 and YD and one wet B/A intervals suggest a weaker and stronger ISM, respectively. In contrast, the speleothem $\delta^{18}O_{SW}$ show an opposite trend during the deglacial period. The divergence in the $\delta^{18}O$ values between the Arabian Sea and the BoB suggests different monsoon dynamics or isotopic fractionation. The highest Ba/Ca ratios and lighter $\delta^{18}O_{sw}$ during the early Holocene indicate an increase in GBM outflow and an intensified ISM. Our data corroborate that the high Ba/Ca ratios in the eastern Arabian Sea during the early Holocene (at 8.75 ka) was an independent event that could be linked to the low salinity Bay of Bengal surface water. The declining trend in Ba/Ca ratios and $\delta^{18}O_{SW}$ suggest a reduction in the GBM runoff, consistent with the northern Indian speleothems' records, during the late Holocene.

A lake-based reconstruction of late Holocene hydroclimate variability in the Garhwal Himalaya, India and links to the Indus Valley Civilization

Prof. David Porinchu [1], *Ms. Emily Niederman* [2], *Prof. Bahadur Kotlia* [3]

1. *University of Georgia,* ***2.*** *Stetson University,* ***3.*** *Centre of Advanced Study in Geology, Kumaun University, Nainital, 263002, Uttarakhand, India*

High-resolution analysis of a 3.80 m sediment core recovered from Deoria Tal, a mid-elevation lake located at 2393 m a.s.l. in the Garhwal Himalaya, documents long-term and abrupt hydroclimate fluctuations in northern India during the mid- to late Holocene. Analysis of lake sediment elemental concentrations, determined using XRF, and sub-fossil chironomid remains, pollen and sediment geochemistry were used to distinguish anomalous hydroclimate conditions during the interval spanning the rise, expansion, and eventual decline of the Indus Valley Civilization (IVC). The IVC was a socially complex, agrarian, and highly urbanized society, with well-developed infrastructure, including extensive sanitation facilities and hydraulic irrigation systems, located in northern India and Pakistan. It has been hypothesized that the stepwise decline and spatial contraction of the IVC was triggered by a severe and extensive drought episode associated with the widely recognized 4.2 ka event. The multi-proxy record presented here identifies major hydroclimate anomalies in the Garhwal Himalaya at 4200 and 3100 cal year BP.

General associations established between specific elements (K, Ti, Rb, Sr, Th) and sediment source and elemental ratios (Mn/Ti, Fe/Mn) and redox conditions suggest that the elevated Fe/Mn, lower Mn/Ti, and increase in allogenic detrital input evident between 4350 and 4200 cal yr BP, together with the shift chironomid assemblages and sediment geochemistry, reflect increasing lake levels and a positive hydroclimate anomaly during this interval. At 4200 cal yr BP an abrupt change, marked by prominent fluctuations in Th, Rb, Ti, Zr, Fe/Mn, and Mn/Ti, is inferred to reflect the onset of lake drawdown and is consistent with the occurrence of a negative hydroclimate anomaly between 4200 and 4050 cal yr BP. An episode of late Holocene peak aridity at ~ 3150 cal yr BP coincides with the timing of the disappearance of Indus culture in northwest India. Notably, this record suggests that the onset of de-urbanization and the deterioration of the Indus civilization at ~ 4200 cal yr BP coincided with largest hydroclimate anomaly evidenced in the Garhwal Himalaya during the last five millennia.

East Asian Monsoon response to abrupt global change during the last glacial period: evidence from the sediments of Lake Suigetsu, Japan.

Ms. Vanessa Nowinski [1], ***Mr. Alexander Francke*** [1], ***Dr. Jonathan Tyler*** [1], ***Mr. John Tibby*** [1], ***Dr. Jack Lacey*** [2], ***Prof. Melanie Leng*** [2], ***Mrs. Megumi Saito-Kato*** [3], ***Dr. Richard Staff*** [4], ***Prof. Takeshi Nakagawa*** [5]

1. *University of Adelaide,* ***2.*** *British Geological Survey,* ***3.*** *National Museum of Nature and Science,* ***4.*** *Scottish Universities Environmental Research Centre,* ***5.*** *Ritsumeikan University*

The East Asian Monsoon (EAM) impacts almost half of the world's population, however it's trajectory for the future remains largely unknown in light of current rapid climate change. This poster presentation will outline project plans and preliminary data with an aim to investigate the underlying mechanisms and long-term contributors to EAM variability. The project focuses on the sediments of Lake Suigetsu, Japan, and the episodes of abrupt global change leading into the last glacial maximum. Building on previous and ongoing research (see Francke et al. and Tyler et al.), this study aims to analyse oxygen isotopes from both biogenic silica and siderite, as well as diatom microfossil species abundances, from Lake Suigetsu's precisely dated varved sediments to reconstruct climate and hydrological change from ~50,000 – 20,000 years before present. In particular, here we will focus on the period of time from ~43,400 – 48,200 years before present, i.e. equivalent to Dansgaard-Oeschger event 12, to explore in detail the interplay between proxies and how they reflect sub-centennial scale teleconnections between Japan and elsewhere around the world. The data will be interrogated in the context of regional climate reconstructions, as well as climate model simulations. By improving the understanding of long-term drivers of the EAM, this study will contribute to improved estimates of future change in the region.

Uncovering Holocene Indo-Pacific linkage changes: proxy and model comparison

Mrs. Isma Abdelkader Di Carlo [1] ***, Dr. Pascale Braconnot*** [1] ***, Prof. Mary Elliot*** [2] ***, Dr. Olivier Marti*** [1]

1. LSCE-IPSL, Laboratoire des Sciences du Climat et de l'Environnement (CEA-CNRS-UVSQ), Paris-Saclay, 2. Laboratoire de Planétologie et Géosciences, UMR 6112, CNRS, Nantes Université, 2 rue de la Houssinière, BP 92208, 44322 Nantes CEDEX 3

The Indo-Pacific is a complex region affected by the El Niño-Southern Oscillation (ENSO), the Asian monsoon, and the Basin (IOB) and Dipole (IOD) modes in the Indian Ocean. Changes in one of these phenomena affect the others. There is still little agreement between future climate projections on how their interaction change under increased anthropogenic CO_2 emissions. To better understand these Indo-Pacific interactions, we focus on the Holocene, which began a little over 10,000 years ago. This allows us to put into perspective on a long time scale the links between changes in variability and changes in the mean state induced by insolation and greenhouse gas forcing. We consider four Holocene transient simulations with state-of-the-art climate models and a collection of paleo-archives in the Indo-Pacific region (planktic foraminifera, corals, and bivalves). Models agree on the long-term variability trends, but differences occur when we focus on finer scales (local sites where paleo-archives are). We analyze how the different simulations compare with the paleoclimate reconstructions and the relative role of temperature and salinity in determining the changes in $\delta^{18}O$ recorded by the various climate archives. We also investigate possible climatic shifts in the Indo-Pacific during the Holocene period.

Reconstruction of density stratification over Bay of Bengal Between LGM and Late Holocene

Mr. Thamizharasan Sakthivel [1], **Dr. Tobias Kluge** [2], **Prof. Prosenjit Ghosh** [3]

1. Centre for Earth Sciences, Divecha Centre for Climate Change, Indian Institute of Science, 2. Geochemistry & Economic Geology, Karlsruhe Institute of Technology, 3. Indian Institute of Science

Changes in density stratification of the Bay of Bengal (BoB) can induce a shift in rainfall patterns over South Asia and affects the socio-economic status of nearly 50% of global population. The instrumental data covering only a few decades from BoB provides conflicting observations on rainfall pattern with varying density stratification at interannual time scales. The demand for understanding the process in the long-term geological record become crucial for better understanding the role of salinity change on the hydrological circulation. In this study, we present the past observation on density stratification of Central BoB (CBoB) during past 25 kiloyears using the combination of conventional high precision IRMS analysis with Laser Absorption Spectroscopy. We apply the newly developed technique of isotope dilution in the analysis of stable oxygen isotope ($\delta^{18}O$) and carbonate clumped isotope (Δ_{47}) composition of surface-dwelling *Globigerinoides sacculifer* (0-25m habitual water depth) and sub-surface dwelling *Neogloboqudrina dutertrei* (50-70m habitual water depth) planktic foraminifera. The $\delta^{18}O$ value of foraminifera is a function of seawater $\delta^{18}O$ at equilibrium and the temperature of the surrounding where the organisms thrive. The evaporation process over the ocean prefers lighter oxygen (^{16}O) in the vapor state as salinity increases and vice versa in the event of precipitation. Our results show a significant correlation between $\delta^{18}O$ in seawater and surface water salinity. In contrast, the carbonate-clumped isotope (Δ_{47}) value is driven by the temperature alone rather than its surrounding fluid. The difference in the Δ_{47} value and the seawater $\delta^{18}O$ for *G.sacculifer* & *N.dutertrei* follow the evolution of temperature and salinity stratification in the BoB, and hence show the density stratification of BoB water during the past 25 kyr. A link between BoB hydrography and South Asian rainfall is suggested by comparing reconstructed BoB density stratification with the available high-resolution record of continental rainfall from multiple proxies.

Stable isotope records of fossil pollen in Lake Suigetsu, Japan, since the last interglacial

Dr. Keitaro Yamada [1]***, Dr. Takayuki Omori*** [2]***, Dr. Ikuko Kitaba*** [1]***, Prof. Takeshi Nakagawa*** [3]

1. *Research Centre for Palaeoclimatology, Ritsumeikan University,* ***2.*** *The University Museum, The University of Tokyo,* ***3.*** *Ritsumeikan University*

Fossil pollen grains are preserved in many terrestrial sediments, often in a large quantity. Their potential as a material for stable isotope analysis have long been recognised (Loader and Hemming, 2004). However, difficulty in extracting fossil pollen grains at high purity was preventing the approach from being implemented for real. The development of a new technology called “flow cytometry” (or “cell sorter”, an instrument that can identify and extract each particle in suspension based on its optical characteristics such as fluorescence) provided us with the possibility (Tennant et al., 2013). Yamada et al. (2021) further improved the method, and finally realised routine extraction of fossil pollen grains at high purity suitable for isotope analyses (Omori et al., submitted).

We applied this new method to the varved sediments from Lake Suigetsu, Japan, and analysed stable isotope ratios of their fossil pollen. The sediments have one of the best age controls of the world supported by >800 radiocarbon determinations and varve counts (Bronk Ramsey et al., 2012; 2020), and thus can be precisely correlated with other palaeoclimate records (Nakagawa et al., 2021). We extracted >0.5 million fossil pollen grains from each target horizon, and submitted the pollen concentrates to pyrolysis mass spectrometry. The oxygen isotope ratios of fossil pollen varied in the range of 15-35‰. Although it is premature to draw any conclusion (at least at the moment of this submission) due to the still insufficient number of data, the fossil pollen isotope ratios of Suigetsu appear to follow roughly the same trends as the Greenland and Hulu Cave records. As the fluctuation range of the fossil pollen oxygen isotope ratio is similar to that of modern cedar pollen collected from across Japan, it is thought that the stable isotope ratios of fossil pollen reflect past environmental changes. Palaeoclimatic information from the terrestrial realms in which humans live can provide a key for investigating interactions among components of the climate system, and the stable isotope ratios of fossil pollen grains has potential to provide such information.

Bottom water oxygenation reconstruction East of Taiwan during the last 19ka based on benthic foraminifera

Dr. Pierrick Fenies [1]***, Dr. Maria-Angela Bassetti*** [1]***, Dr. Natalia VAZQUEZ RIVEIROS*** [2]***, Dr. Nathalie Babonneau*** [3]***, Dr. Gueorgui Ratzov*** [4]***, Dr. Shu-Kun Hsu*** [5]

Heinrich Stadial 1 (HS1, 18.2 – 14.7 ky) is usually associated with a decrease in global marine biological pump efficiency, one of the main reasons put forward to explain the 50 ppm increase in atmospheric CO_2 during this period. However, some recent studies have focused on the marine biological pump behavior at low latitudes during the ice age and have shown intensified primary activity particularly during HS1, making the decrease in the intensity of the marine biological pump unclear in these areas. This study is therefore aimed at constraining the efficiency of the marine biological pump in the subtropical northwestern Philippines Sea since the end of the LGM, a key region reflecting the large reservoir of marine carbon of the low latitudes of the North Pacific.
A multi-proxy study was performed on the sediment core MD18-3523 (EAGER campaign, East of Taiwan, 2972 m water depth), using XRF measurements, benthic foraminifera-related oxygen transfer functions, benthic foraminifera accumulation rates (BFAR) and associated paleo-primary productivity (pPP) and organic carbon flux to the sea floor (Jsf) proxies. The semi-quantitative and qualitative proxies allowed us to reconstruct an increase in oxygenation from the Bølling-Allerød to the Early Holocene that started with suboxic-dysoxic conditions during HS1 and ended in oxic-suboxic conditions during the Holocene. This study highlights the link between the increase in marine primary productivity and the low oxygenation conditions that favored the preservation of organic matter (and carbon) during HS1, suggesting the importance of the local mechanisms in the low-latitude global marine biological pump.

Session 196: Quaternary sedimentary-basins evolution: controlling factors and implications for future scenarios or past reconstructions

Sedimentary processes on shelves of volcanic ocean islands (Santa Maria in Azores archipelago): terrigenous versus carbonate production

Dr. Rui Quartau [1]***, Dr. Sandra Moreira*** [1]***, Dr. Zhongwei Zhao*** [2]***, Dr. Neil Mitchell*** [3]***, Dr. Sérgio Ávila*** [4]***, Dr. Aurora Bizarro*** [1]

1. *Instituto Hidrográfico,* ***2.*** *South China Sea Institute of Oceanology, Chinese Academy of Sciences,* ***3.*** *University of Manchester,* ***4.*** *2CIBIO-Centro de Investigação em Biodiversidade e Recursos Genéticos, InBio Laboratório Associado, Pólo dos Açores*

Cool- and temperate-water carbonate sedimentation in the shallow water realms of continental margins is relatively well documented. However, in volcanic ocean island settings, these carbonate factories are mostly unstudied. Present-day models suggest that in shelves of volcanic ocean islands, sedimentation is mostly restricted to volcaniclastic input, whether from cliff and stream erosion, or from explosive volcanism. However, a sediment-sampling survey around the shelf of Santa Maria Island in the Azores archipelago has shown that we probably need to change this paradigm.

Based on a set of 120 samples collected all around the shelf of Santa Maria Island (20-200m), we have seen a diverse heterozoan accumulation, composed of sand to gravel-sized biogenic skeletal components. These are mainly composed by bivalves, gastropods, echinoderms, bryozoans, foraminifera and polychaetes. Even nearshore (20-50 m), terrigenous particles only account only for 20%-50% of the total sediment. And as we move offshore, to the mid- and -outer shelf (50-200 m), carbonate skeletal particles constitute 80%-100% of the total sediment.

Being Santa Maria an old (~6 Ma) and volcanic inactive, low and dry island, with quite wide shelves (2-8 km), terrigenous input to its shelves is limited. Although wave energy is high in the North Mid-Atlantic, the relatively wide shelves attenuate them and cliff erosion is low. Therefore, in the inner shelf (0-50m), a mixed volcaniclastic- bioclastic sedimentation prevails. Below storm wave base terrigenous sediments seldom reach the middle to outer shelf (50-200m) and carbonate skeletal particles prevails.

Contribution to the knowledge of the marine sedimentary cover of Madeira Island (Portugal)

***Dr. Sandra Moreira* [1], Dr. Rui Quartau [1], Dr. Aurora Bizarro [1], Dr. Joaquim Pombo [1], Dr. Anabela Oliveira [1]**

***1.** Instituto Hidrográfico*

The SEDMAR Program of the Portuguese Hydrographic Institute aims to map the seafloor of the Portuguese margin. Within its scope, in May 2017, multibeam and sediment sampling surveys (down to 2000m deep) were carried out along Madeira Island margin. Twenty-eight surface sediment samples collected along an SW-NE segmented profile were textural and compositional analyzed for characterization of the sedimentary cover of the insular seafloor.

Bathymetric data allowed the identification of the shelf edge, locally placed at 140m deep, and the differentiation of two main geomorphological domains. The later geomorphic feature delimits the shelf, with a low gradient (<8°), from the slope that extends down to the 2000m isobath. The slope is crossed by a channel and several gullies and has a steep surface (>10°) down to ~1650m deep. The lower slope is a slightly inclined ramp (<10°).

The coarse fraction and the mean grain-size of the sediments decrease seawards. Sediments from the shelf have more than 70% of coarse-grained particles and exhibit an average size of 3.5φ-2.7φ (very fine to fine sands), while those deposited along the slope (except in the main channel) tend to have <70% of coarse-grained particles and a mean grain-size between 6.5φ (fine silt) and 3.3φ (very fine sands).

These sediments are mainly constituted by lithoclasts that are, based on the elemental analysis of the non-carbonated component, sourced by the erosion of the outcropping lithologies on Madeira Island. Silicate minerals (pyroxene+plagioclase+olivine) are dominant, while oxide minerals are present in small amounts. Ca-carbonate minerals, associated with the presence of bioclasts, were only detected in sediments collected >120m deep. This is in accordance with the spatial distribution of the Ca-carbonate content that shows a progressive increase along Madeira's shelf up to 18%, whereas in the insular slope its content is variable (14%-48%) without an evident distribution pattern.

Further work will focus on the in-depth study of the analyzed parameters, complemented by the identification and characterization of lithoclastic and bioclastic particles, to establish the morpho-sedimentary sectors and the prevailing deposition conditions in the two geomorphological domains.

Morphotectonic and sedimentary evolution of Quaternary intermontane basins in the Apennines: the Colfiorito case-history (Umbria-Marche Apennines, Central Italy)

Dr. Fabio Silvani [1]***, Prof. Francesco Mirabella*** [1]***, Prof. Laura Melelli*** [1]***, Prof. Massimiliano Rinaldo Barchi*** [1]

1. *Department of Physics and Geology, University of Perugia*

The intermontane basins of the northern Apennines represent the sedimentary record related to extensional tectonics which has displaced the contractional structures since the Early Pleistocene. The Colfiorito basins system belongs to the easternmost alignment of the active normal faults, which is still active today. It consists of seven intermontane tectono-karstic basins in the Umbria-Marche Apennines, developed in a NW-SE direction at altitudes between 750 and 900 m. It therefore represents an excellent study case to understanding the Quaternary morphotectonic evolution of the area, made possible by the detailed geological surveys founded by the CARG project, the revision of the subsurface data (geognostic and geophysical surveys), the analysis of geomorphic features and the characteristics of the sedimentary record. The oldest evidence of this evolution is represented by the remnant land-surfaces disposed today at altitudes up to over 1300 m, testifying the first uplift phase of the Apennine ridge between the Late Miocene and the Pliocene. They are related to morphoclimatic conditions associated with large-scale areal erosional processes. The oldest sedimentary records are associated to the Early and Middle Pleistocene, cropping totally out only in the southern area of Cesi and San Martino, thanks to the current fluvial erosion. In the Colfiorito basin tectonic subsidence has played a predominant role and these units are buried underneath the more recent deposits of the Late Pleistocene. These are divided into large alluvial fans vanishing to the basin surface and thick stratified slope waste deposits, developed in different morphoclimatic and morphodynamic conditions. The sequence is closed by the Holocene deposits, fed by seasonal flooding with a fluvio-karst flow. Limited outcrops of older deposits, referable to the Middle Pleistocene, can be traced in the northern areas only inside the Dignano basin, where they are carved by the Late Pleistocene deposits, or on sub-flat surfaces displaced by the normal faults. Characterized by a NE-dipping stratification with recognisable conjugated structures orientated according to the main one, these faulted deposits revealed the constrain of the main fault bounding the Colfiorito basin to the North-East, postdating his influence in the morphotectonic evolution of the area.

Facies Analyses and Petrography of Volcaniclastic Deposits Associated with Kos-Nisyros-Yali Volcanism on The Bodrum Peninsula (MUĞLA / TÜRKİYE)

Ms. Cennet Ulukavak [1]***, Prof. Cüneyt Akal*** [1]***, Dr. Ökmen Sümer*** [1]***, Dr. Fatma Şişman Tükel*** [2]

1. *Dokuz Eylul University,* ***2.*** *Istanbul University-Cerrahpasa*

The volcaniclastic deposit which is defined at the top of the stratigraphic sequence of the Bodrum peninsula (Mugla/Türkiye) in Western Anatolia, located along the western coastline of the peninsula. The pumice and glass shard- rich deposit which presents ~8 m thickness, is observed 1-1.5 meter below sea level. Base on limited definitions in the previous studies, this sequence is named as the Kos Plateau Tuff of the Quaternary Kos - Nisyros - Yali volcanic activity.

The internal structure of the deposit, which presents variable colors in yellow tones, forms mineral and glass-rich volcanic ash, accretionary lapilli, pumice lapilli and volcanic lithic fragments. The fragments of angular and rounded pumice (up to 26.5 cm long) consist of glass fragments - euhedral quartz – biotite – feldspar – plagioclase – sanidine phenocrysts. The angular volcanic lithics in the composition of trachyandesite – trachyte – andesite reaches a maximum of 17 cm in length. The maximum diameter of accretionary lapilli, identified at each level of the pyroclastic sequence, was measured as ~2 cm. Morphology of accretionary lapilli and glass splinters in volcanic ash present a sharp and plate-like morphology indicating a phreatomagmatic eruption with a vapor (wet) phase. Detailed examinations carried out on a microscopic scale, revealed the presence of shell fragments, carbonization of wood components and highly argillized components in the volcaniclastic deposit.

Isopach and thickness maps were created based on the numerical values of pumice and volcanic lithics, which are the main components of the pyroclastic succession, it has been determined that the grain size increases with distance from the volcanic eruption center. Contrary to normal conditions, it offers grain size, the presence of irregularities in the sequence observed at the field scale and the presence of shell fragments belonging to the seafloor identified at different levels of the volcaniclastic deposit led us to question the existence of a tsunami-like geological event during the last Kos - Nisyros - Yali volcanic activity.

Data from *Homo sapiens* MSA-LSA occupations in Eastern Morocco are well-known from cave and rockshelter sequences (e.g., Ifri n'Ammar, Rhafas, Taforalt). In contrast, open-air settlement dynamics has been little studied so far, and the only data currently available come from disperse and unstratified lithic scatters.
Systematic surveys and archaeological excavations at the Aïn Beni Mathar – Guéfaït basin (Jerada province) have been undertaken during the last sixteen years. Our bilateral Spanish-Moroccan research project has allowed us to discover several stratified open-air localitieswith different archaeological horizons including lithics and faunal remains associated to the Middle Stone Age (MSA) and Late Stone Age (LSA).
These new sites are located in the Sahb el Gahr – Swiwina plain and the Tahya-Oued Za River area, mostly on slopes and exposed surfaces of riverbanks, nearby springs, and always associated with areas rich in biotic and abiotic resources. The palaeoecological reconstruction shows open semidesert environments with vegetation concentrations related to water points and lakes, very similar to the current landscape.
From a technological point of view, the MSA sites are characterized by homogeneous flake assemblages from

Levallois and discoidal knapping strategies but also opportunistic ones. Retouched tools are abundant (mainly denticulates and scrapers), and “Aterian” assemblages with tanged pieces and bifacial foliates have been also documented. The LSA sites show a higher density of lithic remains composed of standardized laminar and flake assemblages showing the typical technological attributes characterizing the Iberomaurusian culture. These assemblages are associated to structured hearths that can be interpreted as domestic areas.
In this paper, we present new data from the systematic excavations of the Sahb el Gahr 1 and 2, Oued Charef and Tahya 3 MSA sites, and from preliminary test pits at Tahya 4 and Ain Tifirassine LSA sites. Moreover, we will introduce our methodology of excavation including a new software developed for computerizing, automating and systematizing field data recording.
These interdisciplinary results provide a novel overview of the MSA-LSA dynamics in open-air contexts, focusing on the subsistence strategies, the mobility across the territory, and the type of occupations depending on the available resources in the area.

The Early Pleistocene in the Lake Garda area

Dr. Giancarlo Scardia [1]***, Dr. Giovanni Monegato*** [2]

1. *Universidade do Estado de São Paulo,* ***2.*** *CNR - IGG*

The reappraisal of well-known Early Pleistocene sites of the Lake Garda area with modern analyses and the study of new drillings allow to improve our knowledge about the Early Pleistocene of Lake Garda area. On the western side, in the Valsabbia sector an ancient lacustrine basin with a regressive succession from fine-grained deposits with travertine to conglomerate at the top has been chronologically constrained to the pre-glacial Matuyama by the occurrence of M. meridionalis (2.5–0.98 Ma) and reverse magnetization. Near Ciliverghe, in the proximal plain SW of Lake Garda, a 30-m deep core with shallow marine deposits provided Reticulofenestra asanoi (1.14–0.91 Ma) and a normal to reverse polarity (bottom to top) referred to the Jaramillo and the late Matuyama, respectively. Stratigraphically above, in the nearby Ciliverghe hill, the core succession is completed by glacial and fluvioglacial deposits, also bearing reverse magnetization. The same polarity is documented in glacial and fluvioglacial deposits also along the Chiese River succession, north of Ciliverghe, and in glaciolacustrine deposits at Salò. At East, reverse polarity has been also retrieved in fluvioglacial deposits at Sirmione. On the whole in the Lake Garda area, as in other basins of the Alps such as Leffe, the pre-glacial Early Pleistocene is documented by long-standing lacustrine basins, which end with a high-energy event ascribable to the onset of major Pleistocene glaciations at 0.9 Ma. The accommodation space required to develop the lacustrine basins is possibly related to local tectonics subsidence. In the plain, the whole Ciliverghe sequence documents that the Lake Garda area passed from shallow marine to braidplain sedimentation when the first major glacier faced at the outlet of the Lake Garda Valley at 0.9 Ma. Remnants of this first Early Pleistocene glaciation, including all typical facies of the glacial depositional system, are sparse along the western sector of Lake Garda because of the recent tectonic uplift this part with respect to the eastern sector. On the eastern side, just a small and isolated outcrop in the Sirmione peninsula documents the transition from a glacial proximal outwash plain to an interglacial braidplain system.

The issue of land subsidence in coastal-alluvial plains: a new approach from the Campania Plain (southern Italy)

Dr. Carla Buffardi [1], *Prof. Alessandro Mandolini* [1], *Prof. Daniela Ruberti* [1]

1. Dipartimento di Ingegneria, Università degli Studi della Campania Luigi Vanvitelli

One of the main causes of the natural subsidence of the alluvial/coastal plains is the poor geomechanics characteristics of the Holocene deposits that filled them, i.e. silt, clay, and peat. The contribution of these sediments to the phenomenon was assessed for the alluvial plain of the Volturno River (southern Italy), which is characterized by medium-high subsidence rates in the order of 15-20 mm/yr. This area benefits of a unique stratigraphic condition that allows a good understanding of the main drivers of subsidence: the Holocene sedimentary sequence is underlined by a continuous stratigraphic marker, the Campanian Grey Tuff (CGT), a volcaniclastic unit vented by a 39 ka Campi Flegrei eruption, from the Tyrrhenian side of the Campania Plain. The sediments above the CGT surface can be classified as fine-grained soil with high compressibility and low strength from a geotechnical point of view. These layers may experience two different types of consolidation: i) primary consolidation, due to a variation of effective stresses; ii) secondary consolidation, the deformation of soil under steady stresses. Moreover, the peaty intercalation and the presence of organic matter led to high values of the coefficient of secondary compression.

The above considerations highlight the importance of providing not just geological modeling but also an accurate geotechnical characterization of the different layers, in order to understand the mechanism behind the variation of the subsidence rates. In the study area, the latter was carried out by processing the CPT tests, and obtaining different geotechnical parameters. Usually, soils like clay, silt, or sand have geotechnical parameters that vary according to the lithology; nevertheless, among the same lithology it is not unusual to observe different behavior. Comparing the Soil Behavior Type Index, Ic, with the different lithologies and the inferred depositional facies, it was highlighted the strong relationship between Ic and the depositional facies. In this way, facies analysis and geotechnical characterization allowed on one hand to highlight the natural causes of subsidence in the Volturno alluvial and coastal plain and, on the other hand, to improve the stratigraphic characterization by using CPT tests.

Stratigraphic and tectonic evolution of two wedge-top basins (Sciacca-Ribera area, south-western Sicily) during the early Pleistocene.

Dr. Alessandro Bonfardeci [1], ***Dr. Maurizio Gasparo Morticelli*** [1], ***Dr. Giuseppe Avellone*** [1], ***Prof. Mauro Agate*** [1], ***Prof. Alessandro Incarbona*** [2], ***Dr. Martina Gennuso*** [1], ***Dr. Cristina Muraro*** [3], ***Prof. Attilio Sulli*** [1]

1. *Dipartimento di Scienze della Terra e del Mare, Università degli Studi di Palermo,* ***2.*** *University of Palermo,* ***3.*** *Italian Geological Survey ISPRA, Rome*

The area comprised between Sciacca, Caltabellotta and Ribera, in the south-western Sicily, represents a very important sector to analyse the late Neogene and Quaternary evolution of the Sicilian foreland-basin-system. In this area, a fragment of the Sicilian Fold and Thrust Belt (FTB) crops out, mainly constituted by south-verging tectonic units of Meso-Cenozoic carbonate and open-shelf clastic successions (Saccense Domain), unconformably covered by middle Miocene to Pleistocene pelagic, clastic and terrigenous deposits. These latter could be considered as wedge-top basin deposits progressively involved in the Sicilian FTB. Near Ribera area late Miocene to Quaternary marine sedimentary successions, belonging to the Gela Thrust System (GTS), crop out and appear to be remarkably affected by the most recent deformation phases of the Sicilian FTB evolution.

Two sedimentary sections (Nadore and Maienza) located in different tectono-stratigraphic setting were analysed using a multidisciplinary approach, through sedimentological, micropaleontological, stratigraphic and structural analyses.

The Nadore section, located north of the Sciacca town, is composed by a succession of about 50-70 m of hemipelagic clayey-marls and turbiditic sandy-silts, evolving to sands and resedimented calcarenites upward. This succession, belonging to the marly-arenaceous Formation of Belice, has been dated to the late Piacenzian-Gelasian interval and appears strongly deformed, indicative of infra- and/or post-Gelasian compressional tectonic pulses.

The Maienza section, instead, located south-east to the Ribera town, is a 50 m thick succession composed by hemipelagic dark gray and brownish marly clays with resedimented quartz, gypsum and reworked planktonic foraminifera, evolving to pelagic and hemipelagic light gray marls, silty clays and calcilutites upward, with a thin sandy-conglomerate level on the top. The evidences collected in this latter stratigraphic record, ascribed to the Monte Narbone Formation (late Pliocene - early Pleistocene), indicate that this basin recorded active tectonic event up to the middle-late Gelasian and by standstill of the tectonics during the Calabrian stage.

Therefore, the target of this work was to compare the depositional and tectonic dynamics of two wedge-top basins during the early Pleistocene, in order to obtain additional information about the recent evolution of the southern Sicilian FTB.

Session 197: How can archaeology, palaeoecology, traditional knowledge, and more-than-human approaches contribute towards a more sustainable and culturally informed future?

Reconstructing Indigenous-managed landscapes through changing climates in southeast Australia

Dr. Michela Mariani [1]***, Dr. Annika Herbert*** [2]***, Dr. Simon Connor*** [3]***, Dr. Janelle Stevenson*** [3]***, Prof. Simon Haberle*** [2]

1. *University of Nottingham,* ***2.*** *ARC Centre of Excellence for Australian Biodiversity and Heritage, School of Culture, History and Language, The Australian National University,* ***3.*** *School of Culture, History and Language, College of Asia and the Pacific, Fellows Rd., The Australian National University, Acton*

In Australia, the recent unprecedented wildfires of 2019-2020 sparked debates around managing fuel loads in a context of climatic warming and increased fire risk. Ethnohistorical evidence suggests that for tens of millennia, Indigenous peoples of Australia practiced cultural burning, which limited understorey woody growth, resulting in less intense wildfires. Therefore, Indigenous cultural burning has been raised as a potential management tool for mitigating against climate-driven catastrophic events. However, one of the barriers to the implementation of cultural burning in southeast Australian is uncertainty around its spatial extent, frequency and impacts on biomass (i.e. fuel loads) prior to colonial settlement in 1788.

The quantification of past land cover is needed to address such debates and fill this important knowledge gap. Pollen is the key proxy to track past vegetation changes, but pollen spectra suffer from some important biases e.g. taphonomy, pollen productivity, dispersal capability. Many pollen records are dominated by pollen from a few high pollen-producing plant taxa, which mask the less producing taxa. In effect, there is a non-linear relationship between pollen percentages and plant cover. Estimating past vegetation cover from sedimentary pollen composition requires to correct for productivity and dispersal biases using empirical-based models of the pollen-vegetation relationship (e.g. REVEALS). Here we present an application of the REVEALS model on multiple pollen records (n=39) throughout the Holocene across southeast Australia.

We provide the first regional quantification of land-cover changes and we link emerging findings to changing climatic conditions and evidence of human activity across the region. We reveal predominantly open landscapes throughout the Holocene, probably characterised by wildfires of lower intensity than present day due to lower fuel loads. Our deep-time data reaffirm Indigenous narratives about cultural burning, highlighting the need to embed these practices for sustainable wildfire management.

Using novel biogeochemical and modelling techniques to reveal the past extent of key Indigenous food plants in southwest Victoria, Australia.

***Mr. Alastair Wills* [1], Mrs. Faidra Katsi [2], Dr. Michela Mariani [1], Prof. Matthew Jones [1], Dr. Matthew Kent [2], Prof. Barry Lomax [2], Dr. Simon Connor [3], Dr. Janelle Stevenson [4], Prof. Peter Kershaw [5]**

***1.** School of Geography, University of Nottingham, University Park, Nottingham, United Kingdom, **2.** School of Bioscience, University of Nottingham, Sutton Bonington Campus, Loughborough, United Kingdom, **3.** School of Culture, History and Language, College of Asia and the Pacific, Fellows Rd., The Australian National University, Acton, **4.** ARC Centre of Excellence for Australian Biodiversity and Heritage, School of Culture, History and Language, The Australian National University, **5.** School of Earth, Atmosphere and the Environment, Monash University, Clayton Campus, Melbourne*

Since the onset of the Holocene, changes to a landscape's vegetational structure have sometimes been indicative of cultural land usages like forestry and agriculture. Modelled pollen-based vegetation reconstructions, using, for instance, the Regional Estimates of Vegetation Abundance from Large Sites model (REVEALS), have quantified regional vegetation compositions and dynamics. REVEALS is commonly used to quantify only the most common taxa, whereas the taxa of cultural importance for Indigenous peoples, including many indicator plants with morphologically cryptic pollen (unidentifiable using traditional visual identification on a biological microscope), currently lack quantified reconstructions.

Here we studied *Microseris,* an Australian Indigenous staple food plant (Cichorioideae subfamily, Asteraceae Family, known to Indigenous peoples as "Murnong"). *Microseris* abundance and spatial extent can indicate complex pre-colonial Indigenous land and food-cultivation practices. Abundant *Microseris* was described anecdotally across southwest Victoria in early colonists' journals, suggesting that it was much more widespread than its modern post-colonial distribution. However, these descriptions may be subject to prejudices and biases in 17th and 18th-century colonial perceptions, requiring modern objective scrutinization. Its suggested widespread occurrence in the past makes *Microseris* an excellent taxon for regional-scale modelling, but hitherto the cryptic morphology of the Cichorioideae subfamily has limited the quantification of species within the subfamily. Here we present a method for the regional quantification of *Microseris*, combining biogeochemical techniques with pollen-based, landscape-level plant reconstruction models.

The chemistry of sub-fossil Cichorioideae pollen, obtained using Fourier-Transform Infrared (FTIR) spectroscopy, has been compared with a modern library of chemical spectra of native Australian Cichorioideae pollen, including *Microseris*. The modern library samples, like the sub-fossils, underwent complete sub-fossil pollen preparation procedures , allowing comparable species-level identification of sub-fossil Cichorioideae pollen. The chemotaxonomic information derived from FTIR will aid in the identification of sub-fossil *Microseris* and allow subfamily modelling using the REVEALS algorithm. *Microseris* reconstructions will help paint a picture of the complex Indigenous-managed foodplant-landscape that may have persisted since the first human settlement of Australia, as far back as 65,000 years ago, which should be considered in the management of the environments where *Microseris* was -and still is- found.

Living Along the River: Human resilience to fluvial environments in Prehispanic and contemporary Central Nicaragua

***Ms. irene torreggiani* [1], *Dr. William J. Harvey* [1], *Mr. Alvaro Laiz* [2], *Dr. Alexander Geurds* [1]**

1. *School of Archaeology, University of Oxford,* ***2.*** *National Geographic Society*

Water is a key element in the interplay between humans and their social and environmental relationships, ultimately shaping landscapes and the movement of people, goods, and ideas. Located along the Central American Dry Corridor, central Nicaragua is highly susceptible to hydroclimatic fluctuations. Currently, droughts and floods are impacting subsistence economies of rural human communities by threatening agricultural activities, damaging infrastructure, forcing migrations, and contributing to the loss of life. This presentation shows a case-study of human resilience to a river valley, through a multi-scalar analysis of archaeological and paleoenvironmental data spanning the last 1,200 years, interpreted in collaboration with local rural communities. The geoarchaeological analysis of the Roberto Amador site (RA), demonstrates the occurrence of floods during its prehispanic occupation (AD 900–1250). Human responses to alluvial events is evidenced by the differentiated use of the site topography and of the alluvial terraces depending on the likelihood of localized flooding. The inundation that affected the site around AD 1250 ultimately likely led to its abandonment, suggesting that the human communities living in the Mayales River Valley (MRV) used adaptive settlement strategies to select, adjust to, and relocate when exposed to major fluvial changes. By comparing the archaeological data from RA to the 1,200 yr paleoclimatic records produced by the authors for central Nicaragua, it is possible to correlate this inundation to regional hydroclimatic developments. We have been documenting the local knowledge on water through interviews, participative observation and outreach activities. This evidenced how modern land-use strategies, combined by climatic change, are highly affecting the water quality and biota of the Mayales River, alongside demonstrating the deep environmental understanding fostered by the MRV rural communities. This study shows that prehispanic adaptation strategies in the MRV were linked to people's detailed understanding of its alluvial landscape and the river's behavior. We argue that archaeological research, combined with local knowledge, could contribute to envisioning a more inclusive approach for planning sustainable water and land-use practices in central Nicaragua.

Pollen and non-pollen palynomorphs (NPP) as a tool to reconstruct local land uses practices during the Medieval and post-Medieval periods: case studies from the Ligurian Appenines, North-Eastern Italy

Dr. Chiara Molinari [1], ***Dr. Bruna Ilde Menozzi*** [1], ***Prof. Anna Maria Stagno*** [2]

1. Università degli Studi di Genova, Dipartimento di Scienze della Terra, dell'Ambiente e della Vita - DISTAV, 2. Università degli Studi di Genova, Dipartimento di Antichità, Filosofia e Storia - DAFIST

Palynological and non-pollen-palynomorphs (NPPs) analyses at several sites located in Trebbia valley, eastern Ligurian Appenines (north-eastern Italy), have been carried out during the last years by the Laboratory of Archaeology and Environmental History (LASA) of Genoa University and more recently in the frame of the research project "ANTIGONE - Archaeology of sharing practices: the material evidence of mountain marginalisation in Europe (18^{th}- 21^{st} century AD)" (ERC Stg 2019).

The main aim was the reconstruction of main vegetation dynamics and the identification of biostratigraphical information about the local management of environmental resources during medieval and postmedieval periods. Thanks to additional information from archaeological and archival sources, as well as from the observation of the present vegetation cover, these studies clarified how different kind of land-use now completely disappeared (woodland management, permanent and temporary "slash-and-burnt" practices, transhumance systems, etc) changed through time, also in relation to the organisation of local social groups and the transformation in the access right to common-lands. Furthermore, it was possible to underline the ecological, cultural and economic consequences of these changes. In particular, based on specific features of palynological diagrams, it was possible to conclude that - compared to the post-cultural phase - all the sites were characterized by: (1) lower pollen percentages of trees; (2) higher pollen amounts of herbs and shrubs, typical of landscapes with a predominance of open areas; (3) higher percentages of anthropogenic pollen indicators; (4) higher values of palynological richness and thus greater biodiversity; (5) higher amount of microcharcoal fragments in most case studies.

Thanks to an interdisciplinary research team (botanists, palaeoecologists, historians and archaeologists), the results of our investigations demonstrate the necessity of a long-term prospective in environmental reconstructions for the preservation of the cultural landscape. This research also represents a contribution to issues of habitat management and nature-conservation policy.

Transdisciplinary investigation of the vulnerability to climate change of Southwest Madagascar

Dr. Estelle Razanatsoa [1], ***Dr. Malika Virah-Sawmy*** [2], ***Prof. Lindsey Gillson*** [3]

1. Plant Conservation Unit, University of Cape Town, South Africa., 2. Geography Department, Humboldt-Universitat zu Berlin,, 3. Plant Conservation Unit, University of Cape Town South Africa.

Climate models have shown that there will be an increased susceptibility to drought in the future for semi-arid regions. Using a vulnerability framework, this paper assesses the vulnerability of the social-ecological systems along the transect of rainfall gradient in southwest (SW) Madagascar through a transdisciplinary approach, that combines palaeoecological data with local ecological knowledge (LEK) from household surveys. We used existing fossil pollen data from the region alongside analysis and review of regional climate records of the last 2000 years to investigate ecosystem vulnerability to changing climate. The pollen records show that in the face of a drying climate, the landscape has been affected differently in the past and will likely become vulnerable to changes when combined with land use changes in the future depending on availability of adaptation options for communities. Wetter sites, in the northern part of the region, were less sensitive to drought possibly due to the availability of water and the heterogeneity of the landscape offering possibilities of livelihood diversification for nearby communities. Drier sites, in the southern part, are more ecologically vulnerable particularly with an increasing land use as these will lead to disappearance of dry-adaptive taxa and degradation of existing biodiversity as reflected at the near present period. Although some of the adaptations to climate change (CC) might be beneficial in the short-term, adaptation such as migration might be detrimental to biodiversity in land-constrained areas where conservation actions are a priority. Improving the resilience of the landscape in drier sites to CC by focusing on plant functional type as well as monitoring land use is urgently needed while focusing on managing land use within the dry forest is necessary to reduce potential vulnerability in the future.

Settling the debate on anthropogenic origins of high-elevation grasslands in the Nilgiris, southern India - implications for ecosystem management

Dr. Prabhakaran Ramya Bala [1], ***Dr. Anupama Krishnamurthy*** [2], ***Mr. Srinivasan Prasad*** [2], ***Prof. Krishnan Sajeev*** [3], ***Prof. Raman Sukumar*** [3]

1. National Institute of Advanced Studies, Bengaluru, 2. French Institute of Pondicherry, 3. Indian Institute of Science

Ecologists have puzzled over the existence of forests *(shola)* and grasslands in close spatial association in the high-elevation Nilgiris for over a century. A number of authors have speculated about the grasslands that seem to be in apparent 'inequilibrium' – either supporting 'natural bi-stable climax' or 'grasslands are sub-climax maintained by humans' (through fires). In an ancient peatland at Sandynallah valley (>50,000 years old), a number of palynological and stable isotope-based paleoecology investigations have established the antiquity of grasslands here, with high numbers of grass pollen observed in peat even as old as 35,000 years. We conducted pollen investigation on a peat-core with high-resolution chronology from the same valley, and see evidence for the continuous dominance of grass pollen (~40% total pollen) from surface to 1.3 m depth (a span of 38,000 years), and at 3.46, 3.57 m depths, beyond the radiocarbon limit (>50,000 years, AMS). Cyperaceae pollen have continuous presence, increasing towards the surface, with the lowest abundance (5%) at the bottom of the profile, indicating beginnings of peatland formation. We see herbaceous pollen taxa that co-exist with grasslands on the slopes throughout, from Gentianaceae, Apiaceae, Ranunculaceae and Valerianaceae families, also indicative of grassland persistence. Although *shola* forest members from dominant family Lauraceae are not preserved in pollen records, we see *Michelia, Olea glandulifera, Glochidion, Daphniphyllum, Rapanea, Ilex, Elaeagnus, Viburnum, Celtis* and *Meliosma* with some of these taxa appearing throughout the profile. In general, arboreal taxa exhibit higher diversity in the Holocene, typical of wetter conditions. We also see swamp flora *Eriocaulon, Xyris, Impatiens, Laurembergia* and *Commelina* and arid markers *Artemisia* and Amaranthaceae/Chenopodiaceae with vegetation dynamics responding to climatic changes. Through these results, similar to other researchers before us, we are able to show dynamic *shola*-grassland vegetation through time, consistent with other global vegetation mosaics. It is important to note that early misunderstanding of these grasslands led to widespread planting of commercial woody species eucalypts, Australian wattle and pines, which together cover >40% of the reserve forest area on the plateau. These and other alien invasive species threaten this ancient grassland ecosystem which has been subject to historical mismanagement.

Stratified landscapes as information pools for sustainable land management: the case of Porto Selvaggio (Nardò, Lecce – Italy).

Regione Puglia (the Region of Apulia), through the *Piano Paesaggistico Territoriale Regionale* (PPTR), has begun to make progress in learning about the human-nature relationship that created the current landscape. Archaeological research had a central role in recognizing the practices that ensured the stability of the territorial resources and the growth of the communities over time. In the landscape we can see the traces and models of the use of stratified territories as tangible and intangible heritage and identify the "Structural Invariants" of the territory that ensures a development balanced between the environment and the needs of the community. Thus, a wrong or partial interpretation of the structural invariants provides inadequate tools of territorial planning.

Considering the Technicity and Territoriality concepts developed by Raffestìn and adopting them in the elaboration of the PPTR, Museo della Preistoria di Nardò (LE) is testing the possibility of reconstructing the cycles of territorialization preserved in the prehistoric sites of the Natural Regional Park "Portoselvaggio-Palude del Capitano" (Nardò-LE) and Salento. In these regions, the richness of Paleolithic sites allows us to cross-check techno-cultural, hydro-geomorphological and paleoenvironmental data and to reconstruct the strategies used by human beings to organize the territory through time.

Indeed, the data from the Paleolithic contexts suggest that those human groups had a broad range of technical and geographical knowledge but with low environmental impact and through it organized the territory systematically. However, the theoretical system that led to the interpretation of the long-term processes and use of the territories in the PPTR has only been able to recognize this ability starting from the Neolithic "Revolution". This understanding results in the exclusion of much of the human history in Apulia and of the past resource management practices. The underestimation of the organizational knowledge of the Paleolithic groups is likely linked to fewer and more subtle traces that characterize the life of nomad groups and possibly to our inclination to attribute greater importance to evidence related to permanency.

Preliminary results of the research indicate the existence of at least five cycles, continued inter-disciplinary studies will allow us to better understand this developmental framework.

Session 204: Late Quaternary Faulting and Earthquake Geology in volcanic areas

Challenges and perspectives of volcano-tectonic studies for the analysis of faulting and earthquakes in active volcanic areas

Dr. Gianluca Norini [1]

1. *CNR Istituto di Geologia Ambientale e Geoingegneria, Milano, Italy*

During the last three decades, much effort has been made in the understanding of the structural evolution of volcanic systems. These studies have been mostly devoted to the analysis of volcano-tectonics interplay, volcanic eruptive and lateral collapse hazard, and exploration of geothermal reservoirs and epithermal ore deposits. Nowadays, an increasing number of works and research projects recognized the importance to study the peculiar behaviour of volcanic systems and volcanic successions also for the analysis of seismic events and coseismic-aseismic surface ruptures.

Regional faults and stress field, contrasting rheology of volcanic successions, basement inherited structures, load of the volcanic pile, and geometry and dynamics of the plumbing and hydrothermal systems have been identified as the main factors conditioning the structural architecture of volcanic systems. These factors play a major role in faulting, migration of the magma toward the surface, opening of eruptive fissures, and volcanic spreading, all of which may generate hazardous seismic activity.

Despite the scientific, economic, and social importance of "Earthquake Geology" studies in volcanic areas, reliable volcano-tectonic and structural models are lacking or incomplete for many of the major active volcanoes worldwide. Also, morpho-structural, structural, neotectonics, geological fieldwork and paleoseismological methodologies (and their integration with geophysical and geodetic analysis) developed in non-volcanic areas may be inadequate when studying volcanic systems, because of the complex interaction among the abovementioned factors. Finally, the large volumes of volcanic products commonly emplaced on volcanoes can cover up partly or completely tectonic and volcanotectonic structures, making the study of surface faulting and ruptures even more difficult.

An overview of complex volcano-tectonic settings and methodologies for their study is presented, with the aim to provide adequate conceptual tools for the analysis, from the "Earthquake Geology" perspective, of ground deformations, faulting, fracturing, opening of eruptive fissures, and gravitational instability of active volcanoes. Future challenges in the understanding of the relations between tectonic and volcano-tectonic Quaternary faults, coseismic and aseismic surface ruptures, magmatic activity and seismic events in volcanic areas, and their importance for civil protection and land use plans, are also discussed.

Multidisciplinary Approach for Capable Fault system study at Ischia Island, northern sector of Mt Epomeo (MACFI project): preliminary results.

***Dr. Rosa Nappi* [1], *Dr. Marta Pischiutta* [2], *Dr. Giuliana Alessio* [1], *Dr. Rosella Nave* [1], *Dr. Argelia Silva Fragoso* [3], *Dr. Gianluca Groppelli* [4], *Dr. Gianluca Norini* [5], *Dr. Vincenzo Sapia* [2], *Dr. Valerio Materni* [2], *Dr. Valeria Siniscalchi* [1], *Dr. Paolo Marco De Martini* [6], *Dr. Stefano Maraio* [7], *Dr. Sabina Porfido* [8], *Prof. Luigina Vezzoli* [3], *Prof. Alessandro Michetti* [9]**

__1.__ Istituto Nazionale di Geofisica e Vulcanologia, Sezione di Napoli Osservatorio Vesuviano, Naples, __2.__ Istituto Nazionale di Geofisica e Vulcanologia, Sezione Roma 2, Rome, __3.__ Università degli Studi dell'Insubria, Como, __4.__ CNR-IGAG, Milano, __5.__ CNR Istituto di Geologia Ambientale e Geoingegneria, Milano, Italy, __6.__ Istituto Nazionale di Geofisica e Vulcanologia (INGV), Roma, __7.__ Istituto Nazionale di Geofisica e Vulcanologia (INGV), __8.__ CNR-ISA INGV OV, __9.__ Università degli Studi dell'Insubria; INGV OV

The study's aim is constraining the source characteristics of the Casamicciola Terme active and capable fault system at Ischia Island for providing a contribution to the local seismic hazard. Ischia is an active volcanic island on the NW side of the Gulf of Naples and belongs to the Campanian volcanic province. On August 21st 2017 a Md 4.0, 1,5 km depth volcanotectonic earthquake reactivated the Casamicciola Terme capable fault. The epicentral location of the relevant earthquake in the last three centuries, in particular the ones of 1796, 1828, 1881, and 1883, are systematically confined within few km^2 in Casamicciola Terme area. Here, a clear stratigraphic and morphological trace is preserved and represented by the graben at the base of the N flank of Mt Epomeo, which formed as the result of Holocene extensional tectonic deformation. The Mt. Epomeo (787 m a.s.l.) uplift is the final stage of the resurgence phase that created the main morphological structure emerging nowadays, with an average rate of ca. 3 cm/yr in the last 30 kyr. The Mt. Epomeo is clearly asymmetric, with a maximum displacement on the N flank linked to an E–W normal fault system where all the significant seismic activity is centered.

The MACFI project consist of a multidisciplinary approach, including:

i) a geophysical survey of the 2017 earthquake epicentral area by 3D Deep Electrical Resistivity Tomography with three ERT profiles across the Casamicciola Terme graben; ii) a drone aerial survey with a LiDAR (Light Detection and Ranging) scanner generating a 5-10 cm resolution DTM, and a radiometric thermal camera areas, for identifying the morphological and thermal signature of faulting and progressive offset along primary surface ruptures along the southern portion of the Holocene graben; iii) the occurrence of directional amplification effects as an effect of the fault activity and rock fracturing at depth.

The combined aerial LiDAR and thermal remote sensing by drone allow to map with unprecedented precision the surface traces of the main and minor faults and fractures along the southern portion of the Holocene graben, and to identify possible correlations with the ascent of geothermal fluids.

Earthquake Environmental Effects on Mt. Etna: ESI-07 scale isoseismals, intensity-attenuation relationships and perspectives for seismic hazard assessment

Dr. Giorgio Tringali [1]***, Dr. Francesca Ferrario*** [1]***, Dr. Domenico Bella*** [2]***, Dr. Franz Livio*** [1]***, Ms. Sofia Brando*** [1]***, Ms. Alice Camarda*** [1]***, Dr. Rosario Pettinato*** [2]***, Prof. Alessandro Michetti*** [3]

1. *Università degli Studi dell'Insubria, Como,* ***2.*** *Studio di Geologia Domenico Bella,* ***3.*** *Università degli Studi dell'Insubria; INGV OV*

Earthquake Environmental Effects (EEEs) are macroseismic data that can be effectively integrated in the evaluation of past seismicity, and to depict possible scenarios of earthquake-induced effects. EEEs are particularly effective in the setting of the Mt. Etna volcano, where seismic events cause extensive surface faulting, typically strictly related with building damage. We analyze a dataset of 53 selected earthquakes occurred on the Etna flanks, since year 1865 to present-day, evaluating their ESI-07 (Environmental Seismic Intensity Scale, 2007) macroseismic field. We collected data directly in the field for the latest two strongest earthquakes (i.e., the Dec. 26, 2018, Mw 4.9, Fleri; and the Oct. 29, 2002, Mw 4.4, Santa Venerina eqs.). The main EEEs found are ascribable to surface faulting and ground breaks, with some minor landslides and drywall collapses, reaching an epicentral intensity between VII and X ESI-07. We compare our ESI-07 intensity results with the macroseismic data measured with the European Macroseismic Scale 1998 (EMS-98) for every earthquake in the dataset. We notice a striking disagreement between ESI-07 and EMS-98 intensity for the latest events (e.g., the 2002 and 2018 events). Furthermore, whereas the ESI-07 intensity for similar earthquakes along the same fault remained constant over time, the EMS-98 intensity has decreased from X to VIII in recent years. We argue that the intensity of the damage-based macroseismic scales might be affected by the new reinforced concrete structures and the introduction of new building codes, resulting in a decrease of EMS-98 intensities for earthquakes occurred in the last decades. The analyzed data allow us to suggest that the ESI-07 scale provides better macroseismic information of earthquakes generated in the Mt. Etna volcano-tectonic environment, where building damage is mainly located along the trace of surface faulting. As already observed at Ischia Island, the ESI-07 scale seems to provide a more time-invariant descriptor of the shallow-focus volcanic earthquakes effects, allowing a consistent comparison of other local seismic events occurred in the last centuries. Combining the ESI-07 scale with the EMS-98 scale can lead to a better description of all the earthquake's effects and as a result a better seismic hazard assessment.

Understanding Holocene fault slip-rates along the Casamicciola Terme graben, Ischia, Italy

Prof. Alessandro Michetti [1], ***Dr. Rosa Nappi*** [2], ***Prof. Luigina Vezzoli*** [3], ***Dr. Giuliana Alessio*** [4], ***Dr. Rosella Nave*** [4], ***Dr. Argelia Silva Fragoso*** [3], ***Dr. Gianluca Groppelli*** [5], ***Dr. Gianluca Norini*** [6], ***Dr. Sabina Porfido*** [7]

1. Università degli Studi dell'Insubria; INGV OV, 2. Istituto Nazionale di Geofisica e Vulcanologia, Sezione di Napoli Osservatorio Vesuviano, Naples, 3. Università degli Studi dell'Insubria, Como, 4. Istituto Nazionale di Geofisica e Vulcanologia, Sezione di Napoli Osservatorio Vesuviano, 5. CNR-IGAG, Milano, 6. CNR Istituto di Geologia Ambientale e Geoingegneria, Milano, Italy, 7. ISA-CNR, Avellino; and INGV OV

We conducted new UAV Lidar mapping, geomorphic, stratigraphic, and structural analyses along the 2 km long, E-trending, Casamicciola Terme Holocene graben, which follow the base of the 800 m high Mt Epomeo range front, in the N part of the Ischia Island, and is regarded as the source of the local damaging seismicity.
We used UAV Lidar DEM at 10 cm resolution in order to map the graben capable normal faults and the sequence of the displaced marine terraces preserved in their footwall and hangingwall. This allow us to identify in detail the primary surface ruptures accompanying the August 21, 2017, Md 4.0 and July 28, 1883, Mw 5.2, earthquakes. We defined a new stratigraphic model of the graben area based on 25 available drilling data calibrated with 2 new stratigraphic boreholes at Piazza Maio and Grande Sentinella sites.
Our new data, and comparison with available radiocarbon dating of the marine terraces along the N coast of Casamicciola and Lacco Ameno, and Ar/Ar dating of the Fundera lava flows, allow to constrain Holocene slip-rates for the synthetic and antithetic faults bounding the epicentral area of the strong 2017, 1883, 1881 and 1828 earthquakes. The S dipping fault at the S border of the Gran Sentinella terrace shows a slip-rate of ca. 6 mm/yr during the Late Holocene. The two parallel synthetic faults at the N-border of the Mt Epomeo slope show a cumulative slip rate of 26 mm/yr. The E-trending, N-dipping faults between Piazza Maio and the Montecito fumaroles represent one of several splays of the master fault responsible for the Holocene uplift of Mt Epomeo; which in turn is the source fault of the strong earthquakes occurred historically in the Casamicciola Terme and Lacco Ameno sector of the Ischia Island.

Evaluation of the earthquake environmental effects produced by the 1920 Xalapa earthquake, through the use of the ESI-07 scale

Mr. Andrés Núñez Meneses [1], *Dr. Pierre Lacan* [1], *Dr. M. Magdalena Velazquez-Bucio* [1]

1. Centro de Geociencias, UNAM, Queretaro

The Trans-Mexican Volcanic Belt (TMVB) is an active continental arc related to the subduction of the Cocos and Rivera tectonic plates under the North American Plate. It is located in the central part of Mexico, where more than 50% of the total population of the country is concentrate. The TMVB is characterize by the presence of different systems of active crustal faults that are responsible for several destructive historical earthquakes, among which the Xalapa earthquake that occurred on January 3, 1920 with a magnitude of 6.4 stands out.

Even though the Xalapa earthquake represents the second deadliest earthquake in the history of Mexico after the 1985 Michoacan earthquake, there is still uncertainty concerning the location of the fault source and discussion about the gradient intensity in the affected area. some works have been carried out based on descriptions of architectural damages using different intensity scales (Cancani and Mercalli). However, the use of these scales is limited by the poor distribution of the population in this area at the earthquake time.

Analysis of historical documents, fieldwork and interviews with chroniclers and inhabitants of the area, associated with the analysis of digital elevation models and aerial photographs led us to obtain a new precise inventory of the location and description of all the architectural and environmental effects caused by the seismic event. In this work, a new isoseismic map is proposed where the epicentral intensity of the earthquake and the macroseismic field are precised, from the evaluation and classification of the earthquake environmental effects (EEE), through the use of the Environmental Scale Intensity ESI-07.

Analysis and 3 D Model of the Seismic Swarm of the Parícutin-Tancítaro Volcanic Region (PTVR) in Michoacán, Mexico 2020.

Prof. Mónica Martínez [1]***, Dr. Diana Soria*** [2]***, Dr. Pedro Corona-Chávez*** [3]***, Mr. Daniel Alberto Gómez-Calderón*** [4]***, Dr. Ángel Gregorio Figueroa Soto*** [5]***, Prof. María Concepción González-Fabian*** [3]

1. *National Institute of Statistics and Geography,* ***2.*** *Laboratory of Palinology, Universidad Michoacana de San Nicolas de Hidalgo,* ***3.*** *Instituto de Investigaciones en Ciencias de la Tierra, Universidad Michoacana de San Nicolás de Hidalgo, 58030, Morelia, Mexico,* ***4.*** *Escuela Nacional de Estudios Superiores unidad Morelia. Universidad Nacional Autónoma de México,* ***5.*** *nstituto de Investigaciones en Ciencias de la Tierra, Universidad Michoacana de San Nicolás de Hidalgo, 58030, Morelia, Mexico*

The geology of the state of Michoacán is characterized by the subduction process of the Cocos Ocean Plate under the North American continental plate along the coastline actively occurs. This geodynamic process constantly generates tectonic activity linked to seismicity and volcanism, on the coasts and interior of the state. In fact, it is no coincidence that two of the most important historical volcanoes in Mexico are located in this area, they are: the Jorullo Volcano (1759-1774) and the Parícutin volcano (1943-1952).

The Parícutin-Tancítaro volcanic region is located at southwest of the Michoacán-Guanajuato volcanic field. In this region, seismic swarms have been recorded in 1997, 1999, 2000, 2006, 2012 and recently in 2020, 2021 and 2022. Our study show a spatiotemporal and statistical analysis of the data of the 2020 swarm and analize the possible correlation with those of the years 2021 and 2022.

We have relied on the data available and geolocated by the Mexican National Seismological Service (SSN, Mexico). The spatial tendency (vertical and horizontal) of the hypocenters was analyzed, as well as their distribution over time, comparing their behavior with the available information of seismic swarm events occurred in the same region.

In this work a 3D model is presented, which allows us to observe the evolution of the seismic swarm at different depths. Seven linear groupings are distributed in a focused manner under the Parícutin-Tancítaro Volcanic Region. The vertical and lateral spatial migrations of the hypocenters suggest the controlled rise of magma forming dikes and sills respectively, with a finite supply of material from a deeper reservoir.

Monitoring underwater volcanic degassing using Exail (iXblue) SeapiX volumetric sonar

Dr. Guillaume Jouve [1], ***Dr. Corentin Caudron*** [2], ***Dr. Guillaume Matte*** [1], ***Dr. Frédéric Mosca*** [1], ***Mr. Tehei Gauthier*** [1], ***Dr. Mario Veloso*** [3]

1. *iXblue sonar systems,* ***2.*** *Laboratoire G-Time (Geochemistry: Tracing with Isotope, Mineral and Element), Université Libre de Bruxelles, Avenue Franklin Roosevelt 50, 1050, Brussels, Belgium,* ***3.*** *GEOMAR Helmholtz Centre for Ocean Research Kiel, Kiel, Germany*

Volcanic gases are a main trigger of explosive eruptions, but the largest amounts are emitted through passive, non-eruptive, degassing during quiescence. It is thus necessary to accurately map bubble clouds, and to monitor their dynamics, to reduce volcanic risks. We present results from near-surface geophysics of sedimentary deposits and water column gas seepage at the Laacher See (Eifel, Germany), using iXblue Echoes high-resolution sub-bottom profiler and Seapix 3D multibeam echosounder. Backscatter profiles of water column elements distinguish gas bubbles and fishes and highlight several bubble plumes. Target Strength (TS) of bubbles is centered around -70 dB, suggesting they are of very small size (35 µm), much smaller than observed elsewhere using single beam echosounders. This would explain why, in the same spot, we did not observe any gas bubbling using camera mounted on ROV. Recent measurements at the nadir of a gas flare, in static positioning, using the steerable mills cross multibeam capability of the SeapiX, offered a 4D observation of the gas bubbling. It also provided an equivalent TS of the bubbling we observed two years earlier. We will also present CO_2 flow rates that were also extracted from backscatter of gas bubbling in 4D. These calculations are currently being constrained using different backscatter models and represent the last technical aspect before developing an efficient early warning system. Meanwhile, Echoes 10 000 provides high-resolution paleoenvironmental reconstruction using 3D modeling of remobilized materials, and gas diffusion through the sediment. Fusion of all geophysical data using Delph Roadmap allows 3D modeling of gas flare dynamic from 40m in sediment to water-atmosphere interface. Our scientific approach contributes to improve forecasting of volcanic and limnic eruptions and participates to improve early warning systems by constant collaborations with academic research.

Session 205: The environment background and human adaptations during the transition or shift from archaic humans to modern humans in East Asia

Environmental change and human adaptations in China between 125 and 30 ka.

Prof. Robin Dennell [1]

1. *the University of Exeter*

The main driver of environmental change between 125ka and 30ka is outcome of the strength of the East Asian monsoonal system versus the Siberian weather system. More specifically, this affects China in three ways: first in North China and the Tibetan Plateau, oscillations between cold, arid or semi-arid conditions and more temperate intervals that opened up corridors for immigration from outside and allowed expansion to the north; second, in South China, variations in the extent of sub-tropical rainforest versus more open woodland which would also have favoured population movements; and thirdly, the distance from the sea off the East China coastal shelf that affected the depth of penetration of monsoonal rain. These three factors combine to produce a complex picture of faunal, floral and population response.

Assessing human adaptations in this period is harder because of the lack of faunal and floral evidence from occupation sites. Nevertheless, we can detect the use of starch plant resource (as in other regions); some evidence of specialised hunting strategies; greater use of hafting and composite tools; and greater curation of lithic resources. In north China, the main adaptations are probably social, and are shown in the development of extensive social networks indicated by a common use of ornaments and ochre over an enormous area covering the Altai Mountains, Transbaikalia, Mongolia and north China. These shared items would have helped sustain viable information, social and mating networks that supported human populations in a hostile and harsh environment.

Environment Conditions Affected Arising and Dispersal of Modern Human in the North China and Mongolian Plateau

Prof. Fahu Chen [1]***, Ms. Zhongwei Shen*** [2]***, Prof. Xin Wang*** [2]***, Dr. Zhenxiu Jia*** [3]***, Prof. Hao Li*** [3]***, Prof. Dongju Zhang*** [2]

1. *State Key Laboratory of Tibetan Plateau Earth System, Environment and Resources, Institute of Tibetan Plateau Research, Chinese Academy of Sciences; College of Earth and Environmental Sciences, Lanzhou University,* ***2.*** *College of Earth and Environmental Sciences, Lanzhou University,* ***3.*** *State Key Laboratory of Tibetan Plateau Earth System, Environment and Resources, Institute of Tibetan Plateau Research, Chinese Academy of Sciences*

Currently, undisputed evidences of modern humans and modern human behaviors from the North China started to appear around 40 ka, while before that, archaic humans with diverse morphological traits and behaviors widely dispersed. During the conversion from archaic humans to modern humans, environment change might have played an important role. However, we still know very little about it. Here we report the results of paleoenvironmental reconstruction from Daihai Lake (a 48-m long continuous sediment core) in the southern Mongolian Plateau, covering the past 80 ka when archaic humans disappeared but modern humans emerged in this region. Based on analyses of *n*-alkanes and hydroxy glycerol dialkyl glycerol tetraethers (OH-GDGTs), two proxies of plant productivity and lake level change, we find that proxies values were very low during 74-50 ka, indicating sparse vegetation in the lake basin and low lake level of Daihai Lake. To check this finding in a wider region, we collect droughty related records from 10 (paleo)lake basins in the North China and southern Mongolian Plateau, and find that most of former lake basins were covered by eolian dune or sand. It was a period of very harsh environment from 74 to ~50 ka for human survival in the wide region, which we thus name as the “Great Gobi-Desert” (GGD) period. Interestingly, the GGD period is simultaneous with very few paleolithic sites in the region comparing before and after, and also the conversion from archaic humans to modern humans. We hypothesize that the harsh environment of the GGD period, may extremely threatened the survival of simultaneous archaic humans, forcing them to move south or shrink to suitable refugia (e.g., Baishiya Cave of the Ganjia basin), leaving a sparsely populated wide region for the upcoming modern humans. After GGD period, environment started to ameliorate gradually, which might have contributed importantly in the flourishing development of modern humans.

Hominin paleoenvironment in East Asia: The Middle Paleolithic Xuchang-Lingjing (China) mammalian evidence

***Dr. Hua Wang* [1], *Prof. Thijs van Kolfschoten* [2], *Prof. Zhanyang Li* [1], *Prof. Haowen Tong* [3]**

***1.** Institute of Cultural Heritage, Shandong Uni, **2.** Faculty of Archaeology, Leiden University, Einsteinweg 2, 2333, CC, the Netherlands, **3.** Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences, Beijing, China*

The Chinese open-air site Xuchang-Lingjing (Henan) is located near the border between the Palearctic and the Oriental biozone in a lowland depression at the southern edge of the North China Plain. The site yielded a Middle Palaeolithic assemblage that includes the two fragmented, incomplete human (possibly Denisovan) skulls (Xuchang 1 and Xuchang 2), more than 15,000 artefacts and more than 40,000 mammalian remains representing at least 20 taxa. The composition of the faunal assemblage is biased by hominin hunting activities; it is, however, diverse and "natural" enough to be used as a proxy to reconstruct the paleoenvironmental condition during the human occupation of the site. The Palearctic faunal assemblage indicates a grassland-dominated palaeoecological environment, with a mosaic of scattered forest and mixed forest vegetation as well as along rivers and/or lakes the occurrence of swampy areas and with bushes. The OSL-dates and the assumed correlation with the last interglacial (MIS 5) palaeosol strongly suggest that we are dealing with an interglacial fauna. However, the fact that the Lingjing assemblage represents the southernmost Palearctic fauna questions the assumption that the Lingjing Middle Palaeolithic finds date from an interglacial period. A late Middle Pleistocene (MIS 6) or Late Pleistocene glacial or stadial phase (MIS 4) seems more likely.

Denisovans from Baishiya Karst Cave on the Tibetan Plateau

Prof. Dongju Zhang [1], ***Prof. Fahu Chen*** [2]

1. *Lanzhou University,* ***2.*** *College of Earth and Environmental Sciences, Lanzhou University; Institute of Tibetan Plateau Research, Chinese Academy of Sciences; Center for Excellence in Tibetan Plateau Earth Sciences, Chinese Academy of Sciences*

In East Asia, mysterious Denisovans so far are only found in Baishiya Karst Cave (BKC) on the Tibetan Plateau. A human mandible found in the 1980's in BKC is confirmed to be from a Denisovan at least 160-thousand-years-old based on paleoproteomic analysis and U-series dating of carbonate crust outside of the fossil, providing the first Denisovan fossil evidence outside of Denisova Cave and the earliest human occupation evidence on the Tibetan Plateau. Subsequent archaeological excavation in BKC reveals that prehistoric human occupied the cave for a long time from the late Middle Pleistocene to the Late Pleistocene. Comprehensive studies of stratigraphy, chronology, archaeology and mitochondrial DNA extracted from the sediments in BKC suggest that Denisovans occupied the cave ~100 thousand and ~60 thousand years ago (ka) and possibly as recently as ~45 ka. Analysis of the rich lithic and faunal remains collected during the excavation shows that simple core and flake technology was mainly used for lithic production and various wild animals, including rhinos (probably wooly rhinos) and hyena, were hunted. Paleoenvironment studies in the site and Ganjia Basin where BKC is located indicate that Denisovans had experienced large environment fluctuations in this high-altitude region. The longterm and intensive occupation of BKC by Denisovans suggests that they may have adapted to life at high altitudes and may have contributed such adaptations to modern humans on the Tibetan Plateau.

Investigations of Middle Palaeolithic Levallois cores from Guanyindong cave in Southwest China

Dr. Yue Hu [1] ***, Prof. Ben Marwick*** [2]

1. *Sichuan University,* ***2.*** *Washington University in Seattle*

The Levallois strategy at Guanyindong cave site dated 170-80 ka exhibits an early Levallois stone-tool technology application in East Asia. Since publication, the finding has caused widely attentions. Meanwhile the validity of Levallois stone-tool technology at Guanyindong also has been questioned. Detailed information and analysis given from the previous paper is limited, here we present analytical descriptions, technological illustrations, and quantitative analysis on prepared core found from Guanyindong. Our investigations further evidence the usage of Levallois concept at Guanyindong cave, indicating diversity knapping sequences during Late Middle Pleistocene in East Asia.

Evolution of vegetation and climate variability on the Tibetan Plateau over the past 1.74 Myr

The Tibetan Plateau exerts a major influence on Asian climate, but its long-term environmental history remains largely unknown. Here, we present the first high-resolution record of vegetation and climate changes over the last 1.74 million years from a lake-sediment core from the Zoige Basin, eastern Tibetan Plateau. Results show three intervals with different orbital- and millennial-scale features superimposed on a stepwise long-term cooling trend. The interval 1.74-1.54 million years ago is characterized by an insolation-dominated mode with a strong ～20,000-year cyclicity and quasi-absent millennial-scale signal. The interval 1.54-0.62 million years ago represents a transitional insolation–ice mode marked by ~20,000-year and ~40,000-year cycles, with superimposed millennial-scale oscillations. The last 620,000 years are characterized by an ice-driven mode with 100,000-year cyclicity and less frequent millennial-scale variability. The most pronounced transition occurred 620,000 years ago, as glacial cycles intensified. These new findings reveal how the interaction of low-latitude insolation and high-latitude ice-volume forcing shaped the evolution of the Tibetan Plateau climate during the Quaternary.

Palaeoproteomics in the Middle and Late Pleistocene: prospects & challenges.

Dr. Frido Welker [1], Ms. Ragnheiður Diljá Ásmundsdóttir [2], Ms. Dorothea Mylopotamitaki [3], Dr. Zandra Fagernäs [1]

1. Globe Institute, University of Copenhagen, Denmark, 2. University of Copenhagen, 3. College de France

The elucidation of the complex evolutionary relationships between Neanderthals, Denisovans, and modern humans has recently revealed a new picture of our own ancestral past. How preceding hominin populations fit into this framework is partly unknown. Such hominins were present across Africa and Eurasia, with large portions of the hominin fossil record outside the reach of ancient DNA research. Palaeoproteomic analysis of skeletal proteomes has recently emerged as a potential additional biomolecular approach across the Pleistocene that reaches much further back in time compared to ancient DNA. As a result, palaeoproteomics could provide molecular evidence on hominin evolutionary relationships on a global scale not reachable via other molecular methods. Based on several case studies and ongoing research of the ERC Project PROSPER, I will discuss and present recent developments in the field of palaeoproteomics that might make it possible to retrieve sufficient quantities of proteomic sequence information from Middle and Late Pleistocene hominin fossils, and how they might play a role in future discourse in human evolution studies.

Improving access to Pleistocene hominin skeletal proteomes

Dr. Zandra Fagernäs [1]***, Ms. Ragnheiður Diljá Ásmundsdóttir*** [2]***, Mr. Gaudry Bruno Troché*** [1]***, Dr. Frido Welker*** [1]

1. *Globe Institute, University of Copenhagen, Denmark,* ***2.*** *University of Copenhagen*

Palaeoproteomic analyses of hominin skeletal materials have in recent years shown tremendous promise in a wide range of areas, such as species identification and studies of evolutionary relationships between taxa, beyond the general preservation limit of ancient DNA. However, ancient proteomes are often severely fragmented and damaged, and few endogenous proteins remain, posing significant challenges to palaeoproteomic analyses of Pleistocene material. Thorough method development and optimization are thereby essential parts of palaeoproteomic research, in order to ensure that the maximum amount of information is gained from each sample, while causing minimal damage to these rare and valuable materials. Here, we present results from testing the effect of digestion enzyme choice on the quantity and coverage of Pleistocene skeletal proteomes. First, we compare several different enzymes that are used for digesting proteomes prior to mass spectrometry, using faunal skeletal material from a range of time periods and preservation environments. Thereafter, we explore the effects of sequential digestion with different proteases, aiming to increase protein sequence coverage. The results from this study will allow researchers in the field of palaeoproteomics to optimize their laboratory protocols, in order to achieve robust and reliable results while minimizing the amount of destructive analyses that are performed.

Middle and Late Pleistocene hominin subsistence and ecology at Baishiya Karst Cave

Ms. Huan Xia **[1]*, Dr. Jian Wang* [1]*, Prof. Fahu Chen* [2]*, Prof. Dongju Zhang* [3]*, Dr. Frido Welker* [4]**

1. *College of Earth and Environmental Sciences, Lanzhou University,* ***2.*** *College of Earth and Environmental Sciences, Lanzhou University; Institute of Tibetan Plateau Research, Chinese Academy of Sciences; Center for Excellence in Tibetan Plateau Earth Sciences, Chinese Academy of Sciences,* ***3.*** *Lanzhou University,* ***4.*** *Globe Institute, University of Copenhagen, Denmark*

In 2010, geneticists reported a new archaic human group- “Denisovans”, by analyzing the mitochondrial and nuclear DNA sequences of a fragment of hominin phalanx from Denisova cave, in the Altai Mountains in Siberia. As a sister group of Neanderthals, Denisovans have attracted widespread attention from researchers in archaeology, paleoanthropology, genetics and other fields. Based on a decade of genomic research, geneticists reveal that Denisovans have contributed DNA to several present-day modern human populations, including East, South and Southeastern Asian populations, as well as aboriginal Americans and Oceanica populations, which implies that Denisovans might have been widely distributed in eastern Eurasia during Middle and Late Pleistocene. Moreover, palaeoanthropological data also support this hypothesis, suggesting Denisovans were capable of adapting to diverse environments, likely from high-latitude Siberia, to the high-altitude Tibetan Plateau, and low-latitude tropical regions of southeast Asia. However, due to limited archaeological evidence, we know little about Denisovan behaviours, including subsistence strategies, across the vast areas they likely occupied. Here, we describe the late Middle to Late Pleistocene faunal assemblage from Baishiya Karst Cave from in the north-eastern Tibetan Plateau (hereafter TP), where a Denisovan mandible and Denisovan sedimentary mtDNA was found, by integrating proteomic screening into traditional zooarchaeological analysis. The results indicate that the faunal assemblage includes a diverse range of animals, including locally extinct animals, species endemic to the Tibetan Plateau, and species common in the Palaearctic realm today. Frequent cut marks and percussion traces indicate that human activities are responsible for the fauna accumulation. Complete usage of acquired animal carcass resources might have helped Denisovans to survive through the last glacial-interglacial cycle on the high altitude Tibetan Plateau. Our results reveal Denisovan subsistence strategies, including behavioural adaptations that allowed archaic hominins to successfully occupy the high-altitude Tibetan Plateau environment.

Luminescence dating of the Sanggan River terraces in the Nihewan Basin, North China

Dr. Xue Rui [1]***, Mr. Bo Li*** [2]***, Dr. Tim Cohen*** [3]***, Prof. Jia-fu Zhang*** [4]

1. *College of Earth Sciences, Jilin University,* ***2.*** *Centre for Archaeological Science, School of Earth, Atmospheric and Life Sciences, University of Wollongong, Wollongong, New South Wales, 2522, Australia,* ***3.*** *Wollongong Isotope Geochronology Laboratory, School of Earth, Atmospheric & Life Sciences. One of the most important regions for early human occupation in East Asia is the Nihewan Basin in North China, which is well-known for an abundance of archaeological sites with ages spanning the last 2 Ma. However, many Paleolithic sites found in the river terraces in the basin are either with no age data (e.g., Huoshigou site), or with controversial ages (e.g., Xibaimaying site). The lack of reliable ages for these sites affects our understanding for the development of the stone-tool technology in the Nihewan Basin. The aim of this research is to study the formation ages and the evolutionary history of the Sanggan River terraces (main river of the Nihewan Basin). Samples from different sedimentary facies of terrace deposits are systematically dated using post-infrared infrared stimulated luminescence techniques. With depositional age of each terrace, a reference geochronological framework is available for these discovered sites, which can be helpful for understanding the development of the stone-tool technology in the Nihewan Basin. The geomorphic evolutionary processes of the Sanggan River are also discussed which have significant implications for the relationship between human occupation and environmental change in Nihewan.

The Trans-Asian Mountain Corridor and Pleistocene Hominin Dispersals

1. *King's College London,* ***2.*** *Department of Geography, King's College London,* ***3.*** *Max Planck Institute for Geoanthropology,* ***4.*** *Department of Earth Sciences, Uppsala University,* ***5.*** *Geography and Environmental Sciences, Northumbria University, Newcastle, UK,* ***6.*** *Institute of Archaeology and Ethnography, Siberian Branch of the Russian Academy of Sciences,* ***7.*** *University of Malta,* ***8.*** *Australian Research Centre for Human Evolution, Griffith University*

Archaeological, fossil and genetic data indicate a rich tapestry of interbreeding between ourselves, Neanderthals and Denisovans in Asia between ~200 and 45 ka, as well as perhaps other, as yet unidentified, hominins. Hominin habitats and ranges were likely highly dynamic, expanding and likely connecting repeatedly during periods with favourable ecologies, and contracting to refugia during (pan-)regional climatic downturns. This has been identified as an important driver of palaeodemography, population evolution, and material culture exchange in regions including Africa and central Asia. However, our understanding of dispersal routes that may have provided such connections, and of refugia in western and northern Asia remains limited. Key questions remain: By what *specific* routes, and at what *specific* times did opportunities exist for hominins to disperse across the vast tracts of south-west and central Asia, and interact? Where and when did refugia exist between such windows of opportunities?

We present a newly identified facilitator of hominin dispersals across northern and western Asia – the 'Trans-Asian Mountain Corridor' (TAMC), a single connected, spatially discrete route that allowed dispersal across Asia, stretching from the Levant and through northern Iran and Central Asia to the Altai. Our analyses indicate this belt of favourable environments exists today and repeatedly offered a suitable migration route, mostly during interglacials, but also some interstadials. The TAMC fractured into refugia during intervening periods, as suggested by both palaeoclimate models and regional environmental records. This repeated waxing and waning of ecological connections between disparate regions may have been a key driver of hominin dispersals, and of population and interspecific concentration into refugia, and thus opportunities to interact. Importantly, some periods when this nearly 5000km long corridor opened coincided spatially and temporally with the distribution of known archaeological markers of dispersal such as the Initial Upper Palaeolithic, and the general spatial pattern of archaeology across western Asia appears to closely relate to its broadly contemporaneous extent. We hypothesise that the TAMC may have functioned as an important pump for human dispersals and interaction, influencing their tempo and pattern. Its dynamics and internal refugia may well have created opportunities for hominin introgression in western Asia.

Chronology and artistic creation of Tibetan hand and foot prints

Prof. David D Zhang [1], ***Dr. Leibin Wang*** [1], ***Dr. Haiwei Zhang*** [2]

1. *School of Geographical Sciences, Guangzhou University, Guangzhou 510006, China,* ***2.*** *Institute of Global Environmental Change, Xi'an Jiaotong University, Xi'an 710054, China*

Discovery of the middle Pleistocene hand- and footprints on Tibetan Plateau has generated great attention as the implication of the finding is so important for the research fields of archaeology, art history, human evolution and palaeo-environmental studies. The key points of the discovery are the date of the imprints were made and whether they can be called as "parietal art". In this report, we systematically provide the dating strategy and design in sampling, dating and stratigraphic analysis for the imprints and reveal the new dates of the imprints. Stratigraphic analysis demonstrates that there were multiples phases of travertine deposition in Quesang hot springs. The stratigraphic analysis, dating results from stratigraphic sequences and geochemical measurements indicate that the imprint-bearing travertine layer is in a "close system'. The dating sampling from the squeezed crests between fingers of a handprint shows that the imprints were made between 207~188 ka B.P. We also provided the dating results from ESR and ITL, which confirm the U-Th dates of the travertine and the reliability of the U-Th dating.

Extensive citations from current research on paleolithic-art validate that the term "Parietal art" is the most suitable term to describe the hand- and footprints discovered on Tibet. Based on the performance of modern artists, the definitions of 'art' from modern and ancient philosophers, estheticians and dictionaries, the evidence extracted from the pressing process, art elements and cognition of the imprints reflect that the imprints are an artistic creation of the hominine on Tibetan Plateau.

Thermoluminescence dating of Quesang Travertines from Tibetan plateau

Dr. Leibin Wang [1], ***Prof. David D Zhang*** [1], ***Dr. Haiwei Zhang*** [2], ***Prof. Hai Cheng*** [3], ***Prof. Chunru Liu*** [4], ***Dr. Shengda Zhang*** [1], ***Dr. Teng Li*** [1], ***Prof. Fahu Chen*** [5]

Travertine is one of the common terrestrial sediments associated with the intensive tectonic and geothermal activity. As a secondary calcite deposits, travertine documents abundant background information of the corresponding period during its formation, including paleoclimate variation, ecological environment, hydrogeological information, seismic activity, and even ancient human activities, etc.. Accurate chronological research of travertine is crucial and fundamental for the archaeological, paleoclimatic and paleoenvironmental applications. To date, plenty of dating approaches have been widely adopted, such as radiocarbon, uranium series, electron spin resonance (ESR) and thermoluminescence (TL). However, the scientific and effective dating method based on the cross-validation of travertine has been rarely discussed. In this research, we explore and evaluate the new thermal luminescence dating methods of travertine at Quesang hot spring in Tibetan Plateau, using the comprehensive methodology of thermoluminescence (TL) of isothoermal TL, MAAD and MAR. The results indicate the Quesang travertine dates to older than 400 ka. Comparison analysis revealed that TL dating method was promising in dating travertine, while ESR dating approach can be applied to travertine as well but with larger error. Other kinds of calcite deposition such as fossil, snail, loess calcite could be conducted in further research. This research provided solid technological reference for the travertine chronological research, as well as scientific basis for the prehistoric "human-land" relationship evolution research in high Tibetan Plateau.

The peopling of the hinterland of the Tibetan Plateau: A late MIS3 blade assemblage at Nwya Devu site

Prof. Xiaoling Zhang [1]***, Ms. Peiqi Zhang*** [2]***, Prof. Shejiang Wang*** [1]***, Prof. Xing Gao*** [1]***, Dr. JUNYI GE*** [1]

1. *Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences, Beijing, China,* ***2.*** *Department of Anthropology, University of California, Davis*

Homo sapiens started venturing up in the high-altitude Tibetan Plateau by the late Marine Isotope Stage 3. Yet, it is still unclear why the late Pleistocene hunter-gatherers expanded into such a harsh environment, where they came from, and how the interactions were between the highlanders and lowlanders. To address some of these questions, we examine lithic assemblages from Nwya Devu, which is an open-air site in the hinterland of the Tibetan Plateau. We analyze the features that characterize the Nwya Devu assemblages, and the results show that it is a generic Upper Paleolithic blade technology. As the earliest blade site lacking antecedents within the highland, it points to a technological association with the blades at Shuidonggou site in North China and in the two regions of the Siberian Altai and North Mongolia in lowlands. Then, we apply a Least Cost Path analysis to model optimal routes from the possible origins of the blade technology to study how human populations would have migrated up to the high-elevation Plateau. We note that there are two possible scenarios to migrate up to the Tibetan Plateau from North Asia: the shorter path cutting through the Gobi Desert; bypassing the Gobi and moving through the margin of it. Shuidonggou site is an important stop connecting the two areas. Overall, the blade technology at Nwya Devu site might have been brought to the Plateau from the Steppe, at a time when early modern humans migrated into East Asia.

Ancient DNA and multimethod dating confirm the late arrival of anatomically modern humans in southern China

Dr. Xuefeng Sun [1]***, Dr. Shaoqing Wen*** [2]***, Prof. Huayu Lu*** [3]***, Prof. Hong-Chun Li*** [4]***, Prof. Hai Cheng*** [5]

1. *1. School of Geography and Ocean Science, Nanjing University, Nanjing 210023,* ***2.*** *Institute of Archaeological Science, Fudan University,* ***3.*** *School of Geography and Ocean Science, Nanjing University,* ***4.*** *National Taiwan University,* ***5.*** *Xi'an Jiaotong University*

The expansion of anatomically modern humans (AMHs)from Africa around ca. 65 to 45 ka led to the establishment of present-day non-African populations. Some paleoanthropologists have argued that fossil discoveries from Huanglong, Zhiren, Luna, and Fuyan caves in southern China indicate one or more prior dispersals, perhaps as early as ca. 120 ka. We investigated the age of the human remains from three of these localities and two additional early AMH sites (Yangjiapo and Sanyou caves, Hubei) by combining ancient DNA analysis with a multimethod geological dating strategy. Although U–Th dating of capping flowstones suggested they lie within the range ca. 168 to 70 ka, analyses of ancient DNA and direct AMS^{14}C dating on human teeth from Fuyan and Yangjiapo caves showed they derive from the Holocene. OSL dating of sediments and AMS^{14}C analysis of mammal teeth and charcoal also demonstrated major discrepancies from the flowstone ages; the difference between them being an order of magnitude or more at most of these localities. Our work highlights the surprisingly complex depositional history recorded at these subtropical caves which involved one or more episodes of erosion and redeposition or intrusion as recently as the late Holocene. In light of our findings, the first appearance datum for AMHs in southern China should probably lie within the timeframe set by molecular data of ca. 50 to 45 ka.

Lithic technology, cultural development, and human interaction: reevaluation of flake tool assemblages in North China during MIS 3

Dr. Wencheng Li [1]

1. *School of History, Captical Normal University*

North China is an essential region for understanding the evolution of hominins and their lithic technological behaviors, especially during the MIS 3 when anatomically modern humans and symbolic behavior emerged. Previous research in this region focused more on indicators of intrusive population such as large blade technology, but the vast areas were still largely occupied by producers of small-sized flake tools. This paper provides a new perspective on flake tool industry in North China to understand the lithic technology, cultural development of local inhabitants and their interaction with neighbors in the far north.

Systematic analysis of flake tool assemblages during MIS 3 North China indicates that local lithic technology in general inherited the “small-sized tool tradition” which was regionally prevalent throughout the Pleistocene, but differences in core reductional methods could be observed compared with earlier sites. On the other hand, MIS3 sites in North China also demonstrated variations in raw material selection and toolkits, which imply high regional diversity in behaviors within the same cultural tradition.

Meanwhile, some new cultural traits, including personal ornament, ochre, formal bone tool, grinding tool, and end-scraper, emerged in North China from ca. 41 ka cal BP gradually and sporadically, indicating there were limited but repeated cultural transmission and human interaction at the northern rimland between the blade and flake tool industries. Evaluation of probability density of radiocarbon dates indicates a near-simultaneous rise in North China and areas farther north since around 42ka, suggesting communication between blades and flake tools was possibly triggered by the population growth of both groups during the same period.

Archaeological occurrences of ostrich eggshell beads in late Pleistocene through early Holocene Mongolia and Northeast Asia

Dr. Arina Khatsenovich [1]***, Dr. Alexey Klementiev*** [2]***, Mr. Alexander Fedorchenko*** [2]***, Mrs. Daria Marchenko*** [2]***, Dr. Dashzeveg Bazargur*** [3]***, Dr. Yadmaa Tserendagva*** [3]***, Dr. Tsedendorj Bolorbat*** [3]***, Dr. Byambaa Gunchinsuren*** [3]***, Dr. John W. Olsen*** [1]***, Dr. Evgeny Rybin*** [2]

1. *School of Anthropology, University of Arizona,* ***2.*** *Institute of Archaeology and Ethnography, Siberian Branch of the Russian Academy of Sciences,* ***3.*** *Institute of Archaeology, Mongolian Academy of Science*

Personal ornaments is considered to be the one of the marker of the *Homo sapiens* cultural suite along with volumetric uni- and bidirectional large blade production, Levallois technological elements, and specific tool types, well-known as Initial Upper Paleolithic. Ring-shaped beads are known from many Initial /Early Upper Paleolithic sites. This shape did not play a pivotal role in IUP artistic fashion in Europe and Siberia, but became a common form in Mongolia and, later, in North China, because the raw material used to fabricate these beads dictated its own terms: this type of bead was made of a specific raw material – ostrich eggshell (OES). The Asian ostrich inhabited the region now defined by modern Mongolia, North China, and southern Siberia from the middle Miocene to the early Holocene (ca. 13.65 ma to 8,900 cal BP). Here, we consider a broad spectrum of prehistoric human-ostrich interactions, reconstructed based on the chronology and regional distribution of ostrich eggshell (OES) beads in Central and Northeast Asia, focusing on Mongolia. This research provides additional paleontological, archaeological, and experimental data on ostrich eggshell bead production, yielding evidence that this type of personal ornamentation could have been manufactured by hand-drilling beginning in the Initial Upper Paleolithic. Ostrich eggshell bead production, along with the use of ochre as a pigment to color beads, is one of a suite of material cultural traits linking the Initial and Early Upper Paleolithic of Mongolia, southern Siberia, and the Transbaikal region. We tackled the complex problem of Asian ostrich eggshell taxonomy using pore measurements taken on OES fragments and beads. Bead-making technology was reconstructed through use-wear analysis and experimental replication. Microscopic examination identified various modes of potential prehistoric bead use ranging from personal ornamentation to clothing decoration. This is the first comprehensive analysis of the appearance and spatio-temporal distribution of OES beads associated with early *Homo sapiens* in the region, as well as the diachronic transmission of a bead-making tradition among later human populations up to the Mesolithic.

Linking cultural and biological evolution dynamics during the Pleistocene. Insights from bone technologies in China

Dr. Luc Doyon [1], ***Ms. Shuwen Ma*** [1]

1. *Institute of Cultural Heritage, Shandong University, Qingdao, China*

The origin and development of bone technology in China are reviewed in the light of recent discoveries and compared to trends emerging from the European and African archaeological records. Three categories of osseous tools are targeted: (1) unmodified bone fragments bearing traces of use in technological activities; (2) bone fragments modified to a variable extent with techniques generally used in stone technologies; (3) osseous fragments entirely shaped with techniques fit for the manufacture of formal bone tools with a high degree of precision. Early evidence of bone technologies in China are sporadically found in contexts dated between 1.8–1.0 Ma and appears to have been introduced in the archaeological record by *Homo erectus* groups dispersing in the region. By the late MIS6–early MIS5, bone tools are well-integrated in the technological systems of Pleistocene populations and the rules guiding their use appear increasingly standardized. In addition, the first evidence for the use of osseous material in symbolic activities emerges in the archaeological record during this period. Finally, between 40–35 ka, new manufacturing techniques and products are introduced in Late Palaeolithic technological systems. It is first apparent in the manufacture of personal ornaments and followed by the production and diversification of formal bone tools. By that time, population dynamics seem to become materialized in different aspects of material culture. Despite regional specificities, the cultural trajectories identified for the evolution of bone technologies in China appear broadly similar to those observed in other regions of the Old World. We argue that prior to the emergence of formal bone tools, it remains difficult, given the current state of our knowledge, to establish links between cultural and biological evolution dynamics. We posit that this limitation may be overcome by investing further efforts in recognizing expedient osseous technologies and investigating how their role in past culturally adaptive systems evolved throughout the Pleistocene.

The complexity and diversity of hominin groups in South China during the Late Pleistocene: An archaeological perspective

Prof. Hao Li [1]

1. *Institute of Tibetan Plateau Research, Chinese Academy of Sciences*

Paleolithic culture in South China has long been regarded as stable and without remarkable changes throughout the Pleistocene time, and this has been often used as evidence to support the regional continuity of human evolution in China, and East Asia as well. However, recent archaeological findings and research are changing this traditional perspective. Here, through analyses of several representative Paleolithic sites that were discovered in the different regions of South China, we aim to demonstrate the existence of complex lithic techno-complexes, along with other advanced behavioral characteristics. In general, the sites of Shanghu and Xiaojia which were found in the Jiangxi Province and were dated to ca. 35-12 ka, yield clearly miniaturized lithic assemblages primarily made on quartz. The site of Sandinggai was found in the Hunan Province and has been dated to ca. 96-13 ka, covering most period of Late Pleistocene. A co-existence of a Large Cutting Tool techno-complex and a small flake and flake tool production system occurred at the Sandinggai site, with the latter playing a more prominent role in the whole lithic assemblage. In addition, the sites of Tianhuadong and Longtan that were located in the Yunnan Province, have been selected for analysis. The age of these two sites has been dated to ca. 95-40 ka. Interestingly, a large quantity of Quina-like scrapers were identified from these two sites. These scrapers were mainly made on thick flake blanks, with scaled retouching scars distributed on either side or transversal edges of the tool. Overall, the analyses of sites from different regions of South China clearly demonstrate the diversified and complicated nature of lithic techno-complexes in the Late Pleistocene South China, which furthermore, provides important evidence for our understanding of the complex relationships among distinct hominin groups lived at that time period.

Climatic Fluctuation and Behavioral Diversity in Late Pleistocene Central China and Surrounding Areas

***Dr. Yue Feng* [1], *Prof. Youping Wang* [1]**

1. School of Archaeology and Museology, Peking University

Global environmental change and the fluctuation of East Asian Monsoon have played an important role in cultural development and human migration during Late Pleistocene. Located in the heartland of East Asia, Central China witnessed a gradual development of local flake tool industry during the warm and humid MIS3, together with the emergence of complex behaviors such as well-organized campsites and symbolic structures. With the arrival of harsh MIS2, bladelet-microblade technology appeared in this region for the first time, which might have been the result of a southward migration of Northeast Asian populations, and microblade technology continued to evolve till the end of Pleistocene.

Recently excavated materials in Chinese frontiers further exhibited several waves of population dispersal and cultural exchange during this time. The discovery of Tongtiandong Cave in Xinjiang, northwest China indicated an eastward expansion of Mousterian industry. In southwest China, archaic hominins carrying Acheulean artifacts have reached the southeast margin of the Tibetan Plateau since late Middle Pleistocene. At Qingtang Site in Guangdong, south China, the presence of small-sized flake tools at the onset of the LGM suggested that subtropical areas possibly have functioned as a refugee for populations used to live in the north, and the following prevalence of Sonvian Culture demonstrated connection with Southeast Asia.

These findings demonstrate that southward migration occurred majorly during glacial periods, while east-west communications became more convenient during warm intervals. Such movements generally involved various populations with very different technological traditions and adaptational strategies, and their behavioral diversity should not be simplified into a single “Out of Africa” event.

Environmental changes since the last interglacial recorded by loess deposits in the eastern Tibetan Plateau

Prof. Shengli Yang [1]***, Ms. Li Liu*** [1]***, Mr. Zixuan Chen*** [1]***, Ms. Pushuang Li*** [1]***, Dr. Qiong Li*** [1]

1. *MOE Key Laboratory of Western China's Environmental Systems, College of Earth and Environmental Sciences, Lanzhou University*

Aeolian loess deposits are widely distributed in arid and semi-arid regions of the world, and provide a valuable terrestrial sedimentary record containing rich paleoenvironmental evolution information. However, little is known about the loess distributed in the eastern Tibetan Plateau (TP), which is valuable paleoenvironmental archives for reconstructing the environmental history related to the Indian summer monsoon (ISM). In this study, we conducted optical stimulated luminescence (OSL) dating and detailed magnetism parameter analysis of the Ganzi loess sequence that developed since the Last Interglacial. Our results are as follows: (a) OSL dating can provide good age constrain for the Ganzi loess since the last interglacial. (b) The pedogenic processes dominated the magnetic enhancement, and magnetic parameters can be used to reconstruct precipitation history. (c) The reconstructed precipitation shows that rainfall in the eastern TP had varied dramatically, and the wettest periods over the last glacial cycle were the later interglacial and the Holocene. High frequency and amplitude variations changes occurred in the MIS3. We infer that the ISM and precipitation in the eastern TP were mainly driven by the combined effect of orbital changes, global ice volume, atmospheric CO_2 concentration, and internal climate forcing on the glacial-interglacial timescale.

Dietary niche reconstruction of Pliocene and Pleistocene Equidae from the Linxia Basin of northwestern China based on stable isotope analysis

Dr. Jiao Ma [1], **Dr. Tao Deng** [2]

1. Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences, Beijing, China, 2. Institute of Vertebrate Paleontology and Paleoanthropology, Chinese Academy of Sciences

In this paper, stable isotope (δ^{13}C, δ^{18}O) analyses of five equid species from the Linxia Basin, northwestern China, were conducted to investigate dietary niche turnover during a critical Pliocene-Pleistocene phase in the evolution of Old World Equidae. In the Early Pliocene Shilidun fauna, *Proboscidipparion pater* is inferred to have mainly fed on C_3
grasses in open grasslands as indicated by their relatively high δ^{13}C values (−9.1± 0.4‰, five teeth, n=61), whereas *Cremohipparion licenti* and

Sivalhippus platyodus were possibly mixed feeders inhabiting woodlands and grasslands because of their comparatively low δ^{13}C values (−10.8± 0.6‰, seven teeth, n=36; −10.6± 0.6‰, nine teeth, n=35). Inhabiting the same environments, both *C. licenti* and *S. platyodus*
went extinct, possibly, because climatic changes led to a decline in woodlands resulting in greater competition. In the Early Pleistocene Longdan fauna, *Proboscidipparion sinense* had higher δ^{13}C values (−9.1± 0.5‰, four teeth, n=23) than coexisting *Equus eisenmannae* (−10.2± 0.5‰, eight teeth, n=57), implying that *P. sinense* had a stronger grazing preference compared to *E. eisenmannae*. Ecomorphological analyses (body size, tooth crown height, and enamel surface complexity) reveal that *P. pater* and *P. sinense* had dental characteristics consistent with a strong grazing preference. Therefore, *P. pater* might have been preadapted to open grasslands during the warm and humid Early Pliocene, which helped its descendent *P. sinense* persist into the Pleistocene. The results of this study reveal distinct dietary niches for these equids for the first time and shed light on some aspects of the evolutionary history of Equidae in East Asia.

Session 207: Not only z-corals: Quaternary reefs across the latitudinal and depth gradients

Not only carbonate frameworks by Mediterranean building organisms: the example of Sabellaria “living rocks”

Prof. Rossana Sanfilippo [1]***, Prof. Adriano Guido*** [2]***, Dr. Claudia Deias*** [3]***, Dr. Mara Cipriani*** [2]***, Prof. Antonietta Rosso*** [1]

1. *Department of Biological Geological and Environmental Science, Catania University,* ***2.*** *Dipartimento di Biologia, Ecologia e Scienze della Terra, Università della Calabria, Rende (CS),* ***3.*** *Department of Biological Geological and Environmental Science, University of Catania*

Relevant biogenic hard structures from the Mediterranean continental shelf include sabellarid, vermetid and coralligenous reefs resulting in complex three-dimensional formations. Either built up by polychaete tube-worms that grow side by side by agglutinating sands, by gastropod shells or intergrowing calcareous red algae, these biogenic structures modify the shape and increase the structural complexity of the seabed on which they develop. Their ecological importance is due to massive settlement and concretion on the bottom, leading to the formation of heterogeneous high porous/vacuolar skeletal frameworks which provide a variety of microhabitats for several organisms (algae, bryozoans, serpulids, foraminifers, sponges) and perform many functions (e.g. sheltered refuges, nursery areas), thus favouring biodiversity.

Among these reefs, vermetid and coralligenous concretions are persistent and solid calcified structures, potentially preservable through time and thus well-known in the fossil record, as they are entirely built by superimposed mineralized skeletons secreted by organisms themselves.

Differently, sabellarid bioconstructions relay on the relevant role of the biocement, an unmineralized glue that agglutinates detrital lithic elements. In fact, gregarious polychaetes of the genus *Sabellaria* (Annelida, Sabellariidae) build their rigid tubes in shallow shelf (mesolittoral to upper infralittoral) by means of secreted proteinaceous adhesives, capturing sand grains by surrounding waters. The still poorly known role and nature of this unmineralized cement, which is the only essential component allowing for the reef formation, is highlighted. The glue shows a bright fluorescence when excited with UV-light confirming its proteinaceous nature and allowing to detect its abundance and distribution in the tube. Glue is distributed in drops and strips and appears as a solid foam with numerous spherical bubbles. The major elements consistently observed in the biocement are C, N, Na, Mg, P, Cl, K and Ca.

Sabellarid bioconstructions can persist for many years but they are highly dynamic structures with cyclical phases of construction and destruction. Contrary to other carbonate Mediterranean bioconstructions and except for a few alleged examples, true sabellarid fossil reefs are still unknown, and due to their feeble fossilization potential, they turn out to be just a mass of sand.

Assessment of coral reef health at Lizard Island (Great Barrier Reef, Australia): benthic communities and foraminifera

Dr. Silvia Spezzaferri **[1]*****, Dr. Elias Samankassou*** **[2]*****, Prof. Daniela Basso*** **[3]*****, Dr. Chiara Pisapia*** **[4]*****, Dr. Stephanie Stainbank*** **[5]*****, Mr. Gioele Pappalardo*** **[2]*****, Mr. Adrien Montillier*** **[2]**

1. *Department of Geosciences, University of Fribourg, Chemin Du Musée 6, 1700, Fribourg,* ***2.*** *Department of Earth Sciences, University of Geneva, Rue des Maraîchers 13, 1205 Geneva,* ***3.*** *milano Bicocca University,* ***4.*** *King Abdullah University of Science and Technology,* ***5.*** *Department of Natural Science, KwaZulu-Natal Museum, 237 Jabu Ndlovu Street, Pietermaritzburg, KwaZulu-Natal, 3201*

Lizard Island represents a classical site for investigating reef ecosystems within the Great Barrier Reef, Australia. In September 2022, we assessed the health status of the island's coral reefs using general observations of benthic communities (e.g., corals, calcareous coralline algae, bacterial mats), relative abundances of benthic foraminifera as well as seawater physicochemical parameters and nutrients. In particular, we applied three foraminiferal-based biotic indices that are widely used to assess coral reef ecosystem health.

The *Amphistegina* Bleaching Index (ABI) is indicative of the degree of photo-inhibitory stress, and with average seawater temperatures around 25°C in September 2022, it showed that this stress was chronic (in term of weeks) and mild or recent and moderate. The on-going investigation of the *FORAM*-Index*, Foraminifera* in Reef Assessment and Monitoring*, (FI) will be used to further evaluate the response of foraminifera and in general of the entire reef ecosystem to potential human impacts (e.g., resort) on the Island. The SEDCON Index, Sediment Constituents, (SI) together with sediment grain size* is indicative of the degree of bioerosion and, together with the FI, will reveal any potential deterioration of the reef environment.

Our current data suggest that, overall, the Lizard Island reefs are in good health and have not noticeably suffered from the temperature-induced bleaching that occurred in 2022. Ongoing research will allow us to further assess the health status of these reefs.

We warmly thank Anne Hogget and Lyle Vail of the Australian Museum's Lizard Island Research Station who helped with the facilities and the Swiss National Science Foundation Grant 200020_201106 for funding this research.

Drowning caught in the act - a mesophotic reef in the Red Sea, Al Wajh, Saudi Arabia

Prof. Hildegard Westphal [1], ***Dr. Fabio Marchese*** [2], ***Ms. Francesca Giovenzana*** [1], ***Dr. Valentina Bracchi*** [3], ***Mrs. Silvia Vimercati*** [2], ***Ms. Ute Langner*** [1], ***Dr. Toshiya Kanamatsu*** [4], ***Prof. Volker Vahrenkamp*** [1], ***Dr. Alexander Petrovic*** [1]

In the geological record, drowning of carbonate platforms is a common feature. It is usually recorded as an unconformity, or as deeper-water or pelagic sediments deposited on top of biogenic shallow-water carbonates in the stratigraphic succession. Drowned carbonate platforms and drowned reefs have been discussed as a paradox in carbonate sedimentology by Schlager (1981), because the accumulation rates of reef ecosystems in most cases exceed the rates of sea-level rise. However, rapid sea-level rises such as those during the last deglacial are well-known to cause drowning. Comparably high rates of sea-level rise are not observed today, so that modern analogues of drowning are rare.

Our study area is located south of the land-attached Al Wajh carbonate platform in the NE Red Sea. It has an elongated shape with 10 km to 4 km in diameter. During a collaborative research cruise between KAUST and JAMSTEC in 2022, the platform was mapped via multibeam, CTD profiles were measured, and sediment samples collected with a Van Veen grab sampler. The southern part is characterized by a thriving shallow water coral reef. The northern part in contrast is submerged in the mesophotic zone, reaching down to 80m water depth. The observed flora and fauna, characterized by abundant red algal crusts and encrusting foraminifera, indicate mesophotic conditions. We interpret this as a transient phenomenon in a rapidly deepening ecosystem where drowning is taking place on a block on the slope of the modern Red Sea, sliding down on plastic Miocene salt.

Mesophotic for-algal nodules: an unexpected bed from the Red Sea

Dr. Valentina Bracchi [1]***, Prof. Sam Purkis*** [2]***, Dr. Fabio Marchese*** [3]***, Mrs. Megan Nolan*** [3]***, Dr. Tullia Isotta Terraneo*** [3]***, Mrs. Silvia Vimercati*** [3]***, Dr. Giovanni Chimienti*** [3]***, Dr. Mattie Rodrigue*** [4]***, Dr. Ameer Eweida*** [5]***, Prof. Francesca Benzoni*** [3]

1. *milano Bicocca University,* **2.** *Department of Marine Geosciences, Rosenstiel School of Marine and Atmospheric Science, University of Miami, Miami, FL, USA,* **3.** *Red Sea Research Center, King Abdullah University of Science and Technology, Thuwal, Saudi Arabia,* **4.** *OceanX, New York, NY, USA,* **5.** *NEOM, Riyadh, Saudi Arabia*

Biogenic carbonate nodules are benthic macroids built by one or more carbonate-producing organisms in approximately concentric layers. They are common constituents of modern mesophotic marine environments, where they form can form extensive beds on the seafloor (e.g. rhodolith beds), which represent an important component of the sea-environment resources, as they promote and support high biological diversity.

In the Red Sea, rhodoliths, both from shallow (Egypt, Saudi Arabia) and mesophotic (Sudan) environments, have been already reported in literature.

In the framework of the northern Saudi Arabian Red Sea (NEOM) giga-project for the exploration of the mesophotic and deep ecosystem of the Red Sea, the scientific surveys and the study of collected samples led to the discovery of free-living mesophotic Foraminiferal-Algal Nodules (FANs) along the coast of the NEOM region. Although an active foralgal factory was already describe from Sudan, where stable build-ups characterized the seafloor, FANs have been never described so far from the Red Sea. FANs aggregate into beds and form a distinct mesophotic benthic ecosystem occupying ~ 6 km^2 and covering ~ 10% of the continental shelf between 60 and 130 m of water depth.

Their coverage ranges between 25% and 100% of the seafloor, and their abundance ranges between 50 and 287 nodules *per* m^2. Radiometric dating informs that FANs can be more than two thousand years old and that they contribute up to 77 g m^2 $year^{-1}$ to the mesophotic benthic carbonate budget and accumulate at least 8937744.8 tons of CaCO3.

The temporal dynamic of these FANs is interesting. The FANs occur on flat or gently seafloor at the external limit of the continental shelf, which can end abruptly. We observe that FANs sometimes fall off the edge towards the deeper parts of the slope, where they eventually accumulate on finer sediment and presumably stop accreting. The nodules therefore represent a transport mechanism for carbonate formed on the shelf into the deep sea.

Our finding are similar to FANs record from Japan, although here there they do not form an extensive habitat as the one described from the Red Sea.

The physical basis for the occurrence of mesophotic reefs in the northern Mediterranean Sea (Adriatic coast)

Some mesophotic bioconstructions and reefs has been recently discovered along the Apulian coast in the southern Adriatic Sea (northern Mediterranean). In this work, the first mesophotic coral reef reported in the Mediterranean area and some massive mesophotic oyster bioconstructions have been analysed with special reference to their physical constrains. A multidisciplinary (geo-ecological) and multiscale (seismic lines, sub-bottom profiler, multibeam, side-scan-sonar, video and meso-micro analysis on samples) approach has been adopted. A laterally continuous set of bioconstructions has been recognized at 35-75 m of water depth along a E-W oriented slope in the central sector of the Apulia shelf. They form a mesophotic system (Coral Reef Facies and Oyster Reef Facies) which gradually passes to a ubiquitous Coralligenous Facies in the shallower and flat portions of the shelf. The transition between Coral and Oyster Reef Facies is placed around 60 m of water depth, the well-known global community break of mesophotic coral reefs. The origin of the E-W oriented slope (transversal to the coastline) is tectonic and corresponds to the northern sector of the Monte Giove submarine relief. Here, a N-dipping transtensional fault, resulting from the reactivation of an inherited normal fault, strikes from the coastline to the eastern shelf sectors for about 25 km. The interaction between this E-W-striking fault and the S-directed circulation of cold and dense water currents induces the formation of upwelling processes which are responsible for the massive presence of mesophotic bioconstructions and reefs in this sector of the northern Mediterranean Sea.

The Holocene development of the Mediterranean algal reef Coralligenous

Several types of biogenic reefs, build-ups and mounds are represented in the Quaternary of the Mediterranean, responding to the complex interplay of geological and environmental controls with a diverse set of habitats, architectures and components. The most important reef of the Mediterranean is the Coralligène (Coralligenous = C), including several types of calcareous algal-invertebrate frameworks growing in normal open marine conditions. The Mediterranean C is an Open Frame Reef, characterized by the variable association of calcareous red algae, bryozoans, annelids, bivalves, and corals. Although the living surface of C have been subject of numerous studies, the processes and the components controlling its development are still poorly known. The Italian project FISR "CRESCIBLUREEF" provided an extraordinary opportunity to explore the development of the Mediterranean C, from inception to present-day morphology and distribution, off the SE coasts of Sicily. Our analyses and the comparison with previous studies on the Ligurian C yielded some results that are relevant both for our understanding of the Quaternary dynamics of the Mediterranean shelf environments and for the present-day management of this unique habitat. Below the depth limit of distribution of the *Posidonia* meadows, the spatial extension of the C hybrid banks over the studied Sicilian shelf controls the hydrodynamics at the seafloor, the carbonate production at the shelf scale, and the biodiversity. The analyzed C are Holocene in age and their development generated a significant change in the seafloor geomorphology. The most part of the framework is invariably built by calcareous red algae, despite the variable occurrence of scleractinians and octocorals on the living surface. The rapid dissolution of the cnidarian remains after death could explain their negligible contribution to the framework, that is very porous, with primary cavities derived from the mode of growth, shape and structure of the skeletonised builders and dwellers. An important secondary porosity derives from bioerosion and other taphonomic processes involving both skeletonised and soft-bodied organisms. A contribution to the construction of the framework is provided also by autochthonous and detrital micrite, with an important role of organic mediation played by sponges for the mineralization of the autochthonous fraction.

Role of bryozoans and serpulids in the present-day Coralligenous off Marzamemi (Sicily)

Coralligenous is a Mediterranean habitat typically developed in shelf settings and known to host a dramatic species richness owing to its structural heterogeneity. Consisting of a plethora of different facies, Coralligenous is characterized by the occurrence/dominance of different types of organisms.
However, accretion of such bioconstructions and their preservation in the fossil register relay on the occurrence of sessile skeletonized organisms, especially coralline algae that form a three-dimensional framework. A restricted number of invertebrates actively participate to construct these biogenic structures acting as subordinate builders, binders and dwellers with their skeletons cemented to each other. Molluscs, foraminifera and barnacles can occur but bryozoans and serpulids usually play a major role encrusting outer exposed surfaces as well as cavities and crevices resulting from the irregular algal convolutions.
The role of these two last groups was investigated in the frame of the FISR project CRESCIBLUREEF focusing on Mediterranean coralligenous bioconstructions developing offshore Marzamemi (Sicily, Ionian Sea) between ca. 30 and 100 metres.
Accounting for less than 5% at both the outer surface and internal sections, bryozoans and serpulids are subordinate in the bioconstructions, but highly diversified. About 140 and 40 species have been identified, respectively. Out of them, 75 bryozoans and 35 serpulids actively contribute to the concretion with different carbonate amounts, depending upon their abundances and the sizes of their colonies and specimens, respectively. Some bryozoan species acting as bafflers during life have either uncalcified or lightly calcified colonies that rapidly decay after death. However, many species developing branching colonies of jointed articles that are attached to the biogenic structure by organic rootlets can be at least partly preserved within crevices together with species (either bryozoans or serpulids) encrusting secondary soft substrata, mostly algae and sponges. Their remains partly fill cavities helping to strengthen the bioconstruction.

Temporal and spatial variability of Mediterranean cold-water coral mound development during the last 400 kyrs

Scleractinian cold-water coral reefs are considered to be key hotspots of benthic biodiversity in the deep ocean. Due to their relevant ecological role and susceptibility to anthropogenic disturbances protection and conservation measures have been applied to these habitats, even though they are far from being completely understood. When coral reefs are under persistent suitable environmental conditions and have a sufficient sediment input, they can develop and form large geomorphic structures known as coral mounds. The latter are sensitive to changes in climate and capable of recording such variations in the chemical composition of the coral skeletons. Prior to this study, coral mound formation data in the Mediterranean was limited to the Alboran Sea and to the last 15 kyr, due to the lack of gravity cores encompassing longer periods of time. A wide range of techniques, including U-Th dating, computed tomography and geochemical analyses were applied to acquire a better understanding of the spatiotemporal distribution of Mediterranean cold-water coral reefs and the processes controlling their evolution into mounds during the last 400 kyr. More precisely, the present study aimed to explore which are the main environmental variables and paleoclimatic events that have controlled coral mound formation in the Cabliers Coral Mound Province and the newly discovered Tunisian Coral Mound Province. In regards to coral mound formation, this work has expanded the current knowledge outside the Alboran Sea and back to 400 ka BP. Almost opposite development patterns were observed between the Cabliers and Tunisian coral mound provinces, with the former mainly developing throughout deglaciations and temperate interstadial periods and the latter during glacial periods. Nonetheless, both provinces seem to depend on a high surface productivity and an appropriate depth of the interface between Atlantic and Levantine Intermediate Waters for the coral mounds to develop. Lastly, the oceanographic alterations caused in the Eastern Mediterranean Basin during Sapropel events also seem to have had detrimental effects for coral mound formation in the Western basin.

Session 208:
Achievements and new perspectives in Quaternary sciences from scientific drilling

Drilling Overdeepened Alpine Valleys (ICDP-DOVE): Quantifying the age, extent and environmental impact of Alpine glaciations

The sedimentary infill of glacially overdeepened valleys and basins is an excellent but yet poorly investigated archive with regard to reconstructing the age, extent, and nature of past glaciations. The already available geological information and infrastructure make the Alps an ideal area to study overdeepened structures. The International Continental Scientific Drilling Program (ICDP) project DOVE investigates a series of drill cores from formerly glacially overdeepened troughs at several locations around the Alps. All sites will be investigated with regard to environmental dynamics during the Quaternary, with focus on the glaciation, vegetation, and landscape history. Geophysical methods will explore the geometry of overdeepened structures to better understand the process of overdeepening. Sedimentological analyses combined with downhole logging, analysis of biological remains, and geochronological methods will enable us to reconstruct the erosion and sedimentation history of the overdeepened troughs. This approach will yield data quantifying the extent and timing of Middle and Late Pleistocene glaciations of the Alps. In a first phase, two sites have been drilled in late 2021 into filled overdeepenings below the past lobe of the Rhine Glacier in Switzerland and Germany, and both recovered a trough filling composed of multiphase glacial sequences. These two sites are complemented by three legacy drill sites that previously recovered filled overdeepenings below the eastern Alpine Isar-Loisach, Salzach and Traun palaeoglacier areas (Germany and Austria). All analysis and interpretations of this DOVE Phase-1 will eventually lay the ground for an upcoming DOVE Phase-2 that will complete the panalpine approach. This follow-up phase will investigate overdeepenings and their connected forelands and foredeeps in the formerly ice-covered areas from the western and southern Alpine margins through drilling sites in France, Italy, and Slovenia.

New insights into Quaternary overdeepened structures from near-surface seismic reflections – results from the ICDP-project 'Drilling Overdeepened Alpine Valleys'

The sedimentary infill of glacially overdeepened valleys is one of the best-preserved (but yet underexplored) direct archives of the extent of past glaciations in and around mountain ranges. The ICDP project "Drilling Overdeepened Alpine Valleys" Phase-1 investigates drill cores from glacially overdeepened structures at five complementing locations along the northern front of the Alps and their foreland. Two of the drill sites, Tannwald (D; ICDP site 5068_1) and Basadingen (CH; 5068_2), both in the catchment area of the former Rhine glacier, were intensively investigated by pre-site reflection seismic surveys. Despite an extensive seismic survey, another inner-alpine location, Lienz (A), will not be drilled.

The reflection seismic surveys comprise classical 2D P-wave and innovative multi-component surveys; for Tannwald, even 3D P- and S-wave data were acquired. As seismic sources, hydraulic and electrodynamic vibratory sources were deployed, which have been specially developed for investigations down to a depth of several 100 metres. The different examples clearly demonstrate the potential of the methods to reveal detailed information about the shape and physical properties of the valleys and their sedimentary fill. Even for the more than 600 m deep Lienz Basin, the data allows to distinguish the various deposits in fine detail, such as slumping, fan delta deposits, and a modified monocline on the basin flank. For Basadingen, we interpreted a rather complex basin structure that is confirmed by the first results of the research drilling. The combination of P-wave and multi-component data in the Tannwald Basin provides complementary information and, thus, allows imaging details of structures that cannot be seen from one dataset alone. The 2D seismic lines were interpreted in terms of seismic stratigraphy and contributed much to the final decisions about the drill sites. Especially the 3D surveys in the Tannwald Basin clearly show glacial tectonics, namely a hitherto never recognized cuspate-lobate folding of the glacial sediments, which was not evident in the 2D data.

The presentation will focus on the potential of near-surface reflection seismic surveys for the investigation of Quaternary structures, especially glacially-overdeepened structures. For each of the three locations, highlights of the interpretations will be discussed.

Reinvestigation of a 880-m-long Pleistocene drill core record from the Eastern Alps (Austria)

The first phase of the pan-alpine ICDP project DOVE (Drilling Overdeepened Alpine Valleys) investigates five drill cores from overdeepened valleys along the northern side of the Alps and their foreland as their sedimentary infill provides an excellent archive of the timing and extent of past glaciations. One of the investigated sites (ICDP-5068-5) is located near Bad Aussee (Austria), in the central part of the Northern Calcareous Alps within the extent of the Pleistocene Traun Glacier. The drilling, which did not reach the bedrock, recovered an 880-m-long succession consisting of lacustrine and fluvial sediments (67 - 880 m) under a thick cover of subglacial till (0 - 67 m). It was first described by van Husen & Mayr in 2007, who proposed the formation of a more than 900 m deep lake caused by the dissolution of a large salt body by subglacial meltwater, which was subsequently filled by the sediments of a prograding delta. However, questions regarding the mechanisms and timing of the formation of this overdeepened structure remain.

Various sections of the drill core show high percentages of metamorphic rocks likely derived from the Austroalpine crystalline basement units. The present-day catchment of the river Traun, which drains the Bad Aussee basin, is largely composed of carbonate rocks. This suggests that the drainage network of this area of the Eastern Alps was very different during certain phases of the Pleistocene. We present results from sediment-petrographic and geochemical analyses which provide new insights into the depositional history and landscape evolution of the Bad Aussee basin. In addition, we present preliminary results from luminescence dating (based on a single grain dating approach for potassium-rich feldspar using post infrared, infrared stimulation @225°C (pIRIR225)), which will help establish a chronology of this unique sedimentary archive.

Uranium isotopes of authigenic minerals trace shifts in water sources to the Dead Sea during the Holocene

Ms. JIE ZHAO [1], *Dr. Yael Kiro* [1]

1. *Weizmann Institute of Science*

The populated south Levant region at the desert fringe is drought-sensitive to the warming climate. Hydroclimate studies of past warm periods may help to picture future hydroclimatic scenarios. The Dead Sea lacustrine record, recovered by the Dead Sea Deep Drilling Project (DSDDP), provides a detailed history of alternating wet and dry intervals over the last ~220 ka. Multiple halite layers indicative of aridity were identified in the DSDDP core throughout the Holocene, with the thickest halite deposition occurring during the early Holocene (~11–10 ka). Here, we aim to investigate shifts in water sources to the Dead Sea during the relatively dry Holocene by analyzing $^{234}U/^{238}U$ activity ratios of authigenic minerals (halite and aragonite) in the core sediments. Our preliminary results show that the most significant fluctuation in the $^{234}U/^{238}U$ ratios occurred between ~11 and 10 ka, which coincides with the thick halite deposition. The $^{234}U/^{238}U$ ratios plummeted from typical values of ~1.4–1.5 that characterize the lake solution over long periods of the Quaternary to values of ~1.0. This change reflects a major shift of water sources from the north and west (Jordan River and Mediterranean-sourced rainfall, $^{234}U/^{238}U$: ~1.5–1.7) to the eastern and southern catchments and flash floods ($^{234}U/^{238}U$: ~1.0–1.2). Thus, the hydrological pattern of the early Holocene is quite different from the present day, in which the Jordan River is the main water contributor to the Dead Sea. At ~7.5 ka, the aragonite $^{234}U/^{238}U$ ratios increased to ~1.6, which is a typical signal of the Jordan River-western catchment sources. We suggest that the Dead Sea may have been stratified due to the large input of freshwater from the Jordan River, and the aragonites were precipitated from the upper freshwater layer and consequently recorded its $^{234}U/^{238}U$ ratios.

First evidence that about 1.07 Ma ago a one-kilometer asteroid striking west African forest triggered a major environmental crisis

Mr. Van Binh Nguyen* [1], Dr. Valérie ANDRIEU [1], Prof. Pierre Rochette [1], Mrs. Eliane Charrat [2], Dr. Bérangère Leys [3], Dr. Chimène Assi-Khaudjis [4], Dr. David Baratoux [5], Dr. Luc Beaufort [1], Mr. François Demory [6], Prof. Alain Kouamelan [4], Prof. Jean Paul Yao N'Goran [4], Dr. Sebastien Nomade [7], Mr. Petanki Soro [4]

Around 1.07 Ma ago an asteroid stroke the pluvial forest of southern Ghana in Bosumtwi, generating a 10.5 km diameter crater and a distal ejecta of glass droplets in the form of tektites (the ivorites) and microtektites. A multi-proxy approach involving paleomagnetism, clay mineralogy, pollen, NPP and charcoal micro-particles was carried out on 40 samples of the IODP core 959 (Gulf of Guinea, N. Atlantic) spanning the period before and after the impact. We also studied 10 modern samples, taken during a recent field survey, along the Comoé and in the pluvial forest of Côte d'Ivoire. The microtektite layer was identified at 12.5 m depth in the core. This layer is found at the beginning of the Jaramillo subchron.

The palynological analyses of the IODP core 959 show that the entire rainforest (*Uapaca*, *Macaranga* Combretaceae, *palms)* but also the littoral mangroves (*Rhizophora*) and freshwater ecosystems (*Nymphaea*, *Lemna*, *Ludwigia*) were largely affected by the impact. Furthermore, megafires were ignited as suggested by the large amounts of microcharcoal and the spores of *Ustulina* and *Gelasinospora*. The large amount of unburned plant particles found in the tektites layer also proves that the forest was blown down by the impact blast, leading to an explosion of detritus feeders (*Coniochaeta*) and accelerated soil erosion (kaolinite, UAB7, *Glomus* peaks). The presence of spores of coprophilous fungi (*Sporormiella*, *Sordaria*) shows that herds of large herbivores were present in the ecosystem at the time of the impact. The sporo-pollinic and NPP assemblages of surface samples which include rainforest taxa, erosion (UAB7, *Glomus*), fire (*Gelasinospora*), vegetation decomposition (*Coniochaeta*) marker NPPs and large herbivores herds indicators (*Sordaria*, *Podospora*, *Delitschia*) confirm that biological and sedimentary material were transported by large rivers to the deep Gulf of Guinea where IODP 959 was retrieved.

This study was funded by ANR ET-MEGAFIRE project (2022-2026): "Tropical megafires triggered by tektite producing asteroidal impacts in the Quaternary".

Morphology of the Belize Barrier Reef as response to postglacial Atlantic sea-level changes (site-survey data for IODP preproposal “BBRdrill”)

Prof. Flavio Anselmetti [1]***, Dr. Stefano Fabbri*** [2]***, Mr. Siro Hosmann*** [1]***, Prof. Eberhard Gischler*** [3]

1. *Institute of Geological Sciences and Oeschger Centre for Climate Change Research University of Bern,* ***2.*** *Institute of Geological Sciences and Oeschger Centre of Climate Change Research, University of Bern, Switzerland,* ***3.*** *Institut fuer Geowissenschaften Goethe-Universitaet, Frankfurt*

The mixed carbonate-siliciclastic barrier and atoll reef system offshore Belize is the largest modern tropical reef complex in the Atlantic Ocean. Based on a recent site survey for an IODP preproposal, which obtained highly resolved bathymetric and shallow seismic data from the area, an unprecedented morphological analysis of the reef tract was conducted to investigate the morphologic response of the reefal margin to sea-level changes. Several conspicuous features were identified that can potentially be correlated with sea-level rises or sea-level stillstands: Above some talus deposits forming a steeply dipping slope, the margin generally forms a vertical wall rising from ~100 to 45-65 m water depth, which is marked systematically by erosional notches at ~80 m, potentially indicating stillstands in sea-level rise. We hypothesize that older, postglacial and glacial reefs are stacked more or less vertically below the outermost ridge and the wall. At several locations, the top of the wall is marked by elongated ridges, up to 15 m high, behind which linear depressions occur.

These data were discussed during a Magellan workshop which lead to the definition of the drilling locations for IODP preproposal “BBRdrill” . Drill cores are expected to provide valuable comparisons with the existing eastern Caribbean (Barbados) and the Indo-Pacific sea-level records. In contrast to the Indo-Pacific, where post-glacial sedimentary successions of coral reefs including relative sea-level data were obtained from outcrops and coring (Vanuatu,Tahiti, Great Barrier Reef), there is only one such record in the Atlantic (Barbados, eastern Caribbean). The Barbados core data provided apparent differences to more recent, IODP-based data, e.g., the evidence of meltwater pulse (MWP) 1B, the timing and height of sea level during the last glacial maximum (LGM), the apparent lack of microbialites, as well as mismatches with Holocene sea-level curves. BBRdrill will aim towards i) reconstruction of the LGM and postglacial sea-level rise in the western Atlantic; ii) reconstruction of environmental parameters using corals, coralline algae, and cryptic microbialites; iii) elucidation of reef paleoecology in relation to postglacial sea-level rise and associated environmental changes; and iv) assessment of microbial life in a barrier-reef system.

Variability in the water column stratification in the Bay of Bengal during the last 1.45 myr

Dr. Sudhira Bhadra [1] ***, Dr. Rajeev Saraswat*** [2]***, Dr. Sanjeev Kumar*** [3]***, Mrs. Sangeeta Verma*** [3]

1. *Indian Institute of Science,* ***2.*** *CSIR-National Institute of Oceanography, Goa, India,* ***3.*** *Physical Research Laboratory*

The seasonally reversing monsoon winds and a large freshwater influx make the Bay of Bengal a hydrodynamically unique basin. The resulting stratification in the water column affects the physicochemical parameters and productivity. The reconstruction of past changes in the upper water column stratification will give insight into the control of monsoon on the water column structure. The scarcity of long-term records from the Bay of Bengal limits our understanding of this on an orbital scale. We have used a 1.16 myr (MIS 47- MIS 8) record of planktic foraminifera assemblages and the difference in the stable oxygen isotopic ratio ($\Delta\delta^{18}O$) between the mixed layer dwelling *Globigerinoides ruber* and thermocline dweller *Neogloboquadrina dutertrei* from the IODP Site U1446 to understand the change in water column stratification and its relationship with the monsoon through the mid-Pleistocene transition (MPT). We report a higher thermocline assemblage and low $\Delta\delta^{18}O$ during the warm interstadials and higher mixed layer assemblage and high $\Delta\delta^{18}O$ during the cold stadials. We infer a stronger stratification during the warm interstadials and comparatively weaker stratification during the cold stadials. The strengthened summer monsoon induced high direct rainfall, and riverine influx inhibited mixing in the upper layer and created a shallow thermocline during the interstadials. We also report a shallower thermocline during the post-MPT period because of the strengthened summer monsoon.

On the heterogeneity of Plio-Pleistocene African hydroclimate: Processes and patterns from North (ODP Site 659) and East (Baringo-Tugen Hills-Barsemoi Basin) Africa

Mr. Bryce Mitsunaga [1], ***Dr. Rachel Lupien*** [2], ***Dr. Amy Jewell*** [3], ***Ms. Samantha Ouertani*** [1], ***Ms. Solana Buchanan*** [1], ***Mr. Brandon Stubbs*** [1], ***Dr. Alan Deino*** [4], ***Dr. John Kingston*** [5], ***Dr. Mona Stockhecke*** [6], ***Dr. Erik Brown*** [6], ***Dr. Anya Crocker*** [3], ***Dr. Timothy Herbert*** [1], ***Prof. James Russell*** [1]

1. Department of Earth, Environmental, and Planetary Sciences, Brown University, 2. Aarhus University, 3. School of Ocean and Earth Science, University of Southampton, 4. Berkeley Geochronology Center, 5. Department of Anthropology and Museum of Anthropological Archaeology, University of Michigan, 6. Large Lakes Observatory & Dept. of Earth and Environmental Sciences, University of Minnesota Duluth

The Plio-Pleistocene (5-0 Ma) encompasses several key changes in the frequency, amplitude, and trends of global climate, including the intensification of Northern Hemisphere glaciation (iNHG) (~2.75 Ma) and 41-kyr cycles in temperature / ice volume. Late Pliocene proxy records also inform model simulations of a >400-ppm pCO_2 world. Changes in the trend and periodicity of African climate across the Plio-Pleistocene are particularly important given their potential influence on human evolution, and yet existing records are often short, low-resolution, and / or regionally biased. As a result, many triggers of African climate change have been hypothesized—local insolation forcing, high-latitude teleconnections, Indian Ocean surface temperatures—that are difficult to distinguish with existing data.

Here, we use high-resolution (3-4 kyr) *n*-alkane-specific leaf wax hydrogen isotope (δ^2H_{wax}) records from Ocean Drilling Program Site 659 (3.6-2.5 Ma) and central Kenya's Baringo Basin (3.3-2.6 Ma) to compare the evolution of East and Northwest African rainfall regimes across the Plio-Pleistocene boundary. At Site 659, δ^2H_{wax} values and *n*-alkane concentrations vary strongly on 23-kyr timescales, with no significant secular change. Summer insolation, which remains constant across iNHG, is likely the primary driver of Northwest African rainfall. δ^2H_{wax} values are ~10 ‰ more deuterium-depleted than the late Pleistocene, implying that drying occurred well after iNHG, perhaps coeval with increased dustiness around 2 Ma.

In contrast, Baringo δ^2H_{wax} values display prominent 41-kyr variance and are most spectrally coherent with the north-south insolation gradient. δ^2H_{wax} values decrease by 11.5‰ around 3.05 Ma, indicating the onset of *wetter* conditions. They and most other long (>200 kyr) East African records covary with the IO zonal surface temperature gradient and West Australian hydroclimate on extra-orbital timescales (>100 kyr), showing that Walker circulation regulates rainfall along the IO rim.

Unlike the last deglaciation, Plio-Pleistocene climate transitions may be regionally heterogeneous across northern and equatorial Africa, with pronounced environmental gradients caused by the differing sensitivity to regional versus remote forcing. This illustrates the need for additional geographically-diverse, high-resolution paleohydrological archives.

Continental Scientific Drilling for Quaternary Paleorecords: Program Capabilities and Future Directions

Dr. Anders Noren [1]

1. University of Minnesota, Continental Scientific Drilling Facility, Dept of Earth and Env. Sci., USA

The Continental Scientific Drilling (CSD) Facility at the University of Minnesota is funded by the US National Science Foundation to support any project worldwide requiring drilling or coring on land or in lakes. Facility staff, frequently collaborating with the International Continental Scientific Drilling Program (ICDP), engage with community scientists to develop and implement CSD projects and advance community goals. Obtaining high-quality core samples from modern or ancient sedimentary basins to understand Quaternary paleoclimate and paleoecology continues to be a major research motivation, as emphasized in long-range science plans produced by ICDP and by the US scientific community. Numerous scientific drilling projects in development or queued for operations include modern lakes, paleolakes, and other sedimentary basins in the Tibetan Plateau, the Brazilian Amazon, Colombia, Guatemala, the western United States, Chad, Tanzania, Kenya, and Botswana, among several other locations for projects focusing on timeframes prior to the Quaternary or on scientific disciplines related to active processes (geomicrobiology, hydrology, geothermal, fault zones, seismicity, etc). Since 2018, major changes in community infrastructure and resources have required a new approach that leverages commercial drilling contractors, community facilities, and distributed expertise to provide the needed capabilities to reach project goals. This presentation provides a perspective on the timelines and developments for the largest recent and upcoming CSD projects, on changes in relevant program and facility capabilities, and the pathway to drilling operations in the coming decade.

The impact of fire and different forest management strategies on Sphagnum-dominated peatlands – a case study from northern Poland

Dr. Katarzyna Marcisz [1]***, Mr. Mariusz Bak*** [1]***, Prof. Mariusz Lamentowicz*** [2]***, Prof. Piotr Kołaczek*** [2]***, Dr. Paweł Matulewski*** [3]***, Dr. Dmitri Mauquoy*** [4]

1. *Climate Change Ecology Research Unit, Faculty of Geographical and Geological Sciences, Adam Mickiewicz University, Poznań, Poland,* ***2.*** *Climate Change Ecology Research Unit, Faculty of Geographical and Geological Sciences, Adam Mickiewicz University,* ***3.*** *Anthropocene Research Unit, Faculty of Geographical and Geological Sciences, Adam Mickiewicz University, Poznań, Poland,* ***4.*** *School of Geosciences, University of Aberdeen, Aberdeen, UK*

Sphagnum-dominated peatlands have been affected by various disturbance events throughout their history. In the past, these disturbances were mainly connected with naturally ignited fires or seasonal droughts. With increasing human pressure, the range of most disturbance events has increased. Currently, the most common ones are climate change, mechanical destruction such as peat extraction or peat cutting, drainage, and human-ignited fires. Over the years, the difference in environmental and forest management strategies impacted peatland ecology, making them more vulnerable to disturbances and burning. In this study, we aim to recognize how peatland ecology changed along with changing forest management strategies and how peatland ecology changed in response to disturbance events throughout its history. We studied a core from Stawek peatland in the Tuchola Pinewoods, a Scots pine (*Pinus sylvestris*) monoculture forest in northern Poland. The Stawek peatland is a small kettle hole mire, highly susceptible to the smallest of disturbance events, making it a perfect archive record for palaeoecological reconstructions. We use high-resolution multi-proxy palaeoecology to reconstruct the history of the peatland, including pollen, plant macrofossils, testate amoebae, and a wide range of charcoal analyses: micro- and microcharcoal counts, charcoal morphological types, and Raman spectroscopy. We also support reconstructing the latest disturbance events using dendrochronological analyses of pine. Our results show that the peatland experienced a critical transition in vegetation composition and hydrology when introducing forest management techniques. The surrounding mixed forest was turned into a pine monoculture. The main change was a reduction in fire activity in the Tuchola Pinewoods. This change led to a dominance of *Sphagnum* mosses and an increase in peat accumulation rates. We believe that the results of this study can be helpful for the improvement of conservation planning for peatlands located in forested areas and monoculture forests.

Study funded by the National Science Centre, Poland, grant no. 2020/39/D/ST10/00641.

Informing past fire regimes using microscopic charcoal preserved in deep-sea sediments

Dr. Anne-Laure Daniau [1], ***Dr. Aritina Haliuc*** [2], ***Dr. Marion GENET*** [3]

Large uncertainties remain in understanding the evolution of fire activity under projected warming scenarios because fire is a complex process to integrate into global modelling. Empirical models used for projections lack potential changes in the interaction between climate, vegetation and fire. Process-based models of the coupled vegetation-fire system provide new tools to address this issue. Evaluating those models against benchmark datasets from charcoal sediment records, outside of the modern climate conditions range, is necessary. Long marine charcoal records capture regional-scale biomass burning over a large range of natural climate variability. However, the development of comprehensive data-model comparisons is limited by the lack of common physical units between data and model output: changes in ‘fire activity’ are not directly comparable to simulated fire regime characteristics (such as fire intensity or burnt areas). The ANR BRAISE intends to develop a calibration which, applied on paleofire records, should provide new datasets of regional fire regimes for key periods in the past.

Here, we present the analyses of abundance and morphology of microscopic charcoal preserved in surface sediment samples collected off Iberia and Africa. The spatial distribution patterns of microcharcoal parameters were compared with satellite derived fire regime characteristics on land (fire number, size, intensity and type of burnt vegetation). Results suggest the abundance and morphology of charcoal in marine sediments detect specific fire regimes, in particular fires of high intensity in mixed vegetation in Iberia and in graminoid-mixed ecosystems in Africa. These results are a springboard for converting marine charcoal records into past fire regime history.

Environmental change, fire events, and anthropogenic impact at Olzreuter Lake, SW Germany, over the past 15 kyrs reflected by a multi-proxy approach

***Mrs. Shaddai Heidgen* [1], Dr. Renate Ebersbach [2], Dr. Annett Junginger [1], Dr. Tatiana Miranda [3], Dr. Oliver Nelle [4], Dr. Andreas Koutsodendris [5], Dr. Martin Ebner [1], Dr. Yvonne Tafelmaier [6], Dr. Elena Marinova [7]**

High-resolution multi-proxy analysis was applied to sediments from the Olzreuter Lake, SW Germany, including pollen, diatoms, chrysophytes, macro- and microcharcoal, total organic carbon, and X-ray fluorescence linked to archaeological evidence. The sequence provides detailed integrated records for the development of the lake habitat and the surrounding landscape during the interval from the Late Glacial to the Late Holocene. Vegetation reconstruction based on pollen covers a period from 14.7 to 1.6 calBP, and four zones were recognized. Open vegetation ruled the environment during the Late Glacial. In contrast, the Early Holocene was characterized by the spread of broadleaved trees like *Corylus, Quercus, Ulmus, and Tilia* (ca. 11.7 calBP), followed by the development of mixed oak forests (ca. 8.4 calBP) and finally, in Mid Holocene, from 6.3 calBP onwards dominated by beech forests. Macrocharcoal analysis detected local fire events; those from 16.6-12.9 calBP can be associated with climatic influences rather than anthropogenic activities in the area. However, between 12.9-8.2 calBP, the charcoal record in connection to archaeological evidence suggested increasing use of fire by the human populations. This pattern became pronounced later, especially between 11.7-8.2 and 4.2-1.8 calBP. Diatom analysis includes the section between 12.8-1.6 BP, with scarce diatom preservation between 12.7-7.0 calBP. As derived from diatom communities, lake level changes suggest that a rise in water levels occurred during the mid-to-late Holocene, as indicated by the ratio of benthic/planktonic diatoms. These rises overlapped with periods when the climate was more stable, while the lower water levels corresponded to the short intervals of glacier advances. Ecological characters inferred by diatom analysis showed that Olzreuter Lake generally had a mesotrophic status. At three-time levels - 12.8, 6.8, and 5.1 calBP - oligo-mesotrophic conditions settled in the lake. During the Mid-to-Late Holocene, enhanced sediment and nutrient input into the water body caused changes in the trophy status, which can be attributed to human agency. This study aims to reconstruct past environments and explore the interplay of anthropogenic influence and climatic control on the environment.

Fire variability in the southeastern France over the past 8500 years

The French Mediterranean region is particularly impacted by fires today, with an increase of fire risk as a response of future projected climate change scenarios. However, fire models used for projections need to be evaluated against benchmark datasets from charcoal sediment records, outside of the modern climate conditions range. This study presents a new paleofire record covering the mid and late Holocene in southeastern France based on the analysis of microscopic charcoal preserved in a marine sediment core from the Gulf of Lions, located in the Rhone River prodelta. The relationships between fire, climate and vegetation cover were assessed through multivariate analyses. We found more fire episodes during dry conditions in the mid-Holocene when the vegetation was relatively closed (deciduous oaks, pines, evergreen shrubs, other deciduous trees). Conversely, we observed more fire episodes under wet conditions in the Late Holocene when the vegetation was more open (Artemisia, Olea, Ericaceae, other Herbaceous taxa, Poaceae). We show also that 12 fire episodes among 15 coincide with cold relapses detected in the Gulf of Lions. The presence of these cold events has been attributed to particular synoptic conditions such as the negative NAO mode, generating humid conditions on average but dry and cold wind anomalies, or the East Atlantic Pattern mode of variability leading to dry and cold winds in the Mediterranean region. Today, large fires in southeastern France occur either during negative NAO or during the Atlantic Ridge weather regime, the latter being connected to the East Atlantic Pattern mode of variability. Our results suggest that increases in fire in the southeastearn France during the Holocene were controlled by similar synoptic conditions than present-day leading to dry winds in this area.

Recent Environmental Changes in the Alpine Zone of the Rwenzori Mountains Unprecedented

Ms. Andrea Mason [1]***, Ms. Eleanor Pereboom*** [1]***, Dr. Sloane Garelick*** [1]***, Prof. James Russell*** [1]

1. *Department of Earth, Environmental, and Planetary Sciences, Brown University*

High-elevation tropical regions are believed to be some of the most sensitive environments to climate change. In tropical African mountains, the effects of climate change have already caused glaciers to significantly retreat in the past century, and recent droughts, fires, and floods suggest that warming is impacting a variety of ecosystem processes and services. However, the short duration of observational records limits our ability to test whether these changes result from shifts in precipitation, temperature, or human activities. The Rwenzori Mountains, located on the border between Uganda and the Democratic Republic of the Congo, is one such region where the impacts of climate change are apparent. To assess the driving mechanisms of these modern climatic and environmental changes, we reconstruct fire (macro-charcoal and PAHs), precipitation (dD_{wax}), vegetation ($d^{13}C_{wax}$), and temperature (brGDGTs) to reconstruct climate during the Holocene in the Rwenzori Mountains. We present the highest elevation records of climate and fire in Africa using sediment cores from two different lakes: Lake Africa (3895 m asl) and Lake Kopello (4017 m asl). We find that past fire frequency tracks changes in precipitation with the exception of a significant increase in fire at 2 ka at lower elevation sites in the Rwenzori. We attribute this increase to the rise of pastoralism in Africa. Additionally, we find evidence that fires did not occur in the high-elevation afroalpine zone during the Holocene; this contrasts with the observed fires at this elevation today and suggests that modern fires are not part of natural climate variability and may be human driven.

Teleconnections between Holocene fire regimes in Central Asia and the Neotropics driven by Paleo Monsoon dynamics

Dr. Sandra Brugger [1]***, Prof. Heinz Wanner*** [2]***, Dr. Erika Gobet*** [3]***, Prof. Michael Sigl*** [4]***, Prof. Willy Tinner*** [3]***, Prof. Margit Schwikowski*** [5]

Wildfires play an important role in the global carbon budget and emitted wildfire aerosols contribute to radiative forcing of climate. Nevertheless, the drivers for long-term biomass burning trends on continental to global scale are still debated. Rising fire severity in past decades combined with large uncertainties about long-term fire trends raise major concerns about future fire management strategies. The boreal forests in Central Asia and the Neotropics are important regions for global fire emissions with only few available sediment records. The scarcity of data prevents inferring large-scale regional fire trends without ambiguities. High-alpine ice archives such as Tsambagarav Mountain in the Mongolian Altai and Illimani in the Bolivian Andes can fill this gap. They preserve microfossil records of past environmental change over millennia from large source areas that can be directly compared to many other climate and environmental tracers in the same ice core – thus providing a multiproxy record of supraregional fire and ecosystem change.
We found striking and surprising similarities between the Central Asian and Neotropical ice core paleofire records with declining fire activity during the Late-Holocene suggesting teleconnections between regional fire activity possibly due to shared climate drivers in the Northern and Southern hemisphere. Well-documented records of South American summer monsoon activity over the Holocene show a consistent strengthening towards the Late Holocene. The related southwards shift of the Intertropical Convergence Zone (ITCZ) resulted in increased monsoonal precipitation that reduced flammability of evergreen vegetation. In contrast, Asian paleo records suggest gradually weakening monsoon activity towards the Late Holocene that resulted in regionally drier conditions. These climate trends induced retractions of boreal forests, thus limiting fuel availability and fire incidence. We conclude that the main driver of fire activity in these two regions was not temperature but rather monsoonal-driven moisture sources regions. Therefore, paleo precipitation information and its influence on past vegetation conditions are crucial for global fire models. Siuch data will help to better assess the causes of regional paleo fire activity changes.

Mid- and late Holocene fire history in Central Siberia: effects of climate changes and human impact

Prof. Elena Novenko [1]

1. Lomonosov Moscow State University

Recent climate change in Siberia is increasing the probability of dangerous forest fires. The development of effective measures to mitigate and prevent fires is impossible without an understanding of long-term fire dynamics. We present the new multi-site palaeo-fire reconstruction based on macroscopic charcoal data from 16 peat and lake sediment cores located in different landscapes across the permafrost area of Central Siberia. The studied sites are situated in three model areas: the Putorana Plateau, the middle part of the Central Siberian Plateau (Lower Tungiska River basin, near the settlement of Tura) and the marginal part of West Siberian Lowlands (Yenisei River basin, near the town of Igarka). Charcoal records cover the last 7000 years. We used the Paleofire R package version 1.2.4 as the standardization technique of the obtained data to compare the local fire reconstructions from the study area. The composite cureve of biomass burning was compated with pollen and plant macrofossil data, reconstruction of total forest covarage by best modern analogue technique and paleotemperature reconstructions. The obtained results show similar temporal patterns of charcoal accumulation rates in the cores under study, and near synchronous changes in fire regimes. The paleo-fire record revealed moderate biomass burning between 7.0 and 5.9 and between 3.4 and 2.6 ka BP. The periods of lowest fire activity occurred in 5.9-4.2 and 2.6-1.5 ka BP, that coincided with regional climate cooling and moistening, and reduction of forest vegetation in the study regions. Charcoal accumulation rates increased to the mean values during the interval from 1.5 to 0.8 ka BP and appears to be partly synchronous with climate warming during the Medieval Climate Anomaly. Since 0.8 ka BP charcoal influx raised and exceed the main value until the present time. With exception of charcoal records from the Putorana Plateau the decrease of fire frequency during the Little Ice Age revealed from tree-ring data from Central Siberia was not recorded by the charcoal data from peat cores. Fire frequency and charcoal accumulation increased abruptly during the last 150 years, obviously due to human impact.

Forest fire history in the central part of the East European plain in the Holocene

Mr. Dmitriy Kupriyanov [1]

1. -

The forest zone of the central part of the East European Plain is characterized by a complex combination of landscapes and a long history of human impact. The present study aimed to the reconstruction of the Holocene forest fire history for the central part of the East European plain (within the European part of Russian Federation). The study was carried out on the base of 17 sections of peat deposits located within the middle and southern taiga, the zone of mixed forests, in broadleaved forests and on the border of the forest zone and forest-steppe in different landscape positions. The main method of analysis macrocharcoal (particle size >125 μm) concentration in the peat deposits. Data processing was carried out in the «tapas» software (Finsinger, Bonnici, 2022). In the «Paleofire» package (Blarquez et al., 2014) was modeled an integral curve describing the trends of burned biomass over the past 8500 cal. years. Palynological analysis and other analyses were performed for each section to reconstruct the interaction of forest fires with climatic conditions and anthropogenic impact.

The results of the study showed that there are three stages in the history of forest fires in the center of the East European Plain. The first stage is from 6000-11700 cal yrs BP are characterized by frequent forest fires, which formed postpyrogenic forest communities with a predominance of *Punus* and *Betula* with a minimal proportion of broadleaved species. The maximum activity of forest fires is 7500-9000 cal yrs BP. Probably, the abundance of forest fires at this time is caused by climatic conditions. The second stage (2500-7000 cal yrs BP) is described by low activity of forest fires in colder and wetter conditions. At this time, broad-leaved or coniferous-broadleaved forests predominate (depending on the type of landscape). After 2500 cal yrs BP there has been an increase in the number of forest fires, probably caused by anthropogenic impact. This has led to a significant transformation of forests. The dating of 2500 cal yrs BP is conditional and varies according to the history of the development of different landscapes.

Holocene fire history: Methods, current knowledge, and potential for understanding past vegetation and climate dynamics in China

Dr. Qiao-Yu Cui [1]

1. Key Laboratory of Land Surface Pattern and Simulation, Institute of Geographical Sciences and Natural Resources Research, Chinese Academy of Sciences

Understanding the role of fire in the terrestrial biosphere and its consequences for ecosystem-climate dynamics is of key importance for projecting the climate changes in the future. The long-term interactions and feedbacks among fire, climate, and land use have been recorded in various sedimentary archives with which we can measure. Hence, numerous charcoal records have been accumulated produced as the by-products of pollen analysis have accumulated in China; however, several continuous or high-resolution charcoal records are required from different regions and ecosystems to synthesise the long-term trends in fire regimes and to examine the key drivers of fire activity. Herein, this paper reviews the state-of-the-art methodologies commonly used to study fire dynamics and present the examples of fire regimes by regions and biomes based on sedimentary charcoal records. Subsequently, specific concerns about the requirement of further studies on past fires at multi-spatial-temporal scales in China are addressed, which will help improving our understanding of the links among fire, ecosystems, and climate dynamics.

Determining the past fire regimes on the southeast coast of Australia

Mr. Alexander Pecenko [1], ***Prof. Simon Haberle*** [1]

1. Centre of Excellence for Australian Biodiversity and Heritage, School of Culture, History and Language, Australian National University, Canberra ACT, Australia

Wildfires are an integral force shaping Australia's ecosystems, influenced by the stratification and composition of the vegetation, the climate, and human habitation. Although the presence and spread of past fires in Australia have been the subject of many studies, their temperature and intensity have been considerably less investigated to date.

This conference paper will present the main findings from the research on the changes in the fire regime (focusing on quantifying the temperature and intensity) during the Holocene at the Jervis Bay lagoon, on the south-east coast of Australia. The paper will firstly outline how a charcoal reference dataset was created for the main tree taxa from Jervis Bay (i.e., *Eucalyptus sp.*, *Casuarina*, *Banksia*, *Melaleuca*, and *Avicennia*). It will be described how the wood samples of these taxa were heated to between 200 °C and 700 °C in a muffle furnace and by open flame combustion, and the obtained charcoal samples analysed by Fourier Transform Infrared Spectroscopy (FTIR) to identify a range of spectral responses and their associated chemical structures. The data from FTIR were then correlated with the temperatures acquired from the heating of the tree taxa samples, and thus a reference dataset was created. The paper will then present the results of the FTIR analysis of the charcoal from the soil cores at Jervis Bay, representing the entire Holocene period, which were interpreted against the reference dataset, and in this way, the periods of higher and lower temperature of past fires through the Holocene were identified. The outcomes of this research can contribute to a better understanding and more effective management of present and future fires, especially considering the current unprecedented climate changes.

Reconstructing changes in paleofire regimes on the African continent using microcharcoal from marine sediments

Dr. Aritina Haliuc [1], ***Dr. Anne-Laure Daniau*** [2]

1. Univ. Bordeaux, CNRS, Bordeaux INP, EPOC, UMR 5805, F-33600 Pessac, France ; University of Suceava, MANSiD, Suceava, Romania, 2. Univ. Bordeaux, CNRS, Bordeaux INP, EPOC, UMR 5805, F-33600 Pessac, France

Fire is a ubiquitous component of nearly every terrestrial ecosystem and has been responsible for shaping the Earth system for millions of years. In the context of current and anticipated climate warming scenarios, the projected changes in temperature, precipitation and increase of anthropogenic activities are expected to increase fire occurrence and severity with consequences on the environment and human society. Despite the recent scientific advances, there are still large deficiencies in understanding the interaction between fire and other components of the Earth system and, thus, limitations in integrating this process in global models. Africa is a fire-prone continent, accounting for most of the worldwide burnt area and more than half of fire-carbon emissions. Still, few charcoal records from continental and marine sediments are available here.

Marine records provide information regarding long-term changes in biomass burning and can aid in understanding the relationships between climate change and fire activity. However, the signal represents only relative levels of biomass burning, and thus, the relationship between the fire regime on the continent and charcoal deposition in the ocean still needs to be completed. The present study uses an integrated approach to link the charcoal accumulation in marine surface sediment samples of modern ages from sites across the African coast and fire regimes on land. Our results show that charcoal concentration and morphometry changes are linked with the fire regime and the type of burnt vegetation on the adjacent continent. This modern-land ocean calibration is further applied on a long marine record MD96-2098, off Namibia, to reconstruct fire regimes over the past 23,000 years using fire proxy and modelled climate (temperature and precipitation) information. Such reconstructions can help to better understand the local to regional processes that govern the fire signal and contextualise current and past environmental changes.

Dust-borne soluble iron delivery to the Last Glacial Maximum oceans: Source inheritance versus atmospheric processing

Dr. Nicolás Cosentino [1]***, Dr. Douglas Hamilton*** [2]***, Dr. Fabrice Lambert*** [1]***, Mr. Fabian Riquelme*** [1]***, Dr. Jiang Zhu*** [3]***, Dr. Samuel Albani*** [4]***, Dr. Natalie Mahowald*** [2]

1. Pontificia Universidad Católica de Chile, 2. Cornell University, 3. National Center for Atmospheric Research, 4. University of Milano-Bicocca

During the last 800,000 years, atmospheric CO_2 concentration during glacial periods was between 25 and 45% smaller than during interglacial periods. Roughly one fourth of this difference is estimated to be due to a dust-induced stronger biological pump, mostly in the iron-limited southern oceans and northern Pacific, during dustier glacials. How was dust-borne soluble iron delivered to the glacial oceans? In the present-day climate, dust-borne iron at emission is mostly insoluble and solubilized through proton- and organic ligand-promoted atmospheric processing. However, this may not have been the case during glacials. First, drier glacials may have implied less chemical weathering of continental dust sources, thereby raising source-inherited iron solubility. Second, present-day anthropogenic gas emissions acidify the atmosphere and enhance the solubility of dust-borne iron during atmospheric transport, an effect which was absent during glacials. We thus hypothesize that during glacials dust-borne soluble iron inputs to iron-limited oceans were more strongly controlled by source-inherited iron solubility, and less so by atmospheric processing, compared to the present. To test this hypothesis, we will perform a set of Last Glacial Maximum (LGM, 21 ka BP) and pre-industrial (1850 AD) simulations using the Community Earth System Model 2, with coupled atmospheric and land components and with an atmospheric iron processing module. Dust emission rates will be tuned against a compilation of LGM and present-day dust deposition flux observations, and sensitivity analyses will be performed on two parameters: source-inherited iron solubility of dust and the intensity of atmospheric processing. Results will be discussed in the session.

Sources of Danubian loess

Dr. Kaja Fenn [1], ***Dr. Ian Millar*** [2], ***Dr. Anna Bird*** [3], ***Dr. Daniel Veres*** [4]

***1.** University of Liverpool, **2.** British Geological Survey, **3.** University of Hull, **4.** Romanian Academy*

Sediment provenance can be a powerful tool in sediment system dynamics and transport pathways research. Through understanding sediment sources new insights into past environmental and climatic processes can be gained. This is particularly true for loess-palaeosol sequences which are one of the key archives of terrestrial environmental change. By coupling loess source information with chronological data we can quantify rates of process, such as dust transport and deposition processes, dust fluxes, and sediment generation mechanisms over the longer term, which is crucial when using loess as palaeoclimatic and palaeoenvironmental proxies.

Sources of sediment in loess sequences along the Middle and Lower Danube have been well studied with great improvements in our understanding gained through use of detrital zircons and their ages. However, some uncertainties, such as contributions from Saharan regions into Central Europe, still persist. Some geochemical palaeo studies suggested that Sahara made negligible contributions, and others produced inconclusive results. Conversely modern dust research shows relatively frequent contributions. This ambiguity limits our understanding of atmospheric conditions and transport patterns.

Here we build on our recent loess provenance work in the Danube corridor that focused on detrital zircon U-Pb ages and hafnium isotopes (Fenn et al. 2022), and expand it with loess Sr-Nd isotopes from loess deposits along the Danube (Croatia, Serbia, and Bulgaria). These are compared with corresponding potential source regions data with an emphasis on North Africa, to begin disentangling Saharan contributions to Danubian loess. We also explore bulk sample elemental composition and explore statistical ways that can bring these big datasets together to provide a clearer provenance picture. Finally, by combining the results with chronological information we explore any potential provenance changes over time.

Shutting down dust emission during the middle Holocene drought in the Sonoran Desert, Arizona, USA

***Mr. Guy Tau* [1], *Dr. Onn Crouvi* [1], *Prof. Yehouda Enzel* [2], *Dr. Nadya Teutsch* [1], *Prof. Paul Ginoux* [3], *Prof. Craig Rasmussen* [4]**

***1.** Geological Survey of Israel, **2.** Institute of Earth Sciences, The Hebrew University of Jerusalem, **3.** Geophysical Fluid Dynamics Laboratory, National Ocean and Atmospheric Administration, **4.** Department of Environmental Science, University of Arizona*

Long-term relationships between climate and dust emissions remain unclear, with two prevailing but opposite hypotheses for the effects of climate shifts: (1) increased dust emission due to increasing aridity imposing a vegetation change, or (2) decreased dust emission due to increasing aridity which imposes a less stormy climate and reduced sediment supply. Here we test these hypotheses by analyzing an 11-m-long core archiving Holocene dust trapped in Montezuma Well, a natural sinkhole in Arizona (southwestern United States), alongside current dust sources and transport pathways. Major elements indicate that Montezuma Well sediments originate from two end members: local carbonate bedrock and external siliceous dust. Core sediments are similar to the adjacent siliceous soils accumulated atop the bedrock, pointing to their eolian origin. Particle-size distributions reveal fine dust transported during winter from the northwestern Sonoran Desert and the Mojave Desert, and coarse dust transported during summer from the southwestern Sonoran Desert, similar to current climate systems and dust pathways. A survey of potential dust sources indicates that current summer and winter dust sources in the Sonoran Desert are under a supply-limited state. Dust fluxes were higher during wetter phases of the Holocene when winter sources dominated. During the middle Holocene drought, dust fluxes were minimal and dominated by summer sources until dust input ceased as drought conditions did not produce enough floods to refill sources with sediments. We propose that in the Sonoran Desert, dust emission is strongly connected with climate, increasing during humid intervals and enhanced by fluvial sediment replenishment at dust sources.

PADI: the Italian platform for optical properties of dust in ice cores

Dr. Claudio Artoni [1], ***Dr. Luca Teruzzi*** [2], ***Dr. Llorenç Cremonesi*** [1], ***Dr. Claudia Ravasio*** [1], ***Dr. Deborah Fiorini*** [1], ***Prof. Barbara Delmonte*** [1], ***Prof. Marco Potenza*** [2], ***Prof. Valter Maggi*** [1]

1. University of Milano-Bicocca, 2. University of Milan

For past climate conditions, ice cores offer an unique opportunity to study the optical properties of mineral dust aerosol and its role on climate evolution, as they preserve a pristine atmospheric input from the past. Aeolian dust preserved in deep polar ice cores has several properties providing key paleoclimate information such as: dust concentration, proxy for continental aridity, source intensity and hydrological cycle; dust grain-size, related to atmospheric transport; dust geochemical composition, indicative of dust provenance and environmental conditions at the sources and dust morphology (shape), that is a key parameter to assess the radiative effect.

For this reason an analytical platform dedicated to the optical characterization of dust in ice cores was created at the European Cold Laboratory Facilities of the University of Milano Bicocca. Currently, the system is made up of three instruments to retrieve the optical properties of such particles: an Abakus laser sensor, an instrument based on Single-Particle Extinction and Scattering (SPES) and a novel tool for Digital Holography. These instruments can provide information on the shape, size and absorption of dust particles. At the end of the analytical line a sampler collects discrete samples and additional instruments can be added to improve the measurement capability. This platform was developed to better meet the analytical needs requested by projects in the Italian Alps and in Polar regions (such as ADA270, EAIIST, OPTICE, Beyond Epica).

Study of eolian dust transport and its activity in the formation of the regional climate of the Caucasus (Georgia)

Prof. Teimurazi Davitashvili [1]

1. Iv. Javakhishvili Tbilisi State University

Dust aerosols represent one of the main pollutants on the territory of Georgia and impact on regional climate. In this study, the WRF/Chemistry model with dust module was used to study dust particles transportations on the territory of Georgia from the Sahara and Sahel in Africa, Arabian and ar-Rub' al-Khali deserts located in the Middle East, Kyzyl-Kum, Karakul and Great Salty in the Central Asia. The results of calculations have shown the WRF model was able to well simulate dust aerosols transportation on the territory of Caucasus in conditions of a complex relief of the environment (verified with CALIPSO and MODIS satellite products and HYSPLIT model). In addition, we have executed sets of 30 years simulations (1985–2014) with and without dust effects by RegCM 4.7 model with 16.7 km resolution over the Caucasus domain and with 50 km resolution encompassing most of the Sahara, the Middle East, the Great Caucasus with adjacent regions. Results of calculations have shown that mineral dust aerosol influences on temperature and precipitations (magnitudes) spatial and temporally inhomogeneous distribution on the territory of Georgia. According to results of comparisons of the simulated dust aerosol optical depth seasonal distributions against to the observed ones gave a good agreement. Also dust radiative forcing inclusion has improved simulated summer time temperature, and seasonal distribution of simulated precipitation, but gives over estimation in annual total precipitation. Results of calculations have shown that dust aerosol is an inter-active player in the climate system of Georgia.

High resolution dust fluxes and palaeowind reconstructions from Southern Hemisphere and Southern Ocean terrestrial records of the last 20 kyrs: new approaches and potential pitfalls

In recent decades, the circumpolar Southern Hemisphere Westerly winds (SWW) have strengthened and contracted closer to Antarctica. This process has been associated with rapidly warming temperatures on the Antarctic Peninsula, enhanced Agulhas ocean current leakage, increased basal melting of ice-shelves, reduced precipitation supply to the southern continents, and a reduction in the carbon-sink capacity of the Southern Ocean. Although the SWW play a crucial role in driving global climate change, their millennial-centennial scale variability remains poorly constrained, limiting our ability to predict the impact of future changes. Over the last 10 years, we have collected new palaeoenvironmental records from lakes and peatlands on several Sub-Antarctic islands within, and peripheral to, the core SWW belt. In this poster, we: 1) use geochemical analysis of the bulk minerogenic component in peatland records to reconstruct local and long-distance dust fluxes, and provide a direct proxy of past changes in wind conditions across the Southern Ocean; 2) compare peatland dust flux data with independent (biological) proxies from the Sub-Antarctic islands alongside other terrestrial (lake and ice-core) records and models of changing wind strength; 3) examine new approaches to, and the potential pitfalls of, palaeowind reconstruction, such as using calibrated X-ray fluorescence core scanning (XRF-CS) data to increase the resolution of dust flux reconstructions to centennial (possibly) decadal timescales, and Hg isotopes as precipitation and wind proxies.

Understanding the atmospheric variability of the last glacial-interglacial transition in the Southern Hemisphere through paleoclimatic studies of high-altitude loess-paleosol sections in Argentina

Dr. Gabriela Torre [1], ***Dr. Diego Gaiero*** [2], ***Dr. Gael Le Roux*** [3], ***Dr. François DeVleeschouwer*** [4], ***Dr. Nicolas Cosentino*** [5], ***Dr. André Sawakuchi*** [6]

1. CICTERRA-CONICET, 2. CICTERRA (UNC-CONICET), 3. Laboratoire écologie fonctionnelle et environment (EcoLab), 4. CNRS/CONICET/IRD/UBA, 5. Pontificia Universidad Católica de Chile, 6. São Paulo University, Institute of Geoscience

Atmospheric aerosols can have a significant impact on the global climate system due to the changes in the solar energy balance and the thermal radiation they produce, and also by affecting the primary productivity of oceans associated with increased deposition of iron. The loess-paleosols sequences located in Argentina are the most extensive continental paleo-records of aeolian material in the Southern Hemisphere, recording the deposition of dust transported by two major zonal wind systems: the southern westerly winds and the subtropical jets. In order to increase the understanding of paleo-atmospheric circulation over the Southern Hemisphere during the late Pleistocene-early Holocene, we are planning to determine physical properties (grain-size distribution and magnetic susceptibility) of two loess-paleosols sequences located in elevated regions. These analyses will be followed by optically stimulated luminescence (OSL) dates and provenance studies through radiogenic isotopes. In this sense, we will increase the existing spatial coverage of high-resolution paleoclimatic studies of loess sequences in southern South America, by adding to our previous studies two fairly unexplored sections: one located in the mountainous regions of NW Argentina (2100 m a.s.l.) and another in the Plateau of the Pampean Ranges (1600 m a.s.l). We hypothesize that these loess-paleosols records located in elevated regions, record the deposition of dust transported exclusively by the high-altitude circulation of the subtropical jet streams and grain-size variations of the deposits will evidence changes in the wind intensity. Therefore, these new sections will provide valuable complementary information for the Pampean loess belt about past variability in wind belts' position/intensity. Also, these studies will improve our understanding of the influence of the dust sources located in the Puna-Altiplano Plateau, and the latitudinal movement of the subtropical jet stream circulation over the past climatic hemispheric variability. Ongoing results will be discussed in the conference session.

Simulation of Global Dust Cycle and its Climate Effects During the Last Glacial Maximum

Dr. Qifan Lin [1], *Prof. Yonggang Liu* [1], *Dr. Ming Zhang* [1]

1. Peking University

Dust in the atmosphere affects climate by directly absorbing and scattering solar radiation. In present days, most of the dust is emitted from dry regions over North Africa and Arabian Peninsula. It has been shown that it impacts on global mean surface temperature, African monsoon, the number of tropical cyclones over the Atlantic Ocean, ENSO variability and the strength of Atlantic meridional ocean circulation (AMOC). The Last Glacial Maximum (LGM) is the most recent glacial period with a cold and dry climate. Observations and simulations both show that the dust loading and dust deposition rate during this period are much higher than those during the interglacial period due to the enhanced wind, weakened hydrological cycle and expanded dust sources. In this study, we use the fully coupled global climate model CESM1.2.2 to simulate the climate impact of changes in both vegetation distribution and dust cycle. It is found that the cooling effect of the vegetation change during the LGM was partially compensated by the change in the dust cycle. Moreover, the distribution of dust particle size varied mainly due to the change in dust sources.

4800 years of human induced atmospheric input of heavy metals and mineral matter recorded in an alpine peatland in Tyrol, Austria

Dr. Clemens von Scheffer [1], ***Dr. François DeVleeschouwer*** [2], ***Dr. Gaël Le Roux*** [3], ***Prof. Ingmar Unkel*** [4]

The European Alps have been subject to permanent environmental change during the Holocene, driven either by climate change or the impacts of land use in the form of pastoralism, mining and forestry as well as the continuing expansion of roads, settlements and tourism. The Piller Moor peatland in the Central Alps in Austria is among the few well-preserved peatlands in the region with a high potential to record some of the above-mentioned developments.

Our study uses geochemical data, measured by portable XRF and ICP-MS in a peat core covering the last 4800 years BP, to reconstruct and quantify past atmospheric fluxes of mineral matter and heavy metals in high-resolution. Our results indicate several episodes of metallurgical activities, which were largely unknown so far. The two most striking signals are recorded around 4500 cal BP and 1450 cal BP, with 0.8 and 0.65 $mg*a^{-1}*m^{-2}$ respectively, before any mining operations are historically documented. Furthermore, mineral input over the time of peat accumulation very well reflects erosive land use, like deforestation and grazing, and thus appears to be linked to it almost exclusively. This is most obvious around 2400 cal. years BP with nearly 9 $g*a^{-1}*m^{-2}$ and later in the Middle Ages and modern period. Although climate does not seem to have been the main driver of the signals recorded in the Piller Moor, cold episodes have very likely interacted with both mining and land use. Our results illustrate the high impact of land use on mountain landscapes like the Central Alps by adding a new level of quantitative geochemistry-based detail to knowledge that is mainly based on pollen and archaeological studies.

Present-day and historical dust emission from East Asia associated with climate change and land-use management

Dr. Zhiwei Xu [1]

1. School of Geography and Ocean Science, Nanjing University

Identifying dust sources and investigating the causes of dust emission are crucial not only to understand the comprehensive picture of dust cycle, but also to interpret the preservation of dust (loess) as paleoclimatic records. This study first investigates the spatiotemporal pattern and recent trend of dust emission from China and Mongolia using remote sensing techniques. A relatively long satellite-based time series of dust activity from 2001 to 2020 has been obtained, and it reveals that the Tarim Basin, Gobi and Qaidam Basin Deserts are three major dust sources in East Asia. It also finds that dust activity in northern China has been substantially reduced, and this trend and its pronounced interannual variability can be linked with recent changes in both climatic conditions and land-use management. Secondly, sedimentary records from one typical semi-arid dune field in northern China were used to reconstruct historical dust emission. It is found that dust emission has diminished significantly around 300 years ago because of policy-driven vegetation rehabilitation and dune stabilization. However, changes in human land-use since about 200 years have resulted in dune reactivation, and a large amount of dust was released due to erosion of pre-existing soil surfaces. These results indicate that dust emissions both during the historical period and at present in northern China are strongly influenced by climate change and land-use management. It also implies that the combined effects of climate change and human interference should be considered when evaluating the future potential of dust emission from these regions.

Holocene and Last Glacial Maximum dust deposition rate: Updated global datasets and interpolated fields

Dr. Nicolás Cosentino [1], ***Dr. Gabriela Torre*** [2], ***Dr. Fabrice Lambert*** [1], ***Dr. Samuel Albani*** [3], ***Dr. Aloys Bory*** [4]

1. *Pontificia Universidad Católica de Chile,* ***2.*** *CICTERRA-CONICET,* ***3.*** *University of Milano-Bicocca,* ***4.*** *Laboratoire d'Océanologie et Géosciences, Université de Lille-Unversité du Littoral Côte d'Opale-Centre National de la Recherche Scientifique*

Mineral dust aerosols are a key component of the Earth system, as their dynamics are controlled by and affect climate through diverse mechanisms. To quantify the role of dust on climate variability at glacial-interglacial time scales, it is key to retrieve information on past dust activity as registered geologically in loess deposits, peat bogs, lake and marine sediments, and ice. The two main dust parameters that can be quantified from these archives include deposition rate and particle size distribution. Quantifying these parameters is essential for guiding Earth system simulations with prognostic dust.

Several compilations of these parameters exist spanning the last □30 thousand years before present (ka BP), the newest released seven years ago. During these last years, there has been significant progress in the global coverage of paleo-dust proxies. Here, we update these previous compilations of global paleo-dust deposition flux and grain size observations. Two improvements are introduced. First, given the expected high variability of dust deposition fluxes during the last deglaciation, this new compilation discriminates between pre-industrial Holocene (PIH, year 1850 AD-11.7 ka BP) and Last Glacial Maximum (LGM, 19.0-26.5 ka BP) observations, filtering out dust flux constraints corresponding to the last deglaciation. Second, we derive an explicit uncertainty of bulk and <10-μm paleo-dust deposition fluxes, specific to each site and time period. We do so by compiling metadata necessary to calculate deposition fluxes, and their measurement uncertainties. Based on these new datasets and Climate-Krigger, a recently released global kriging interpolation algorithm, we will produce global interpolated fields of LGM and PIH dust deposition rate, including uncertainty maps that consider both data density and measurement error.

We obtained more than 200 LGM and more than 350 PIH records of bulk and <10-micron dust deposition rate. During the session, we will discuss these new datasets and the resulting interpolation and uncertainty maps, and what new insights they provide on last glacial-interglacial dust activity compared to previous compilation efforts.

Insoluble dust from the Dye 3 ice core

Greenland ice cores provide a vast array of information of climate over the past glacial and interglacial periods. The drilling of the Dye 3 ice core took place at the Southern part of the central Greenland ice sheet (65°11'N, 43°50'W) in 1979-1981. The southern location is characterized by high accumulation rates and it was only the second such deep ice core to be drilled at the time. The core was after retrieval analysed by state of the art methods in the 1980's and for dust analysis coulter counter was applied. The ice has since been in freezer storage both in the USA and in Denmark and other analysis have been conducted.

We analysed the Dye 3 ice core by means of continuous flow analysis (CFA) 40 years after its retrieval (CFA, Bigler 2011,Simonsen, 2018) at the Physics of Ice, Climate, and Earth (PICE) group at the University of Copenhagen. As part of the CFA the quantity and grain size distribution of insoluble particles were measured by means of an Abakus laser particle counter. The sections analysed i 2019 covers the depths of 1753–1820m and 1865–1918m and represents both Holocene, Younger Dryas and Glacial sections (GS 5 to 12). We compare the new high-resolution insoluble dust ABAKUS CFA records with the previous analysis done by coulter counter and thus evaluate the two datasets from different decades against each other. Further we discuss the changes in the dust size distributions over the different climatic periods represented in the ice core. We also evaluate even shorter term fluctuations in dust sizes and their sources –suggesting some volcanic influence.

Monitoring present-day Saharan dust above and below the ocean surface

Prof. Jan-Berend Stuut [1]***, Dr. Catarina Guerreiro*** [2]***, Dr. Michèlle Van der Does*** [3]

1. *NIOZ - Royal Netherlands Institute for Sea Research,* ***2.*** *MARE - Marine Environmental Sciences Center,* ***3.*** *AWI - Alfred Wegener Institute for polar and marine research*

Mineral dust plays an important role in the ocean's carbon cycle through the input of nutrients and metals which potentially fertilise phytoplankton, and by ballasting organic matter from the surface ocean to the sea floor. However, time series and records of open-ocean dust deposition fluxes are sparse. Here, we present a series of Saharan dust collected between 2015 and 2021 by dust-collecting buoys that are monitoring dust in the equatorial North Atlantic Ocean, as well as by moored sediment traps at the buoys' positions at ~21°N/21°W and ~11°N/23°W directly below the major dust Saharan-dust plume offshore northwest Africa. We present dust-flux data as well as particle-size distribution data, and make a comparison of the dust collected from the atmosphere at the ocean surface with the dust settling through the ocean and intercepted by the submarine sediment traps. See: www.nioz.nl/dust

Elemental analysis and reconstruction of Late Holocene climatic and environmental changes on the NE Tibetan Plateau

Dr. Steve Pratte [1], ***Dr. Lydia Mackenzie*** [1], ***Dr. Hongwei Li*** [1]

1. *School of Earth Sciences, Zhejiang University*

Alpine ecosystems are particularly sensitive to climatic and anthropogenic change. The Qinghai-Tibetan Plateau is located near several deserts and drylands and is under the influence of various wind systems including the Westerly Jet and the East Asian winter monsoon (EAWM), which may affect mineral dust supply to the Plateau. As such this region is an important study area of past changes in climate and earth surface processes, and hence the Asian dust cycle.

Sediment cores from lakes and wetlands on the NE Tibetan Plateau were collected to reconstruct climatic variability and landscape evolution during the Holocene. This project aims at reconstructing climatic/environmental changes and anthropogenic activities during the Holocene using sedimentary, biological and geochemical proxies from wetland archives. Dunes nearby the study sites were also sampled. Samples from the sediment cores and dune samples were analyzed for elemental inorganic geochemistry (major and trace elements) in order to determine the composition of the mineral matter of the wetlands and to infer potential environmental and climate changes.

A 3.0m core was collected at Xing Cuo wetland, and the base was dated to 13.0ka cal BP. The core displays several changes between lacustrine sediments and peat ca 4.0ka cal BP, when the wetland was fully established. The timing of the inception of peat accumulation is similar in the other sampled wetlands and suggests a climatic influence over autogenous processes. Preliminary results on rare earth elements suggests the mineral matter in the Xing Cuo wetland is a mixture of local sources such as the dunes surrounding the site, and the deserts of northeastern China. Based on the preliminary age from 4.0ka to 1.5ka cal BP, the REE flux is relatively high and then displays a gradual decrease from 1.5ka onward, suggesting a change either in local environmental conditions or a broader climatic change (potentially changes in WJ or EAWM intensity).

Late Holocene atmospheric particulate loads over the north-western Pacific Ocean: volcanism, dust and human perturbation.

Dr. Sam Marx [1], ***Dr. James Hooper*** [2], ***Dr. Tomohisa Irino*** [3], ***Dr. Osamu Seki*** [3], ***Dr. Nicola Stromsoe*** [4], ***Dr. Krystyna Saunders*** [5], ***Ms. Atun Zawadzki*** [6], ***Prof. Anthony Dosseto*** [7], ***Dr. Geraldine Jacobson*** [5]

Atmospheric particulate transport over the North Pacific Ocean is known to be significant for regional biogeochemical processes and climate. Despite this, there has been little work tracing the changing sources and relative loads of particulate aerosols in this important region over the Holocene. The deserts of northern East Asia are the 2nd largest global dust source, while the eastern extent of East Asia forms part of the Pacific ring of fire, therefore tephra forms a significant, albeit episodic component of atmospheric particulate loads. In this study, we use peat mires from the Daisetsuzan Mountains in central Hokkaido, Japan, to reconstruct atmospheric particulate deposition over the mid to late Holocene. The rare earth element (REE) and eNd composition of sediments deposited in the mire are used to examine particulate origin and to unmix the relative contribution of different particulate sources during the past 4 kyr. During the majority of the record, mineral flux was relatively low and was dominated by dust sourced from mainland China. However, within the past one thousand years more significant changes were in the peat. This includes the deposition of two major tephras. Although short lived, these significant eruptions resulted in an increase in atmospheric particulate flux in the mire by approximately 25 times compared to background dust flux. Further changes are recorded in the very top sections of the peat mire where Chinese dust input increases, especially after 1980 CE. This change is well constrained by ^{210}Pb and fallout radionuclides ($^{239+240}Pu$) and reflects agricultural intensification in China. The onset of significant anthropogenic dust is accompanied by an increase in accumulation of 'industrial' metals, such as Pb and Cu in the studied peat mire. Collectively, this demonstrates the scale of human perturbation of atmospheric particulate, even within a region where the atmosphere is loaded with 'natural' particulate aerosol.

A New Assemblage of Proboscidean Fossils from Central India and Associated Stratigraphic and Taphonomic Observations

Proboscidean fossils from India have been discovered and studied since the 19th century. While the Narmada basin of central India is highly fossiliferous, discoveries of abundant skeletal elements of proboscideans in minimally-disturbed contexts are rare, with the majority of the collections being isolated fragments recovered from surface contexts. Here, we present a new fossil assemblage from the fossil hominin site of Hathnora, which was found to contain multiple skeletal elements such as ribs, humerus, vertebrae, etc. of a proboscidean, possibly all belonging to a single individual. Some of these skeletal elements have been preserved in an intact form. The minimum tentative NISP of the assemblage is 39 and is likely to increase. The quality of preservation and the reasonably large number of fossil bones provides us with an excellent opportunity to perform multi-dimensional analysis. Preliminary taphonomic observations shed light on the post-depositional history of the skeleton to correlate it with the fossil hominin findspot nearby (though both are stratigraphically independent and spatially separate). This study adds another piece to the puzzle of the evolutionary history of Indian proboscideans.

Human response for postglacial sea-level change in Jomon prehistoric sites around Lake Ogawara, Northern Japan

Mr. Yasushi SAITO [6]***, Dr. Mio TAKAHASHI*** [7]

***1.** National Institute of Advanced Industrial Science and Technology, **2.** Faculty of Letters, Komazawa University, **3.** Faculty of Education, Hirosaki University, **4.** Meiji University, **5.** Misawa City, **6.** Agency for Cultural Affairs, **7.** Hirosaki Gakuin University*

In the Japanese archipelago, geoarchaeological research provides useful insights into the relationship between Holocene sea-level change and human activities. This archipelago is in a far field from the ice sheets and characterized by sea-level maximum during the middle Holocene. We focus on the Lake Ogawara, located in Aomori Prefecture, northeastern Japan, which are characterized by many archaeological sites during the Jomon period, ca. 15,000 to 2,300 calBP, around the lake such as the Futatsumori Shell Midden, one of components of the World Heritage Site “Jomon Prehistoric Sites in Northern Japan”. We conducted coring survey around the lake and reconstructed Holocene environmental changes with help of molluscan and fossil diatom analyses.

During the early to middle Holocene, rapid sedimentation of sandy deposits occurred in the northeastern to eastern coasts. According to molluscan and diatom assemblages, it is inferred that subtidal to intertidal environments had been occurred throughout this period. Shell middens during this period, mainly in the eastern coast, are characterized by abundance of *Meretrix lusoria* which prefers a marine sandy bottom. It is suggested that sea-level rise resulted in stable sandy bottom environment and might promoted selective habitation.

After that, shell middens were distributed mainly in the western coasts. According to the sea-level change curve around the study area (Yokoyama *et al*., 2012), sea-level rise rate slowed down after 7,000 to 6,000 calBP. This probably resulted in decrease in water depth, which indicates that caused environmental changes in the shellfish. It is possible that this environmental change caused people to move their settlements.

Around 4,800 calBP, *Corbicula japonica*, prefers brackish water, replaced M. lusoria. Results in the southern coast and lake bottom (Yamada *et al*., 2010) suggests that water salinity decreased after ca. 5,000 to 4,000 calBP due to developments of sand bars. Sea-level falling after ca. 4,000 calBP likely triggered sand bars development. Decrease in water salinity probably caused shell assemblage changes, and additionally caused archaeological sites migration to the northern coast, near the bay mouth.

Mediterranean coasts have represented great places for relations and exchanges among peoples, especially since the proto-historical periods. In the Mid to Late Holocene (e.g., last 8 millennia) the combined effects of the slowing of sea-level rise and the increase of sediment input caused by both climatic and anthropogenic factors triggered the development of large Mediterranean coastal plains. These plains, heavily colonized by civilizations of pre-historical and historical periods, represent a major archive to better elucidate the millennial man-environment interactions along the Mediterranean coastal landscapes.
Here we present a geoarchaeological investigation carried out at the archeological site of Nora, a major Punic-Roman town placed in southern Sardinia (western Mediterranean Sea). The multiproxy analysis involved meio-fauna (benthic foraminifers and ostracods) and palynological analysis performed on two new cores collected in the coastal lagoons surrounding the archeological site. Furthermore, we carried out a geomorphologic and petrographic study of a number of beachrocks (paleo-shorelines) found few meters below the present sea-level. The chronological frame, based on a new set of 16 radiocarbon dates, allowed to provide fresh insights into the coastal modification of the last 4.3 millennia BP. In particular, we performed a high-resolution reconstruction of the local relative sea-level changes, which did not exceed the 1.35 m in the last 3500 years, and we identified the palaeoenvironmental dynamics that affected the lagoon system. These data allowed reconstruct the shoreline evolution of the area during the main period of occupation of the archeological site (e.g., from the Nuragic to the late Roman periods). This has been compared with the high-resolution mapping of the archeological structures in order to reconstruct their relationship with the paleo-shoreline at the time of their functioning period. Furthermore, palynological data elucidated the millennial variability in the vegetation dynamics as well as the anthropic influence in the changes of vegetational cover during the different archeological periods.

Changes in coastline and human exploitation of marine resources in S of Iberia (province of Malaga, Spain) during the late Upper Pleistocene and Early Holocene (ca. 15 – 11 ka cal BP)

Dr. Jesús F. Jordá [1]***, Dr. J. Emili Aura*** [2]***, Dr. Esteban Álvarez-Fernández*** [3]***, Dr. Adolfo Maestro*** [4]***, Dr. Lidia Cabello*** [5]***, Dr. Juana Molina Salido*** [1]***, Ms. Amaia Aguirre-Uribesalgo*** [6]***, Dr. María Saña*** [6]

On the coastal strip of the S of Iberia (South of Spain), in its central sector corresponding to the province of Malaga, there are numerous karstic cavities with important stratigraphic sequences of the late Upper Pleistocene and Lower Holocene that contain abundant remains of human occupations, dated between ca 15 – 11 ka cal BP. The techno-economic characteristics of its archaeological records indicate that they correspond to the Magdalenian and are characterized by a strong presence of remains of marine animals, both invertebrates (molluscs, crustaceans, barnacles, echinoderms), and vertebrates (fish, birds, marine mammals) that, in their vast majority were contributed, processed and abandoned by the human populations that occupied these caves. At that time, the coastline was in positions lower than the current level (maximum -120 m, minimum -50 m) and at a distance from the current line between 4.5 and 1 km. The main sites that provide a good archaeological record are the Cave of Nerja (Nerja), Victoria Cave (Rincón de la Victoria) and the complex of sites of La Araña (La Cala del Moral). In this work we will focus on the Magdalenian occupations of these sites, located in different environments, from cliffs and coves to sandy beaches, allowing to establish a relationship between their paleogeographic position and the variation in the use of marine resources. This analysis will allow to fix the variations of the coastline throughout the episodes of human occupation, allowing to trace a paleogeographical reconstruction of the coast of Malaga in the final moments of the final upper Pleistocene.

The paleoenvironmental reconstruction of the Sarandapotamos river valley (Amarynthos, Evia Island, Greece): studying long term human-environment interactions.

Mr. Tibor Talas [1]

***1.** Institute of Earth Surface Dynamics, University of Lausanne*

The catchment basin of the Sarandopotamos river on the island of Evia (Greece) has been an environment of habitation and worship since the early Neolithic. During Classical Antiquity, it hosted several settlements, as well as a major sanctuary dedicated to Artemis Amayrisa, which was recently discovered by a Swiss-Greek team. This discovery aside, a significant research agenda is to understand if, and the extent to which, the human history of occupation and abandonment in this region is related to its environmental history. Thus, the aim of this project is to use a suite of paleoenvironmental reconstruction methods to recreate ancient landscapes, environments, and evolution in order to understand society-environment interactions.

A model of the sedimentary dynamics of the catchment is being carried out using LAPSUS software, and sedimentary cores are being obtained in order to understand the relationship between environmental and human-driven (e.g. land use) change in the catchment, the geomorphic response of the delta, and the history of human occupation. The relationship between the delta and eustatic and isostatic history also has to be understood, which emphasizes the complexity of the project.

A multi-disciplinary and multi-scale appraisal of environmental and human history will significantly contribute to a better understanding of human-environmental interactions. This poster will present preliminary modelling results that demonstrate the sensitivity of the land-marine interaction to sea-level rise and delta dynamics from the late Pleistocene through the Holocene to the present.

Impact of human activities on increasing siltation along the south-western coast of India since the inception of the Anthropocene

Prof. Busnur Manjunatha [1]

1. *Department of Marine Geology, Mangalore University*

The South-Western Coast of India (SWCI) between 12^o N 15^o latitudes is the zone of intense south-west monsoon rainfall and often blanketed by evergreen vegetation and forest along the adjoining Western Ghats escarpment. The coastal zone is a narrow strip of land that varies in width from <5 km in the north to around 70 km in the south. The coastal geomorphic features indicate evidence of both sub-mergence and emergence of the coast due to sea-level fluctuations. There are three medium size rivers (~2000 - 5000 km^2) and more than 10 small rivers (< 2000 km^2) draining the area. The coastal zone is densely populated and anthropocentrically clustered with industrial and urban regions. The coastal region is under the stress of deforestation, changes in the lan-duse pattern, urban and industrial expansion and pollution, in terms of the accumulation of excess of silt and often pollutants. Five sediment cores collected from the estuaries and coastal embayments indicate that the silt contents in the coastal sediments increased from 1 % to 60%. The textural analysis of sediment indicates that silt contents generally increase from core bottom to the top over a span of about 70 years on the basis Cs-137 isotope activity. This could be due to the decrease in the velocity of the river flow as a result of the construction of dams and barrages across the rivers, as well as new bridge construction for the expansion of the national highways and construction of many breakwaters. Though the increasing trend in the accumulation of the silt is quite common along the coast, however, at some estuaries and backwater regions, there are sub-surface lows of silt fraction, suggesting episodic increase of sand fraction due to intense rainfall. The common consequences of human impacts on the coastal zone are coastal erosion, reduction in the dissolved oxygen in the coastal water, problems to navigation, accumulation of hazardous contaminants in the fine grained sediments. Due to this, there has been a considerable decrease in the dissolved oxygen concentrations in the coastal water, decline in the benthic fauna population as well as their biodiversity.

Geoarchaeology, chronostratigraphy and human occupation of the cental sector of the Cantabrian coast (North Iberia) during the Late Upper Pleistocene and Lower Holocene: The prehistoric sites of the Sella River estuary (Ribadesella, Asturias, Spain)

Dr. Jesús F. Jordá [1], ***Dr. lidia Cabello-Ligero*** [2], ***Dr. Marian Cueto*** [3], ***Dr. Cristina López-Tascón*** [4], ***Dr. Adolfo Maestro*** [5], ***Dr. Alberto Martínez-VBilla*** [6], ***Dr. Juana Molina Salido*** [1], ***Dr. Jesús Tapia*** [7], ***Dr. Esteban Álvarez-Fernández*** [8]

1. *Universidad Nacional de Educación a Distancia (UNED),* ***2.*** *Universidad de Malaga,* ***3.*** *Instituto Internacional de Investigaciones Prehistóricas de Cantabria (IIIPC)-Universidad de Cantabria,* ***4.*** *Universidad de Oviedo,* ***5.*** *Centro Nacional Instituto Geológico Minero de España - CSIC,* ***6.*** *Abamia Arkeos - Centro Ecomuseo Fauna Glacial de Avín,* ***7.*** *Sociedad de Ciencias Aranzadi,* ***8.*** *Universidad de Salamanca*

The archaeological researchs that have been carried out in the last decade in the Sella river valley (central sector of the Cantabrian coast, North Iberia), in general, and in its stuary, in particular, are making it possible to specify the occupations of the groups of hunter-gatherers-shellfish gatherers who lived in southwestern Europe during the Upper Pleistocene and Lower Holocene. Thus, the review of the stratigraphies and archaeological materials from ancient excavations and the performance of new research projects at the classic sites located at the West bank of the stuary of Sella River (Cova Rosa, El Cierro, Les Pedroses, La Lloseta and Tito Bustillo) have made it possible to obtain new radiocarbon dating that allows us to specify the chronostratigraphic position of the different sequences while achieving a better understanding of the geological processes involved in the formation of these karstic deposits. In addition, the results of these investigations have made it possible to carry out a paleogeographic reconstruction of the coastline throughout the period between OIS 3 and OIS 1.

The TESTEREP project: integrated land-sea research to investigate the evolution of a former peninsula along the Belgian coast as a case study for coastal management

Dr. Víctor Cartelle [1], ***Dr. Soetkin Vervust*** [2], ***Dr. Ruth Plets*** [1], ***Ms. Zoë Vanbiervliet*** [2], ***Dr. Tine Missiaen*** [1], ***Dr. Pieterjan Deckers*** [2], ***Mr. Wout Van Wesemael*** [1], ***Prof. Marc De Bie*** [2], ***Mr. Bart De Smet*** [1], ***Mr. Jan Seys*** [1], ***Ms. Chantal Martens*** [1], ***Ms. Vicky Vermeulen*** [3], ***Ms. Merel Steeland*** [3], ***Dr. Jaak Monbaliu*** [4], ***Dr. Erik Toorman*** [4], ***Dr. Christian Schwarz*** [4], ***Mr. Yağız Arda Çiçek*** [4], ***Dr. Toon Verwaest*** [5]

1. *Flanders Marine Institute (VLIZ), Belgium,* ***2.*** *Multidisciplinary Archaeological Research Institute (MARI), Vrije Universiteit Brussel, Belgium,* ***3.*** *Digital Arts & Entertainment Research (DAE), Hogeschool West-Vlaaanderen, Belgium,* ***4.*** *Department of Civil Engineering – Hydraulics and Geotechnics, Katholieke Universiteit Leuven, Belgium,* ***5.*** *Flanders Hydraulics, Belgium*

Over the past decades, geological, paleoecological, archaeological, and historical research has led to a general understanding of the Belgian coastal plain's evolution during the Holocene and how people interacted with this changing landscape. However, existing research has for the most part been fragmented and fails to connect findings across the land-sea boundary. Questions about the interaction between on- and offshore geomorphological changes and the human impact on the landscape remain unanswered both on short- and long-term scales. In the TESTEREP project, studying the last 5000 years of Belgian coastal evolution, we aim to address these shortcomings through novel interdisciplinary research across the land-sea border. Testerep was once a peninsula located in the middle part of the Belgian coast, separated from the mainland by a broad tidal gully incised during the Iron Age. This gully was embanked and dammed during the Middle Ages and silted up as a consequence. Today, the landward part of the former peninsula has become part of the polders and beach, while the seaward side was lost to the sea. To study the evolution of the Testerep landscape over the past 5000 years, existing data on its historic natural (e.g. palaeo-channels) and artificial (e.g. embankments) features will be supplemented with new on- and offshore data for the area, collected using geophysical surveys, coring, metal detecting, excavations and sampling for radiocarbon and OSL dating. All information will be integrated through GIS analyses to produce palaeo-geographical maps that will form the basis for geomorphological and hydrodynamic modelling. This new land-sea integrated research will ultimately result in a better understanding of the driving factors behind the landscape change, assessing the relative importance of natural changes and human interventions. The project also includes a significant outreach component, using innovative virtual landscape reconstructions to pass on its multidisciplinary knowledge to stakeholders from policy, industry and the general public. This way, the project aims to raise public awareness about coastal dynamics and current threats and to inspire sustainable coastal management strategies for the future.

Reconstructing past environments at Ambergris Caye Belize: Evidence for Holocene wetland development and historical storms using a multiproxy approach.

Ms. Grace Summers [1], ***Dr. Emma Hocking*** [2], ***Prof. Bronwen Whitney*** [2]

1. Department of Geography, Durham University, Durham, DH1 3LE, UK, 2. Geography and Environmental Sciences, Northumbria University, Newcastle, UK

Patterns of long-term environmental and climatic change within the Yucatan Peninsula are fragmentary, with previous research focusing on periods of droughts related to the classic Maya and being restricted to mainland sites. Coastal regions offer an alternative archive for constraining environmental change, due to their sensitivity to both anthropogenic and atmospheric pressures. To improve the spatial and temporal pattern of climate within the Yucatan Peninsula, we present the first coastal palaeoclimatic reconstruction on the island of Ambergris Caye, Belize. We employ both diatom and geochemical analyses, to infer historical storms and wetland development from a 3.5 m peat core covering the last 6000 years. We interpret three periods of alternating hydrological change dating at ~4079-2609 BC, ~2609 BC - 620 AD, and ~1620 AD – present. Determining the hydrology of the bog was complex, with sparse diatom counts and limited preservation throughout. Geochemistry provided alternative means to constrain the hydrological changes within the wetland. Periods of increased moisture were identifiable from the increasing concentration of bog wetness, and redox indicators (Br, Mn). We speculate a correlation between the position of the intertropical convergence zone and moisture content, with northward movement resulting in precipitation. In contrast, drier intervals (~2609 BC- 620 AD) are identifiable by the significant decline in geochemical concentrations and transport of Saharan dust. Peaks in marine (Ca), seawater (Cl) and high energy (V) indicators imply six occurrences of marine inundation dating to approximately 2439 BC, 1591, 1769, 1874, 1930, and 1961 AD, however, there is no clear stratigraphic evidence present. Of the proposed tropical storms, two correspond with the historical records of hurricane Hattie (1961) and the unnamed 1874 event, resulting in four undocumented storms hitting the coast of Ambergris Caye, throughout the modern and palaeo record.

Late Holocene environmental dynamic of the Umm al-Quwain (UAE) lagoon and its implication for the quest for the ancient harbour of Omana

Dr. Luca Forti [1], ***Dr. Michele Degli Esposti*** [2], ***Prof. Mauro Cremaschi*** [3], ***Mr. Federico Borgi*** [4], ***Prof. Andrea Zerboni*** [1]

1. *Department of Earth Sciences, University of Milan,* **2.** *Institute of Mediterranean and Oriental Cultures, Polish Academy of Sciences.,* **3.** *Dipartimento di Scienze delle Terra, Università degli Studi di Milano,* **4.** *University of Milan*

Along the coastline of the Umm al-Quwain lagoon (United Arab Emirates), the Late Pre-Islamic (LPI; 3rd century BC – 3rd century AD) archaeological site of Ed-Dur (4 km inland from the extant coastline) is believed to be the ancient capital of *Omana/Ommana* mentioned by Pliny the Elder and the anonymous writer of the *Periplus Maris Erythraei* in the 1st century AD. On the contrary, the position of the harbour of ancient *Omana/Ommana* is still a matter of debate because the geomorphological configuration of Umm al-Quwain lagoon hides archaeological evidence of its existence. Remote sensing and fieldwork along the lagoon revealed that the north-eastern shoreline of the island of Akab displays a rectangular feature, likely related to human modification. Therefore, the area was investigated through several trenches, preserving sedimentary evidence for the shift of the sedimentary environment with the progressive migration seaward of the mangrove followed by the formation of a sabkha then covered by sand dunes. This evidence suggests that the sea level was higher than today likely supporting the exploitation of the island as a harbour. Archaeological evidence collected during the archaeological survey of the Island by the writers, as well as by old excavations, confirms the occupation of the island during both the Late Pre-Islamic and the middle Islamic (14th-15th centuries AD) periods. Such human presence could lend further support to the interpretation of Akab island as the locus of an artificially excavated harbour, although its precise date remains unknown. The data collected so far allow the reconstruction of a trade route over the Arabian Peninsula and shed light on the correlation between the mainland and an associated lagoon harbour within the context of the landscape evolution linked to Holocene climate fluctuations and the relative sea-level changes along the lower Persian Gulf.

Fungi marine bioerosion in human bones recovered in the Atamaca Desert (Northern Chile)

Dr. MANUEL ABAD [1]***, Ms. Marcela Urizar*** [2]***, Dr. Tatiana Izquierdo*** [1]***, Ms. Romina Figueroa*** [3]***, Mr. Maurice Guicharrousse*** [4]

1. *Department of Biology and Geology, Physics and Inorganic Chemistry, Universidad Rey Juan Carlos,* ***2.*** *Facultad de Humanidades y Educación. Universidad de Atacama,* ***3.*** *Museo Paleontológico de Caldera,* ***4.*** *Corporación de Investigación y Avance de la Paleontología e Historia Natural de Atacama (CIAHN Atacama)*

In 2013 a human burial was found 2 m below the surface in the littoral dunes of Calderilla Beach (Caldera, northern Chile) at approximately 5.8 m above sea level. The bones represent an almost complete skeleton of a young male between 16 to 20 years old and, although no funerary artifacts were found it is possible that the grave had been previously plundered. The intense wear of the molars is characteristic of individuals of the Archaic period that inhabited the coasts of the Atacama Desert between 10,000- and 2,400-years BP. The most significant feature of the bones is that they appear completely bioeroded by endolithic microborings often highlighted by the precipitation of iron oxides or filled with a thin dark material. Al least two morphotypes of traces have been identified. The most common is a complex network of (sub)parallel radiating and ramifying tunnels of up to 100 microns in diameter with a straight to sinuous pattern. They are partly unroofed, in intermittent contact with the substrate surface. The other morphotype show a characteristic tear-shaped segments that gradually widen from a thin filament. A central cavity presents a slightly larger dimension and depth of penetration and develops below an initial point of entry, from which several fine segments (< 20 microns) emerge.

The dimensions and morphology of the microborings strongly suggest a saprophytic fungal tracemaker. In addition, the sandy deposit that appear in the cranium cavities includes siliceous sponge spicules, echinoderm spines, ostracods and marine benthic foraminifera. The taphonomic evidence suggests that the traces were produced during an undetermined period of marine water subaqueous exposure under the ground in a sandy beach (water table). This stage took place prior to one or several episodes of relative sea-level drop, probably caused by the most recent and abrupt coseismic uplift of the coast. Future paleoanthropological and geoarcheological studies will give further insights about the human settlements of the southern Atacama Desert coasts during the Holocene and the consequences of large earthquakes and tsunamis on the prehistoric human societies.

Fennoscandian erratics as a raw material for Neolithic tool manufacturing at the Baltic Sea coast (Rzucewo site)

Prof. Piotr Woźniak [1]***, Prof. Piotr Czubla*** [2]

1. *Faculty of Oceanography and Geography,University of Gdańsk,* ***2.*** *Faculty of Geographical Sciences, University of Łódź*

The multicultural archaeological site in Rzucewo (southern Baltic Sea coast), is a testimony to the use of environmental resources and adaptation to its changes since at least the sixth millennium BC. The area of the Puck Lagoon, on which the site lies, is the result of a multi-stage development: processes occurring during the last ice-sheet decay, transformation of glacial relief in the terrestrial environment, and then the sea ingression and the creation of the lagoon-marine environment.

During archaeological surveys a significant number of stone objects made of Fennoscandian rocks and those from the bottom of the Baltic Sea were obtained there. In the analysed set (334 items), the most common are sandstone, followed by diabases, amphibolites and granitoids. Sorting of a raw material and use its specific types preferred for the production of a given type of tool is recognized. The places of its acquisition shifted with the changes in the configuration of the coast caused by the sea level rise.

The most numerous in the analysed set are axes and adzes (91 specimens). Very common are artifacts that are evidence of the production of stone tools, especially polishing slabs (66 specimens, usually only as their fragments), accompanied by 7 polishing boulders. High intensity of tool use was identified, including reuse of worn and damaged tools, simultaneously with the fairly common presence of semi-finished tools and tools without signs of use. This is confirmed by earlier reports that in Rzucewo there is not only a record of the production of stone tools, but also regular processing of other material, such as wood, in order to make dugouts canoes. The complex of intentionally prepared places for the Neolithic production of stone tools is a very rare archaeological find in the northern Poland, and unique in the area of the Baltic countries.

Pollen and Non-Pollen Palynomorphs to detect the anthropogenic impact in the Mar Piccolo (Taranto, Southern Italy) during the Late Holocene

Mr. Gabriele Niccolini [1], ***Mr. NICCOLO' DEGL'INNOCENTI*** [1], ***Prof. Adele Bertini*** [2], ***Prof. Giuseppe Mastronuzzi*** [1], ***Prof. Massimo Moretti*** [1]

1. *Department of Earth and GeoEnvironmental Sciences, University of Bari,* ***2.*** *Dipartimento di Scienze della Terra, Università degli Studi di Firenze, Via La Pira 4, I-50121 Firenze, Italy*

The Mar Piccolo area has been settled since the Bronze Age whereas the history of its more close center Taranto dates back to the 8th century BC when it was founded as a Greek colony (Taras). Pollen and Non-Pollen Palynomorphs from a core (S05B, 29.49 m thick)) retrieved in the Mar Piccolo basin allow to investigate the paleoenvironmental changes, including those associated to the progressive increase of the anthropogenic impact, during the Late Holocene. Palynological data provide indication on the crops (e.g., Cereals), land use (e.g., *Olea*), farming (e.g., *Sporormiella*-type) and human/domestic animals presence (e.g., *Trichuris* sp.). They are expressed as: i. percentage of single taxa (e.g., *Olea*, *Vitis*, Cereals), ii. anthropic indexes (e.g., Regional Pastoral Index; Anthropogenic Nitrophilous Herbs), iii. concentrations of NPPs having a clear anthropic origin (e.g., *Trichuris*, *Ascaris*). Starting from 10.74 m a concomitant presence of Cereals, *Trichuris* and *Ascaris* attests the presence of settlements in the Taranto area at least since the Bronze Age. The continuous increase in *Olea* and anthropic NPPs highlights an increase in human activities around the basin possibly during the Greek and Roman periods. A subsequently notably increase of agriculture and herding activities during the Middle Ages is attested by both the great abundance of *Olea* and high concentration in *Trichuris* and *Ascaris*. During this time, historical events as famine, wars, or barbaric invasions are in fact well expressed by the percentage changes of some key taxa (e.g., *Olea*). The regional anthropic impact during the historical time, is also evaluated and compared to that recorded in the closest areas (e.g., Lago Alimini Piccolo). Worthy of note is the finding of pollen grains such as *Daphne caucasica* and *Citrus medica* which provide relevant information on chronology and trade.

Spatio-temporal analysis of archaeological radiocarbon dates from Hispaniola, Puerto Rico, and Cuba: implications for island colonization patterns and impacts

Mr. Cesar Arturo Vera Florez [1], ***Dr. Matthew Peros*** [2], ***Mrs. Joanna Iosifidi*** [3]

1. Université Sherbrooke, 2. Bishop's University, 3. Durham University

Island ecosystems are vital to the study of biodiversity, human impacts on the environment, and pathways of migration and colonization. An increased amount of work has focused on the patterns, timing, and causes of the peopling of the insular Caribbean, which shows – among other things – that humans arrived in the Greater Antilles around 6,000 cal BP. However, relatively little work has focused on within-island colonization patterns. In order to address this, we utilize a new archaeological radiocarbon database of the Caribbean and, using a GIS approach, undertake a spatio-temporal "Hot and Cold Spot" analysis of the C14 data to examine within-island settlement patterns for Hispaniola, Cuba, and Puerto Rico. This analysis involved a calibration of all C14 data, which was then analyzed in ArcGIS Pro using IDW interpolation at bins of 800 to 500 years to highlight clusters of dates, representing areas of settlement (i.e., "Hot Spots"), and the inverse (i.e., "Cold Spots").

For Hispaniola, the results show that at 2,500 cal BP, human activity was concentrated at the south-eastern part of the island, but by 800 cal BP settlement shifted to the center-north. In the case of Puerto Rico, at 2,000 cal BP, settlement was focused in the east, whereas by 800 cal BP it had shifted to west. Our findings, while preliminary, will help archaeologists better understand the processes and causes of human dispersal within these large and environmentally diverse islands. In addition, our work has implications for questions to do with mid-Holocene extinctions in the Caribbean, and how early peoples may have altered island ecosystems. Future work will therefore focus on comparing this data with paleontological and paleoecological datasets.

The discovery of rice phytoliths from the late Holocene coastal peat layer in the Haitan Island, Southeast China and its significance

Dr. Xinxin Zuo [1]

1. *School of Geographical Sciences, Fujian Normal University*

The Haitan island in Fujian province, located on the southeast coast of China, is an important junction for the spread of Austronesian-speaking populations, their cultures, and agricultural technology to Taiwan island, Island Southeast Asia, and the Pacific Islands. However, questions regarding the emergence of agriculture in the islands of Fujian remain unclear, which hampers the understanding of the routes and processes of the southward spread of agriculture. In this study, samples from the peat layer of Core CJA2021 (25°37′5.81″N,119°45′28.74″E, a.s.l = 15 m), which is located in the Changjiangao Bay of the Haitan island, were collected for the radiocarbon dating, phytolith and pollen analyses. The dating result shows that the peat layer was developed between 3249 and 3060 cal a BP. *Typha*, Cyperaceae, and reed were the main morphotypes of pollen or phytolith counted in the peat layers, indicating a wetland and swamp condition in the Changjiangao Bay. The identification of rice bulliform phytoliths and cereal-type pollens in the peat layer suggests the emergence of rice agriculture on the Haitan island approximately 3,000 years ago. Rice phytoliths found in the Haitan island are the earliest rice remains in the islands of Southeast China, except for Taiwan island and Penghu islands. This study provides a clue for the further survey of archaeobotanical research on island sites. In addition, it may offer a new perspective to research the spread of prehistoric agriculture and its environmental background on the coastal islands of Southeast China.

Geomorphology, settlements and infrastructures in the ancient lagoon of Venice (Italy)

Prof. Paolo Mozzi [1] ***, Prof. Carlo Beltrame*** [2] ***, Dr. Sandra Primon*** [3] ***, Dr. Stefano Medas*** [4]

1. *University of Padova, Department of Geosciences,* ***2.*** *Ca' Foscari University of Venice, Department of Humanities,* ***3.*** *Free-lance Geologist, Venice,* ***4.*** *University of Bologna, Department of Cultural Heritage*

The natural dynamics of formation and transformation of lagoons depend on the balance between the development of barrier islands, fluvial and tidal sedimentary input to the lagoon basin, and local trends of relative sea level (RSL). The evolution of the lagoon of Venice, the largest in the Mediterranean, is paradigmatic in this sense, as it encompasses all these three forcing factors. Its formation started about 7 kyr ago, thanks to the development of extensive barrier islands fed by longshore currents. These latter have been receiving abundant sediments from the mouth of major Alpine rivers, such as the Po, Adige, Brenta and Piave rivers, that debouch in the northwestern sector of the Adriatic Sea, in a general trend of RSL rise driven by geological land subsidence. The ancient human population and exploitation of the lagoon of Venice took place in this dynamic geomorphological and environmental context. In order to fully understand the processes of formation and preservation of lagoon archaeological sites, and to try to define the territorial dynamics underlying their distribution and function, it is thus necessary to reconstruct the changing structure of the physical landscape. In our contribution, we outline the geomorphological and paleoenvironmental evolution of the lagoon over the last millennia, in terms of coastline modification, re-arrangement of the tidal network, RSL rise, migration of river mouths. We further discuss their geoarchaeological significance in relation to main known settlements and infrastructures dating to the Roman period, as well as to the preliminary results of ongoing investigations (coring, surface and underwater archaeological surveys, geophysical surveys) at specific sites.

AMS radiocarbon ages of the Karekare Marsh, Rarotonga Island, Cook Islands

Prof. Mitsuru Okuno [1], ***Dr. Toshiyuki Fujiki*** [2], ***Mr. Keisuke Sakai*** [3], ***Prof. Hiroshi Moriwaki*** [4], ***Prof. Kei Kawai*** [4], ***Dr. Toshio Nakamura*** [5]

1. Osaka Metropolitan University, 2. Okayama University of Science, 3. Kobe University, 4. Kagoshima University, 5. Nagoya University

Rarotonga Island, situated in the southern Cook Islands, South Pacific Ocean, lies in the western part of Polynesia. The apparent interruption of deposition (hiatus) between 2.8 and 0.7 cal ka BP (about 130 cm depth) in a 4 m-long core from the Karekare Marsh (elevation 1.65 m; area 0.114 km2) on Rarotonga Island, was previously reported. On Mangaia Island, located about 200 km to the southeast, vegetation changes were also reported to have occurred about 2 cal ka BP, suggesting that humans may have arrived during this period. To determine the hiatus of 2.8 - 0.7 cal ka BP is widely spread in this marsh, which may be related to the arrival of humans and the reason of lacking archaeological sites, we collected the 1150 cm-long core “Karekare 19-2”. It consisted of peat from 0 to 17 cm, silt from 17 to 154 cm, peat with plant fragments from 154 to 584 cm, silt from 584 to 1076 cm, and sandy silt from 1076 to 1150 cm. We obtained AMS radiocarbon dates for 37 higher plant fragments from various horizons, of which 11 were rejected due to stratigraphic inconsistency. These are thought to have been contaminated in during core sampling. The lowest radiocarbon age is 6320 +/- 30 BP, suggesting that this core records paleoenvironmental information for the past 7000 years. The hiatus between 2.5 and 1.1 cal ka BP at about 100 cm depth in this core is also recognized. Therefore, there is a high probability that hiatus is widespread in this marsh.

Comparing online versus offline assimilation for paleo-reanalysis

Dr. Anqi Lyu [1]***, Prof. François Counillon*** [1]

1. Nansen Environmental and Remote Sensing Center and Bjerknes Centre for Climate Research

Much of our understanding of historical climate comes from reanalysis based on instrumental data, but their length limits their use in studying longer-term climate variations. Paleoclimate proxy records are long enough to monitor multidecadal variability, and model-based paleo-proxy reconstruction has recently emerged to serve this purpose. However, they are reconstructed using an offline data assimilating approach that linearly combines states from a large dynamical model database – an approach that may misrepresent nonlinear quantities. Here, we compare the offline and online data assimilation approach using the Norwegian Climate Prediction model (NorCPM), which is based on the Norwegian Earth System Model and the Ensemble Kalman Filter data assimilation method. We assimilate coral data to constrain the ocean component of this model. The proxy base model that formulates the ensemble of proxy from the model state is constructed from the instrumental NorCPM reanalysis to mitigate model bias. In the online assimilation, we use 30 members and assimilate proxy every month. For the offline approach, the static ensemble is composed of 300 snapshots sampled from a stable pre-industrial model simulation. The performance of offline and online data assimilation is compared for the period 1950-2010 and validated using instrumental data.

Landslide zones detection with Sentinel-1 radar images: case of instabilities induced by sismic sequance, August 2020 in Mila, Algeria.

Mr. Ahmed Serkhane [1], ***Dr. Rabah DJEDDI*** [1], ***Mr. menad SADI*** [2], ***Mr. Yazid RABAH*** [2]

1. *Algerian geological survey agency/ University of sciences and technology houari boumediene,* ***2.*** *Algerian geological survey agency*

Mountainous regions are subject to lands instability in Algeria and throughout the world. Earthquakes of high to moderate magnitudes are often landslide triggers that aggravate damage and loss. The region of Mila (Algerian NE) suffered on August 2020 an sismic sequence (two earthquakes) of magnitudes Mw=4.9 and Mw=4.4 that triggered many instabilities of ground causing significant damage to dozens of buildings. In order to contribute to the mapping of the inventory of these induced shifts, we used Interferometric analysis by radar imaging (InSAR). Two images from ESA's Sentinel-1A satellite, taken before and after the sismic sequence, were used. The result is very interesting as it allowed us to identify six (6) areas of major landslides whose area varies from 0.58km2 to 6.89km2. This result shows, the interest of new technologies, particularly InSAR, in identifying landslide areas during strong and moderate seismic events or during periods of intense rainfall. On the other hand, it raises the issue of the geo-risks associated with earthquakes in mountainous regions that must be integrated into urban development and expansion plans.

Frontiers of computer vision and artificial intelligence for the monitoring of the coastal systems

Dr. Giovanni Scardino [1]***, Prof. Giovanni Scicchitano*** [1]***, Prof. Pedro JM Costa*** [2]***, Dr. Marco Chirivì*** [3]***, Dr. Antonio Luparelli*** [3]

1. Department of Earth and GeoEnvironmental Sciences, University of Bari, 2. IDL – Instituto Dom Luíz, Faculdade de Ciências da Universidade de Lisboa, 3. CETMA Centro di Ricerca Europeo di Tecnologie Design e Materiali

An assessment of dynamic parameters characterizing a coastal system needs a large amount of data, which can be acquired and processed through new machine learning and computer vision techniques. These techniques allowed to implement a video monitoring system to obtain large spatially and temporally datasets well-distributed along the coasts. On the other hand, the video records can compile a series of continuous frames where a lot of dynamic parameters can be detected, such as wave flow, wave height, sediment movements, etc. In this work, we showed an innovative system composed of a combined approach between geophysical surveys, Convolutional Neural Network (CNN), and Optical Flow techniques to assess some parameters connected to energetic and mass balance of the coastal system. The sandy coast of Torre Canne was studied through a combined approach involving field surveys and video monitoring. A topographic survey was performed through terrestrial laser scanner and GPS-RTK for the coastal stretch continuously monitored by a web cam system. Furthermore, some video records were obtained through action cameras to extract video frames with high frequency. Classification and segmentation techniques were implemented in a CNN to extract the low frequency parameters of the sea-state (such as tide phases and surges) and the coastal landforms imprinted in the video frames. The high frequency parameters (such as wave flow and sediment movements) were extracted through Optical Flow techniques applied on the video records of action cameras. Results obtained through CNN and Optical Flow provide the physical parameters of wave propagation and coastal landforms. The application of CNN and Optical Flow techniques could represent an improvement in the application of monitoring techniques in coastal environments, permitting to automatically collect a continuous record of data that are usually not densely distributed or available.

Reconstructing Late Quaternary sea-level changes in the Western Mediterranean: Preliminary results from Corsica and Sardinia islands.

Late Quaternary interglacials are relevant to understand how our planet responds to moderate warming trends. Late Quaternary proxies highlight that important changes may have occurred in coastal areas under higher global temperatures, leading to the deposition of peculiar morphologies and deposits, and driving changes of faunal distribution patterns. Studying the geological imprints of past interglacials is a fundamental tool to frame modern changes, and to assess the severity of future coastal changes as temperatures continue to raise unabated. The Mediterranean coastal zone has preserved a high number of Late Quaternary deposits, which may be used as archives to study sea-level and coastal environmental changes throughout the Late Quaternary. A recent review article summarized the published literature on Marine Isotopic Stage 5 (~80 to 130 ka) sites in the Western Mediterranean. From this review, it appears clear that the two major islands in this region, Corsica and Sardinia, host a wide variety of Late Quaternary marine and coastal deposits. Both islands appear to be tectonically stable within the Mediterranean context, therefore such deposits might be considered as a good benchmark for MIS 5 sea level in the basin. One aspect emerging from the review is the lack of standardized description and precise elevation measurement of the Late Quaternary deposits in Sardinia and Corsica. This hinders, at least in part, the potential to use them for paleoenvironmental and sea level reconstructions. This presentation belongs to an INQUA fellowship applied by Sebastian Richiano for the study of several localities in both islands joined with the team led by Alessio Rovere at Ca' Foscari University of Venice during May-June 2023. We will develop the two most informative sites and analyse them first to present them to the INQUA conference in Rome.

A new approach for studying sea-level changes using molecular fossils

Dr. Martina Conti [1], ***Dr. Martin Bates*** [2], ***Dr. Natasha Barlow*** [3], ***Mr. Benny Bechor*** [4], ***Prof. Dorit Sivan*** [4], ***Dr. Richard Preece*** [5], ***Prof. Kirsty Penkman*** [1], ***Prof. Brendan Keely*** [1]

Charney School of Marine Sciences University of Haifa, __5.__ University Museum of Zoology Cambridge

Targeted analysis of organic matter in soils and sediments is useful for evaluating past environmental conditions, as specific compounds may be directly linked to organisms and hence to the conditions reflected by their environment. These molecular fossils are abundant, well-preserved in sediments and their degradation patterns are well-understood, thus variations in biomarker distributions, such as lipids and chlorophyll pigments, have become a powerful tool for understanding palaeoclimatic change. The present study uses molecular fossils to provide insights into the impact of transgressive events on primary producers inhabiting a coastal environment, providing a more detailed record of sea-level change. Used alongside palaeontological evidence, molecular fossils can aid in the interpretation of paleoenvironmental changes and fill gaps in interpretation especially where microfossils are poorly preserved or present in low amounts.

Analyses of molecular fossils through a transgressive sequence from a Holocene sediment core from a lake in Scotland showed excellent agreement with the lithological and ecological interpretation and provided further insights into the depth of the transgression; the same approach was successfully applied to Mid-Pleistocene sediment cores where the elevation of the transgressive events was refined due to the higher sensitivity of primary producers to environmental changes. Molecular fossils have been successfully used as an additional method for defining the salt production unit in ancient saltpans and therefore, as a tool for reconstructing past sea level. Importantly, the analysis of organic molecular fossils provided sensitive records of primary producer response to major environmental changes such as a transgression. The molecular fossils analysed can reveal not only shifts in the primary producer organisms inhabiting the site, but also those in the surrounding environment. Linking the pigment and lipid records enables a more accurate record of relative sea-level change and its impact on paleoclimate during the Quaternary.

Mediterranean coasts preserve many sedimentary and geomorphological features commonly correlated to the Last Interglacial (LIG) marine highstand. These are found at different elevations according to variable tectonics and glacio and hydroisostatic adjustment. In many parts of the Mediterranean, sedimentary deposits have been correlated with other oscillations during the MIS5 and/or at older interglacial highstands. However, the dating of these deposits has been problematic and controversial. The Cilento coast (Southern Italy) preserves evidence of relative sea level (RSL) changes within archeological caves, which offer the opportunity to reconstruct the RSL using different dating approaches. In this contribution, we review previous data and we present a new suite of RSL measurements using different markers, supported by U/Th dating on phreatic speleothems as terrestrial limiting points, and for constraining the ages of marine markers (i.e. notches and *Lithophaga* holes). According to our reconstruction, which covers several km of the coast, it is possible to recognize an upper horizon of *Lithophaga* holes between ca. 10-11 m a.s.l., which can be correlated with MIS9e. A second group of markers can be correlated to the LIG. The evidence for the latter comprises a subset of markers at ca. 5-6 m and, 4-2 m a.s.l. which indicates RSL oscillations during the LIG. These markers are older than ca. 120 ka. A suite of speleothems dated to MIS7 and early MIS6 indicate that the MIS7 highstand RSL was consistently lower than ca. 2 m a.s.l.

Reconstructing the rate and magnitude of Last Interglacial sea-level change in the North Sea and its global implications

Sea-level projections are poorly constrained beyond the 21st century because of limitations relating to data availability and understanding of the response of ice sheets to a warmer climate. Under future climate scenarios, the instability of the West Antarctic Ice Sheet and its potential contribution to global and regional sea levels is unresolved. Observations of past sea-level change provide limited scenarios to test climate models under a global climate at least 1.5°C warmer than present, yet during the Last Interglacial global mean temperatures were~1-2°C warmer and sea level was ~5-10 m higher than pre-industrial values. Therefore, the Last Interglacial provides a valuable palaeo-laboratory for studying the mechanisms of sea-level change forced by warmer global temperatures and, in turn, helping to resolve future uncertainties.

We present results of reconstructing changes in Last Interglacial sea-level in the North Sea. We collected a series of sediment cores from the seafloor of the North Sea and developed a novel approach to establish the timing and indicative meaning of transgressive contacts. By combining a suite of sedimentary information with biological and geochemical proxies and new ice sheet and GIA modelling we produce a series of sea-level index points, which reveal the rate of sea-level rise in the North Sea during the Last Interglacial. We show evidence of high rates, with multiple meters of sea-level change in a few millennia during the peak warm period of the Last Interglacial. Because sea-level rise in north-west Europe is particularly sensitive to the source of melting ice, we our work can help constrain the contribution of the Antarctic Ice Sheet to global sea-level rise during the Last Interglacial.

New Relative Sea-Level Reconstruction for MIS 5e Interglacial from US Gulf and Southeast Coasts

The Last Interglacial (Marine isotope stage 5e ~125,000 BP) is an important analog for future sea-level rise as global temperatures increase due to anthropogenic climate change. The World Atlas of Last Interglacial Shorelines created by the WARMCOASTS project has provided a guide for collecting additional datapoints to share with the scientific community. To grow this dataset, we conducted field surveys in the Gulf Coast and Southeast Coast of the United States to precisely identify and measure elevations of MIS 5e sea-level indicators on a passive margin. The survey covers stratigraphically complex areas of coastal beach ridges and preserved paleoshorelines left by highstands, including those where previous data had not been associated with quantifiable measurement errors or an elevation datum. Using precise DGPS measurements, we referenced the interglacial sea-level indicators and their modern analogs to the relevant hydrographic datum. This survey's results will be combined with future surveys to construct a transect of passive margin sea-level indicators in the Western Atlantic over thousands of kilometers, which will serve as a useful evaluation tool for models of glacio-hydro-isostatic adjustment and dynamic topography.

The Pleistocene sea-level record of the Balzi Rossi archaeological area, Ventimiglia, Italy

The caves complex of Balzi Rossi (Ventimiglia, adjacent to the Italian-French border) is recognized as an important site for the study of Palaeolithic settlements within the Mediterranean and Europe. As such, it has been subject to archaeological investigation for over a century but with little regard for the associated coastal and marine deposits. A primary objective of the SPHeritage Project (MUR grant: FIRS2019_0040, P.I.:M. Pappalardo) has been to precisely identify, describe, and geochronologically constrain the numerous palaeo-coastlines that have been documented there. Constraining the sea-level record within the region will help establish the contribution of vertical Earth movements to palaeo and predicted sea-level change.

Former archaeological excavations have removed a significant quantity, if not all, coastal/marine deposits previously described at the multiple sites within the Balzi Rossi complex. In many instances, the deposits are preserved only as fragmented remnants at museums and other repositories. Despite this apparent obstacle, we were able to reassess the 'ghost' stratigraphic sequences using museum and repository archives (including detailed excavation notes) and trace remnants remaining at Balzi Rossi; both of which also served as sources of sample material for geochronological and sedimentological analyses. High-resolution topographic surveys allowed us to constrain the 'ghost' stratigraphy to trace remnants on-site. Various methods of geochronological constraint (U-Th, luminescence, amino acid racemization, Sr-isotope, palaeomagnetism) were applied 'fit-for-purpose', i.e., to those sample types most appropriate for the method. For example, U-Th analysis of flowstones to determine minimum/maximum ages of sedimentary deposits.

We provide a robust reconstruction for the last interglacial highstand, with an uncorrected envelope from sea-level indicators between 7-13 m above present sea level. Older early and middle Pleistocene highstand remnants are more difficult to constrain due to a lack of preserved material; however, the record allows for an estimated rate of long-term uplift for the region.

A Novel Method to Reconstruct Sea Level from Coral Microatolls Using Digital Surface Models

Coral microatolls are precise indicators of relative sea-level (RSL) change as their upward growth is controlled by lowest tides, hence their morphologies reflect RSL trends as the corals grew. Extraction of a vertical (radial) slab through the microatoll for x-radiography is ideal and can uncover details of RSL changes from year to year, but is not always permitted or feasible. Moreover, due to the short periods during which corals are exposed at lowest tides, data collection in the field must be completed within tight time constraints. This usually results in a limited set of observations. Additionally, if the microatoll morphology is misinterpreted in the field or if subtle features are missed, it may not be possible to rectify the issues later.

To overcome these challenges, we are developing and comparing various techniques to acquire high-resolution digital surface models (DSMs) as a novel tool to study and quantitatively document coral microatolls. These techniques include structure-from-motion multi-view stereo photogrammetry, terrestrial LiDAR scans, and the Apple iPhone's built-in LiDAR scanner. DSMs can store large amounts of spatial information, and thus allow for thorough quantitative analysis and, where necessary, objective reanalysis of microatoll morphology even after field work is completed. This DSM approach is inexpensive, quick, and non-invasive. Due to its non-invasive nature, cylindrical cores must still be obtained for geochronological constraints. However, this is more feasible than slabbing. We also introduce a coral microatoll growth simulator created with Blender, an open-source 3D creation suite, to predict coral growth under different RSL histories. We manually tune the simulated microatoll morphologies to those observed in the field, to better constrain RSL histories. We show that DSM-derived metrics are accurate and replicable when compared to measurements made with established field methods, and they allow for rapid collection of detailed observations of an entire population of microatolls.

Sea-level changes in the Last Interglacial. How high, how fast?

The Last Interglacial (LIG, Marine Isotopic Stage 5e, 125 ka) is a process analogue for a future warmer climate. Thousands of coastal relic landforms and deposits dating back to this period are studied today to obtain insights on two pressing questions: what was the peak LIG sea level? Was the LIG characterized by rapid sea-level changes triggered by sudden ice sheet collapses? While the answers to these questions remain to some degree uncertain, the data compiled within a new standardized database of LIG sea-level proxies, the World Atlas of Last Interglacial Shorelines, may help refine our understanding of ice sheets and sea levels under slightly warmer climate conditions.

Ancient sediment-associated taxonomic profiling: comparative assessment of methods, challenges and opportunities of geomicrobiology from tropical sediment deposits

The present study is a maiden attempt to extract ancient microbial DNA from a vertebrate fossil context of Pleistocene sediment near the hominin site of Hathnora in the central Narmada valley. The general area and associated stratigraphy are crucial in terms of geological and paleoanthropological relevance. This is the only location in the entire Indian subcontinent where a partial cranium of an archaic hominin species was reported. Subsequent field visits and surveys by numerous researchers have frequently yielded vertebrate fossil specimens from this site's associated cemented sandy-pebble unit. However, several vertebrate fossils were noticed for the first time eroding out (and *in situ*) from the nearby fine-grained sandy-silty deposits of the Baneta Formation at this site, all of which currently appear to belong to an elephant species. Sediment samples were collected for ancient microbial DNA extraction from the same fine-grained context and stratum as the elephant fossils.
Preliminary studies involved kit-based DNA extraction based on bead beating and column-based methods or the use of nanoparticles. The results show that the DNA preserved in these sediments is highly fragmented <100 base pair (bp) in size, degraded, and present only in minute amounts. It contains large amounts of organic matter (such as humic acids) having a high affinity for DNA, thus making DNA recovery from these soil (nanocrystalline aluminosilicate and allophane) sediments difficult and insufficient. As a result, DNA is co-extracted with humic acids, which prevents its amplification in PCR. Mechanical disruption of soil aggregates and microbial cells and various extraction reagents, as required in conventional methods, may further complicate the output. The present paper discusses such difficulties and possible courses of action to overcome such challenges to develop an efficient process that carries out proper lysis of sediments and removes humic acid and PCR inhibitors. Such a method will enhance the downstream processing, such as 16S rDNA-based amplicon sequencing, which further plays a role in studying the evolutionary relationships of the microbial community in a tropical sediment environment.

INQUA, 14 to 20 July 2023, Rome

Spatial distribution of sedDNA in a small catchment lake: Is a single core enough?

Ms. Tulug Gulce Ataman [1], ***Prof. Inger Alsos*** [1], ***Dr. Youri Lammers*** [1], ***Prof. Antony Brown*** [2]

1. *The Arctic University Museum of Norway, Tromsø,* ***2.*** *Arctic University of Tromso*

The interpretation of sedDNA is contingent upon our understanding of transport mechanisms of DNA into the lake sediment. Further investigation is needed to understand how sedDNA represents the ecosystem spatially and how representative a single core is of the catchment. Here we test the homogeneity and representativity of sampling at two spatial scales: 1) at 42 sampling points distributed in a grid with about 30 m distance covering the lake, and 2) by comparing two separate cores taken 30 cm apart at each 42 sampling points. All samples were lake surface sediment (0-2 cm) from a small lake with two basins (Stabbevatnet, Norway). The lake is ideal for this study as it has a distinctive pattern of surrounding vegetation varying from boreal forest and dwarf-shrub heath to agricultural land. Our datasets are: 1) the sedDNA samples collected using systematic sampling method in the lake, 2) a systematic vegetation survey within the catchment surrounding the lake. Our results showed that the deepest part of the lake basins had the highest richness in taxa which is also best-matched the vegetation survey. Both separate cores that are sampled from the deepest part of the lake showed higher richness in taxa separately in comparison to other samples taken from shallower part of the lake. After merging these core pairs, the four sampling points in the deepest part of the lake provided, on average, 64.1% of the taxa in the vegetation survey and whereas the average taxa detected across all sampling locations was 44.5 %. There was also a spatial pattern in the lake sedDNA which reflects the spatial pattern in the vegetation survey, with common taxa in the vegetation found in most samples, while rarer taxa have a more localized detection. Furthermore, the sedDNA samples closer to the lake shore or shallower than 2 m depth have a higher proportion of aquatic macrophytes in comparison to the other samples. Thus, to detect the major vegetation, one core is generally enough, while more cores will allow detection of scattered taxa. To maximize detection, the core should be collected from the deepest part of the lake.

Tracking the expansion of herding practices and landscape transformations during the Neolithic in Central Europe revealed through ancient Environmental DNA

Central Europe was transformed by agricultural practices during the early Neolithic (~ 7700-6000 cal BP). This process of Neolithisation is interpreted as gradual, with variable progression across ecological mosaics that had been managed by hunter-gatherers since the Pleistocene. The mobility of herding, a key activity for the first agricultural communities, is therefore critical to understand, especially in areas that were peripheral to those favoured for initial cultivation. However, movement of domestic animals across past landscapes can be challenging to detect through analysis of micro- and macro-fossils as these rarely preserve or are difficult to distinguish from wild relatives. In this study, we apply the latest advances in the field of sedimentary ancient DNA to a rock shelter deposit, Velký Mamuťák, with the purpose of further investigating human-environment interactions after the introduction of pastoral land practices, during the Neolithic of Bohemia (Czech Republic). The site is in a sandstone landscape that was heavily forested and unsuitable for cultivation by the earliest Neolithic communities. Here, we find genetic evidence that domesticated animals and their associated microbiomes appeared in the Late Neolithic, around 6000 yr BP, and then persisted through the Bronze Age (3000 cal. BP). We were able to further investigate the mitochondrial DNA phylogeny of key taxa, detecting ancestor lineages of modern domesticated species. Furthermore, we find that the plant DNA record integrates previous botanical results, revealing the persistence of localised forest grazing with gradual transformation of the surrounding grasslands through cultivation. At large, our results suggest that anthropogenic transformations in the peripheral environments of Central Europe did not take place until the Late Neolithic following the expansion of animal management practices.

euka - Rapid characterisation of bilaterian mitochondrial sedimentary ancient DNA using pan-genomics

Ms. Nicola Alexandra Vogel [1], ***Mr. Joshua Daniel Rubin*** [1], ***Mr. Mikkel Swartz*** [1], ***Ms. Juliette Vlieghe*** [1], ***Mr. Peter Wad Sackett*** [1], ***Prof. Anders Gorm Pedersen*** [1], ***Prof. Mikkel Winther Pedersen*** [2], ***Prof. Gabriel Renaud*** [1]

Sedimentary ancient DNA (sedaDNA) has become a crucial resource in paleoecology. Ancient data not derived from fossils has vastly improved our ability to gain insight into ecological environments, as well as population structures and movement. However, analysis of sedaDNA has many challenges, including post-mortem damage, contamination, and short fragment lengths, as well as difficulties typical of environmental DNA samples, such as taxonomic identification and abundance estimation of present species.

Bioinformatic analysis of shotgun metagenomic sequenced sedaDNA typically involves alignment against a linear reference genome and the binning of taxa. Both steps can be time-consuming, depending on the amount of data. Additionally, the variety of DNA fragments in sedaDNA samples can make the taxonomic characterisation of eukaryotes very difficult. Contaminated or incomplete reference databases can lead to false-positive or false-negative results. Commonly used binning algorithms apply strict filters to minimise the number of false-positive identifications, however, this can bias against low-abundance species.

We introduce euka, a subcommand of the Vgan suite of tools for pangenomics. Euka is a tool built to quickly characterise sedimentary ancient DNA samples for bilateran mitochondrial DNA. Its foundation is a curated database of mitogenomes in the form of a variation graph reference structure. We make use of the variation graph (VG) toolkit and especially VG Giraffe, which allows us to quickly map large sedaDNA samples against our entire database simultaneously. We analyse our mapping results using an ancient-damage-aware maximum-likelihood framework, allowing for confident low-abundance detection. Euka accepts FASTQ input and outputs a summary of all taxonomic groups present within the given sample, including their respective posterior abundance estimates plus confidence intervals, damage profile, fragment length distribution and coverage. Euka is built to quickly provide researchers with a summary of their sample, which may be fed into a more optimised downstream analysis, thereby reducing time and money spent on computational analysis of sedaDNA samples.

Ancient DNA metabarcoding uncovers the effects of climate change and human impact on Austrian sub-alpine lake, Großer Winterleitensee

The Alps contain highly biodiverse ecosystems including a large number of endemic flora. As a result of climate change and anthropogenic activities, such ecosystems are at risk from upward vegetation displacement and species loss. To elucidate the effects of climate and anthropogenic activities on plant diversity, multi-proxy vegetation reconstructions have been carried out throughout the Western Alps. However, the palaeoecological history of the Eastern Alps is relatively understudied. Consequently, we are limited in our understanding of how climate and human impact have affected past plant diversity and the formation of the contemporary vegetation in this region. Archaeological research in the Eastern Alps has documented human settlement from ~5.5 thousand years before present (k yr BP) driven by salt and copper mining which has caused significant impact on the ecosystems through mining, deforestation, and pastoral farming. Here, we focus on the Austrian sub-alpine lake, Großer Winterleitensee located at the Easternmost margin of the Alps. We apply sedimentary ancient DNA (*seda*DNA) metabarcoding to reconstruct Holocene plant and mammal dynamics within the lake catchment. Grazing pressure from wild animals had little effect on plant dynamics before the introduction of domestic pasturing to the area. Before this, plant dynamics were driven by temperature and rainfall. *Seda*DNA shows the introduction of domesticated sheep (*Ovis aries*) at ~4 k yr BP. Alongside this, we see an increase in alpine meadow taxa and taxa linked to pasturing activities. At ~1 k yr BP we see evidence of significant tree clearing and a change from pasturing of sheep to cows (*Bos taurus*). Supporting that intensifying human activities since the middle Bronze Age cause artificially low tree lines and enable alpine meadow forbs to persist. Palaeoecological reconstructions of plant biodiversity and their responses to climate change and anthropogenic pressures may be able to provide essential information for future conservation purposes.

Insights, potential, and pitfalls of sedimentary ancient DNA from non-frozen loess at archaeological sites in Alaska

Sedimentary ancient DNA (*sed*aDNA) has huge potential to expand our knowledge of past human resource use and exploitation from open and near-surface archaeological sites. However, sediment from such sites is often not water logged or frozen, and so the vertical movement of free water through the sediment, coupled with root penetration of overlaying vegetation, has the potential to blur and mix *sed*aDNA signals from different stratigraphic horizons. Here, we generated plant and animal metabarcoding together with shotgun metagenomics data from three archaeological sites and the nearby Chisholm Lake in the Tanana River valley of Alaska. By using the Chisholm Lake record as a positive control for expected plant taxa and levels of ancient DNA damage in sediments of concurrent age, we show evidence for a temporally mixed plant *sed*aDNA signal in the archaeological sediments. On the other hand, sporadic animal *sed*aDNA occurrences in the archaeological sediments closely mirror expectations from site-specific zooarchaeological records, including the detection of burbot (*Lota lota*). This suggests that root penetration may be the dominant driver of cross-stratigraphic *sed*aDNA mixing in non-frozen sediments and that such taphonomic factors should be accounted for when assembling plant taxonomic inventories from these settings.

Paleogentic approaches at the Alfred-Wegener-Institute in Potsdam – tracking terrestrial polar biodiversity

Dr. Liv Heinecke [1] ***, Dr. Kathleen Stoof-Leichsenring*** [1] ***, Prof. Ulrike Herzschuh*** [2]

1. *1. Polar Terrestrial Environmental Systems Research Group, Alfred Wegener Institute Helmholtz Centre for Polar and MarineResearch, Potsdam, Germany,* ***2.*** *1. Polar Terrestrial Environmental Systems Research Group, Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research; 2. Institute of Environmental Science and Geography*

Terrestrial polar biodiversity is threatened by climate change, which lead to the turnover of communities and variations in taxonomic richness. Within the research area “High-latitude Biodiversity”, the changes in polar biodiversity in response to climate and land-cover variability over the late Pleistocene to present□day warming are investigated. Our work considers ecosystem-level biodiversity with a focus on the diversity of terrestrial and marine primary producers. We use sedimentary ancient DNA from freshwater and marine archives for tracking biodiversity changes.

Our palaeogenetics lab at AWI Potsdam is a part of the larger molecular genetic facility specialized to analyse ancient sedimentary DNA and is thus placed in a separate building away from the modern and recent environmental lab and Post-PCR areas. We established DNA metabarcoding and metagenomics (shotgun and hybridisation capture) to investigate spatial and temporal biodiversity with the aim of identifying the taxonomic and functional composition in Arctic ecosystems.

Next to the some insight into our lab we would like to present the outcomes of two recent studies from our working group.

Climate induced vegetation alterations in Majuli Island (world largest river island) of northeast India from 2150 BCE to 1450 CE: an interpretation based on modern pollen calibrations

Dr. Swati Tripathi [1], *Ms. ARYA PANDEY* [1], *Mr. Salman Khan* [1], *Dr. Sadhan K Basumatary* [1], *Dr. Biswajeet Thakur* [1]

1. *Birbal Sahni Institute of Palaeosciences, 53-University Road, Lucknow-226007, India*

A 150 cm deep sedimentary soil section from the Sakali wetland of Majuli Island (under Indo-Burma Biodiversity hotspot) has been palynologically analyzed to reconstruct the palaeovegetation and past climate in relation to the palaeoflood episodes in Upper Assam, northeast India. Decadal to semi-decadal variations in annual temperature (T_m) and precipitation (P_m) impacted the dense vegetation of northeast India and therefore, surface soil samples and climate data were collected from 25 sites in Sakali wetland for the modern pollen calibration to estimate the role of anthropogenic and palaeoclimatic signatures in the Majuli Island. Regressive transfer function using modern pollen records, and T_m, P_m variation deciphered climate tolerance in fossil pollen assemblage portraying four pollen phases (SW I-IV). During the first phase between 2150 to 320 BCE (4100 to 2270 cal. BP), the relatively dense and consolidated forest has been reflected in Majuli Island under the warm and humid climate with maximum seasonality recorded by the presence of mixed deciduous tree pollen taxa. The recovery of *Rhododendron, Castanopsis,* and Rosaceae in the palynoassemblage is suggestive of the flood activity in the region. During 320 BCE to 860 CE (2270-1090 cal. BP), the conversion of a mixed deciduous forest to open-dry vegetation was witnessed as evidenced by the decline in moist tree cover under relatively less warm and humid climate, corresponding to the Migration Period Cooling (MPC). During the third phase from 860 to 1450 CE (1090-500 cal. BP), the gradual revival of moist and dry deciduous tree elements was observed under increased warm and humid climatic conditions with the advancement of fluvial activities. This phase was very well associated with the Medieval Climatic Anomaly (MCA) which occurred globally from 900 to 1250 CE. Interestingly during the interval from 860 to 1450 CE, the average values of maximum MAP were the highest recorded (≈2500 mm). Since the last 1450 CE (500 cal. BP), striking dipping in MAT (13-22°C) and MAP (464-1364 mm) range was observed indicating the plausible effect of the Little Ice Age (LIA). Furthermore, the scarce occurrence of tree pollen indicates tropical savanna type of vegetation with increased anthropogenic activities.

New pollen-based evidence on climate oscillation during the mesocratic phase of the Eemian in Central Poland (Garwolin Plain)

Prof. Irena Pidek [1], ***Prof. Anna Hrynowiecka*** [2], ***Dr. Marcin Zarski*** [3]

__1.__ Maria Curie-Sklodowska University, Institute of Earth and Environmental Sciences, Al. Krasnicka 2 d; 20-718 Lublin, __2.__ Polish Geological Institute – National Research Institute, Marine Geology Branch, Koscierska 5 str., 80-328 Gdansk, __3.__ Polish Geological Institute – National Research Institute; Rakowiecka 4 str., 00-975 Warszawa

High resolution palynological studies on three sites of the Eemian palaeolakes (Kozlow, Zabieniec, Puznowka) in the Garwolin Plain (Central Poland) revealed two types of fossil lakes functioning during the decline of the climate optimum of the interglacial. This last interglacial with no human impact on natural climate variability is correlated with Marine Isotope Stage (MIS) 5e. All the pollen diagrams under investigation recorded seven phases of the Eemian called regional pollen assemblage zones (RPAZs): E1-*Betula*, E2-*Pinus-Betula-Ulmus*, E3-*Quercus*, E4-*Corylus*, E5-*Carpinus*, E6-*Picea-Abies* and E7-*Pinus* phase closing the interglacial pollen succession. Detailed palynostratigraphic investigations (with subzonation) performed on these cores revealed several sedimentation gaps in Zabieniec and Puznowka ones, especially during the hornbeam phase closing the mesocratic period of the Eemian, while at the same time extremely long *Carpinus* phase was investigated in the neighbouring Kozlow profile. The E5 RPAZ, which was divided into four subzones, was interpreted in terms of climate changes (air temperature and humidity). The last subzone E5d (*Carpinus–Picea*), lacking in the Zabieniec and Puznowka sites, was of special interest. Our study evidenced that while no drastic climatic change was recorded in the Kozlow pollen diagram during the decline of the Eemian optimum and sedimentation of gyttja deposits continued until the E7 RPAZ, the other two lakes recorded sedimentary hiatus in the E5d subzone which can be interpreted as significant drop in the water level. The start of the peat accumulation could have been associated there with a drier period and increased continentality of the climate conditions (e.g. greater amplitude between the coldest and the warmest months, and lower precipitation totals) or, on the other hand, the water level drop could have been caused by special geologic-geomorphological situation of the Zabieniec and Puznowka palaeolakes in comparison with the Kozlow one. Conclusions on climate changes during the decline of the mesocratic phase of the Eemian were correlated with the observable climate oscillation towards colder conditions reflected in some German pollen profiles.

Research financed by the National Science Center in Poland project No. 2017/27/B/ST10/01905.

Complex responses of vegetation diversity to Holocene climate change in the eastern Tibetan Plateau

Dr. Chen Liang [1], *Prof. Yan Zhao* [2], *Dr. Feng Qin* [2], *Dr. Qiao-Yu Cui* [3], *Dr. Quan Li* [3]

Key Laboratory of Land Surface Pattern and Simulation, Institute of Geographical Sciences and Natural Resources Research, Chinese Academy of Sciences

Biodiversity has attracted much attention recently due to its important relationships with ecosystem function under various global warming scenarios. However, an understanding of biodiversity mechanisms requires study over long time scales. Three high-resolution pollen records of Zoige Basin in the eastern Tibetan Plateau are used to reconstruct changes in vegetation diversity during the Holocene, allowing the mechanisms that drove the dynamic to be quantitatively explored. Rarefaction and Hill's indices are used to estimate the diversity richness and evenness based on pollen data. The results show that changes in palynological richness can be divided into five stages: an abnormal change from 10,500 to 9,000 cal BP, an obvious increase from 9,000 to 6,500 cal BP, a decreasing trend from 6,500 to 4,000 cal BP, an increasing trend after 4,000 cal bp until 1,500 cal BP, and a highly fluctuating stage from 1,500 cal BP to the present. Palynological evenness is relatively stable throughout the Holocene except for during a briefly elevated period from ca. 4,000 to 1,500 cal BP. The result of Boosted Regression Tree analysis indicates that climate is the main driving factor and the effect of temperature is stronger than that of precipitation in the study region. However, during ca. 4,000–1,500 cal BP, palynological diversity is primarily affected by vegetation structure, as shown by an increase in palynological evenness, which can in turn be explained by the climate threshold theory. This research provides a long-term, high-resolution reconstruction of palynological diversity which could be used to infer vegetation diversity change in the ecologically sensitive Tibetan Plateau. The results imply that vegetation diversity in the region may increase under global warming if human impacts are not considered.

Stand scale palynology helps to reveal the role of forest exploitation and climate change in the current distribution of Fagus sylvatica in the NE Pannonian Basin (Hungary)

Ms. Abigail Ofosu-Brakoh [1], *Ms. Réka Csorba* [1], *Prof. Tibor Standovár* [2], *Dr. Ákos Bede-Fazekas* [3], *Ms. Zsuzanna Páto* [2], *Prof. Enikő Magyari* [1]

Centre for Ecological Research, Institute of Ecology and Botany, Vácrátót, H-2163, Hungary

The study investigates how past anthropogenic activities and climate change have affected the modern distribution of European beech (*Fagus sylvatica* L.) in Northeastern Hungary. Sediment cores from mesotrophic fen and lake; Black Lake (Mátra Mts., 730m a.s.l.), Lake Egerbakta (Bükk Mts., 280m a.s.l.) were used to study the former distribution of beech at different altitudes. We used sites qualifying for stand-scale studies for pollen and plant macrofossil analyses to detect the local presence of beech. Lake Egerbakta is in an oak-dominated (*Quercus cerris – Q. petrea*) forest today. We expected that before the medieval forest management, beech was likely more widespread at lower altitudes and might have lived in the surrounding forest. Our study on the Black Lake focused on whether beech has been cleared earlier in this region and particularly, when it first appeared >700m a.s.l. during the Holocene. High-resolution pollen and plant macrofossil analyses were combined with ^{210}Pb, ^{137}Cs, AMS ^{14}C dating, LOI, and chemical element analyses (MP-AES). We found a high amount of *Quercus* (40–75%) and very low *Fagus* (1–6%) count in the pollen record spanning the last ~2000 years. We detected forest clearances at AD 1525, 1660 and 1750, and concluded that the Migration Age and Medieval land use did not decrease beech representation at this altitude since it was a turkey oak – pedunculated oak forest zone. We also detected that the Egerbakta lake has been used for hemp-retting since ~AD 900. At the Black Lake (730m a.s.l.), beech expanded and dominated rapidly at ~4500 cal BP and was already substantially cleared during the early Iron Age (from ~2850 cal BP), likely for charcoal-burning and iron-smelting in the region. After its selective removal, our data shows beech being the dominant canopy component around the lake even during medieval times without any considerable clear-cut. Overall, we can conclude that beech forests of the eastern-slopes were not heavily exploited during the medieval forest management period; their old-growthness can be confirmed. Also, the elevation zone where beech forests were replaced by oak due to preference by medieval forest management can be located >300m a.s.l. in the Bükk Mts.

Holocene climatic and vegetation changes recorded in the Late Holocene sediments from Twai Wild Life Sanctuary, Mizoram, north-east India

Dr. Nivedita Mehrota [1], ***Dr. Santosh Shah*** [2], ***Dr. M. Malsawmliana*** [3], ***Dr. RATAN KAR*** [1]

1. Birbal Sahni Institute of Palaeosciences, 53-University Road, Lucknow-226007, India, 2. Birbal Sahni Institute of Palaeosciences, 3. Government T. Romana College, Republic Road, Republic Vengthlang, Aizawl, Mizoram

The state of Mizoram is the extreme southern region of northeastern India, also sharing its borders with Myanmar. It has three main rivers flowing across the state and reaching towards the Bay of Bengal in the southern ends of the region. The Holocene palaeoclimatic records are absent from this remote location of India. We make an attempt to understand the vegetation and climate variation in this eastern extreme of India during the late Holocene. The impact of Indian summer monsoon is evident in the region having a regional precipitation gradient across the varied topography of the state. The influence of human activities has impacted the vegetation cover in the region. The modern-day practices of slash and burn farming are causing reduction in natural vegetation.A fossil palynological study has been carried out in Late Holocene sediments collected from Twai wildlife sanctuary from a fringe village named Hmuntha, in Aizawl district, Mizoram, north-east India. This record reveals the variations in the vegetation vis-à-vis climate during the late Holocene in the region. The influence of human activities is evident our fossil pollen record and the variation in the paleo-vegetation. The understanding of palaeovegetation shall help us explain the influence of anthropogenic changes on the vegetation in this land-corridor towards East Asia.

Establishing connections between contemporary vegetation distributions, modern pollen representation and the fossil pollen record in the Cape Floristic Region

Ms. Erin Hilmer [1], ***Dr. Adele Julier*** [2], ***Dr. B. Adriaan Grobler*** [1], ***Dr. Nadia Du Plessis*** [1], ***Dr. Lynne Quick*** [1]

1. African Centre for Coastal Palaeoscience, Nelson Mandela University, 2. School of Biological Sciences, University of Portsmouth

Palaeoecological reconstructions provide an understanding of past ecosystem dynamics and climates of a particular area. This understanding can be used to inform conservation and rehabilitation efforts – however, palaeoecological proxy evidence used for these reconstructions (such as fossil pollen) need to be calibrated against a modern equivalent to be interpreted quantitatively. We therefore require an understanding of how pollen is produced and preserved in modern ecosystems, to be able to apply the relevant taphonomic biases to the fossil record. This understanding can be achieved through comparisons of modern pollen rain with surrounding vegetation composition.

Africa, and in particular southern Africa, is an understudied region and severely lacking in pollen calibration data. This study aims to generate the first modern pollen datasets for the southern Cape coast in South Africa, from two case study sites: one is situated in the Western Cape (Pearly Beach, southwest Cape coast) and the one in the Eastern Cape (Nelson Mandela University Reserve, Gqeberha). The pollen calibration data from each site will be used to calibrate fossil records from surrounding areas – this produces more ecologically sound inferences.

The southern Cape coast is important in terms of both biodiversity and human history. Comprising the Cape Floristic Region, conservation strategies need to be optimized for this biodiversity hotspot. It is also the epicentre for a large proportion of the Cape fossil pollen records (which do not have any modern pollen calibration data associated with them). Given the unique context, it is therefore imperative that new pollen calibration data is generated from local sites in the Cape in order to maximize the accuracy and applicability of both palaeoenvironmental research and conservation management efforts.

Long term vegetation dynamics and the climate changes in East Asia

Dr. Fang Gu [1]

1. *1. School of Ocean Sciences, China University of Geosciences, Beijing 100083, China 2.Department of Palynology and Climate Dynamics, University of Goettingen, Göttingen, Germany*

Past vegetation is considered to be one of the most reliable evidence for recovering paleoclimate changes in palynological studies because it is sensitive to temperature and precipitation during the growing processes. The monsoon played an important role in the high vegetation diversity in East Asia by providing humid air masses from the adjacent seas and the Pacific Ocean. However, questions remain unanswered about how the past sea level and the intensity of monsoon climate have changed over time.
The factors with distinct different distribution zones of vegetation communities, high diversity among vegetation types, and unique topography with low altitude coastal plains all place this area as a favorable region for studying the monsoon climate in eastern Asia. Therefore, in this study, the existed paleoclimate records from northern to South Asia will be reevaluated for a comprehensive understanding of the long-term vegetation dynamics and its response to past monsoonal climate and sea-level changes in East Asia.

Drivers of change: climate variability, stone technologies and prey species in Aboriginal Tasmania and Southwest France.

Prof. Richard Cosgrove [1] ***, Dr. Jean-Pierre Chadelle*** [2] ***, Dr. Jillian Garvey*** [1] ***, Prof. Wil Roebroeks*** [3] ***, Dr. Magen O'Farrell*** [1] ***, Dr. Alexander Verpoorte*** [3]

1. La Trobe Univesity, 2. Department of Archaeology, General Council of the Dordogne, 3. University of Leiden

The dynamic climate of the Last Glacial Maximum (LGM) is argued to have had a significant influence on forcing technological adjustments and land use adaptations. The argument that the LGM influenced the direction of lithic technologies has had currency in archaeological debates for some time. If this was a general trend in human societies impacted by similar ice age climates, we should see corresponding patterns in the global mid and high latitudes.

We examine this issue with a comparative study of 13C and 15N stable isotopes from human prey animals excavated and dated from Late Pleistocene limestone cave sites (40,000 – 13,000 calBP) in Southwest Tasmania and Southwest France, zones of similar latitude north and south. Stable isotopes from Bennett's wallaby (*Macropus rufogriseus*) and Reindeer *(Rangifer tarandus)* bones were examined to track climate shifts. Interestingly, this evidence shows similar trajectories of climate alterations in the two hemispheres, despite the stable isotopes coming from the two very different species, one placental, the other a marsupial. These two species were the major human prey animal throughout the LGM.

However, the lithic technocomplexes of modern humans in LGM Tasmania and Southwest France are very different, despite the common climatic challenges. In fact, the rapid changes in European Upper Palaeolithic lithic technocomplexes are not mirrored anywhere in Sahul. If climate variability fails to sufficiently explain the styles in lithic technocomplexes during the LGM in the two regions, we ask; what other factors could be at work?

Recent ancient DNA results from Australia and Europe may illuminate this paradox. In Australia there was very little genetic change in human populations over 50,000 years. It was accompanied by period of lithic conservatism lasting from c.45,000 calBP until c.4,000 calBP. In Europe however, human aDNA patterns suggest the rapid appearance of new lithic technocomplexes throughout the LGM that may have been driven by the arrival of new populations in Western Europe. In this presentation we discuss the implications for the climate-lithic technological paradox.

Preliminary results from excavations at two Late Middle Paleolithic open air sites in the lower Besor Basin, northern Negev, Israel

Dr. Mae Goder-Goldberger **[1]**, ***Prof. Isaac Gilead*** **[2]**, ***Prof. Elisabetta Boaretto*** **[3]**, ***Mr. Lotan Edeltin*** **[2]**, ***Mr. Ron Lavi*** **[4]**, ***Dr. Liora Kolska Horwitz*** **[5]**, ***Dr. Naomi Porat*** **[6]**, ***Dr. Michael Toffolo*** **[7]**, ***Dr. Onn Crouvi*** **[6]**

1. *Ben Gurion University of the Negev,* **2.** *Ben-Gurion University of the Negev,* **3.** *Weizmann Institute of Science,* **4.** *Independant Researcher,* **5.** *Hebrew University, Jerusalem,* **6.** *Geological Survey of Israel,* **7.** *Centro Nacional de Investigación sobre la Evolución Humana*

The Besor basin is the largest drainage system in the Negev desert, extending from the central Negev Highlands and the southwestern Judean hills, and flows into the Mediterranean Sea. The lower segment of the basin is characterized by a series of perennial springs and a savanna like landscape, attracting both animals and humans. During the late Pleistocene the lower Besor basin filled with fluvial loess deposits up to 20 m thick. Subsequent erosion of the loess over the last 12,000 years, resulted in exposure of numerous Paleolithic sites.

In 2020, initial excavations were conducted at two late Middle Paleolithic sites, B37 and B27. Lying under several meters of loess, site B37 is an *in situ* living surface with hearths, rich in stationary finds including fauna and concentrations of conjoinable flint artifacts. In site B27, located 2 km to its north, the archaeological material is embedded within a well-stratified sedimentological layer of fluvial loess, overlain by a thick layer of clay-rich sediments. Although the artifacts at this site are not archaeologically in-situ, they have not been transported a long distance, as indicated by the freshness of their edges, lack of patina and isolated refits.

A critical aspect of prehistoric research in desert environments is understanding landscape evolution, and its influence on past hunter-gatherer mobility and activity patterns. Our ongoing work centers on analyzing the composition of the archaeological assemblages from these two sites. Focusing on the similarities and differences between them, in conjunction with the published nearby site of Far'ah II, opens the way for deciphering land-human interaction in an active and dynamic fluvial system at the edge of the Negev desert.

Shedding light on the mystery Investigating the process of Neolithization in the northwestern Netherlands from the perspective of pollen diagrams

Mrs. Taravat Talebi [1]

1. PhD. Groningen Institute of archaeobotany

One of the important periods in human history is the transition from foraging to farming, in short: Neolithization. Neolithization is a gradual acculturation; hence, hereafter we call it "the process of Neolithization". The process of Neolithization of the Netherlands began 5300 years BC, at the time farmers of the Linear Pottery culture settled in the south of the country. Although the Neolithic way of life could spread across the globe rather consistently, it did not have a consistent movement from the south to the north of the Netherlands. So far, prehistoric evidence suggests that after the introduction of farming to the Netherlands, Mesolithic communities in the north, known as Swifterbant culture, did not change their way of life. Swifterbant chose to remain Mesolithic. Since then, for 1500 years, the Mesolithic Swifterbant and other Neolithic cultures in the country lived as known neighbors to each other but on their distinct subsistence.

According to the available palaeobotanical data, Swifterbant eventually obtained cereal and started to grow crop. However, the time it happened for the first is a question to us yet. Furthermore, the reason for switching to the new method of subsistence after 1500 years of adhering to the Mesolithic way of life is still unknown. Either of questions, palaeobotanical records can help us answer our questions by enabling us to reconstruct past vegetation and vegetation changes.

To enrich our understanding of the subsistence and acculturation of Swifterbant of the northern Netherlands, a palynological PhD project began at the University of Groningen. In this project, we strive to enrich our understanding of Swifterbant subsistence and acculturation through palynological analysis of the peat archive of a number of pingo scars near a Mesolithic site in the northern Netherlands.

Keywords: Swifterbant, Palynology, Neolithization, northern Netherlands, pingo scars

Do Early Bronze Age ditches from Oman allow for the assessment of surficial groundwater response time to mid-Holocene climate change?

Dr. Tara Beuzen-Waller [1]***, Dr. Katharina E. Schmitt*** [2]***, Dr. Lucas Proctor*** [3]***, Dr. Conrad Schmidt*** [4]

1. *Soil science and geomorphology working group, University of Tübingen,* ***2.*** *Institute of Geosciences, University of Mainz,* ***3.*** *Institute for Archaeological Sciences, Goethe University Frankfurt,* ***4.*** *IANES, University of Tübingen*

In Oman, the Holocene Humid Period lasted from roughly 4,000 to 3,500 B.C., followed by the onset of arid conditions, common to this day, with mean rainfall of about 80 mm/year in the piedmont of the Hajar Mountains (Northern part of Oman). During the Early Bronze Age (EBA; end of the 4th millennium B.C. until the end of the 3rd millennium B.C.), societies in Northern Oman (Hafit and Umm an-Nar Periods) would have faced significant environmental changes that could disturb subsistence strategies and access to water. Water resources are a complex topic in arid regions, because itincludes the understanding of the distribution, collection, and management rainwater, surficial water, and groundwater sources. Prior to the invention/ introduction of *aflaj* irrigation systems in Oman in the first part of the 1st millennium (Early Iron Age), it is challenging to evaluate where and how EBA societies found enough water for permanent settlements. Based on original data from al Khashbah archaeological sites and published data from Salut and Bat, here, we argue that EBA ditches can be used as a marker to observe, at a local scale, the depletion of surficial groundwater level following the Holocene Humid Period. Early Bronze Age ditches from Northern Oman were abandoned/filled by the end of the 3rd millennium B.C. and no longer reused, despite the presence of other structures. We hypothesis that ditches were used to reach a shallow alluvial aquifer in quaternary deposits, and subsequently filled by surrounding material when those structures were disconnected from the aquifer by the decreasing of the groundwater level. This indicates that societies from the EBA benefited from a high groundwater level due to its recharge during the Holocene Humid Period, and that the water table slowly dropped during the 3rd millennium.

Boom and Bust in Late Holocene semi-arid environments of the Channel Country, Queensland Australia

Prof. Patrick Moss [1]***, Dr. Duncan Keenan-Jones*** [2]***, Dr. Jennifer Cooling*** [2]***, Ms. Lesley Scanlan*** [2]***, Ms. Charmaine Howie*** [2]***, Dr. Jennifer Silcock*** [2]***, Prof. James Shulmeister*** [3]***, Dr. Michael Westaway*** [2]***, Ms. Shawnee Gorringe*** [4]***, Mr. Joshua Gorringe*** [4]

1. *University of Queensland,* ***2.*** *The University of Queensland,* ***3.*** *University of Canterbury,* ***4.*** *Mithaka Aboriginal Corporation*

The channel country of southwest Queensland is characterised by extreme climate variability, particularly in terms of precipitation, which is driven primarily by the El Niño Southern Oscillation (ENSO) phenomenon. High rainfall years are generally associated with La Niña phases, while drought conditions are linked to El Niño events, which generates a 'boom and bust' environment in terms of biological productivity for the region. The Traditional Owners of the region, the Mithaka people were well adapted to this environment through the development of sophisticated subsistence strategies that supported relatively high population densities during the late Holocene period. This presentation will provide the environmental context for Mithaka occupation of the region through palaeoecological and geochemical analysis of sediments from key settlement across their country sites. In particular, this will provide insight into alterations in vegetation dynamics and fire regimes for the late Holocene, which will provide insight into landscape scale anthropogenic management of the semi-arid environments of the channel country.

An exploratory paleoenvironmental study on a coastal Palaeolithic site in Albania through an integrated stratigraphic approach (Dalani i vogël, Vlora)

1. *CNR - Institute of Environmental Geology and Geoengineering (IGAG), Lab. of Palynology and Palaeoecology, Milan,* ***2.*** *Prehistory Department, Institute of Archaeology, Academy of Albanological Studies, Tirana,* ***3.*** *Università degli Studi di Ferrara / CNR - Institute of Environmental Geology and Geoengineering (IGAG), Lab. of Palynology and Palaeoecology, Milan,* ***4.*** *Leibniz Institute for Applied Geophysics (LIAG),* ***5.*** *Department of Earth Sciences "Ardito Desio", University of Milan,* ***6.*** *University of Milano-Bicocca, Dept. of Environmental and Earth Sciences,* ***7.*** *Consiglio Nazionale delle Ricerche, Istituto di Geologia Ambientale e Geoingegneria (IGAG),* ***8.*** *Regional Directory of Cultural Heritage of Vlora, Ministry of Culture,* ***9.*** *Department of Humanities, Prehistoric and Anthropology Sciences, University of Ferrara*

The Albanian Palaeolithic is probably one of the least explored periods in the entire archaeological record of the country. This is partly because research on early prehistoric studies is fragmentary, in contrast to a greater focus on later periods. The joint collaboration between the CNR-IGAG (Milano and Rome) and the Institute of Archaeology, Academy of Albanological Studies (Tirana) aims to contribute filling this gap by exploring the paleoenvironment of new/poorly investigated Palaeolithic sites in Albania. The Dalani i vogël site was selected for this purpose from a cluster of coastal sites south of Vlora (Triporti-Portonovo area). An outcrop of ca. 7.5 m high and tens of meters wide was sampled for geochronological analyses (OSL and ^{14}C), magnetic susceptibility, sedimentary proxies (LOI steps, calcimetry, main nutrients), microstratigraphy, micropaleontology and microbotanical analyses.

Fieldwork documented the presence of Middle Palaeolithic flint artefacts within oxidized sandy silt deposits overlying a basal clayey layer developed from the weathering of the flysch bedrock. These lithic finds, initially collected by amateurs and later identified, consist mainly of Levallois cores, flakes and scrapers. Superimposed on this unit is a brownish layer ca. 1 m thick, archaeologically sterile, with a clayey texture class and deep cracks, interpreted as a vertic diagnostic horizon. The top of the unit is truncated by an erosional surface also characterised by a concentration of the mycorrhizal fungus *Glomus* and trilete spores. The overlying unit contains Neolithic pottery. Pollen is sparse and poorly preserved along the sequence, and possibly biased by hydromorphic processes, highlighted by the strong concentration of concentric Fe-Mn Ox nodules. However, the identification of almost exclusively upland herbs (Gramineae, Caryophyllaceae, Cichorioideae together with other Asteraceae) suggests an open and patchy environment throughout the record. Preliminary results of OSL dating point to an age younger than 50 ka for the Palaeolithic industries. Considering the geographical position of Albania, finds pertaining to this particular period are expected to shed new light on the Middle-Upper Palaeolithic transition in Southern Europe.

Reconstruction of tree-line shifts during Late Pleistocene - Holocene time in the summer monsoon dominated region of western Himalaya

Dr. IPSITA ROY [1]***, Dr. Parminder Singh Ranhotra*** [2]***, Ms. NIDHI TOMAR*** [3]***, Dr. Naveen Gandhi*** [4]***, Dr. Mayank Shekhar*** [5]***, Dr. Amalava Bhattacharyya*** [5]***, Dr. Pankaj Baghel*** [6]***, Mr. Rajveer Sharma*** [6]

Tree-line fluctuations are an important indicator of climate change. Here we reconstructed the tree-line shift for the past 17 ka BP in the Dokriani glacier valley, western Himalaya, by interpreting the pollen-spore dataset of a 255 m deep subsurface peat sequence from subalpine (3,550 m asl) altitude. We compared the tree-line shifts with glacier retreat episodes in the valley. Presently, the glacier snout is at ~3,900 m asl and the tree-line ecotone is formed by the taxa *Juniperus,* Ericaceae, *Betula*, *Abies* and *Quercus* growing near the vicinity. *Betula utilis* forms the tree-line limit at ~3,700 masl and the conifer limit is formed by the *Abies spectabilis* at ~3,600 m asl. Subsurface pollen record showed that during pre-Holocene (17-11.8 ka BP) the valley was dominated by conifer-steppe vegetation indicating dry conditions. Considering modern pollen and tree-line vegetation relationship as analogue to the past, during the pre-Holocene *Juniperus* sparsely occupied the surrounding moraines. Early Holocene time (11.8–8.3 ka BP) experienced an increase in pollen frequency of *Abies, Betula* and *Quercus* and moisture-loving ground vegetation with a decline of *Pinus*. Moreover, pollen grains of Ericaceae, an above tree-line krummholz taxon, appeared first in the pollen spectra at ~8.6 ka BP. This indicated early Holocene tree-line advancement following the glacier retreat under warm and moist conditions with a strong Indian summer monsoon (ISM). Increase of *Pinus* pollen and decline of *Quercus* pollen during mid-Holocene (~5–3.7 ka BP) probably due to weak ISM coincided with the decline in the rate of glacial retreat. Upper tree-growth limit near the sampling altitude at ~3,550 masl was formed by *Abies* mixed with *Betula* and *Quercus*. Subsequent warming and increase in the ISM corresponding to Medieval Warm Period (1.8–0.9 ka BP) might have helped *Betula, Quercus* and *Abies* to reach current altitudes between 3,500 and 3,600 masl. The cool phase around 0.8–0.2 ka, corresponding to Little Ice Age with enhanced WD, might have resulted in the static tree-line and glacier snout positions. The interplay of climate, topography and edaphic factors remains critical in understanding their roles in vegetation dynamics and needs to be studied temporally and spatially.

Marine dinoflagellate cyst record across the Neogene/Quaternary boundary, Monte San Nicola GSSP, Sicily – preliminary results

Dr. Wieslawa Radmacher [1] ***, Prof. Martin J. Head*** [2]

1. *Institute of Geological Sciences, Polish Academy of Sciences,* ***2.*** *Department of Earth Sciences, Brock University*

The Plio/Plieistocene (Neogene/Quaternary) transition is characterized by enhanced global palaeoceanographic and palaeoclimatic changes leading to intensification of the Northern Hemisphaere glaciation and emergence of glacial-interglacial cycles, distinguishing the Quaternary period (2.58 Ma). The role of heat transfer, water influxes, and salinity/oxygen fluctuations within the Mediterranean basin reflecting the global changes can be detected by study of dinoflagellates. These single-celled, marine organisms are sensitive to environmental perturbations and produce preservable resting cysts resistant to environmental and sedimentological processes. Total of 404 rock samples spanning the Neogene/Quaternary boundary have been collected across 18 m interval during the GELSTRAT- INQUA-SQS International Field Workshops conducted in years 2021 and 2022. Additional 40 samples will be collected from the ~20 cm Nicola bed at Monte San Nicola representing Mediterranean Precession-Related Cycle 250 coinciding with an obliquity maximum representing Marine Isotope Stage 103, which facilitates global correlation. This sapropelic layer is composed of thick reddish laminated sediment that resulted from particularly high summer insolation/humid conditions. Rich and diverse dinoflalgellate cyst assemblages will be for the first time studied at Monte San Nicola at that ultra-high resolution, providing information about nutrient, salinity, temperature and oxygen level within the basin. The study is being undertaken within GELSTRAT, an international program applying various methods, including palynological, micropalaeontological, mineralogical, magnetostratigraphic, geochemical and isotopic analyses to further our understanding of the Neogene–Quaternary transition at the type area and emphasize the correlative potential of the GSSP.

Environmental forcing across the Neogene–Quaternary boundary at the Monte San Nicola GSSP, Sicily, Italy – preliminary results

Dr. Wieslawa Radmacher [1]***, Dr. Malgorzata Lempart-Drozd*** [1]***, Dr. Mateusz Mikołajczak*** [1]***, Prof. Alfred Uchman*** [2]***, Prof. Martin J. Head*** [3]

1. *Institute of Geological Sciences, Polish Academy of Sciences,* ***2.*** *Institute of Geological Sciences, Jagiellonian University,* ***3.*** *Department of Earth Sciences, Brock University*

The Global boundary Stratotype Section and Point (GSSP) for the base of the Quaternary System, Pleistocene Series, and Gelasian Stage is placed at the base of a marly layer immediately overlying the Nicola bed at Monte San Nicola, near Gela, Sicily. The Nicola bed is a ~20 cm thick reddish laminated unit and a prominent marker for the base of the Quaternary. As with other Mediterranean sapropels, the Nicola bed is assumed to have resulted from reduced oxygen availability on the sea floor caused by enhanced river inflow during summers: the freshening of surface waters inhibits their sinking in the autumn and prevents the ventilation of bottom waters. In general, oxygen depletion on the sea floor favours the preservation of organic matter within the sediments and also inhibits faunal activity, including bioturbation. To test these assumptions, and refine our understanding of the formation of the Nicola bed, a detailed ultra-high-resolution study of microlaminations, ichnofabrics and mineralogical diversity are being undertaken. The microstratigraphic succession within the Nicola bed can be distinguished as follows: 1) a lower interval characterised by undisturbed primary laminae typical of anoxic conditions; 2) a middle interval dominated by *Chondrites* isp. that cross laminae and indicate a gradual recovery of oxygen levels; and 3) an upper interval containing a low-diversity trace fossil assemblage, including *Chondrites* isp., *Planolites* isp., and *Thalassinoides* isp., that indicates increasing oxygen levels and enhanced recovery of the bottom tracemaking community. The marly interval overlying the Nicola bed representing the base of Quaternary is more intensely bioturbated. Such a pattern represents a progressive change from dysoxic to oxic conditions within the bottom waters during and after sapropel deposition. The present study utilizes thin-section analyses and X-ray tomography to image laminae and trace fossils in three dimensions. Additional mineralogical analyses employing Fourier Transform Infrared (FTIR) spectroscopy will be used for distinguishing the mineralogical composition of the layers. The work is being undertaken within GELSTRAT, an international program applying various methods, including palynological, micropalaeontological, magnetostratigraphic, geochemical and isotopic analyses to refine our understanding of the Neogene–Quaternary transition at the type area.

Effects of human activities on mountain forest in northern China during the middle Holocene

Ms. Xiuxiu Ren [1], ***Prof. Xiaozhong Huang*** [2]

1. Lanzhou University, 2. College of Earth and Environmental Sciences, Lanzhou University

China has a long history of civilization and agriculture, and its terrestrial ecosystems have long been subjected to anthropogenic impacts. However, we lack detailed knowledge of the nature and timing of human impacts on the development of vegetation ecosystems in the mountain region of northern China during the Holocene, especially during the middle and late Neolithic periods. In this study, we used pollen and charcoal data, combined with the biomization method, from a sediment core from Mayinghai Lake to reconstruct the Holocene vegetation history of a mountain region in northern China. The biome score for forest showed an increasing trend during 11.4–7.5 ka (1 ka=1000 cal yr BP), suggesting the gradual development of a forested landscape during the early Holocene. During 7.5–4.7 ka, the biome results indicate a well-developed forest community which corresponds to the traditional concept of a climatic optimum in the mid-Holocene. During 4.7–2.6 ka, the tree pollen content decreased slightly, and there was an expansion of temperate grassland, dominated by *Artemisia* and Amaranthaceae, and a relatively open forest landscape gradually developed. Considering the relatively warm and wet climatic conditions indicated by independent paleoclimate reconstructions, we conclude that our results provide a record of human impacts on the natural landscapes of the study region since ~4.8 ka (1 ka=1000 cal yr BP), which are mainly indicated by a decrease in the coverage of temperate deciduous forest (based on biomization scores), higher sedimentary charcoal concentrations, and an increase in the number of archaeological sites, both in the vicinity of the study site and throughout the whole of northern China. Our results provide new insights into the role of humans in the ecological evolution of this mountainous region during the Holocene, and we suggest that the impact of prehistoric humans on vegetation succession was potentially significant, which needs to be considered when using pollen records for paleoclimatic reconstruction.

High Tide – Low Tide. Bruges' late-medieval harbour system as a maritime cultural landscape: a sedimentary approach

***Dr. Frieda Bogemans* [1] *, Prof. Wim De Clercq* [2] *, Prof. Vanessa M.A. Heyvaert* [3]**

***1.** Royal Belgian Institute of Natural Sciences, Geological Survey of Belgium, **2.** University of Gent, **3.** Royal Belgian Institute of Natural Sciences*

Sea harbours and their maritime cultural landscapes are hubs connecting and transferring goods, people and thoughts, and as such connect the local with the global setting and vice versa. Medieval Bruges (Belgium) constitute a classic historical example of such a hub in an international trading system which connected the North Sea area with the Baltic, the Mediterranean and even with the Asian silk route.
As Bruges itself was located inland and had no direct access to the seashore, the connection with the North Sea was assured via a tidal channel, known as the Zwin. Along the Zwin an interconnected system of outer harbours developed. To obtain an overall picture of the medieval maritime cultural landscape along Bruges harbour system an interdisciplinary project was started up, incorporating geological (sedimentological and palaeo-ecological), archaeological and historical research. Research questions such as 'the origin of the medieval Zwin waterway, how the port system interacted with the environment', are tackled for the first time.
Our contribution to the project is the reconstruction of the sedimentary environments developed in the "Zwin area" during the timelapse from the last millennia of the Late Holocene until the decay of the high economic activity in Bruges. The Zwin area hides in his shallow subsurface a complex network of tidal channels composed of several generations of tidal channel systems with varying morphology and sedimentology. The late medieval "Zwin" mentioned in all historical texts is the final one of the many tidal channel systems that developed. Although located in the eastern coastal plain of Belgium, tidal activity did not take place earlier than the Late-Holocene in the area. Together with the sedimentary reconstruction topics like 1) the silting up of the late medieval Zwin, 2) the forcing factors behind the entrance of the Late-Holocene tides in the area, are touched on.

The Long walk to the ‘Neolithic’: Early agro-pastoralists in Tamil Nadu, South India

***Dr. kumar akhilesh* [1], *Ms. Sutonuka Bhattacharya* [2], *Dr. R. Sivanantham* [3], *Dr. Prachi Joshi* [1], *Mrs. Bakialakshmi K.* [3], *Mr. Paranthaman S.* [3], *Prof. K. Rajan* [4], *Prof. Shanti Pappu* [5]**

The presence of early agro-pastoral communities in Tamil Nadu, southeast India, has been documented since the late 19th c, with sporadic research occurring in the past few decades. Traditionally defined as constituting part of the Southern Neolithic, little is known about processes leading to the appearance or evolution of these communities. Among numerous questions that require consideration, we note aspects of past environments and ecological niches, associated material cultural remains or plants/animals domesticated and chronologies. Further, we know little about transitions from the preceding hunter-gatherers of the early Holocene and relationships with megalithic monuments noted in the same landscapes or with the chronologically simultaneous or subsequent Iron Age cultural phases. Here, we discuss concepts related to classifying cultural phases in the early and middle Holocene in the Indian context. We also review major questions related to early farming communities in Tamil Nadu. We suggest new approaches towards the examination of these cultural phases. We present our recent research in surveys and research at these sites across parts of northern Tamil Nadu, situating these within the framework of the broader South Indian Neolithic and early Iron Age cultural phases. We highlight the behavioural significance of celt-manufacturing strategies in our study region and the significance of past landscape scales of behaviour. Lastly, we highlight long-term continuity in the significance attached to polished stone tools through time, culminating in their ritualistic use in modern Indian villages.

The Rachgoun Prehistoric Coastal Site (Northwestern Algeria), an Upper Pleistocene Occupation : Contribution of Geoarchaeology

Prof. Slimane Hachi [1], ***Ms. Saloua Chibane*** [1], ***Mr. Djamal Yataghane*** [1], ***Dr. Louiza Aoudia*** [1], ***Prof. Abdelkader Derradji*** [1], ***Dr. Smail Iddir*** [1]

1. Centre National de Recherches Préhistoriques, Anthropologiques et Historiques, Algeria

The prehistoric site of Rachgoun (north-western Algerian coast) is an important feature in the knowledge of the coastal quaternary chronology. During the excavation carried out in the last century, it provided a rich archaeological material as well as burials attributed to the Iberomaurusian culture.

In this work, we try to use the multidisciplinary tools of geoarchaeology to decipher the regional stratigraphy of the quaternary surface formations of the lower Tafna basin, which vary between volcanic deposits and coastal dune formations, and the local stratigraphy of the site in order to define the recent prehistoric human occupation in its natural setting.

The first results of recent excavations, prospecting and ancient data associated with isotopic dating allowed us to assign a Pleistocene / Holocene chronology to the site (upper Pleistocene) that corresponds/confirms that the archaeological levels of the Rachgoun site belong to the late Iberomaurusian culture.

Poster - sessions 3, 16, 24, 41, 74, 80, 134, 196

Expression of the stages MIS 13 to MIS 11 in a southern tropical rainforest: preliminary results of pollen analysis of the basin of Colônia, Brazil.

Ms. Olga Aquino Alfonso [1], ***Dr. Marie-Pierre Ledru*** [2], ***Dr. Rudney de Almeida Santos*** [3], ***Dr. Charly Favier*** [4]

The Atlantic Forest, situated mostly along the Atlantic coastal margin of Brazil, presents exceptional levels of species diversity and endemism and, it is a key provider of ecosystems services. However, it is extremely threatened by anthropogenic activities and near future global warming consequences. Despite that, little is known about tropical forests dynamics through past climatic variability, e.g., glacial-interglacial cycles. Indeed, long continental records covering deep past times are scarce in South America. Located in the Atlantic Forest domain, the Colônia crater site (23°52´03” S, 46°42´27” W, ca. 700 m a.s.l, São Paulo, Brazil) is a key place to palaeoecological and paleoclimatic studies in tropical region, due its location and its modern climatic setting (under the southernmost influence of the South American Summer Monsoon and polar air advections, as consequence the humidity is distributed all year round). The main purpose of this work is to reconstruct past vegetation dynamics during marine isotopic stages 13 to 11 (~ 533 to 374 ka BP). For that, we analyzed the pollen content of a section (10.58 to 14.62 m) of core COL 17c. The preliminary pollen results show a continuous cool-moist forest expansion during glacial and interglacial times.

MIS12/11 transition and the MIS 11 interglacial in the Alboran Sea: palaeoenvironmental and climatic insights from a high-resolution marine record

Dr. Dael Sassoon [1], ***Dr. Vincent Lebreton*** [1], ***Dr. Nathalie Combourieu-Nebout*** [1], ***Dr. Odile Peyron*** [2], ***Dr. Marie-Hélène Moncel*** [1]

1. *Muséum National d'Histoire Naturelle,* **2.** *Institut des Sciences de l'Évolution de Montpellier*

The transition from Marine Isotope Stage (MIS) 12 to 11 (430–400 ka BP), is regarded as one of the largest shifts in climatic conditions over the last 900 ka. This period is particularly important as it represents a phase of innovation for Hominins. We present here a high temporal resolution pollen record that encompasses the period between MIS 12 and MIS 10 (433–365 ka BP), recovered from the ODP Site 976 in the Alboran Sea. This study aims to provide new insights into the response of vegetation in climatically sensitive region, and to highlight changes in seasonal aridity and precipitation in the continent during the MIS 12/11 transition and MIS 11 interglacial. Pollen-based quantitative reconstruction techniques (MAT, WA-PLS and BRT) were implemented to produce climatic reconstructions for this period.

The ODP Site 976 pollen record shows the shift from glacial to interglacial, highlighted by the transition from predominantly herbaceous and steppic taxa and a high abundance of *Pinus*, to an assemblage comprised of temperate and Mediterranean taxa. The climatic reconstructions show a significant rise in mean annual temperatures and precipitation. A climatic optimum for temperate and Mediterranean taxa is identified between 420–405 ka BP, equivalent to MIS 11c and synchronous with maxima in temperature, precipitation and insolation. Substage MIS 11b, characterised by an increase of *Pinus*, *Cedrus* and steppic taxa is reflected by a drop in temperature and precipitation. Finally, substage MIS 11a was determined as a period of increased variability characterised by fluctuations in forest communities and high-amplitude changes in temperature and precipitation towards the MIS 10 glacial.

Our record from ODP Site 976 provides evidence for the strong climatic transition during Termination V. Our results confirm the intense shift during the MIS 12/11 transition and show that this region is uniquely sensitive to millennial-scale climatic variation during MIS 11. The abrupt shifts in vegetation observed in this record may be used to infer that Hominins, particularly the ancestors of Neanderthal, would have had to adapt to these climatic shifts and fluctuations by finding new strategies of subsistence and technologies.

Sensitivity of Caucasus Glaciers to Regional Climate Change

Prof. Teimurazi Davitashvili [1]

1. I.Vekua Institute of Applied Mathematics of Iv. Javakhishvili Tbilisi State University

The glaciers of the Caucasus (Georgia) have undergone significant changes against the background of global warming. Most of them have disappeared, and some have suffered degradation. The glacier area has decreased during the retreat, but at the same time the total number of glaciers has increased. Generally, the glaciers play a major role in formation the water balance of the region and their reduction or disappearance poses significant damage to the natural ecosystems and economy. This article presents an analysis of the change in the surface area of the glacier using multitemporal data sets for the Greater Caucasus, based on manual digitization of large-scale (1:50,000) topographic maps of the 1960s. and satellite images of 1964 (Corona), 1986 (Landsat 5) and 2014 (Landsat 8, ASTER). The paper deals with major meteorological factors operating on glaciers and the melting of direct solar radiation on the basis of the melting energy model of the Enguri basin glacier. Modern climate change is characterized by fluctuations in the balance of radiative energy in the lower troposphere, which determines the process of fluctuations in glaciers (melting of the thickness). Since the interaction between glacier and climate is a complex non-linear process, we use mathematical modeling to predict the future adaptation of Georgia's glaciers to current climate changes. With the help of a two-dimensional mathematical model of the dynamics of changes in the thickness of the glaciers, the configuration of the upper surface of the Caucasus glaciers were studied. Some typical problems of mathematical and numerical modeling of glaciers are discussed. For the first time, with the help of mathematical modeling, the process of melting of the Caucasus glaciers (Kazbegi 5030m) was estimated. Some simulation results are presented and analyzed.

Northwest African monsoon strength, ecosystem variability and wind patterns during the Mid-Pleistocene Transition

Dr. Nicholas OMara [1]***, Dr. Charlotte Skonieczny*** [2]***, Prof. David McGee*** [3]***, Dr. Gisela Winckler*** [4]***, Dr. Aloys Bory*** [5]***, Dr. Louisa Bradtmiller*** [6]***, Dr. Bruno Malaizé*** [7]***, Dr. Pratigya Polissar*** [8]

***1.** Yale School of the Environment, Yale University, USA, New Haven, CT 06511,* ***2.** Université Paris-Saclay, CNRS, GEOPS, 91405, Orsay,* ***3.** Massachusetts Institute of Technology,* ***4.** Lamont-Doherty Earth Observatory, Columbia University,* ***5.** Université de Lille, CNRS, Université Littoral Cote d'Opale, UMR 8187, LOG, Laboratoire d'Océanologie et de Géosciences, Lille,* ***6.** Department of Environmental Studies, Macalester College, St. Paul, MN,* ***7.** UMR CNRS 5805 EPOC, Université Bordeaux I, 33405 Talence,* ***8.** Ocean Sciences Department, University of California Santa Cruz, Santa Cruz, CA*

Proxy and model evidence suggest that Northwest Africa transitioned from a wet landscape covered with expansive vegetation during the Pliocene toward drier and less vegetated conditions during the late Pleistocene, however, our understanding of the nature of this transition is hampered by a paucity of paleo-records that bridge these two well-studied intervals. The Mid-Pleistocene Transition (~1.2–0.9 Ma), during which glaciations intensified and increased in duration, is perhaps one of the most important yet poorly understood global climate reorganizations of the past several million years. Here we generate new plant-wax isotope as well as dust and opal flux records from ~1.1–1.0 Ma to evaluate both the orbital-scale controls of Northwest African hydroclimate and vegetation during the MPT and, in context with previously published records, the drivers of long-term climate and ecological trends over the Plio-Pleistocene. The tempo and magnitude of the Northwest African monsoon rainfall variability closely track changes in cross-equatorial moisture transport related to low latitude insolation gradients. However, a pronounced decline in monsoon strength following the MPT was most likely forced by an increase in Atlantic meridional sea surface temperature gradients. The northward extent of grassland, savanna and forest ecosystems in Northwest Africa do not linearly track changes in monsoon strength, but are more likely influenced by changes in rainfall seasonality and ecosystem disturbances. Synchronous declines in dust and opal flux unrelated to changes in rainfall are consistent with equatorward migrations of wind belts as the pole-to-equator temperature gradient increased in response to high-latitude Northern Hemisphere cooling since the MPT.

Contrasting vegetation response during Heinrich events 4, 5 and 6 in Western Europe

Dr. Tiffanie Fourcade [1], ***Prof. Maria Sanchez-Goñi*** [2], ***Mr. Jonathan Lesven*** [3], ***Prof. Christelle Lahaye*** [4], ***Prof. Anne Philippe*** [5]

1. *University Bordeaux-Montaigne, UMR 6034, Archéosciences-Bordeaux,* ***2.*** *Ecole Pratique des Hautes Etudes, Paris Science Lettres University,* ***3.*** *Laboratoire Chrono-Environnement, UMR 6249 CNRS, Université de Bourgogne Franche-Comté,* ***4.*** *Université Bordeaux Montaigne, UMR 6034, Archéosciences-Bordeaux,* ***5.*** *Laboratoire de Mathématiques Jean Leray, Nantes Université*

The amplitude, timing and duration of the European vegetation responses to orbital and millennial-scale changes, in particular to the major episodes of North American iceberg discharges, the so-called Heinrich events (HEs) that punctuated the Last Glacial Period (~115- 27 ka) are still poorly known.

The multiproxy study, pollen and planktonic assemblages, sedimentological and geochemical analyses of two deep-sea cores retrieved in the Bay of Biscay (MD04-2845, 45°21'N, 5°13'W) and the Gulf of Lion (MD99-2343, 40°29'N, 4°01'E) reveals the vegetation and climatic changes of southwestern and southeastern France to the HEs 4, 5 and 6. These records are well chronologically constrained by numerical dating (new IRSL ages for the MD04-2845 deep-sea core) and new age-depth models, based on Bayesian statistics and stratigraphic constrains. They show different magnitudes in the semi-desert expansions in response to HEs 4, 5 and 6. In southwestern France, the development of the semi-desert is more pronounced during HE 6 compared to HE 4 and 5, while in the southeast HE 6 is marked by an exceptional and still unexplained strong forest development. In this later region, HE 4 allowed the development of a more forested landscape compared to HE 5. The comparison of our results with other well-dated terrestrial records show similar vegetation and climate patterns. The contrasted vegetation responses during these events appear to be the result of different intensities of the thermohaline circulation and local oceanic processes associated with the instability of the Laurentian ice sheet.

Investigating uplift driven diversification of the Kashmir Himalayas using multiproxy data

Dr. Showkat Mir [1]***, Dr. Reyaz Dar*** [2]***, Dr. Christian Zeeden*** [3]***, Prof. Julia Meister*** [4]***, Dr. Irfan Rashid*** [5]

1. *Physical Geography, Institute of Geography und Geology, University of Wurzburg, Germany,* ***2.*** *Department of Earth Sciences, University of Kashmir, Srinagar-190006, Jammu and Kashmir, India,* ***3.*** *Leibniz Institute for Applied Geophysics, Hannover, Germany,* ***4.*** *University of Würzburg,* ***5.*** *Department of Botany, University of Kashmir, Srinagar-190006, Jammu and Kashmir, India*

Topographically complex regions, such as large mountain ranges, feature hotspots of biodiversity that reflect geological influences on ecological and evolutionary processes. A popular but little-tested hypothesis is that tectonic uplift creates environmental conditions. that increase the rate at which resident species divide and evolve to form new ones. Thus, one of the most common hypotheses for rich biodiversity found in mountains is uplift driven diversification known as orogeny, which creates conditions that favor rapid in-situ speciation of resident lineages. Testing hypothesis about how these topographic diversity gradients arise, persist, or diminish requires demonstrating coincidence and interaction in time and space between causal factors and biogeographic responses. The regional phytolith records and other sediment proxies along with the rate of uplift of the mountainous regions may provide evidence for this spatial and temporal turnover of the paleo-vegetation and geographic distributions respectively. The current investigation analyzes multi-proxy data including phytoliths, sedimentological (e.g., grain-size), magnetic susceptibility and geochemical data (e.g., TOC, C/N ratio, element composition) as well as the chronology of a representative sedimentary sequence (Shankerpora section) along with the rate of uplift to get insights for the uplift driven diversification in the Kashmir Himalayas. This approach will help us to trace the histories of multiple groups of plants and to infer the tempo (rate) and mode (colonization versus in situ diversification) of biotic assembly through time and space during the Late Quaternary in the high altitudinal ranges of the Kashmir Himalayas. This study will be a base for future paleoenvironmental and paleoclimate investigations using phytoliths from regional sediment archives in high-mountain ranges.

Polyaromatic hydrocarbons in a deep lake sediment core from eastern Romania

Ms. Denisa Igescu [1], ***Dr. Virgil Dragusin*** [2], ***Dr. Sorin Avramescu*** [3], ***Dr. Elena-Alina Olaru*** [2]

1. *Faculty of Biology, University of Bucharest,* ***2.*** *Emil Racoviță Institute of Speleology, Romanian Academy, Bucharest,* ***3.*** *PROTMED Research Centre, University of Bucharest, Bucharest*

We present here preliminary polyaromatic hydrocarbon (PAH) data measured from a 60 m long sediment core from Obanu Mare paleolake (SE Romania) that spans several glacial-interglacial cycles. As most PAHs are generated during the burning of organic matter, high molecular weight PAHs can be useful proxies for fire intensity while low molecular weight ones could be used to studying past fire activity. Also, in certain conditions, several PAHs are generated by geogenic processes and are a common occurrence in hydrocarbon deposits. Following accelerated solvent extraction, PAHs were determined by liquid chromatography using a fluorescence detector. Predominantly were identified high molecular weight PAHs (dibenz(a,h)anthracene, benzo(g,h,i)perylene, and indeno(1,2,3-C,D)pyrene) but low molecular weight PAHs such as fluoranthene, pyrene or benz(a)anthracene were also present. While Obanu Mare dried out at some point in the past, other similar neighboring lakes are still active and are fed by mesothermal water rich in H_2S and CH_4 whose origin lies in deep hydrocarbon deposits. The water table of the sulphidic aquifer is controlled by the nearby Black Sea level and by identifying geogenic PAH indicators in sediments we should be able to constrain periods with high sea level stands. Moreover, during periods with pyrogenic origins of PAHs, we can reconstruct the local fire history and contribute this information to the multi-proxy paleoenvironmental reconstruction of this region.

This research was supported by a grant of the Romanian Ministry of Education and Research, CNCS - UEFISCDI, project number PN-III-P4-ID-PCE-2020-2282.

Application of Non-destructive Core Scanning Techniques on Characterizing Turbidite Sequence

Ms. Jun-Ting Lin [1]***, Dr. Steven Jyh-Jaan Huang*** [1]***, Ms. Yen-Hsi Wu*** [1]***, Prof. Chih-Chieh Su*** [1]***, Ms. Chin-Wen Yang*** [2]***, Prof. Ludvig Löwemark*** [3]***, Mr. Chuan-Yi Lin*** [4]***, Prof. Yuan-Pin Chang*** [2]

1. *Institute of Oceanography, National Taiwan University, Taipei, Taiwan,* ***2.*** *Department of Oceanography, National Sun Yat-sen University, Kaohsiung, Taiwan,* ***3.*** *National Taiwan University,* ***4.*** *Taiwan Instrument Research Institute, National Applied Research Laboratories,Hsinchu, Taiwan*

Turbidites in marine sedimentary records have been widely used to infer extreme events, such as earthquakes, submarine landslides, tsunamis, and floods. Characterizing such event deposits with their triggering mechanisms becomes the critical step to infer long-term event risk. In this study, more than 700 turbidites have been identified based on the optical and computed tomography (CT) images in a 12.77 meters long core MD18-3538, which was retrieved from the distal part of the Taitung Submarine Canyon off eastern Taiwan. A data-driven approach to objectively classify the characteristics of turbidites thus was developed by combining multivariate statistics (i.e., principal component analysis, PCA; cluster analysis, CA) with non-destructive core scanning techniques (i.e., multi-sensor core logger, MSCL; XRF-scanning; spectrophotometer reflectance; and CT). The results show that turbidites in core MD18-3538 can be characterized by higher density, P-wave velocity, and XRF counts of Ca and Sr. Moreover, the turbidite layers can be further divided into layers with high and low magnetic susceptibility. An entropy analysis using CT images was performed to further study the internal structures of these turbidites to provide detailed structural information and, eventually, its sedimentary dynamics. This study offers new prospects for turbidite classification off eastern Taiwan and other places with similar geological settings. The triggering mechanisms of turbidites can therefore be further disentangled, and the complete event history of the region may finally be reconstructed.

The fate of aragonitic pteropods preservation in the late Quaternary sediments of the Indian Ocean

Pteropods are marine gastropods made up of aragonitic shells, a metastable polymorph of $CaCO_3$, which is more susceptible to dissolution than calcite. Hence, their preservation and accumulation on the seafloor are controlled by the aragonite compensation depth and changes in the properties of water masses. The analyses of the late Quaternary pteropods preservation records from the Indian Ocean reveal characteristic changes in the water masses and water column chemistry from the last glacial period to the present. Generally, better preservation is reported during cold periods and very poor preservation during Holocene. The poor preservation during the present interglacial is a subject of interest since they are the most vulnerable among the major plankton producers of $CaCO_3$ in the current ocean acidification scenario. The recent changes in the aragonite saturation depth (shoaled significantly by 25-155 m) in the Indian Ocean due to the absorption of anthropogenic CO_2 in the subsurface water masses and also due to increased organic matter decomposition rates. Modern aragonite preservation has dropped nearly as low as those experienced in the late Pleistocene interglacial periods. However, pteropod preservation is better during the last interglacial period (Eemian). The poor preservation/absence of pteropods during the Holocene in the Indian Ocean may have implications on ocean acidification driven by enhanced atmospheric CO_2 concentration. The preservation spikes are present in all the records, which are well correlated with time. The last preservation spike was during the deglacial period, consistent with Atlantic and Pacific Ocean records. The deglacial preservation spike indicates the global nature of deepening aragonite compensation depth, changes in water column chemistry, and intermediate water circulation

Flooding and anthropogenic influences on artificial lakes in the Red River Delta

***Dr. Richard Walton* [1], Prof. Andrew Henderson [2], Prof. Andy Large [1], Ms. Emily Sear [1], Dr. Duc Trinh [3], Dr. Nga Do [3], Ms. Jodie Brown [4], Dr. Virginia Panizzo [4], Prof. Suzanne McGowan [5]**

__1.__ School of Geography, Politics and Sociology, Newcastle University, Newcastle-upon-Tyne, NE1 7RU, UK., __2.__ Newcastle University, __3.__ Vietnam Atomic Energy Institute, __4.__ School of Geography, University of Nottingham, University Park, Nottingham, United Kingdom, __5.__ Department of Aquatic Ecology, Netherlands Institute of Ecology (NIOO-KNAW), 6708PB, Wageningen, the Netherlands

Artificial lakes and wetlands created for ecological conservation or to store water for anthropogenic use require careful management to prevent changes to water quality. In highly dynamic environments of tropical mega-deltas, such water environments are susceptible to seasonal variations in hydroclimate and extreme weather events. It is therefore important to understand how climate change may impact artificial lakes. In addition, rapid urbanisation and its associated anthropogenic activities pose high risks to water quality through nutrient enrichment and industrial pollutants. The Red River Delta (RRD) in northern Vietnam is highly vulnerable to projected changes in climate and is experiencing high rates of population growth. Monitoring of contemporaneous water quality in some artificial lakes meant for human consumption or in the wider catchment is ongoing by resource managers in the RRD, but there is a lack of long-term data to assess trends in changing hydrology and flooding in lake and wetland catchments. Moreover, little is known about the impacts of anthropogenic activity on aquatic ecosystems, making palaeolimnology an essential tool for lake and wetland managers to provide longer term trajectories of change. In this study, we use multiple sediment cores recovered from artificial lakes in the Ninh Binh and Hanoi provinces. Radiometric dating using 210Pb has established geochronology and multi-proxy analysis to establish flood histories and ecosystem change using particle size analysis, magnetic susceptibility, XRF, and pigments to assess water quality changes over the recent past are presented.

Towards a quantitative reconstruction of past environment: Cladocera training set.

Dr. Izabela Zawiska [1], ***Prof. Monika Rzodkiewicz*** [2], ***Prof. Jarosław Jasiewicz*** [2], ***Prof. Michał Woszczyk*** [3]

1. *Institute of Geography and Spatial Organization, Polish Academy of Science, Warsaw, Poland,* ***2.*** *Institute of Geoecology and Geoinformatics, Adam Mickiewicz University, Poznań, Poland,* ***3.*** *Biogeochemistry Research Unit, Faculty of Geographical and Geological Sciences, Adam Mickiewicz University*

Lakes are important components of post-glacial landscapes, sensitively responding to environmental changes on a local and global scale. Lake catchment characteristics, such as land cover and land use, have a direct impact on the amount of nutrients reaching the lake waters and therefore also on the trophic status of lakes. Global processes shaping the climate also play an important role in shaping the physicochemical processes in lakes. The current state of the lake ecosystem is recorded in sediments that constantly accumulate at the bottom of water reservoirs. In the lakes of north-eastern Poland, sediments have accumulated since the end of the last glaciation. The source of information about the past are the physical and chemical characteristics of the sediment, as well as the remains of organisms living in the lake. The remains of planktonic organisms such as Cladocera are considered as reliable bioindicators. They respond to changes in many environmental parameters and are commonly found in lake sediments. Therefore, they are used to create quantitative reconstructions of selected environmental parameters, e.g. total phosphorus, temperature, water depth. However, to make this possible, it is necessary to create a database, a training set, including the results of in-situ measurements and laboratory analyzes of contemporary lake water parameters and the species composition of local biocoenoses preserved in sediments. Then, using statistical methods, the relationship (transfer function) between environmental factors and the composition of the population is determined. This approach has been successfully applied in paleolimnology in recent years, but there are few such test sets in Central-Eastern Europe. To enable quantitative reconstructions using Cladocera we created a new training set consisting of 64 lakes located in north-eastern Poland. The selected lakes represent a wide range of trophic states (from oligo- to eutrophic). The test set will be used to better understand and assess the impact of climate change and human activity on the current state of the lakes. The research was fully founded by the NCN research grant 2016/23/D/ST10/03071.

The use of modern diatom assemblages in paleoenvironmental reconstructions

Prof. Monika Rzodkiewicz [1], ***Dr. Izabela Zawiska*** [2], ***Prof. Michał Woszczyk*** [3], ***Prof. Jarosław Jasiewicz*** [4]

1. *Adam Mickiewicz University, Institute of Geoecology and Geoinformation, Biogeochemistry Research Unit,* ***2.*** *Institute of Geography and Spatial Organization, Polish Academy of Science, Warsaw, Poland,* ***3.*** *Biogeochemistry Research Unit, Faculty of Geographical and Geological Sciences, Adam Mickiewicz University,* ***4.*** *Institute of Geoecology and Geoinformatics, Adam Mickiewicz University, Poznań, Poland*

Lakes sediments are excellent archives of physical, chemical and biological conditions of lakes. There preserve remains of organisms that lived in the water column and therefore. represent communities of entire lacustrine habitats. They reflect seasonal changes as well as spatial differentiation. The most important bioindicators related to the lake environment include diatoms and Cladocera. Both indicators are essential components of plankton. They respond to environmental changes such as nutrient concentration, pH, access to light, and temperature and are common in aquatic environments. This species composition is the basis for the quantitative and qualitative reconstruction of past environmental changes.
In recent years, the use of advanced statistical methods has been of great importance in the paleoecological studies of lakes. Transfer function aproach is among most commonly used for the quantitative reconstruction of various environmental variables. For this purpose, scaled training sets are created that combine modern assemblages e.g diatom, physicochemical parameters of water along with the ecological gradient of interest to us. Knowing the environmental factors that affect the presence and abundance of individual taxa in contemporary biocoenoses, it is possible to reconstruct the conditions previously prevailing in the reservoir using statistical methods.
We will present a new diatom test set consisting of 64 lakes located in northeastern Poland. The selected lakes represent a wide range of trophic statuses (from oligo- to eutrophic). Such studies are essential to understand the relationship between dominant taxa, phosphorus concentrations and other environmental variables, enabling long-term observations of lake eutrophication changes. This is of crucial importance in the context of protecting water resources. It will also be possible to trace changes in the eutrophication of lakes from the last glaciation to the present day and thus determine the impact of climate change or man on the increase in lake productivity. Knowledge of the ecological requirements of diatoms from various habitats (pelagic, sublittoral, and littoral) will also be supplemented, increasing the precision of paleolimnological reconstructions based on the analysis of their species composition.
The research was fully funded by the NCN research grant 2016/23/D/ST10/03071.

Vegetation dynamics in a cultural landscape from Late Pleistocene to Holocene

Dr. Feli Hopf [1]***, Prof. Simon Haberle*** [2]***, Dr. Georgia Stannard*** [1]***, Ms. Hahjung Chin*** [1]

1. *Centre of Excellence for Australian Biodiversity and Heritage, School of Culture, History and language, Australian National University, Canberra ACT, Australia,* ***2.*** *ARC Centre of Excellence for Australian Biodiversity and Heritage, School of Culture, History and Language, The Australian National University*

We compare vegetation and fire records from four sediment cores from the Mersey River valley in northern lutruwita/Tasmania, Australia to explore vegetation stability during the Holocene. The records span a range of time scales from >60,000 years through to the last 4000 years and reveal the nature, pace and drivers of vegetation change at a range of time scales and sample resolution within the same cultural landscape. The sites are located within dry eucalypt forest and woodland with some pockets of wetter forest and this appears to have been stable throughout the Holocene, despite climate change during that period, and likely reflects the ongoing maintenance of the cultural landscape by Aboriginal people.

Morpho-sedimentary structure of new mud volcanoes on the Moroccan Atlantic continental margin (Gulf of Cadiz)

Ms. Olga Sanchez Guillamon [1]***, Dr. Desirée Palomino*** [1]***, Dr. Juan-Tomás Vázquez*** [1]***, Mr. Ricardo León*** [2]***, Ms. M. Carmen Fernández*** [3]***, Ms. Nieves López-González*** [1]***, Ms. Teresa Medialdea*** [2]***, Mr. Luis Miguel Fernández-Salas*** [4]***, Mr. Luis Somoza*** [2]

Multibeam bathymetry, sub-bottom parametric profiler, multichannel seismic reflection data and sediment cores were used to detail the nature, morpho-sedimentary and internal structure of five newly discovered mud volcanoes (MVs) in the Moroccan margin of the Gulf of Cadiz. The Henriet and Subvent MVs are located at 300-400 m water depth, while Chueca, Demetrio de Armas and Puerto Real MVs are at 1100-1800 m water depth. Two main types of morphologies are identified: regular cone-shaped edifices (Subvent MV) with a pronounced crater (Henriet MV) in the eastern province; and ridge- attached oval-shaped conical edifices (Chueca, Demetrio de Armas and Puerto Real MVs) in the western province. The overall seismic architecture of these MVs is the result of successive events of mud extrusion and outbuilding alternating with periods of dormancy. The Henriet and Subvent MV system is composed of stacked bicones and intrusive complexes, which penetrated upper Miocene-Quaternary sedimentary units rooted in the Gulf of Cadiz wedge. Major phases of mud extrusion and outbuilding took place since the Late Pliocene with re-activation during mid-Pleistocene. Mud breccias interbedded with hemipelagic/contourite sediments were collected for all MVs. Cores attest recent periods of mud outflows lasting from the Late Pleistocene (180 ky) whereas the end of MV activity could date back to historic times (the last 0.8 ky). The most active MV points out to the Subvent MV. These new MVs are formed in response to the extensional and compressional system within the Gibraltar Arc. In the eastern side, MVs are related to extensional faults forming deep sedimentary basins and forcing overpressured fluids to migrate upwards coeval with thick contourite deposits. On the western side, MVs are related to compressional ridges at the front of fold-thrust systems which act, as pathways to deep-seated fluids to ascent to seafloor

Geomorphic and acoustical signatures of hydrothermal vents in the Calent mound, Columbretes Islands (western Mediterranean Sea)

1. *Instituto Español de Oceanografía (IEO, CSIC), Centro Oceanográfico de Málaga,* **2.** *(IEO-CSIC), Centro Oceanográfico de Baleares,* **3.** *(IEO-CSIC), Centro Oceanográfico de Canarias,* **4.** *(IEO-CSIC), Sede Central Madrid,* **5.** *IGME*

The Columbretes Islands are a volcanic archipelago located in the southern sector of the Ebro continental shelf in the western Mediterranean composed by four islands, islets and small submarine mounds and peaks. Two oceanographic expeditions were carried out in the area during 2020 and 2021 supported by LIFE-IP-INTEMARES project. During the expeditions, several datasets were obtained: (i) Multibeam echosounder (Kongsberg EM710) bathymetry and backscatter, (ii) water column data were recorded and they have been used to detect and compare acoustic flares, (iii) very high resolution parametric profiles (TOPAS PS18) and (iv) several rocks and superficial sediment samples by divers and shipek dredge, respectively. All these data has allowed characterizing the geomorphology of Calent mound (in the south of the archipelago) and the study of the fluid venting processes that nowadays are active in the area. Calent is a rounded mound of 1.2 km wide and 40 m high located between 37.5 and 80 meters depth. Several outcrops in the summit, up to 2 m high, showed the highest backscatter values. A total of 24 acoustic flares were detected with heights between 20 and 40 m revealing a release of gas from the seafloor into the water column. Also, gas bubbles have been observed and filmed by divers in the flares at 40 m depth. Crusts are present as fine-grained deposits composed of iron oxyhydroxides. Some of the sediment samples obtained from the base of the flares, once on board, emitted a strong odor of hydrocarbon. They are composed mainly by biogenic coarse sands and gravels with a carbonate content from 25% in the base to more than 40% in the summit. In the very high resolution parametric profiles, several micropockmarks (about 1 m diameter) have been observed as small disruptions in the most superficial continuous reflectors. These microstructures are not related to the acoustic flares observed and could indicate active flows in the recent past that now are inactive. The results observed indicate that the Calent mound is the most active hydrothermal volcanic area in the Spanish western Mediterranean.

Morphometric analysis of mud and fluid migration morphology documented offshore Scoglio d'Affrica islet (Tuscan Archipelago, Northern Tyrrhenian Sea)

Mr. Simone Napoli [1], ***Dr. Daniele Spatola*** [1], ***Prof. Daniele Casalbore*** [2], ***Dr. Martina Pierdomenico*** [3], ***Prof. Francesco Chiocci*** [4]

1. *Department of Earth Sciences, Sapienza University, Rome, Italy,* ***2.*** *Department of Earth Sciences, Sapienza University of Rome,* ***3.*** *Institute of Anthropic Impacts and Sustainability in marine environment, National Research Council (IAS-CNR), Italy,* ***4.*** *Department of Earth Sciences, Sapienza University, Italy*

Mud and fluid migration producing active seepage at the seafloor is a global phenomenon documented in different geodynamic contexts. Scoglio d'Affrica islet is part of the Elba-Pianosa Ridge, a N-S morpho-structural high, where submarine methane emissions have been studied since the 1960's and where violent gas outbursts such as that in 2017 are documented. The first morphometric analysis of positive and negative mud and fluid migration morphologies occurring in study area by means of high-resolution bathymetric data is presented in this work. Mud and fluids, migrating through a thick Eocene-Early Miocene siliciclastic succession and overlying sedimentary layers form a number of positive morphologies including seven large sub-circular mud volcanoes with steep flanks, up to ~ 400 m wide, and up to 35 m high. Their morphometric parameters (e.g., flatness value) allow us to interpret, classify the mapped positive morphologies as mounded, flat topped and conical shape features. Moreover, a crude mathematical approach based on buoyancy-driven model, usually applied to igneous volcanoes and successively developed for submarine mud volcanoes on Earth as well as on Mars, allows to calculate the mud source depth, resulting in shallow reservoirs. As regarding negative features, more than 250 pockmarks with planform shape from sub-circular to elongated and U/V-shaped cross-section have been mapped. They are mostly arranged as isolated, in clusters or organised in N-S oriented strings, running almost parallel to the fault escarpments which represent the main structural features of the area. Pockmarks have been classified based on their size parameters (i.e., depth, mean diameter) according to the more recent literature. Considering the probability of mud volcanoes explosive activity, the high-magnitude outburst occurred in 2017 and the shallow water setting, the morphological characterization of fluid seepage features is also an important baseline study since it can provide insight for marine geohazard assessment.

Seafloor fluid vents imaged by multibeam versus 3D seismic datasets : a comparison from the Amazon deep-sea fan

High resolution bathymetric datasets of the deep seafloor continue to offer new perspectives on the processes and products of seafloor fluid venting to the ocean. On the Amazon deep-sea fan, multibeam hydroacoustic data acquired across the upper slope by SeaSeep in 2016 have previously been shown to reveal dozens of water column gas flares, most rising from low seafloor mounds associated with higher reflectivity. Here we compare examples of seafloor fluid vents in a ca. 200 km^2 area of the upper Amazon fan in water depths of 1000-1200 m, observed on the SeaSeep multibeam imagery (peak frequency 12 kHz, 30 m grid resolution) and on seafloor extracts from an exploration 3D seismic volume (peak frequencies ≈40 Hz, 10m grid resolution). The two datasets reveal a variety of seafloor features, including mounds, depressions and mounds within depressions, with relief of up to tens of meters and widths of hundreds of meters. The high frequency content of the multibeam data provides information on the seafloor and near-seafloor sediments to depths of a few meters, and reveals subtle morphological features and changes in reflectivity, including possible sediment flows. The much lower frequency content of the 3D seismic data integrates the upper 10-15 m sub-seafloor, but its higher spatial resolution nonetheless reveals surprising additional details of seafloor morphology. Together these datasets show that the morphology of the mounds is consistent with small mud volcanoes, some with crater-like depressions at their summits; some mud volcanoes sit in larger depressions interpreted as calderas due to localised subsidence, while a few isolated (unfilled) depressions may be either calderas or pockmarks. The Amazon fan is an area of high sedimentation rates, and the observation of relatively small positive- and negative-relief seafloor morphologies, and local high backscatter signatures, suggests recent extrusive activity. However, only a few of the mud volcanoes coincides with water column gas plumes imaged in 2016, possibly indicating episodic activity.

REVEALS-based reconstruction of changes in vegetation cover during the last interglacial – a case of the Wola Starogrodzka site, E Poland

Dr. Magdalena Fiłoc [1]***, Prof. Mirosława Kupryjanowicz*** [2]***, Ms. Edyta Żuk-Kempa*** [3]***, Dr. Marcin Żarski*** [4]

1. *Department of Paleobiology, Faculty of Biology, University of Białystok, Poland,* ***2.*** *University of Bialystok, Department of Paleobiology, Faculty of Biology, Białystok, Poland,* ***3.*** *Doctoral School of Exact and Natural Sciences at the University of Bialystok, Poland,* ***4.*** *Polish Geological Institute – National Research Institute, Warsaw*

We present the first (and probably also for the whole of Central Europe) quantitative pollen-based reconstruction of changes in vegetation cover during the Eemian Interglacial (last interglacial, MIS 5e). We describe these changes using the Regional Estimates of VEgetation Abundance from Large Sites (REVEALS) model. REVEALS has been applied to 6 profiles from the Wola Starogrodzka site, E Poland (a large number of profiles produces more reliable land-cover estimates with lower standard errors) to reconstruct the percentage cover of 21 plant taxa assigned to 9 plant functional types and 3 land-cover types. Due to the impossibility of determining the absolute age of studied sediments (their age is beyond the limits of the radiocarbon method), the windows for reconstructions are not time windows, but they are biostratigraphical windows determined on the basis of a detailed regional palynostratigraphy of the Eemian Interglacial. In Poland, seven regional pollen assemblage zones were distinguished (E1 to E7 R PAZs). This division well corresponds to other European regional palynostratigraphies, that enables the correlation of regional pollen zones across Europe. Almost every Polish regional pollen zone is divided into 2-4 subzones (R PASZs) – a total of 24 R PASZs is distinguished. They are, in this study, the windows for a REVEALS-based reconstructions. Each such window groups all the pollen spectra representing it in all analyzed profiles from the Wola Starogrodzka site.

Issues related to the interpretation of the results in terms of landscape openness and climate-induced vegetation changes are discussed. We showed, for example, that the land-cover of open communities throughout the early Eemian (E1-E3 R PAZs) was much larger than we previously estimated on the basis of the percentage pollen data. On the other hand, the land-cover of *Carpinus* in the hornbeam phase of the middle Eemian (E5 R PAZ) was significantly smaller than we had previously assumed.

This is followed by a review of the future potential utility and development of this reconstruction for the Eemian Interglacial.

The research was partially financed under projects no. 2017/27/B/ST10/01905 and 2019/03/X/ST10/01114 of the National Science Center, Poland.

Enhanced late Quaternary pluvial episodes in south-eastern Australian highlands during glacial episodes as revealed by optical dating

Dr. Xiao Fu [1], ***Dr. Tim Cohen*** [2]

1. *Zhejiang University,* ***2.*** *Wollongong Isotope Geochronology Laboratory, School of Earth, Atmospheric & Life Sciences. University of Wollongong. Wollongong, NSW Australia*

Fluvial sediments in Australia provide important archives for assessing late Quaternary flow regime changes. In south-eastern Australia abundant evidence exists of enhanced runoff conditions throughout and beyond the last full glacial cycle. These include palaeochannel deposits and fluvial terraces which were interpreted as evidence for pluvial episodes and enhanced flow regimes. The hydrological setting in the east of the Great Dividing Range is characterised by a series of smaller coastal-draining catchments (< 1000 km^2) surrounded by much larger basins extending to the west of the great escarpment and with areas > 5000 km^2, such as the Hunter and Shoalhaven. Recent single-grain (SG) optically stimulated luminescence (OSL) study on three fluvial terraces in the upper Hunter catchment showed that extreme fluvial aggradational episodes in the catchment are mainly correlated with glacial or stadial periods since MIS 6. This study presents the latest OSL dating results of several previously undated fluvial terraces in the Shoalhaven and upper Hunter catchments, namely the Larbet terraces, the lower and upper Mayfield terraces. SG quartz and/or SG K-feldspar dating were applied to fluvial sediments collected from these terraces. These include several challenging samples in terms of luminescence dating, exhibiting complex luminescence properties and/or strong bioturbation, or are close to signal saturation. A comparison between SG quartz and feldspar equivalent dose distribution was used to assess the extent of bleaching for individual samples and to select the most reasonable dose population for age estimation; new statistical models were used to provide more reliable chronologies for samples near saturation. Our dating results extend the fluvial sedimentary record in south-eastern Australia to Marine Isotope Stage 8. These new chronologies, together with previously published data, suggest that enhanced river valley aggradation in the south-eastern Australian highlands took place mostly during glacial or stadial periods throughout the late Quaternary. Phases of valley-floor aggradation in south-eastern Australian highland are inferred to be a function of increased sediment supply during the cold periods in the late Quaternary, resulting from strong periglacial activities in the adjacent Australian highlands.

Seasonal variances in the palaeolake of Tayma (Saudi Arabia) seen in Ostracoda and Foraminifera during the Early Holocene Humid Period

Dr. Anna Pint [1]***, Ms. Ella Quante*** [2]***, Prof. Peter Frenzel*** [3]***, Ms. Eilyn Becher*** [2]***, Dr. Max Engel*** [4]

***1.** University of Jena,* ***2.** Institute of Geosciences, Friedrich Schiller University of Jena,* ***3.** Friedrich Schiller University Jena, Institute of Earth Sciences,* ***4.** Universität Heidelberg*

Tayma in Saudi Arabia is an important archaeological and historical oasis city, with Neolithic finds and an almost permanent settlement history since the Early Bronze Age. During the Early Holocene Humid Period (EHHP), a perennial lake was located in the endorheic depression north of the modern settlement. While the climate in this area is arid to hyperarid today, it was arid to semiarid during the EHHP. A deep lake phase occurred around the 8.2 ka BP climate deterioration that led to general cooling and drying on the Arabian Peninsula. Foraminifers and ostracods in the sediments of the sabkha basin represent a brackish to hypersaline inland water fauna, which provides valuable information on the past precipitation/evaporation balance. In the lower part of an analysed core section from the deepest part of the basin, they reflect the beginning of the EHHP with a transition to a more humid phase and the development from slightly saline wetlands to a shallow brackish lake, shown by increasing microfossil abundances, a decreasing adult/juvenile-ratio in ostracods, and an increase of δ^{13}C. This culminated in a deep lake phase at ca. 8.3 cal. BP. Varved sediments from two sections contain ostracods (*Cyprideis torosa*) and foraminifers (*Ammonia tepida* and *Quinqueloculina seminula*) which are more abundant in the dark layers, indicating more favorable living conditions during deposition of these layers. This is also indicated by higher frequencies of juvenile carapaces in the light layers, suggesting possibly higher juvenile mortality rates. A sieve pore analysis in *C. torosa* valves proposes distinctly higher salinities during deposition of the light layers. The seasonal variances in the microfossil assemblages may reflect generally dry summers and more humid winters, a seasonal pattern preserved within the alternating varves.

In the uppermost part of the section, a decrease in both microfossil and macrofossil frequency, and stable isotopes in the ostracod shells indicate the transition to drier conditions in the mid-Holocene, at ca. 8.1–7.9 cal. BP.

Agropastoral practices and water stress in Central Asia: first insights given by the lake sediment sequence of Kanbeshbulak (Hissar mountains, Uzbekistan)

Dr. Elodie Brisset [1], ***Dr. Camille Rhoné-Quer*** [2], ***Mr. Charbel Alchidiac*** [3], ***Dr. Kazuyo Tachikawa*** [4], ***Dr. Frédéric Guiter*** [1], ***Ms. Feruza Makhmasobirova*** [2], ***Dr. Morteza Djamali*** [5], ***Dr. Farhod Maksudov*** [6]

1. *Aix-Marseille Université, CNRS, IRD, Avignon Université, IMBE, Europôle de l'Arbois, 13545 Aix-en-Provence, France,* ***2.*** *IREMAM, Aix Marseille Univ, CNRS, MMSH, Aix-en-Provence, France,* ***3.*** *Aix Marseille Univ, Avignon Univ, CNRS, IRD, IMBE, Aix-en-Provence, France,* ***4.*** *Aix Marseille University, CNRS, IRD, INRAE, College de France, CEREGE, Aix-en-Provence, France,* ***5.*** *Institut Méditerranéen de Biodiversité et d'Ecologie,* ***6.*** *National Center of Archaeology, Uzbekistan Academy of Sciences, Tashkent, Uzbekistan*

This contribution aims to analyse what were the adaptation strategies of agropastoral systems vis à-vis water stress over the last millennium in Central Asia. Based on paleoenvironmental analyses carried out on the sediment infilling of Lake Kanbeshbulak (southern part of the Hissar mountain range, Uzbekistan), we will reconstruct the long-term variability of soil erosion (sedimentology and, elemental geochemistry) in relation to indicators on the nature and relative intensity of the agropastoral practices (palynology carried out on the same cores). Those results will be put into a Human perspective through comparisons with historical sources. In particular, we will propose a special focus on the Medieval Islamic Period to discuss the hypotheses that regional climate changes, by modifying water resource availability locally, might have impacted crops and pastoral livestock productions, triggering economic losses and social contestations unevenly addressed by the succeeding political powers.

Aridification in Mid Holocene in the south-eastern Mongolia

Prof. Yukiya Tanaka [1], ***Ms. Kang sumin*** [1]

1. *Kyung Hee University*

There are many depressions with lacustrine terraces in the south-eastern Mongolia. This area is located at the summer monsoon limit without glacier melting water. This means that the climate of the eastern Mongolia is strongly affected by strength of summer monsoon due to climate change. The present study aims to elucidate palaeohydrological environment change of the south-eastern Mongolia through analysis of lacustrine terrace deposits (Uidzegiin lake and Bolgoin Govi). Uidzegiin lake is located at the Ongon Soum, the south-eastern Mongolia. These depressions are desiccated saline lake with highest lacustrine terrace (1070m a.s.l.). The lacustrine terrace is widely distributed around present Uidzegiin lake and Bolgoin Govi (Palaeolake). Sudden coarsening of lacustrine deposits shows the sudden lowering of lake level surface associating with reduction of contents of biogenic silica and organic matter. This event is dated around 5,000 yrBP by 14 C dating. Because this area is stable tectonically without influence of glacier melting water, this means that the precipitation of this area reduced suddenly in the Mid Holocene. On the other hand, the climate of this area was humid and lake level was at least 1070 m a.s.l. until Mid Holocene. At this time the paleolake was expanded and flowed out northward possibly.

Paleoclimatic and socio-environmental dynamics in northwestern Arabia during the Holocene: wetland and dune archives in the AlUla oasis

Mr. Amaury Fernandes [1], Prof. Laurent Lespez [1], Dr. Louise Purdue [2], Dr. Hatem DJERBI [2], Prof. Jean-François Girard [3], Dr. Gourguen Davtian [2], Mrs. Segolene Saulnier-Copard [4], Dr. Sophie Costa [2], Dr. Alain Carré [2], Dr. Valentina Villa [2], Mr. Claude Rouvier [5]

***1.** Laboratoire de Géographie Physique CNRS UMR 8591, Université Paris Est-Creteil, **2.** Université Côte d'Azur, CNRS, CEPAM UMR 7264, Nice, France, **3.** Université de Strasbourg, Ecole et observatoire des sciences de la terre, **4.** CNRS, Universite Paris1, **5.** Independant Researcher*

Oases are man-made environments which are adapted responses to hydro-climatic constraints in arid environments. They offer a unique opportunity to understand the interaction between agrarian, social and climatic dynamics as they record and provides sedimentary archives which are key to understand the causes of socio-environmental transformations and the adaptations of agricultural societies to these changes. Research conducted in northwestern Saudi Arabia reveals the paucity of our knowledge on these questions in this part of the peninsula, particularly after 3000 B.C., i.e. at the beginning of the Bronze Age.

The fluvial oasis of AlUla in Northwestern Saudi Arabia provides a unique research background following the development of archaeological and environmental research projects in this oasis since 2019. Located at the foot of the Harrat al-Uwayrid formation which separates the sandy deserts of northern Arabia (Hamra Desert) from the Red Sea, AlUla is characterized by the development of emblematic sites such as the Late Bronze Age site of Dadan, the Nabataean site of Hegra, and the old city of AlUla. While providing information on settlement dynamics, recent research has also revealed the development of agro-pastoral activities since the Neolithic and hydro-agricultural development from the Late Bronze Age onwards.

In order to better understand the environmental and climatic background in which the oasis developed, alluvial, eolian and playa sedimentary archives were studied in the AlUla watershed. Geomorphic mapping, core drilling, stratigraphic description of exposed sedimentary archives were conducted in the field and samples collected for sedimentological analyses (grain-size, geochemistry, Magnetic Susceptibility) and chronology (14C and OSL).

Our results highlight a long-term tendency towards aridification since the second part of the Holocene as well as short-term climatic oscillations. The confrontation of our results with available archaeological and environmental data available at the regional scale allow us to draw first hypothesis on the impact of the climate on the local societies for the last 10 millennia.

Human-landscape interaction through time in prehistoric and ancient Sicily: a GIS based approach

Dr. Vincenza Forgia [1]

1. Dipartimento Culture e Società, Università di Palermo

Sicily, the main Island in the Mediterranean Sea, is an interesting open-air laboratory where experiment different tecniques and approaches in order to study the human-landscape interaction at least over the last sixteen millennia. Data from historic, cartographic, aerial images and satelite archives, and the availability of Digital Elevation Model and Digital Terrain Model helps in the interpretation of data from archaeological research and in the contextualization of human activities within the peculiar territory of the Island.

A GIS-based approach combining different kind of raster data-source with georeferenced archeological and paleoenvironmental sites of interest has been devoted to the study of the human-landscape interaction through time. In particular, the attention has been focused on Slope and Aspect computation, Viewshed Analysis, Least Cost Analysis in order to deal with settlement strategies, in a diachronic perspective, on a regional scale.

Hilly and mountainous territories have played a central role in the settlement strategies offering peculiar resoureces: natural refugia (dolines, caves and rockshelters in karst environments), strategic visual control points and a fast and direct mobility system, with paths exploited at least over the last ten millennia. Coastal landscapes, where human settlement have been concentrating during the whole Holocene, particularly after the Greek colonization, have been intensely exploited and partly modified by farming and herding activities. The ancient road system, besides, has shaped a new Island, creating new connections among (un)connected territories.

Quantifying human impact during industrialisation on the evolutionary trajectory of Vosgian streams (NE France): the value of documentary archives

Mr. Timothée Jautzy [1], Dr. Nicolas Jacob-Rousseau [2], Ms. Salomé Berthier–Laumond [1], Ms. Margaux Claudepierre [1], Dr. Gilles Rixhon [3], Prof. Laurent Schmitt [1]

***1.** Laboratoire Image, Ville, Environnement (LIVE UMR 7362), Université de Strasbourg, 3 rue de l'Argonne, 67000 Strasbourg, France, **2.** Archéorient, UMR 5133, University of Lyon 2-CNRS, 5 Avenue Pierre Mendès, 69676 Bron, France, **3.** Laboratoire Image, Ville, Environnement (LIVE UMR 7362, ENGEES), Université de Strasbourg, 3 rue de l'Argonne, 67000 Strasbourg, France*

The anthropogenic pressure on European rivers has greatly intensified since the Industrial Revolution through channelisation, rectification, and building of dams and weirs. Against this background, focusing on the Vosges Mountains (NE France) is particularly relevant since it is a heavily populated low-mountain range whose hydrographic network was accordingly impacted by widespread human modifications. No less than ~5000 hydraulic structures (HS) mostly involving levees and weirs were built along and across the main streams draining the massif. Contrary to large rivers (e.g. the Rhine), the edification periods of these HS in smaller catchments remains largely unknown yet, thereby impeding a precise chronological reconstruction of the main phases of human pressure and environmental trajectories.

In this study, we aim to gain insight into the spatio-temporal anthropisation of three main streams draining the southern part of the Vosges, i.e. the Fecht, Vologne and Moselotte, and to evaluate their historical morphodynamic adjustments from the end of the 18th century onwards. We took advantage of the abundant paper archives, i.e. written reports, plans…, from the "*Ponts et Chaussées*" administration, which collected at the local scale every official request to build HS along and across streams from the 18th to the 20th century. Firstly, we characterised and mapped every weir and levee along the three studied streams to produce an updated database of the present distribution of HS. Secondly, we analysed the archives to date the construction (and in some cases deconstruction) of the HS. Finally, we reconstructed the diachronic evolution of the channel pattern, from an ancient topographical map (1866) and two orthophotos (1951, 2018). Our results allow a first quantification of human impacts: the construction year of present weirs across the Fecht, Moselotte and Vologne was dated to 12%, 31% and 56%, respectively. Most of them were probably built in the middle of the 19th century. Importantly, we also evidence a spatio-temporal correlation between the construction of HS and the simplification of the channel pattern. Although the use of historical documents has several limitations (e.g. loss, destruction, unavailability), we demonstrate that they are valuable archives that usefully complement field observations and investigations.

Modular geomorphological approaches along urban-rural gradient in the city of Rome (Italy)

Dr. Michele Delchiaro [1], *Dr. Alessia Pica* [1], *Prof. Daniela Piacentini* [1], *Prof. Francesco Troiani* [1], *Dr. Francesca Vergari* [1], *Prof. Maurizio Del Monte* [1]

1. *Department of Earth Sciences, Sapienza University of Rome*

The urban environment is generally characterized by an urban-rural gradient where the anthropic impact decreases from the historic city center (where anthropogenic pressure is heavier) to the suburbs and peri-urban areas (where a greater presence of open spaces and green areas is affirming). In the Anthropocene, urbanization and correlated infrastructure building highly impact and sometimes completely obliterate natural landscapes. Although urban geomorphological mapping, modeling, and reconstructions are fundamental in understanding human-landscape interaction and associated geomorphological risk, human activity as a morphogenetic agent along the urban-rural gradient is not yet fully understood.

In the framework of the national geomorphological cartography project, our work presents interdisciplinary techniques used to reconstruct the transient landscape between natural and anthropogenic environments and the geomorphological histories of the city of Rome.

Case studies within a 600 km^2 area surrounding the Italian capital city will be presented, showing the modular approaches applied along the urban-rural gradient. In detail, a traditional geomorphological survey was applied in natural areas. Whereas, in modified to completely urbanized landscapes, the analysis of data covering the entire urbanization time, including archeological data, historical and recent topographic maps, and digital elevation models, were fundamental to detect the anthropic modifications on the natural landscape.

Geoarchaeology of the largest prehistoric mound in Europe: multidisciplinary investigations in the Hill of Udine (NE Italy)

Prof. Alessandro Fontana [1], ***Dr. Giacomo Vinci*** [2], ***Dr. Livio Ronchi*** [3], ***Mr. Andrea Mocchiutti*** [4], ***Dr. Giuseppe Muscio*** [5], ***Dr. Paola Visentini*** [6], ***Dr. Michele Bassetti*** [7], ***Dr. Massimo Domenico Novellino*** [3], ***Dr. Federica Badino*** [8], ***Dr. Giorgia Musina*** [9], ***Dr. Simonetta Bonomi*** [9]

According to legend, the hill dominating the city of Udine (NE Italy) was built by Attila the Hun's soldiers in the 6^{th} century, but its natural or anthropogenic origin has been debated until now. In particular, in the last decades the researches mainly pointed to a tectonic origin of the relief as an uplifted remnant of glacial or fluvioglacial deposits of the Middle Pleistocene. The hill rises for about 30 m over the surrounding alluvial plain and its flat top hosts the palace built over the ruins of the castle destroyed by the earthquake of 1511 CE.
In the framework of a collaboration between Ministry of Culture, Municipality of Udine and University of Padova, five new stratigraphic cores were drilled in 2020-22 up to 40 m of depth from the hilltop and some new archaeological excavations on the hill and at its base were carried out. The geoarchaeological and other multidisciplinary analyses, supported by the comparison with the archaeological and ethnographic data, allow to demonstrate that the hill is an anthropogenic mound built in the final part of the Bronze Age and that the folklore transformed the ancestral memory of its origin into legend. The hill, which measures 30 m in height and over 400,000 m^3 in volume, had already these dimensions since the its first construction and, thus, it is the largest prehistoric mound in Europe. Paleopedologic, paleobotanic and geochronological investigations allow to reconstruct the environmental setting existing when the mound was built, evidencing some peculiar characteristics that favored the flourishing of the settlement in the area of Udine.
The mound consists of alternations of gravelly and soil lenses quarried in the surroundings and this excavation led to create a depression extending for almost 100,000 m^2 that was used as a water basin for supplying the settlement. This discovery reveals unprecedented skills in earth construction and territorial management, confirming the significant anthropogenic modifications of the environment during the Bronze Age.

Paleomagnetic and rock magnetic investigations of cave sediments in Lipiška Jama: insight into Classical Karst (SW Slovenia) evolution

***Mr. Šimon Kdýr* [1], *Dr. Nadja Zupan Hajna* [2], *Mrs. Astrid Švara* [2], *Dr. Petr Pruner* [3], *Prof. Pavel Bosák* [3]**

***1.** Institute of Geology of the Czech Academy of Sciences, Rozvojová 269, 165 00 Praha 6, **2.** Karst Research Institute ZRC SAZU, Titov trg 2, SI-6230 Postojna, **3.** Institute of Geology of the Czech Academy of Sciences, Rozvojová 269, 165 00 Praha 6; Karst Research Institute ZRC SAZU, Titov trg 2, SI-6230 Postojna*

The Lipiška jama Cave at the south edge of the Kras Plateau (Slovenia) is a 1,400 m long, inclined to the SSW. It is recently functioning in epiphreatic and vadose regimes. Three allogenic sedimentary sections, each 2 to 3 m thick, deposited in three different levels of the same cave passage (i.e. Kozinski rov), were sampled (bottom, middle, top). With the exception of the bottom level section, which was disturbed by slides and slumps, the other two sections were sampled using high-resolution method. For magnetomineralogical characterization of the sediments rock magnetic methods such as acquisition of isothermal remanent magnetization, S-ratio, anisotropy of magnetic susceptibility (AMS), etc., were used. Magnetic susceptibility shows a wide variation of values in all three sections. A low coercivity mineral (e. g. magnetite) is identified as the main carrier of magnetization. The AMS shows dominantly oblate fabric, which corresponds to fine-grain sedimentation. Alternating field demagnetization was applied to determine characteristic remanent magnetization (ChRM). Primary magnetization, and the presence of both normal (N) and reverse (R) polarity samples, were determined. The section in the bottom level of the cave passage, which was extensively influenced by post-depositional features, displays a chaotic distribution of the ChRM components. The section in the middle level of the cave passage reveals R and N polarity zone within the allogenic sediment with a nearly antipodal position of their mean directions, as well as basal flowstone with R polarity. The highest positioned section reveals mainly R polarity and occasionally N polarity samples. Although the homogenous non-laminated clay forms this sedimentary sequence, AMS parameters suggest some samples suspected of slumps behaviour. The presence of R polarity zones in two studied sections in the Lipiška jama suggests an age at least within the Matuyama Chron. Correlation with other sections in the area will help the understanding the evolution of the Classical Karst.

This research is supported by Mobility Plus Project (No. SAZU-22-08) and Research Plan of the Institute of Geology of the Czech Academy of Sciences (No. RVO67985831).

Paleo- and rock-magnetic investigations from the upper unconsolidated sedimentary sequence of a drill core (20HCL04) from the Jeokjung-Chogye basin (impact crater), Korea: Towards chronostratigraphic constraints

Dr. Hyeon-Seon Ahn [1], Dr. Jin-Young LEE [2], Dr. Yuhji Yamamoto [3], Dr. Wook-Hyun Nahm [2]

1. Korea Institute of Geoscience and Mineral Resources, 2. Korea Institute of Geoscience and Mineral Resoiurces, 3. Center for Advanced Marine Core Research, Kochi University

The Jeokjung-Chogye basin situated in Hapcheon County, southeastern Korean Peninsula, is presumed as a Quaternary meteorite impact crater. In the impact crater basin, we retrieved a drill sediment core called '20HCL04', which was the azimuthally non-oriented drill core, with a drilling depth up to 66.0 m. From high-resolution discrete samples (collectively, n= 747) from the unconsolidated sedimentary sequence at the 14.0–42.0 m depth interval, we has conducted paleo- and rock-magnetic investigations, which aims to test the usability for obtaining chronological constraints for the core. Progressive alternating field demagnetization (AFD) behavior of natural remanent magnetization (NRM), and results from strong-field high-temperature thermomagnetic analysis and the high-temperature three-axis isothermal remanence (IRM) Lowrie test indicate the existence of two (or more) low-coercivity magnetic minerals as major remanence carriers, probably magnetite and greigite, and notably allow to confirm predominant greigite contribution at many parts of the investigated interval. Based on the initial magnetic susceptibility values and characteristic remanence (ChRM) determinations from the NRM AFD results, we preliminarily construct and evaluate a magnetostratigraphic record consisting of ChRM inclinations and tentative relative paleointensity (RPI) values for the core, conservatively excluding those data that are potentially regarded as derived from greigite authigenesis. The constructed magnetostratigraphy allows us to recognize that the whole analyzed interval corresponds to a single persistent normal-polarity chron, in which there are multiple, large-amplitude directional swings associated with respective remarkable RPI lowering. This finding has the potential to provide us key tie-points of age-depth relationship for ultimately reconstructing the best reliable, accurate, high-resolution chronology for the core. We, accordingly, believe that further paleomagnetic researches will be necessary in future.

Paleomagnetic and rock magnetic analyses on sedimentary cores from Ross Sea, Antarctica (CHIMERA project, PNRA)

1. *Istituto Nazionale di Geofisica e Vulcanologia, Rome (Italy),* ***2.*** *Istituto Nazionale di Geofisica e Vulcanologia (INGV),* ***3.*** *Istituto di Scienze Polari, Consiglio Nazionale delle Ricerche, ISP-CNR,* ***4.*** *Department of Math and Geosciences, University of Trieste,* ***5.*** *CNR-ISMAR Bologna*

A paleomagnetic and rock magnetic investigation was conducted in the framework of the multi-disciplinary project CHIMERA (CryptotepHra In Marine sEquences of the Ross Sea, Antarctica: implications and potential applications) funded by the Programma Nazionale di Ricerche in Antartide (PNRA). Data was acquired by taking 1-cm spacing magnetic measurements from sediment cores collected in the continental shelf basins of the Ross Sea (Antarctica) in the frame of previous PNRA research project. The analyzed sediment shows good paleomagnetic properties which allow the reconstruction of well-defined characteristics remanent magnetization (ChRM) showing some inclination features that can be related to the already know excursion of the past geomagnetic field. Moreover, the relative paleointensity (RPI) curves constructed for the sedimentary successions, coupled with tephrostratigraphic and biostratigraphic studies, provide high resolution chronological constraints for age calibration. Finally, the rock magnetic parameters trend throughout the cores gives us information useful for the paleoenvironmental reconstruction linked to the advancement-retreat phases of the ice shelf in this region in the last climatic cycle.

Integrating 40Ar/39Ar, paleomagnetic and geochemical data to evaluate the geomorphic response to water-lava interaction in Swan Valley, Idaho, USA

Dr. Tiffany Rivera [1], ***Ms. Stacy Henderson*** [2], ***Dr. Pete Lippert*** [3], ***Dr. Brian Jicha*** [4]

1. *Westminster College,* ***2.*** *Montana State University,* ***3.*** *University of Utah,* ***4.*** *Department of Geoscience, University of Wisconsin-Madison, Madison, WI 53706, USA*

Volcanism on the Earth's surface plays a major role in the evolution of the landscape. The timing and progression of river systems that have been diverted by lava flows can be examined through high precision geochronology of the lavas. The Snake River (Idaho, USA) was dammed multiple times, and in several locations, by voluminous basaltic lavas, resulting in the reorientation of the Snake River. Understanding the origins and ages of these lavas are important to understanding the development of the present-day landscape. In eastern Idaho, the Swan Valley graben preserves a record of water-lava interaction through the development of a lava dam. Intercalated subaerial lavas, pillow lavas, and hyaloclastite suggest prolonged interaction between volcanism and standing water. Previous workers hypothesized that the lava dam generated an extensive, albeit short-lived, paleo-lake that existed until the lava dam was breached, causing the Snake River to divert its course into its present-day canyon. In this work, we examine the geochemistry and paleomagnetism of the basalt lavas in the graben to determine an eruptive history, estimate the volume and fill rate for the paleo-lake, and calculate incision rates of the diverted Snake River through Quaternary basalts. Our results show that multiple Quaternary lavas flowed within the graben, culminating in the 904 ka eruption that produced the hyaloclastite dam. We further propose that the paleo-lake was less extensive than previously described and instead shallow marshy, wetland conditions existed to produce the hydrovolcanic deposits. Finally, for the period between 900 and 60 ka, we determine an incision rate of 0.014 cm/yr for the Snake River to carve through a succession of Quaternary basalts, which is consistent with, albeit slightly higher than, rates calculated from 60 ka to present.

Major dune construction during Younger Dryers along the Kankakee River Valley, Midwest USA

Prof. Xiaodong Miao [1]
1. Linyi University

Sand dunes and sand sheets are located along the south side of Kankakee River Valley in Illinois and Indiana, which overlie glaciofluvial outwash, lake sediments, and bedrock of Middle Paleozoic shales and carbonates. Dunes are prominent feature of the landscape, and most dunes are 4.5 to 8 meters high, and some reach 50 feet. Due to the lack of natural exposure and roadcuts, three dunes were sampled by hand augering for optically stimulated luminescence (OSL) dating. Ground penetrating radar (GPR) surveys were conducted for a better understanding of the stratigraphy where exposures are not available. Results show that all three sites contain ages within the Younger Dryas chronozone (11.5-12.8 ka). More importantly, we found that at site 1 there are about 8 meters of eolian sand yielded 5 ages within the Younger Dryas chronozone. Although the large error bar of singular individual OSL age (about 6-9%, about 0.8-1.2 ka) usually does not allow for the determination of a specific climatic event, multiple ages from multiple sites of these dunes and striking thickness in this study all fall into the range of Younger Dryas chronozone. Thus, we believe that the rapid climatic changes before, during and after Younger Dryas play key roles in the dune construction here in the Kankakee River Valley. These changes of the ages are consistent with GPR image and lithology changes observed in the field.

A revised Greenland ice-core chronology for the last 3800 years: the GICC21

Dr. Giulia Sinnl [1], ***Dr. Mai Winstrup*** [2], ***Dr. Tobias Erhardt*** [3], ***Dr. Eliza Cook*** [1], ***Dr. Camilla Jensen*** [4], ***Prof. Anders Svensson*** [1], ***Prof. Bo Vinther*** [1], ***Prof. Raimund Muscheler*** [5], ***Prof. Sune Rasmussen*** [1]

1. *Physics of Ice, Climate and Earth, Niels Bohr Institute, University of Copenhagen,* **2.** *Technical University of Denmark,* **3.** *Helmholtz Centre Alfred Wegener Institute for Polar and Marine Research, Bremerhaven, Germany,* **4.** *University of Bern,* **5.** *Lund University*

Ice-core timescales are vital for the understanding of past climate; hence they should be updated whenever significant amounts of new data become available. Here, the Greenland ice-core chronology GICC05 was revised for the last 3835 years by synchronizing six deep ice cores and three shallow ice cores from the central Greenland ice sheet.

The new timescale is younger than GICC05 by about 13 years at 3835 years ago. The most recent 800 years are largely unaffected by the revision. Between 800 and 2000 years ago, the offset between timescales increases steadily, with the steepest offset occurring between 800 and 1100 years ago.

By analysis of the common variations in cosmogenic radionuclides, the new ice-core timescale is found to be in alignment with the IntCal20 curve.

Do standard treatment and storage techniques contaminate environmental archaeological samples and affect the reliability of radiocarbon dating

***Dr. Becky Briant* [1], *Dr. Philippa Ascough* [2], *Dr. Fiona Brock* [3], *Dr. David Smith* [4]**

***1.** Department of Geography, Birkbeck, University of London, **2.** Scottish Universities Environmental Research Centre, **3.** Cranfield Forensic Institute, Cranfield University, **4.** Classics, Ancient History and Archaeology, University of Birmingham*

There is concern in the archaeological community to reduce the use of chemicals that contain carbon compounds in plant and insect sample processing and storage. This is to avoid contamination of samples that are otherwise valuable for ^{14}C measurement. These chemicals (e.g. paraffin, ethanol, glycerine) can introduce carbon that has a different ^{14}C age to that of the sample into the sample matrix. If this carbon cannot be removed during pretreatment, it will compromise the accuracy of a sample^{14}C measurement. Yet, these chemicals have significant value for processing and storage, significantly reducing sample preparation time and enabling archive samples to be stored and studied at a later date. Whilst individual projects have both successfully dated material after periods of storage and removed other preservatives, there has been no systematic chemical analysis of this particular problem.

We present results from a series of experiments designed to address this problem. The experiments have been undertaken on modern-day seeds and beetles which have a ^{14}C date in equilibrium with current atmospheric levels. Samples that have been paraffin-floated and stored in ethanol for c. 10 years have been compared with recently resampled material from identical locations that have been subjected to a range of controlled treatment and storage protocols. Fourier transform infrared (FTIR) spectroscopy will be undertaken on these samples and on blanks of each relevant chemical, to determine whether traces of processing chemicals are retained in the sample matrix. In this way we can fully characterise the spectra and monitor the removal of processing chemicals.

This project has important implications for the workflows used in environmental archaeology. If researchers can be confident that paraffin-floated and variously stored samples are not contaminated and can still be ^{14}C dated it will significantly increase the efficiency of sample processing.

Palaeoclimatic and morphodynamic interpretation of periglacial landforms in Jotunheimen (South Norway) applying Schmidt-hammer exposure-age dating (SHD)

Prof. Stefan Winkler [1]

1. University of Würzburg

The potential of periglacial landforms in the context of palaeoclimatic interpretation is based on their connection to climate-driven permafrost conditions for both their development and subsequent activity. Its utilisation to extract certain palaeoclimatic signals is, however, complicated by the challenge to obtain reliable numerical age date for these landforms. Many represent rather transitional or diachronous processes of certain duration than clearly defined single events. Additionally, postdepositional disturbance by frost-related processes is quite common.

With the resulting sample sizes required for obtaining representative data for boulder-dominated periglacial landforms, an application of cosmogenic radionuclide dating (CRN) seems hardly viable both financially and timewise. The calibrated-age dating technique of Schmidt-hammer exposure-age dating (SHD) has, by contrast, been successfully utilised for this purpose during the past decade. If independent (numerical) age data allows to establish local or regional age-calibration curves, SHD offers the fundamental advantage of obtaining large sample sizes (hundreds or even thousands of boulders) to overcome the abovementioned limitations of CRN.

The potential of SHD will be highlighted by a study of patterned ground and related solifluction features on Juvflye in Jotunheimen (South Norway). Application of a reliable local SHD age-calibration curve revealed that all studied patterned ground and solifluction features seem to have become stabilised and inactive prior or around the onset of the Holocene Thermal Maximum. With their development likely commencing after local deglaciation around the Preboreal Oscillation their morphodynamic activity was restricted to the Early Holocene despite that fact that in both higher and middle altitude the features have continuously been underlain by permafrost during the entire Holocene until present. And whereas an altitudinal gradient with slightly longer activity at higher altitude was detected with sorted circles, no similar signal was detected for sorted stripes and solifluction features.

Summarising, the SHD stabilisation ages obtained challenge the general application of large patterned ground features as palaeoclimatic indicators for permafrost. From a morphodynamic point of view permafrost *per se* cannot be the sole factor for efficient formation of patterned ground. Factors such as soil moisture, availability of suitable substrate etc. need to be taken into account.

Evidence of mass mortality of the long-lived bivalve Mercenaria stimpsoni caused by a catastrophic tsunami

Dr. Kaoru Kubota [1] ***, Dr. Kotaro Shirai*** [2] ***, Dr. Naoko Sugihara-Murakami*** [2] ***, Dr. Koji Seike*** [3] ***, Dr. Masayo Minami*** [4] ***, Dr. Toshio Nakamura*** [4] ***, Dr. Kazushige Tanabe*** [2]

1. *Japan Agency for Marine-Earth Science and Technology,* **2.** *The University of Tokyo,* **3.** *National Institute of Advanced Industrial Science and Technology,* **4.** *Nagoya University*

Tsunamis are huge disasters that can significantly damage benthic organisms and the sea-bottom environment in coastal areas. It is of great ecological importance to understand how benthic ecosystems respond to such destructive forces and how individual species are affected. Investigating the effect of such disasters on animals that are seldom caught alive is particularly difficult. Bivalve mollusks are especially suitable for investigating how a tsunami affects coastal benthic species because they preserve an environmental record in their shells that can be extended back in time by crossdating the records of multiple individuals. Here we studied dead shells of *Mercenaria stimpsoni*, a long-lived clam, and precisely determined the time of death by using nuclear bomb–induced radiocarbon (bomb-14C) and by counting annual growth increments (sclerochlonology). First, a quasi-continuous, regional bomb-14C record was created by analyzing the shells of 6 live-caught *M. stimpsoni* individuals. Then 27 dead shells collected from the seafloor of Funakoshi Bay were 14C-dated and analyzed. The results showed that the huge tsunami that struck northeastern Japan on 11 March 2011 caused mass mortality of this bivalve in Funakoshi Bay. Nine of the 27 clams died during the March 2011 tsunami, probably by starvation after burial by tsunami deposits or exposure above the seafloor as a result of sediment liquefaction during the earthquake. The dating method used in this study can help us understand how long-lived marine organisms with low population density are affected by huge natural disasters such as a tsunami.

Holocene marine radiocarbon reservoir effect derived from C-14 and U-Th dating of corals for the Penghu Island, Taiwan

Dr. Shing-Lin Wang [1]***, Mr. Yueh-Yang Lee*** [1]***, Prof. Chuan-Chou Shen*** [2]***, Mr. I-Chin Yen*** [3]***, Prof. J. Bruce H. Shyu*** [1]

1. *Department of Geosciences, National Taiwan University,* ***2.*** *High-Precision Mass Spectrometry and Environment Change Laboratory (HISPEC), Department of Geosciences, National Taiwan University, Taipei 10617, Taiwan, ROC,* ***3.*** *National Central University*

Studying the regional marine reservoir effect and its change over time is essential for precise radiocarbon dating of marine samples and the study of past ocean-current information. However, there are only a few marine reservoir ages (R) and marine reservoir corrections (ΔR) available from pre-bomb shells collected at northeastern Taiwan during the 19th century. Here we provide the first report of R for Penghu Island (23°34' N, 119°34' E) in the Taiwan Strait for the past 6700 years, obtained from XRD examination, and ^{14}C and U-Th analyses of shallow-water corals. The R varied from 200 to 420 ^{14}C years during the past 5000 years, and higher Rs, up to ~600 ^{14}C years, were observed between 5700 and 6700 cal BP. The weighted mean ΔR value in the past 5000 years is -154±51 years based on MARINE20, similar to the pre-bomb values from the same site and the Ryukyu Islands, but much lower than the previous shell data of northeastern Taiwan (-78±46 years, recalculated also based on MARINE20). According to the R variation, our results agree with previous studies from the Great Barrier Reef in the southern Pacific Ocean and the South China Sea (center at 15°N), indicating that the ocean current with depleted ^{14}C values during the mid-Holocene extended from the equatorial Pacific up to the Taiwan Strait, and likely to the further north of the continental shelf. More data collection along the Taiwan coast is in progress.

Palaeoearthquake history revealed by a combined detrital zircon U-Pb and OSL ages: a case study at Inbo site on the Southern Yangsan Fault, Korea

Dr. Tae-Ho Lee [1], *Dr. Jin-Hyuck Choi* [1], *Dr. Youngbeom Cheon* [1], *Ms. Shinae Lee* [2], *Dr. Yann Klinger* [3]

1. Korea Institute of Geoscience and Mineral Resources (KIGAM), 2. Korea Basic Science Institute, 3. Institut de Physique du Globe de Paris, CNRS

Earthquake rupture can induce changes in the landform and depositional environment. Such modification in topography and depositional setting makes changes source to sink system of sediment. If the timing of topographical changes is strictly constrained, the period of paleoearthquakes can be tracked. Here, we conducted OSL with detrital zircon U-Pb age datings on the unconsolidated units of the Inbo trench excavations in the Yangsan Fault, the southeastern part of the Korean peninsula reported by Cheon et al. (2020). In this study, the depositional ages for four units of the Inbo trench excavations are identified from far earlier than 70 ka to after 29 ka by the OSL ages, and three units were rapidly deposited at ca. 70 ka. The most recent and the penultimate earthquakes are determined after 29 ka and between ca. 70 to 50 ka, respectively. Clustered three units having depositional ages of ca. 70 ka show twice abrupt changes in U-Pb ages of detrital zircon along with the replacement of the sedimentation setting from fluvial and sag-pond to slope sediments. Since such dramatic changes in U-Pb ages of detrital zircon imply at least twice paleoearthquakes events, the Inbo site means that at least four paleoearthquakes have occurred. This study suggests that the period of additional fault activity can be identified using multiple techniques obtained by OSL and detrital zircon U-Pb age in paleoearthquake studies.

Cheon, Y. et al., 2020, Late Quaternary transpressional earthquakes on a long-lived intraplate fault: A case study of the Southern Yangsan Fault, SE Korea. Quaternary International, 553, 132-143.

Application of burial dating using multiple cosmogenic nuclides in Korea: from Quaternary geology to Geoarchaeology

Dr. Yire Choi [1], *Dr. Hoil Lee* [2], *Dr. Tae-Ho Lee* [1], *Dr. Jin-Hyuck Choi* [1]

1. Korea Institute of Geoscience and Mineral Resources (KIGAM), 2. KIGAM

Deeply buried sediment and artifacts can be dated using multiple cosmogenic nuclides for timescales up to 5 million years through the radioactive decay of these two nuclides. Various research has proven that in situ cosmogenic nuclides can be successfully used in various scientific fields, including Quaternary geology, geomorphology, geoarchaeology, and paleoseismology. Burial dating provides a reliable tool for figuring out the ages of key layers when other dating methods are sometimes unavailable. Since the method has been successfully applied to a number of those scientific fields, this research introduces the application cases and results of burial dating using Multiple Cosmogenic Nuclides (With the proven 10Be/26Al nuclide pair, quartz-bearing material can be numerically dated from about 100 ka to 5 Ma) through samples obtained from drilling cores and trenches in Korea.

Intense Holocene eruptions and landslide activity at Tacaná Volcanic Complex (Mexico) constrained by 36Cl surface exposure dating, lichenometry and dendrochronology

Usual methods are unfortunately not suitable for accurately date Holocene deposits and landforms from active volcanoes. An example is Tacaná Volcanic Complex (TVC), situated in the State of Chiapas in southern Mexico, and the San Marcos Department in Guatemala. The complex is formed by four main structures: Chichuj, Tacaná, and San Antonio volcanoes and the Ardillas dome. Here, we have undated lava domes (summital and Ardillas), lava (Andesitic) and a horseshoe shaped crater's cliff and we determined their age using surface exposure dating with in situ-produced cosmogenic ^{36}Cl, lichenometry and dendrochronology. The ^{36}Cl exposure ages (9.3 ± 1.9 ka; 8.9 ± 0.9 ka; 8.6 ± 1.7 ka) of the summit domes suggest that they were emplaced during Early Holocene whereas the southern part of collapsed crater yielded ages ranging from 5.3 ± 0.6 to 7.0 ± 0.8 ka. The ^{36}Cl exposure age of an andesitic lava (0.4 ± 0.1 ka), emplaced to the SW of Tacaná, agrees with the chronology provided by lichenometry and dendrochronology (> 347 yr). These ages could represent a gravitational collapse event associated with phreatic explosions vented close to a scar collapse.
However, the ^{36}Cl exposure ages derived from the southeastern edge of the Ardillas lava dome (0.3 ± 0.1 ka) did not represent its emplacement age because the dome is covered by 760 ± 30 yr BP (^{14}C) old pyroclastic deposits. Therefore, the rock sampled at the Ardillas dome may represent the remains of a landslide scar and associated rock-avalanche. Overall the combination of in situ-produced cosmogenic ^{36}Cl, lichenometry and dendrochronology constitute a solid approach to determine the age of undated volcanic landforms contributing to the reconstruction of the volcanic history.

36Cl surface exposure dating reveals the youngest eruptions in Sierra de Chichinautzin to the South of Mexico City

Aix-Marseille Université, CNRS, Collège de France, IRD, INRA, CEREGE, 13545 Aix-en-Provence, France

Conventional methods are unable to accurately date many Holocene landforms. Knowing the Holocene volcanic history is however necessary to mitigate hazards and related risks, which is particularly relevant in the case of active volcanic fields lying at the periphery of highly populated areas. An example is the Sierra Chichinautzin, located south of Mexico City where several Holocene volcanoes have been dated using radiocarbon. Based on this data, the youngest edifice of this monogenetic field is Xitle volcano (316-430 cal AD) but the age of other young volcanoes remains poorly constrained, calling for the use of other methods.
In this study, we applied *in situ*-produced cosmogenic ^{36}Cl dating to constrain the age of Texcal and Chichinautzin volcanoes whose well-preserved morphologies suggest similar to younger ages than Xitle. Texcal was previously mistaken as part of the older Guespalapa volcano and radiocarbon ages for these volcanoes are few and inconclusive. The results show that lava from Texcal volcano, which forms a 21 km long lava flow fed by a row of spatter cones and ramparts, yields an age of 1028 ± 324 years. On the other hand, lava from Chichinautzin volcano, which forms a broad shield capped by a small cone, yields an age of 1059 ± 333 years. Therefore, both volcanic structures are younger than Xitle, being the youngest eruptions reported in Sierra de Chichinautzin. Hence, *in situ*-produced cosmogenic ^{36}Cl constitutes a solid approach to define the age of Holocene volcanic landforms allowing to revise and significantly improve the reconstruction of the volcanic history.

Soil organic carbon dating of paleosoils of alluvial fans in a blown sand area (Nyírség, Hungary)

The most widely-used dating techniques in quaternary research are the radiocarbon and optically stimulated luminescence (OSL) dating methods. In some environments, the investigated sediments do not contain enough material for radiocarbon dating. In these cases, radiocarbon dating of bulk sediment may be used as a last resort.

The major aim of the present study, was to determine the reliability and limitations of the different fractions of the soil organic carbon (SOC) C-14 ages in the Nyírség blown-sand study area, in Hungary. Therefore, the low- and high-temperature combustions of SOC (LT-SOC and HT-SOC) C-14 age of fossil soils were compared with the charcoal ages from the same fossil soil layer, and their (LT-SOC, HT-SOC and charcoal) age reliability was verified independently by applying OSL to the quartz fraction of the sediment samples.

From the Nyírség blown sand area, 8 stabilised sand dunes were chosen for sampling. These dunes contain clearly observable fossil soil layers. For Accelerator Mass Spectrometry radiocarbon measurements, we collected soil and charcoal samples from the same fossil soil horizon at 8 difference locations. From 5 locations, OSL samples were also collected 50 cm below and above the investigated fossil soils to control the radiocarbon results.

The radiocarbon data show variable agreement with OSL ages. Charcoal fragments were collected from some of the best material for radiocarbon dating and their ages are in agreement with the LT and HT-SOC C-14 ages and OSL data. The radiocarbon age LT-SOC gives a reliable, credible ages, which were confirmed by independent OSL measurements. If buried soils do not contain any other macroscopic remnants for radiocarbon dating, the LT-SOC C-14 ages can be used, in the case of the Nyírség study area. The LT-SOC, which is the younger fraction of the soil organic carbon, may be considered to represent the burial time of the fossil soil layer. The HT-SOC radiocarbon ages are sometimes unrealistically older than expected and cannot be considered to be reliable.

Constraining the chronology of Quaternary fluvial sediments in the Pannonian Basin.

The correlation of terrestrial deposits with the marine oxygen isotope record is often challenging due to the lack of continuous stratigraphic sequences and material for radiometric dating. The Great Hungarian Plain contains large basins with a thick alluvial succession, almost 500 m in depth, providing a long-term record of Quaternary terrestrial deposits. Five fully cored boreholes have been collected from the Körös and Jászság basins and Makó Trough. Two paleomagnetically-dated boreholes from the Körös Basin were correlated with the other three boreholes by the magnetic susceptibility of the sediments and the first and last appearance of the freshwater gastropod *Viviparus boeckhi*. The cyclic nature of the magnetic susceptibility throughout the stratigraphy, in relation with the early postglacial degradation of mountain permafrost, provides a mechanism for correlation between the boreholes. This also enables correlation to the marine oxygen isotope record.

The chronology established by this approach was tested using amino acid geochronology. Calcitic opercula from bithyniid freshwater snails were analysed using the intra-crystalline protein decomposition (IcPD) approach to build a relative chronology across the five boreholes. The operculum specimens were obtained from the Krolopp Malacological Collection. This was the first time that IcPD analysis of opercula was used to develop a time signal for cores of depths greater than 65 m; despite concerns that the degradation reactions might be impacted by the geothermal gradient, results from the IcPD analysis support the chronology developed using magnetic susceptibility stratigraphy. This demonstrates the potential for the use of amino acid geochronology for correlating deep cores throughout the entire Quaternary period.

Pretreatment of sorted pollen grains for radiocarbon dating

Dr. David Chivall [1], *Dr. Rachel Wood* [1], *Dr. Keitaro Yamada* [2], *Dr. Takayuki Omori* [3], *Prof. Takeshi Nakagawa* [4]

1. Oxford Radiocarbon Accelerator Unit, School of Archaeology, University of Oxford, UK, 2. Research Centre for Palaeoclimatology, Ritsumeikan University, 3. The University Museum, The University of Tokyo, 4. Ritsumeikan University

Sedimentary deposits can provide a challenge for radiocarbon dating because the ultimate sources of the carbon contained within bulk sediment from each horizon are often many and unknown. Isolating and dating one component of the sediment allows for a better understanding of the carbon source and, thus, a better interpretation of the measured age but is technically difficult and reduces the amount of carbon available for analysis.

Because of their wide-geographic distribution, relatively high abundance, resistance to diagenesis and terrestrial origin, pollen grains are an ideal material for the accurate radiocarbon dating of sedimentary horizons. Moreover, sedimentary horizons are frequently examined for their pollen composition. The recent development of an extraction method to isolate fossil pollen grains from sediment using flow cytometry (Yamada et al., 2021) provides an opportunity for the exploitation of pollen for radiocarbon dating (Omori et al., 2022).

Ritsumeikan University and University of Oxford Radiocarbon Accelerator Unit now offer a joint service to isolate and radiocarbon date pollen grains extracted from bulk sediment. This poster describes the pretreatment of the sorted grains produced by Ritsumeikan University necessary for accurate dating.

Comparing and optimising Bayesian age-depth modelling approaches from European lacustrine varved records through the Holocene.

Dr. Paul Lincoln [1], ***Prof. Simon Blockley*** [1], ***Dr. Celia Martin-Puertas*** [2]

1. Department of Geography, Royal Holloway University of London, London, United Kingdom, 2. Royal Holloway, University of London

Lacustrine varved sequences provide some of the most important palaeoclimatic archives through the Holocene, as they offer records of past climate change at an annual to seasonal resolution.

Varve chronologies provide independent timescales based upon annual layer counting, but robust age-depth models are required to verify and anchor varve chronologies, and temporally analyse and compare floating records on sub-centennial calendar timescales. This is most readily achieved by constructing age-depth models using Bayesian statistical approaches. There are now a range of age model packages available to palaeoclimatic researchers, which utilise different approaches to produce sedimentary age-depth models, but there is no standardised approach in which to construct age models for varved records. Typically, varved chronologies are anchored to calendar timescales using a single package and a single modelling setup, with no justification on why the chosen model was selected. This approach inevitably leads to sub-optimal accuracy and precision. New coding packages including 'geochronR' and 'LANDO' provide the potential to efficiently compare and combine different age-depth modelling approaches and iterations for varved records, to identify the optimum approaches to construct the best calendar chronologies for different palaeo-records.

This presentation will discuss comparisons of different age-depth modelling approaches (e.g. 'rBacon', 'Oxcal','Bchron') on Holocene varved records, including the continuously laminated Diss Mere sequence in southern England. The aim of these comparisons is to identify the best age modelling approaches to produce precise calendar age-depth models from different sources of chronological information (e.g. varve layer counting, tephras and radiocarbon dates). The presentation will then summarise some of the limitations of using only a single age model, and why a more systematic approach is required to optimise age model outputs for Holocene varved records.

Viscous remanent magnetization dating of the subsurface late Pleistocene fluvial gravel beds beneath the Tokyo Lowland, Japan

Dr. Yuki Haneda [1], ***Dr. Susumu Tanabe*** [1], ***Dr. Hirokuni Oda*** [1]

1. Geological Survey of Japan, National Institute of Advanced Industrial Science and Technology

Fluvial gravel deposits filling late Pleistocene incised-valleys beneath coast planes of Japan are significant key marker beds to correlate strata laterally, reconstruct basin evolutions, and evaluate active tectonics. However, it is very difficult to date the fluvial gravel beds due to the lack of organic material, microfossils and tephra beds. Therefore, many of these depositional ages and spatial-temporal variations of the sediment distribution are unclear in many cases. In this study, we attempted to constrain the depositional age of lowstand fluvial gravel beds in the Tokyo Lowland, by a viscous remanent magnetization (VRM) dating approach, which has been applied to estimate the reworking age of massive boulders by geological hazards.

Igneous pebbles were collected from all-core boring samples obtained from the Tokyo Lowland. The pebbles were cut into specimens with approximately 1 cm^3. To infer magnetic minerals in specimens and those magnetic domains, we conducted magnetic measurements including hysteresis curves, first order reversal curves (FORCs), thermomagnetic (Js-T) curves, stepwise isothermal remanent magnetization (IRM) acquisition experiments, and viscous decay experiments of IRM at temperatures. Natural remanent magnetizations (NRMs) were measured during progressive thermal demagnetization experiments upto 600 ˚C in 5–20 ˚C-increments.

The Js-T curve (Curie temperature), the IRM acquisition curve (magnetic coercivity spectra), and FORC diagram (magnetic domain distribution) exhibit that examined specimens mainly contain titanomagnetite and/or poor-Ti titanomagnetite with vortex state and multi-domain (MD) sizes. In a ThD result, a low-temperature component in an NRM, which is probably a VRM, was clearly distinguished from a high-temperature primary component at ca 230˚C. Based on the result of the viscous decay experiment of IRM, we determined a parameter to calibrate the effect of vortex state and MD size titanomagnetites to the age estimation. Using the demagnetization temperature of the VRM, calibration parameter, and an observed temperature at 50 m deep in the Tokyo Lowland, the depositional age of the pebble was calculated as late MIS 2, which is consistent with inferred age based on C-14 dating obtained from mud beds above and below the fluvial gravel bed. The accuracy of age constraints will be improved by increasing the number of specimens.

A new cosmogenic nuclide dating laboratory in CENIEH, Spain

1. Centro Nacional de Investigación sobre la Evolución Humana, Burgos, Spain, 2. Centro Nacional de Investigación sobre la Evolución Humana (CENIEH), 3. Centro Nacional de Investigación sobre la Evolución Humana

Centro Nacional de Investigación sobre la Evolución Humana (or National Research Centre on Human Evolution, CENIEH) is located in Burgos, northern Spain. The centre is dedicated to human evolution research worldwide, including Atapuerca, a world heritage archaeological site where the oldest human fossil in Europe to date have been discovered. To support the needs of characterising geological and sedimentological context of archaeological sites, the institute also features a wide range of geological analysis (e.g., Laser diffraction grain size analyser, XRD, XRF, Raman Spectroscopy, SEM, Micro CT, Digital mapping and 3D analysis) and geochronology laboratories (including palaeomagnetism, OSL, ESR and U-series). In 2020, a new cosmogenic nuclide dating research line has initiated to strengthen the existing geochronological capabilities in the centre, particularly, at timescales of early-mid Pleistocene and beyond. To date, we have established a procedure for routine quartz separation and ^{10}Be-^{26}Al extraction. Current projects include ^{10}Be-^{26}Al burial/isochron dating of cave deposits, fluvial terraces and artefacts in the context of archaeological and landscape evolution research. In this paper, we present a general setup of the laboratory, its capacity and current projects as well as future prospective.

The Late Holocene climate variability and their impact on cultural dynamics in the central India

Ms. Diptimayee Behera [1], ***Dr. Anoop Ambili*** [2], ***Dr. Sharmila Bhattacharya*** [3], ***Dr. Praveen Mishra*** [4], ***Dr. Panduranga Sabale*** [5]

***1.** Indian Institute of Science Education & Research Mohali, **2.** Indian Institute of Science Education and Research - Mohali, Punjab, **3.** Indian Institute of Science Education and research Mohali, **4.** Cluster University of Jammu, **5.** Deccan College Postgraduate and Research Institute, Pune, India*

The understanding of long-term climate variability may provide valuable perspective on possible response of human societies to modern climate changes. The present study, based on the geochemical and sedimentological analyses on well dated (using AMS 14 C and optically stimulated luminescence-OSL dates) alluvial sediments from Sina River (in Maharashtra, central India) provides a detailed understanding of complex interplay between climate and cultural dynamics during the Late Holocene. The radiocarbon dates of the organic residues from the potsherds represents the Medieval period (~1600 to 950 cal yr BP), whereas the OSL sample shows the age of ~7.5±0.4 ka. Further, several cultural objects (e.g., potsherds, shell bangles, and copper artefacts) available at the site were also investigated in order to understand the extent of human activity in the region. The temporal changes in the proxies along with the abundance of cultural materials in the fluvial section during the medieval period suggest that the human population attempted to adapt against the fluctuating climate conditions. The regional comparison of geo-archaeological data sets shows that the pronounced weakening of the monsoonal rainfall during the Late Holocene coincides with the disruption, migration and resettlement of the indigenous societies, deciphering the possible impact of climate on human settlement.

Extending 40Ar/39Ar geochronology of clinopyroxene into the Quaternary

Dr. Brian Jicha [1]

1. *Department of Geoscience, University of Wisconsin-Madison, Madison, WI 53706, USA*

Clinopyroxene is a common phenocryst phase in mafic to intermediate composition volcanic and plutonic rocks. It is highly resistant to alteration compared to other co-existing mafic phenocrysts such as plagioclase. Several recent studies have shown that clinopyroxene can now be precisely $^{40}Ar/^{39}Ar$ dated using a new generation of multi-collector noble gas mass spectrometers. Thus far, $^{40}Ar/^{39}Ar$ dating of clinopyroxene has primarily been conducted on Neoproterozoic to Jurassic dolerites as well as mid-Cretaceous to Miocene submarine basalts. To assess the viability of $^{40}Ar/^{39}Ar$ dating clinopyroxene at the youngest end of the geologic timescale, incremental heating experiments were performed on tens of milligrams of inclusion-free clinopyroxene from a variety of mafic lithologies and tectonic settings (subaerial arc basalts, gabbros, andesites, submarine basalts from mantle plumes), all of which are younger than 34 Ma. Most samples produced relatively precise plateau ages including several subaerial basalts to andesites that gave plateau ages ranging from 2.5 to 0.6 Ma. All data are indistinguishable from new and/or published $^{40}Ar/^{39}Ar$ and U-Pb ages on other minerals within these samples, which demonstrates that clinopyroxene can be utilized to obtain accurate and precise $^{40}Ar/^{39}Ar$ ages for Quaternary mafic to intermediate volcanic rocks.

Tephra compositional data: are we doing it right?

Dr. Simon Larsson [1] ***, Mr. Matthew Bolton*** [2]

1. Department of Physical Geography, Stockholm University, 2. University of Alberta

Tephrochronology has become a powerful chronological tool that enables precise dating and correlation of palaeoclimate reconstructions. Tephra horizons preserved in natural archives act as common time markers and anchor points in age models. Using tephras for such purposes relies upon confident identifications based on the geographic and stratigraphic contexts combined with the morphology and the geochemistry of the tephra glass shards. The global tephra community continuously collects compositional data of new tephra findings, which further increases the complexity of this field of study (for example by introducing new candidates for correlation of tephras once thought to be unique).

Analysis of a tephra sample's glass geochemistry is commonly performed by electron probe microanalyser and reported as major-oxide weight percentages (as expressed by the instrument and/or as volatile-free normalised percentages). These results are then explored by the tephrochronologist and compared to datasets of previously reported findings to find candidates for identification by correlation. While this identification method has worked well in most cases, it is sometimes difficult to distinguish between tephras with overlapping geochemistries, where multiple candidates are viable. The likelihood of this scenario happening increases as new data are reported.

Statistical approaches such as principal component or discriminant function analysis have been used to differentiate sample populations and find statistically motivated identifications. However, the validity of these methods often requires certain assumptions not to be violated (e.g., data should not be collinear). Unfortunately, compositional data suffers from the constant-sum constraint—an issue which is rarely explicitly considered—and must be converted by log-ratio transformations for specific statistical analyses to function correctly. As there is no consensus on a tephra compositional data curation procedure that includes log-ratio transformations, we have explored several options to arrive at a formal recommendation for such a procedure.

Schmidt-hammer exposure-age dating (SHD) of glacial landforms in the Western Taurus Mountains, SW Turkey

Mr. Onur Altinay [1], ***Prof. Mehmet Akif Sarıkaya*** [1]

1. Istanbul Technical University, Eurasia Institute of Earth Sciences, 34469 Maslak, Istanbul

Schmidt hammer exposure-age dating (SHD) is a cheap and practical relative dating technique that measures the time of exposure of surficial rocks to atmospheric conditions. The Schmidt hammer has been used in a variety of geomorphological studies, including determining the rate of weathering, measuring rock hardness, and even assessing the relative age of landforms. Several landscapes can be studied using the SHD method, such as moraine deposits, fault scarps, rock glaciers, mass movements, and coastal elevations. Combined with terrestrial cosmogenic nuclide dating (TCND), the SHD was used in the first trial in the mid-2000s. Since the 2010s, these studies have gained in popularity. In this study, for the first time, the SHD method was employed in Turkey. The study took place in the Western Taurus Mountains in southwestern Turkey. In this region, over 200 cosmogenic surface exposure-ages have been obtained. SHD, as a fast and inexpensive means of dating, some undated locations could be studied by using the existing cosmogenic surface exposure-age data as age control points. Thus, the Western Taurus Mountains can be assigned a more comprehensive glacial chronology. In this study, the first outputs of the measurements with the Schmidt hammer performed on 137 moraine blocks and 2 bedrock surfaces bearing the traces of Quaternary glaciations in the Western Taurus will be presented.
This study was funded by the Scientific Research Projects Coordination Unit (BAP) of the Istanbul Technical University (Project ID: MDK-2022-43674).

Revised marine reservoir offset values (ΔR) for molluscs and marine mammals: Arctic North America and the Barents Sea–Svalbard region

Dr. Mark Furze [1]***, Dr. Anna Pienkowski*** [2]***, Dr. Katrine Husum*** [3]***, Mr. Roy Coulthard*** [4]***, Ms. Ammandine Missana*** [5]***, Dr. Nil Irvali*** [6]***, Dr. Dmitry Divine*** [7]***, Ms. Vårin Eilertsen*** [8]

1. *Dept. of Arctic Geology, The University Centre in Svalbard, Longyearbyen, Svalbard,* ***2.*** *Institute of Geology, Adam Mickiewicz University, Poznań,* ***3.*** *Geology & Geophysics Section, Norwegian Polar Institute, Tromsø,* ***4.*** *Dept. of Physical Sciences, MacEwan University, Edmonton, Alberta,* ***5.*** *Dept. of Physical Geography, Stockholm University, Stockholm,* ***6.*** *Dept. of Earth Science, University of Bergen, Bergen,* ***7.*** *Oceans & Sea Ice Section, Norwegian Polar Institute, Tromsø,* ***8.*** *Dept. of Geosciences, Arctic University of Tromsø, Tromsø*

Using appropriate marine-terrestrial offset values (ΔR) when calibrating marine radiocarbon dates underpins accurate chronologies necessary for comparisons between environments, regions, and across different geochronological methods. However, ΔR values are strictly valid for the specific calibration curve that their calculation is based on. Here we summarize recently published revised ΔR values for the Marine20 calibration curve from two Arctic-Atlantic ocean gateways, the Canadian Arctic Archipelago (CAA) and the Barents Sea-Svalbard region. Our calculations are based on previously-published ^{14}C dates on pre-bomb live-collected marine molluscs and cetaceans, and bowhead whale-driftwood age comparisons from the same glacio-isostatically uplifted shorelines.

For the CAA, molluscan-based ΔR terms are: Chukchi/Beaufort sea coasts, 265 ± 116 ^{14}C yrs; NW CAA, 188 ± 91 ^{14}C yrs; NE Baffin Island, 81 ± 18 ^{14}C yrs; SE Baffin Island, 14 ± 58 ^{14}C yrs; Hudson Strait, -73 ± 64 ^{14}C yrs; Ungava Bay, 0 ± 86 ^{14}C yrs; Foxe Basin, 175 ± 89 ^{14}C yrs; Hudson Bay, -21 ± 72 ^{14}C yrs; James Bay, 209 ± 114 ^{14}C yrs. Species-specific marine mammal ΔR terms are 108 ± 60 ^{14}C yrs for beluga and 9 ± 69 ^{14}C yrs for bowheads.

For the Barents Sea, molluscan ΔR values are: western Svalbard, -61 ± 37 ^{14}C yrs; Franz Josef Land, -277 ± 57 ^{14}C yrs; Novaya Zemlya, -156 ± 73 ^{14}C yrs; N Norway, -86 ± 39 ^{14}C yrs. Cetacean ΔR are: toothed whales, -161 ± 41 ^{14}C yrs; baleen whales, -158 ± 43 ^{14}C yrs; combined baleen-toothed whales, -160 ± 41^{14}C yrs.

Our revised ΔR values are applicable for as long as those broad oceanographic conditions (circulation, ventilation) have persisted, i.e., through much of the Holocene. Whilst molluscan values may be applicable to other marine carbonate materials (e.g., foraminifera), cetacean ΔR terms are valid only for the species they were calculated for and should not be applied to other marine mammals such as polar bears, seals, and walrus.

Building a new amino acid geochronology based on enamel intra-crystalline protein degradation dating of Sicilian dwarf elephants

Dr. Marc Dickinson [1]***, Dr. Victoria Herridge*** [2]***, Prof. Laura Bonfiglio*** [3]***, Dr. Carolina Di Patti*** [4]***, Dr. Gianni Insacco*** [5]***, Dr. Gabriella Mangano*** [3]***, Prof. Kirsty Penkman*** [6]

***1.** Department of Chemistry, University of York, **2.** Natural History Museum, **3.** Museo della Fauna, Messina, **4.** Museo Geologico "G.G. Gemmellaro" - Universita' degli Studi di Palermo, **5.** Museo Civico di Storia Naturale, Comiso, **6.** Department of Chemistry, University of York, United Kingdom*

The elephants of Sicily are one of the most striking examples of insular dwarfing, a process that is likely to have occurred several times during the Middle-late Pleistocene. Proboscideans are excellent swimmers and appear to have colonised Sicily from the mainland during the Pleistocene, becoming isolated on the island when sea levels changed. Accurately dating the timings of colonisation presents a significant challenge, as several of the deposits are found in cave sites with complex stratigraphy. Numerous techniques have been employed to date the Mediterranean dwarf elephants (e.g. radiocarbon, electron spin resonance, U-series), but none of them can be universally employed. Additionally, application of these techniques has been shown to have a low reliability/precision in many instances, making correlation between sites difficult.

Pioneering work in the 1980s and early 1990s used tooth enamel to date several Sicilian cave sites using the epimerisation of the amino acid isoleucine and kinetic modelling to obtain absolute age estimates. More recently our understanding of the limitations and approach to dating tooth enamel has progressed significantly and we are now able to revisit the direct dating of dwarf elephants using amino acids.

We present here a new relative geochronology for Sicilian dwarf elephants based on intra-crystalline protein degradation of tooth enamel amino acids. By targeting a closed system fraction found within tooth enamel, we negate issues of leaching and contamination, and do not rely on kinetic modelling. By enabling direct dating on the key elephantid material, this provides a valuable approach for hypothesis testing of different evolutionary models.

A Late Holocene isochron for SE Europe based on human-induced Pb contamination

Dr. Andreas Koutsodendris [1], ***Dr. Stefanie Kaboth-Bahr*** [2], ***Dr. André Bahr*** [1], ***Dr. Ulrich Kotthoff*** [3], ***Dr. Jörg Lippold*** [4], ***Dr. Dimitris Sakellariou*** [5], ***Prof. Oliver Friedrich*** [1], ***Prof. Jörg Pross*** [1]

The integration of the unique archeological/historical record of the Eastern Mediterranean region with Holocene paleoclimate datasets suggests potential causal links between abrupt climate change and sociocultural transitions. To date, however, the study of human-climate interactions during the Holocene in that region remains poorly constrained, with one reason being difficulties in the precise correlation of individual records stemming from dating uncertainties. To circumvent inconsistencies related to regionally variable radiocarbon reservoir ages and/or even to the lack of datable material, direct alignment of regional records can be achieved through the use of event markers. We here introduce a new isochron for the Aegean Sea region based on atmospheric Pb contamination of sediments associated with metallurgy and mining activities in the Late Holocene. Specifically, we examine the geochemical composition of robustly dated cores from across the Aegean Sea region using a combined approach of X-ray fluorescence (XRF) core scanning and inductively-coupled plasma (ICP-MS) elemental concentration analysis. Our results document a synchronous 2–3-fold increase in Pb content from natural background levels at ca. 2.3 kyrs BP, and considerable variability from this time onwards that is uniform across all investigated sites. These results suggest that anthropogenic Pb contamination has left a distinct imprint on regional sedimentary archives over the past three millennia. We suggest that the timing of changes in Pb content can serve as a regional isochron in the Aegean Sea region allowing for the direct correlation of marine and terrestrial records with archaeological soil profiles, thereby circumventing the inherent uncertainties of direct dating techniques.

Sedimentary facies and stratigraphy of late Pliocene-Quaternary shallow-water contourite deposits on the Hupo Basin, East Sea of Korea

Dr. Seok-Hwi Hong [1], ***Dr. Dong-Geun Yoo*** [1], ***Dr. Gwang-Soo Lee*** [1], ***Dr. Jin Cheul Kim*** [2], ***Dr. Sangheon Yi*** [2], ***Dr. Gil Young Kim*** [1], ***Dr. Byoung-Yeop Kim*** [1]

The shallow-water contourite deposits of the Hupo Basin shelf are analyzed using sedimentary structures, grain size textures, sediment color, and Optically Stimulated Luminescence (OSL) and Accelerator Mass Spectrometry (AMS) ages of a long sediment core (19ESDP-101, 120 m). The shallow water contourite deposits can be divided into seven sedimentary facies grouped into four Facies Associations (FA): 1) contourite drift, 2) contourite drift/channel transition, 3) contourite channel/drift transition, and 4) contourite channel. FA1 is interpreted to result from the interaction between hemipelagic, low-density gravity flow and settling induced sedimentation. Both FA 2 and FA3, due to their relative increase grain-size and the presence of subtle indicators of bedload transport, are indicative of higher bottom current compared to FA1. FA 4 shows massive to slightly bedded sand, representing a contourite channel environment related to high energetic conditions. Fluctuations in the bottom current activity, related to the intensification and deceleration of the North Korean Cold Current (NKCC) have primarily caused fluctuations between contouritic and hemipelagic dominated periods. The vertical sedimentary facies stacking patterns observed in the Hupo Basin site suggest that, over time, the depositional processes changed at the site where the sections were located. The facies associations suggest the lateral migration of the contourite depositional system and continuous flow of the NKCC. This study serves as a reference for shallow water contourite recognition both in modern environments and the ancient record. Moreover, by establishing the depositional processes of sediment behavior a schematic model is provided that improves interpretation of the shallow-water contourite deposits.

Holocene Maximum Flooding Surface on the Danube Valley - preliminary results –

Following the Black Sea reconnection to the World Ocean (ca. 9500 years ago) the sea level rose rapidly, drowning the lower valleys of the Black Sea tributaries and turning them into large rias, some of which remained submerged until today (e.g. Dnister, Dniepr, Don). The Lower Danube Valley (LDV) was not excepted, and recent studies indicate a likely extension of the marine waters in the early Holocene beyond its current delta apex. In the present study, we track the Maximum Flooding Surface (MFS) in the LDV, identifying the most landward position of the transgressive systems tract in terms of stratigraphy and brackish microfauna. For this purpose, preliminary results performed on five cores (12 - 16 m long) from LDV are presented. These cores have been analyzed for multiple proxies, including 14C datings, grain-size, loess on ignition, magnetic susceptibility, and microfauna (ostracods and foraminifera). Four main depositional facies have been identified (A-D in ascending order): Facies A is composed of massive fluvial sand that became laminated and finer to the top; Facies B is laminated, very fine sand with mud drapes, and contains brackish microfauna; Facies C and D are represented by floodplain deposits composed of multiple layers of sand and mud (C) and by mud and peat (D). Facies B has a thickness between 1 and 8,5 meters, dated between ~8000 and 7200 cal yrs BP, when the stratigraphy turnaround from retrogradational to progradational one. It has a big sedimentation rate (>3mm/y) in a period with a rapid sea level rise, so in this facies interval lies the MFS. The presence of brackish microfauna in SRT core, ~140 km inland from the present river mouth, implies that the brackish water of the Black Sea reaches the confluence between Siret and Danube at about 1500 years after the reconnection with the Mediterranean Sea.

This research was supported by two grants, one from the Romanian Ministry of Education and Research and one from a Norway grant: PN-III-P1-.1.-TE-2016-1750, and RO-NO-2019-0415.

Pleistocene paleoenvironmental reconstruction from subsoil dataset: from neritic to fluvioglacial domain in the upper central Po Plain (N-Italy)

***Mr. Mariangelo Baio* [1], *Prof. Donata Violanti* [2], *Andrea Pezzotta* [1], *Prof. Andrea Zerboni* [1]**

***1.** Dipartimento di Scienze della Terra "A. Desio", Università degli Studi di Milano, **2.** Dipartimento di Scienze della Terra, Università degli Studi di Torino*

The Po Plain (N-Italy) is a foreland sedimentary basin bounded by two mountain ranges (the Alps to the North and the Apennines to the South), controlling its sedimentary facies and body geometries. However, the Quaternary succession of the Po Valley is mainly sealed in the subsurface: outcrops are scanty, and data from the few deep wells are not easily accessible. Therefore, data derived from perforation cuttings of water wells are a useful tool to investigate the buried stratigraphy and to better constrain subsurface geological reconstructions and correlations. Detailed sampling of sediments from cores and a high density of sampling sites over the region add important information about lithostratigraphy, micropaleontology and sedimentary source area, allowing the detailed reconstruction of the Pleistocene paleoenvironmental evolution of the Po Plain. We present data from a selection of boreholes from a repertory of ca. 35 wells drilled in the upper central part of the Po Plain, including the description of cores sedimentology, petrography, and fossil content. The studied boreholes implement the database of the area and add new significant evidence to interpret and correlate the subsurface stratigraphy of the Po Plain to the regional dynamic from the Lower Pleistocene to the end of the Last Glacial Maximum (LGM). At the bottom of most of the selected boreholes, transitional-marine and marine deposits, dated thanks to their foraminiferal assemblages to the Lower Pleistocene (Gelasian-Calabrian), are preserved. Micropaleontological data allow the correlation of these layers to the neritic domains of the Pleistocene regressive sequence of N-Adriatic Sea and Po Plain. The overlying Middle-Upper Pleistocene continental succession documents the transition from a distal alluvial plain, characterized by meandering rivers evolving in deltas and lagoons, to a proximal alluvial plain, formed by the migration of braided river systems. Finally, in the LGM an outwash plain formed in front of the glacial systems located at the southern foothills of the Central Alps.

The impact of precipitation and temperature shifts on the Levant basin during late Pleistocene: assessment from biological and geochemical indicators from Lake Hula, Israel

Mr. Abdel-Aziz Abdrahamane Yassine [1]***, Mr. Shah Parth*** [2]***, Prof. Mina Weinstein-Evron*** [2]***, Dr. Ilaria Mazzini*** [3]***, Prof. Nicolas Waldmann*** [4]

Charney School of Marine Sciences University of Haifa,* ***2.*** *University of Haifa, 199 Aba Khoushy Ave., Haifa, 3498838, Israel,* ***3.*** *Consiglio Nazionale delle Ricerche, Istituto di Geologia Ambientale e Geoingegneria (IGAG),* ***4.*** *University of Haifa*

The Levant is known to be a sensitive region responsive to any small-scale hydro-climate variability in the geological past. Recently, recurring draughts, temperature extremes and increased in anthropogenic activity have heavily affected the region which in turn might have played a key role in local geopolitical instabilities. Terrestrial archives from this region can thus be valuable sentinels to understand the unique patterns of natural climate variability and its forcing factors, as well as their ecological and environmental impacts. A multi-proxy approach is applied on a >160 m long sedimentary record from Lake Hula to identify the possible impact of precipitation and temperature changes on the hydrological system during the late Pleistocene. The analysis include sedimentology (grain size), geochemistry (elemental content, mineralogy, total organic matter content), and biological proxies (ostracods), in order to reconstruct the processes occurring both within the limnic environment and the terrestrial surroundings. Initial investigation of the lithology and elemental ratio concentrations shows alternating intervals that appear to be associated with low runoff from the lake catchment (identified as a decrease in allogenic minerals and increase in authigenic components), intercalating with intervals characterized by an opposite trend. This initial interpretation implies intercalation between dry and wet climate conditions. Furthermore, variations in the sediment lithology and geochemical proxies suggest fluctuations related to the dominating precipitation regime (winter rains from the Mediterranean), thus proposing that a millennial-scale orbital forcing variability could potentially be disentangled out from the record, as it is well constrained by the chronology. In parallel, Ostracods taxa identification and associated analytical measurements are highly important for assessing the salinity of the lake waters, depths, temperature, Hydraulic condition, bottom grain sizes or sedimentation rate. Moreover, by reconstructing the reaction of the lake system to hydro-climate variability through time, we can better disentangle the current impact of anthropogenic stress and assess future trends. Overall, this study provides a comprehensive picture of the different mechanisms driving abrupt climate changes in the region and explores their potential relevance to future climatic studies.

Stratigraphic and sedimentological features of lower Pleistocene deposits in the geological Sheet n° 628 "Sciacca" (south-western Sicily, Italy)

Prof. Mauro Agate [1]***, Dr. Alessandro Bonfardeci*** [1]***, Dr. Maurizio Gasparo Morticelli*** [1]***, Dr. Giuseppe Avellone*** [1]***, Dr. Nicolò Parrino*** [2]***, Dr. Giuseppe Rizzo*** [1]***, Prof. Alessandro Incarbona*** [3]***, Dr. Simona Todaro*** [1]***, Dr. Cristina Muraro*** [4]***, Prof. Attilio Sulli*** [1]

1. *Dipartimento di Scienze della Terra e del Mare, Università degli Studi di Palermo,* ***2.*** *Dipartimento di Scienze della Terra e del Mare, Università di Palermo, Italy,* ***3.*** *University of Palermo,* ***4.*** *Italian Geological Survey ISPRA, Rome*

As part of the Italian National Cartography Project (CARG) at 1:50.000 scale, we carried out geological field surveys and in-depth sedimentological, biostratigraphic and structural investigation on the lower Pleistocene sedimentary successions outcropping in the Sheet 628 "Sciacca".

In the studied area, located in south-western Sicily, lower Pleistocene deposits belong to different formations, respectively:

- **M.te Narbone Fm.** (NAB): light grey marls and slightly silty clays alternating with grey to brown clayey-marly levels (sapropel layers), with abundant planktonic and benthic foraminifera, calcareous nannofossils and mollusks specimens; it deposited during the middle Piacenzian – earliest Calabrian (Santernian) age in upper slope environment.
- **Agrigento Fm.** (AGG): yellow, slightly quartz calcarenites and sands alternating with sparse, thin levels of bio-calcirudites and conglomerates, with abundant bivalve shells, gastropods, echinoderms, bryozoans, corals, vermetids, rhodoliths; some calcarenite horizons display cross lamination and prograding geometry; levels with finer grain size (pelites and arenitic marl) sediments are also present. At places, arenitic and pelitic levels are organized in shallowing-upwards packages cyclically arranged. The AGG deposited during the lower and middle part of the Calabrian stage (Santernian - Emilian) in a coastal-inner shelf environment.

In the area of Sheet 628 "Sciacca", the stratigraphic transition between these two formations is continuous, gradual and characterized by a progressive enrichment in the sandy fraction. It crops out as weakly cemented arenitic levels in the upper portion of the NAB, followed upward by increasingly thick and cemented calcarenitic horizons up to about ten meters thick that are typical of the AGG.

Lithofacies of such transition highlights a regressive sedimentary evolution from a slope environment with hemipelagic sedimentation to a neritic-littoral environment with hybrid mainly bioclastic carbonate sedimentation and variable inputs of detritic quartz.

Given these general characteristics, some differences exist in the sedimentological features and vertical organization of the lower Pleistocene successions (NAB+AGG) between the western and the eastern sectors of the Sheet 628 "Sciacca". These variations are probably due to the different structural positions occupied by the sedimentation basins where the two successions accumulated: the wedge of the Gela Thrust Wedge to the east and the Sicilian orogenetic wedge to the west.

Tectonic and morphological factors controlling the contrasting stratigraphic setting of late orogenic intermountain basins: a comparison between the Norcia and Amatrice basins, Central Apennines of Italy

***Dr. Maria Chiara Caciolli** [1], **Prof. Massimiliano Rinaldo Barchi** [1], **Dr. Marco Mancini** [2], **Dr. Massimiliano Moscatelli** [2]*

***1.** Department of Physics and Geology, University of Perugia, **2.** Istituto di Geologia Ambientale e Geoingegneria (IGAG), Consiglio Nazionale delle Ricerche, Via Salaria km 29,300, Monterotondo Stazione, 00015 Rome, Italy*

Norcia and Amatrice basins are two late orogenic intermountain basins, located in the Central Apennines of Italy, bordered by active and seismogenic normal faults, active since Late Pliocene.

The 2016-2017 seismic sequence in Central Italy produced a dramatic devastation in both these valleys, despite of the diversity of the contexts: although the Norcia and Amatrice basins are spatially very close and of similar size, they are quite different from a morphological point of view, as well as for their geological evolution and subsoil architecture, i.e. thickness of the Quaternary infill and nature of the bedrock.

The present work is devoted to model the contrasting subsoil setting of the Norcia and Amatrice basins, analysing the factors which controlled their different tectono-sedimentary evolution.

To this purpose, available measurements from existing databases were examined and elaborated, aiming to reconstruct the internal geometry of the basin infilling and first of all the bedrock topography.

The spatially continuous sedimentary succession infilling Norcia basin reaches an extimated maximum thickness - still debated in bibliography - between 350 and 600 m in the depocenter, located in the south-western portion of the Norcia settlement. The continental succession, covering a Mesozoic-Paleogene carbonatic bedrock, includes about 100 m of lacustrine deposits, passing upward to fluvial body and alluvial fan. Although the eastern flank of the basin is bordered by the Norcia normal fault, with antithetic faults on the opposite flank, the very thin sedimentary infill of the southern half of this basin suggests that the tectonic activity is not the only factor controlling the sedimentary infill distribution.

In the Amatrice basin, the Quaternary succession, superposed to a Miocene turbiditic substratum, is distributed in several, localized minor remnants. The terraced succession, whose maximum thickness reaches 60 m, doesn't include lacustrine deposits but only fluvial and alluvial fan on a hiatus and erosional vacuity. Here, the local subsidence due to normal faulting and the concurrent regional uplift did not offer a suitable accommodation space to develop a thick basin, and the subsequent fluvial incision contributed to reduce the thickness of the post-orogenic sedimentary succession.

The Paglia - Tevere Graben, Italy: Plio-Pleistocene sedimentation and structural architecture

Dr. Marco Mancini [1], ***Dr. Silvia Giallini*** [1], ***Dr. Federica Polpetta*** [1], ***Dr. Pietro Sirianni*** [1], ***Prof. Gianluca Vignaroli*** [2], ***Dr. Maria Chiara Caciolli*** [1], ***Dr. Carolina Fortunato*** [1]

1. Consiglio Nazionale delle Ricerche, Istituto di Geologia Ambientale e Geoingegneria (IGAG), 2. Dipartimento di Scienze Biologiche, Geologiche e Ambientali, Alma Mater Studiorum Università di Bologna

Extensional basins in retro-arc and hinterland areas allow sediment accommodation and preservation of thick coverage in well organised depositional sequences. The Peri-Tyrrhenian area of northern-central Apennines (Italy) is characterised by a widespread occurrence of syn-tectonic basins framed within a horst-and-graben structural setting produced in response to the SW-NE trending continental extension since the Miocene.
Among these syn-tectonic basins, the Paglia-Tevere Graben represents a 60 km long, NNW-SSE-striking morpho-structural depression hosting marine-to-continental Plio-Pleistocene sediments up to 1 km-thick lying above substrate made of turbiditic sequences. The Plio-Pleistocene sedimentary succession is organised in two main syn-rift and high rank depositional sequences, from the open marine to coastal-transitional environments: the first one is Zanclean-early Gelasian in age, while the second spans from the late Gelasian to the early Calabrian. The continental succession ends with post-rift and syn-uplift fluvial terraces, travertines and volcanic deposits of the Vulsini Volcanic District, since the late Calabrian (1.3 Ma).
Detailed surveys and geological mapping, combined with an intense bibliographic review of biostratigraphic, tephrostratigraphic and strontium isotopes data, were performed to improve the knowledge of the geological evolution of the graben in its northern part. Stratigraphic and sedimentological analyses have been devoted to detail the stratigraphic organisation of the Plio-Pleistocene sequences. We identified: i) minor transgressive-regressive cycles associated with recurrent stages of west-directed progradation and retrogradation of coarse-grained fan-deltas sourced from the western mountainsides of the Apennines; ii) transgressive marker beds of bioclastic calcarenite levels with *Amphistegina* (zone MPL5b), as indicators of climate warm phase.
The structural analyses revealed the occurrence of multiple fault sets, variably dissecting both the Plio-Pleistocene sequences and the Miocene turbiditic substrate. A polygonal setting (in map view) of normal faults occurs in the eastern part of the graben, represented by decametre-to-hectometre-long fault segments striking NW-SE, N-S, and NE-SW, and accommodating a cumulative stratigraphic offset of tens of metres. Strike-slip faults, mostly striking NNE-SSW, locally cut the normal ones, contributing to the disarticulation of the morphostructural basin. Our preliminary data can be used to constrain the geometry, the opening rate and the sedimentary evolution of the Paglia-Tevere Graben during the Quaternary.

Reconstruction of a 3D geological model of the quaternary deposits filling the Cassino intramontane basin (central Italy)

Mr. Matteo Rompato [1], ***Prof. Michele Saroli*** [1], ***Dr. Matteo Albano*** [2], ***Prof. Francesca Bozzano*** [3], ***Prof. Gabriele Scarascia Mugnozza*** [4], ***Mr. Vincenzo Colagiacomo*** [1]

1. *Department of Civil and Mechanical Engineering, University of Cassino and Southern Lazio,* ***2.*** *Istituto Nazionale di Geofisica e Vulcanologia (INGV),* ***3.*** *Department of Earth Sciences, Sapienza University of Rome,* ***4.*** *Department of Earth Sciences, Sapienza University of Rome, Italy*

The aim of this work is to show how classical geological investigations and geophysical measurements can be combined with implicit 3D modelling to reconstruct detailed geological models of quaternary intramontane basins and to describe the relationship between the different lithological bodies composing the post-chain filling deposits.

To this aim, has been chosen the urban area of Cassino in southern Lazio ((central Italy). The area is located at the end of the Latina Valley, and it is bordered by the carbonate structures of Mt. Cairo to the NW, Venafro Mts. to the NE and SE, and several main tectonic elements mainly in Apennine development.

For reconstructing the lithostratigraphic structure of subsoil, about 200 stratigraphic surveys and about 100 seismic noise measurements were analyzed and homogenized. These have been correlated with the deposits and depositional environments described in the literature. Seven main stratigraphic units were recognized. The results show that the carbonate bedrock is very articulated because of tectonics. On its top, lies a clay and sandstone unit attributable to the Frosinone Flysch (Upper Miocene), followed by a complex of alloantigen series attributable to a generic Messinian sea-lake environment (Lower Pliocene). These sediments are covered by the lacustrine sequence of the *Lirino* Lake, formed by an alternation of clayey silt and sand with gravel, with thicknesses ranging from a few meters near the carbonate reliefs up to about 150 m in the NW of the Cassino urban area. It should be noted that this sequence, close to the relief of Mt. Cassino, is characterized by the presence of layers of gravel and sand attributable to the *Paleo-Rapido* riverbed, today diverted by anthropic activity, which probably constituted an ancient tributary of the *Lirino* Lake, which occupied the Cassino plain in geological times. Traces of the course of the *Paleo-Rapido* riverbed can also be observed in the buried morphology of the carbonate Bedrock.

The characterization of the subsoil has led to the definition of a conceptual geological model that highlights the persistence of the condition of the river-lake environment at least until the end of the Late Pleistocene.

Pliocene-Pleistocene interregional unconformities in the Apulian Swell and Bradano Foredeep Basin as tracers of oblique plate collision and orogenic translation of the surrounding collisional belts (Northern Ionian Sea - Central Mediterranean)

Dr. Andrea Artoni [1], ***Dr. Nicolò Chizzini*** [1], ***Dr. Jessica Basso*** [1], ***Prof. Luigi Torelli*** [1], ***Dr. Alina Polonia*** [2], ***Dr. Luca Gasperini*** [2], ***Dr. Mariagiada Maiorana*** [3], ***Dr. Aasiya Qadir*** [1]

1. University of Parma - Dipartimento di Scienze Chimiche, della Vita e della Sostenibilità Ambientale, 2. ISMAR-CNR, BOLOGNA, 3. Dipartimento di Scienze della Terra e del Mare, Università degli Studi di Palermo

The Apulian Swell and the adjacent Bradano Foredeep Basin, along the Africa/Adria/Eurasia plate boundary, represent a natural recorder of Pliocene-Pleistocene tectonic processes due to their location between Southern Apennines (SA), Calabrian Arc (CA) and Dinarides/Hellenides. Integrated analysis of seismic reflection profiles, exploration well logs, and seafloor bathymetry, allowed us to unravel the basin architecture and the interplay between tectonics and sedimentation, providing stratigraphic and structural evidences on deep processes and shallow morpho-structural development. We find that the Pliocene-Pleistocene tectonic evolution is marked here by two major tectonic events, whose effects are recorded in four sedimentary sequences bounded by inter-regional unconformities. They were related to 1) flexure/bending of the subducting Adria plate, under the load of the advancing Calabrian Arc and Hellenic wedge; 2) buckling in response to compression of the surrounding orogens (southern Apennines, Hellenides); 3) roll-back and eastward retreat of the Adria plate. During Pliocene times, an obliquely convergent margin led to collision between SA and CA, associated to turbidite deposits in the continental shelf and the deep basins. Around the Pliocene-Pleistocene boundary (2.58 Ma), a sudden and widespread rearrangement took place. The SA front, along with portions of the earlier obliquely collisional margin, started to move toward the NE, through progressively deeper detachments involving the lower Adria plate. During this phase, a fast translation of the SA orogenic wedge was followed by uplift and shortening, associated with folding reaching up to the seafloor. This second phase is marked by deep marine deposits in the central part of the basin, and clinoforms in shallower western and northern sectors. At the same time, the Apulian Swell, affected by inherited and rift-related Permo-Triassic normal faults, shows transpressive and positive tectonic inversions followed by extension, related to the coeval advancement and shortening of the Hellenic fold/thrust belt. The complex deformation pattern observed represents the response to the interaction of (small-) plates, which is still active and important to be considered in neotectonics and paleoseismological reconstructions.

Geological investigation of mud volcanoes in the periadriatic area of the central Marche region: fluid circulation models

Ms. Michela Principi [1], ***Dr. Gabriele Giuli*** [1], ***Prof. Alessandra Negri*** [2], ***Mr. Pietro Paolo Pierantoni*** [3], ***Dr. Miller Zambrano*** [1]

1. Geology Division, School of Science and Technology, University of Camerino, 2. Dipartimento di Scienze della Vita e dell'Ambiente, Università Politecnica delle Marche, 3. University of Camerino

Mud volcanoes are the surface expression of geological subsurface processes system characterized by transport of large volumes of sediments and fluids (water and gases). The subsurface processes may also create piercement structures such as diapirs and domes, not necessarily generating a mud volcano. The main driving mechanisms of the mud volcanism correspond to a combination of gravitative instability of sediments, and pressure of the hydrostatic system (i.e., overpressure of gas) allowing the migration through fractures or faults zones.

This work is framed in a macro project focused on investigating the geological and mineralogical characteristics of a series of mud volcanoes distributed along the eastern thrust fronts of the Italian peninsula, more precisely in the Marche region. These structures are distributed on a monocline (NE-dipping) composed by Miocene and Plio-Pleistocene deposits, covering several thrust-related folds and thrust faults in the peri-Adriatic area. The geometry and the mud source of these mud volcanoes are poorly studied.

Here, we present preliminary results of an integrated methodology (geophysical, mineralogical and micro-paleontological) applied on a key mud volcano located at Monteleone di Fermo to characterize its structure at local scale and the mud source. To reconstruct the 3D subsurface model, a 3D Electrical Resistivity Tomography (ERT) was performed using a FullWaver system (Iris) allowing to determine the near-surface (depth <100m) geometry of a mud volcano. To investigate the possible sources of the solid fraction of the erupted muds and consequentially to reconstruct a probable fluid migration pathway, we have integrated mineralogical (Powder X-Ray Diffraction and Scanning electron microscope) and micro-paleontological investigation.

We expect to provide new insight about source(s) and composition of the erupted material, proposing a new migration model involving high angle faults. Our study may serve as example methodology for the characterization of similar mud volcanoes in the area. Also, the circulation models and the mud apparatus' reconstructed geometry, can be used as an analogue element to characterize off-shore mud volcanoes and cold seeps in general.

Paleomagnetism and rock magnetism from sedimentary core collected in the NW Barents Sea in the framework of PRA2021-IRIDYA project

Dr. Chiara Caricchi [1], *Dr. Leonardo Sagnotti* [2], *Dr. Patrizia Macrì* [1], *Dr. Renata Lucchi* [3]

1. Istituto Nazionale di Geofisica e Vulcanologia, Rome (Italy), 2. Istituto Nazionale di Geofisica e Vulcanologia (INGV), 3. National Institute of Oceanography and Applied Geophysics OGS

We present a paleomagnetic and rock magnetic dataset from sedimentary cores collected in the NW Barents Sea. This investigation is conducted within the framework of project PRA2021- IRIDYA (Integrated reconstruction of ice sheet dynamics during Late Quaternary Arctic climatic transitions). All the analyzed cores show consistently good paleomagnetic properties, which allow for the reconstruction of well-defined characteristic remanent magnetization (ChRM) throughout the sedimentary successions. Rock magnetic and paleomagnetic parameters were used for high-resolution continental margin cross correlation with other existing cores. Moreover, the paleosecular variation (PSV) and relative paleointensity (RPI) trends of geomagnetic field have been defined, providing chronological constraints for the ages and rates of past depositional events. The results from this study allow us to tie-in cores collected far from each other and distributed along a 330 km-long transect crossing the north-western margin of the Barents Sea and western margin of Spitsbergen, providing a set of information that can be used as a benchmark for the reconstruction of the paleoclimatic evolution of this region.

Sedimentary architecture of submarine mid slope deposits with relics of gas hydrate fractures revealed by X-ray CT scanning: new insights from the Tuaheni Landslide Complex, North-East of New Zealand

Dr. Morgane Brunet [1], *Dr. Jean Noel PROUST* [2], *Dr. Ann Cook* [3]

1. Université Rennes, 2. CNRS, IPG Paris, 3. The Ohio State University

The Hikurangi subduction margin in northern New Zealand is a seismically active zone that triggered a great number of submarine mass-transport deposits. It is also well-known for free gas and gas hydrates occurrences in near-seafloor sediments., including close to the Tuaheni Landslide Complex (TLC). Among the multiple submarine deposits associated to the TLC, the T2 deposit was interpreted as a creeping submarine landslide considering its uncommon morphology and chaotic signature on seismic data. In 2017, IODP 372 Expedition collected c.200 m-deep drilled cores through the entire T2 deposit. High-resolution line and X-CT scans on these cores allow to precise the composition and internal architecture of the T2 deposit in terms of lithology, deformation and sedimentary structures. X-CT data reveal the occurrence of low-density, near-vertical structures invisible to the naked-eye that are here, interpreted as relics of gas hydrate filled-fractures. Thus, we propose to re-assess the nature of the T2 Deposit as a marine composite sedimentary complex with a basal and multiple internal weak-layers, formed by sea level variations since the Late Pleistocene. A surficial mud-flow deposit (< 11 ka) potentially emplaced after a seismically-induced event, buried hydrate-bearing sediments below the BSR, driving gas hydrate dissociation and weak layers formation. These results bring new evidence for gas hydrates implication into slope instability processes and marine geohazards.

The study presents the results of micro-scale analysis that supplements the mesoscale investigation of the unconsolidated lacustrine sandy and silty sediments, deposited during MIS 5d, at Dyburiai study site in north-western Lithuania. Detailed macroscale analysis of the 4.5-m thick sediment succession revealed ten internally deformed layers with exceptionally well-developed liquefaction-induced soft-sediment deformation structures (SSDS), interbedded with undeformed sediments. Erosional features at the tops of the layers containing SSDS clearly indicate that the multiple deformation events were separated by periods of erosion, followed by the subsequent deposition of new sediments. Consequently, it is concluded that the likely trigger mechanism for the sediment deformation was recurrent phases (at least seven) of seismic activity. Seismic activity was most likely caused by reactivation of a fault within the sub-Quaternary substratum in response to ice unloading during Saalian deglaciation.

Four thin sections, prepared from undisturbed oriented samples collected from the different sediment layers containing SSDS, were analysed to constrain the processes accompanying deformation. The recognized microstructures include, injection structures (sand-filled veinlets), disharmonic synforms (load casts), pseudonodules, recumbent folds, detachments, subhorizontal shears and small-scale faults. The thin sections reveal that the relative intensity of the deformation is highly heterogeneous. In some areas of the thin sections the primary sedimentary structures are still visible, however elsewhere within the same thin section the sediments are highly deformed and disrupted. In some cases, the highly deformed sediments occur between laminae of low-permeable silt or clay. Cross-cutting relationships between the deformation structures indicate that soft-sediment deformation accompanying each seismically induced liquefaction event consisted of numerous successive stages: (1) initial recumbent folding and thrusting, (2) liquefaction and sediment injection (hydrofracturing) often accompanied by faulting, and (3) compressional folding. The results indicate that individual liquefaction processes affecting any layer with SSDS consisted of multiple deformation stages generating complex deformation microstructures.

This work presents the results of a trenching and geophysical investigation conducted in a late Pleistocene terrace affected by normal faulting and underlain by salt-bearing bedrock of a diapir. The study area is located in the 34-km-long, N-S trending Ayora-Cofrentes graben at the junction zone between the Betic Cordillera and the Iberian Chain, eastern Spain. This 5-6-km-wide graben has a continental Mio-Pliocene fill pierced by a salt wall of Triassic evaporites along its axis, that splits the basin into two half-grabens. The normal faults bounding the Ayora-Cofrentes graben offset up to several hundred meters Jurassic to Miocene formations but are onlapped by Pliocene lacustrine limestones that record the final stages of the endorheic basin fill. Quaternary fluvial incision governed by the Júcar River base-level has generated deeply entrenched longitudinal and transverse valleys across the uplifting diapir, locally forming nice examples of drainage antecedence. Here, the river has developed a sequence of 14 terraces from +130-135 m. This work focuses on N-S-oriented normal faults spatially associated with salt-bearing units of the salt wall that offset the +25-30 m terrace (T9) of the Júcar River, dated by U/Th and OSL at ca. 90-132 ka (MIS 5). ERT sections acquired across the fault zone in the terrace underlain by evaporitic bedrock revealed a lineal collapse structure with a throw of around 30 m. A 108 m long and 4.5 m deep trench was excavated across the main west-facing fault scarp and the associated trough, exposing a 64 m wide half-graben structure. A long-term slip rate of 0.015-0.03 mm/yr has been estimated considering the net throw (3.1-3.9 m) and the maximum age of the terrace. The stratigraphic and structural relationships reveal an episodic displacement regime for the fault system, with a minimum of three faulting events at: 137-127 ka (X), 99-90 ka (Y) and ca. 2.8 ka (Z). The spatial association of the deformation with the Triassic halite-bearing bedrock (Keuper), and the lack of clear offset across the collapse structure imaged in the ERT section suggest a gravitational origin, despite some tectonic influence by basement faults cannot be ruled out. In Central Italy, the damage induced by the 2016-2017 seismic sequence to the building and infrastructural heritage and the need to consider the surface fault rupture hazard in the reconstruction process incentivized Seismic Microzonation studies focused on capable faults. The presence of capable faults, that produced dislocation of the ground surface at least once within the past 40.000 years (cf. Italian Civil Protection guidelines), is, in fact, one of the exclusion criteria for post-earthquake reconstruction.

In 2020-2022, the Italian Government Extraordinary Commissioner for post-earthquake reconstruction funded a program of studies on capable faults affecting urbanized zones in the epicentre area. Some of the inhabited centers being studied are located along the NE, E and SE borders of the Rieti intermountain basin.

The formation and evolution of the box-shaped Rieti basin is closely related to the extensional regime that affected the western flank of the eastward migrating Apennine chain during the Quaternary, in combination with regional uplifting. During the Early Pleistocene, the evolution of the basin was controlled by a normal fault located along the eastern edge, with NNW-SSE orientation. This structure acted as a master-fault, determining a progressive deepening of the half-graben, thus favoring the deposition of thick sequences of fluvial deposits, first of alluvial fan (Fosso Canalicchio Synthem) and then alluvial plain (Monteleone Sabino Synthem) facies. The E-W oriented structures along the northern and southern margins of the basin acted as transfer structures, linked to the eastern border fault. During the Middle Pleistocene, along the margins of the basin, the Early Pleistocene deposits were displaced by a few hundred meters, developing a further deepening of the Rieti basin and the northward diversion of the hydrographic network of the Velino River.

The 17 new paleoseismological trenches, with 52 radiometric dates and extensive geophysical prospecting, carried out in 2021 and 2022 by ISPRA and Insubria University with INGV, discovered Late Pleistocene and Holocene activity along the investigated faults. The collected data will be analyzed at the basin scale to reconstruct recent tectonic activity, define the current seismic hazard and recognize the possible presence of seismic cycles in the Rieti Basin.

Towards deciphering past seismic activities of the North Tehran fault through the dating of colluvium and fault gouge

1. Institute of Earth and Environmental Sciences, University of Freiburg, Albertstr. 23b, 79104, Freiburg, Germany, 2. Research Institute for Earth Sciences, Geological Survey of Iran, Azadi Square, Meraj Avenue, P.O. Box 13185-1494, Iran, 3. University of Jena, 4. Albert-Ludwigs-Universität Freiburg

The North Tehran fault (NTF) is the main tectonic structure of the megacity of Tehran. It extends over 68 km along its northern fringe and has received considerable attention in the context of geohazard analysis. However, our knowledge about past major activities is limited to only a few studies in which the activity of the NTF has been probed by identifying offsets of geomorphic features or distinct stratigraphy. Notwithstanding, the historical records suggest the occurrence of major devastating earthquakes on this active structure.
In this study, we aim to apply luminescence-dating methods that have proven applicable in earlier studies in the region to constrain the timing of the last activities throughout the Late Quaternary. Our research is twofold and consists of indirect and direct dating of past earthquakes. In our contribution, we will present the first dating results of our first fieldwork season. Samples have been taken from several Quaternary colluvial and alluvial units in various spots along the NTF linked to seismic activity-caused ruptures. More importantly, our work includes the first results of luminescence dating of fault gouges along the NTF. With this, we respond to the research question as to whether the fault gouge dating, in combination with the luminescence technique, is a promising approach to reveal the timing of past earthquakes along the NTF.

Paleoseismic studies of the Rhine Graben Faults (Germany)

Prof. Klaus Reicherter [1], *Ms. Sara Pena Castellnou* [1], *Ms. Vanessa Steinritz* [1], *Dr. Jochen Huertgen* [1], *Dr. Stephane Baize* [2]

1. Institute of Neotectonics and Natural Hazards, RWTH Aachen University, 2. Institut de Radioprotection et de Sûreté Nucléaire

The Rhine Grabens in Central Europe are one of the most seismically active intra-plate regions and host damaging earthquakes in historical times (e.g., the 1356 Basel earthquake, Düren 1756, Verviers 1692), all below M 7. During the last decades, several research efforts have been undertaken to characterize the seismic hazard associated with the Rhine Grabens and have focused mainly on the western margins of the grabens unraveling Upper Pleistocene-Early Holocene surface rupturing faults. However, paleoseismic studies resulted in incomplete estimations of the faulting history and the seismic potential of the faults, because the models applied incorporate “period and characteristic” fault theories in earthquake geology. Our research aims to characterize the seismogenic faults Rhine Grabens by studying their neotectonic imprint in the landscape and establishing a chronology of seismic events along each fault or fault segment. We performed geomorphological mapping of faults, Quaternary deposits, trenching of paleoseismic features and calculated several morphometric parameters to depict fault segmentation along the faults and include long-term deformation. We provide data that prove the kinematics of the faults and allow us to define areas with varying tectonic activity. We trenched several sites for paleoseismological studies including extensive geophysical surveys in the Upper and Lower Rhine Grabens: 1) six trenches along and across the secondary topographical fault scarp of the eastern Rhine Graben Boundary Fault north of Ettlingen-Oberweier (Karlsruhe); 2) three trenches across the Rhine River Fault scarp, which cuts the distal parts of the Neumagen alluvial fan near the village of Tunsel (Freiburg), and; 3) and two trenches across the Feldbiss Fault near Aachen. In all study sites, we found surface rupturing earthquakes providing the first evidence of Late Pleistocene and Holocene tectonic activity with M >6 and, hence, we contribute significantly to the completeness of the earthquake history.

Inheritance of Detrital Charcoal and lacustrine shells: Implications for Age Estimates on Paleoearthquakes

***Prof. Thomas Rockwell* [1], *Prof. Aron J. Meltzner* [2]**

1. (7) Department of Geological Sciences, San Diego State University, San Diego, CA 92182, US, 2. Earth Observatory of Singapore, Nanyang Technological University Singapore

We have compiled over 900 stratigraphically constrained radiocarbon dates from seven stratigraphic sequences to determine the extent to which detrital charcoal and lacustrine shells are either reworked or carry inherited age. We combine 296 dates (out of 423) from Lake Cahuilla (Rockwell et al. 2022) with 95 dates from a new study at Salt Creek, also from Lake Cahuilla, and show that nearly half of all dates are older than underlying strata, indicating significant age inheritance. Similarly, inheritance ranges between 30% for the Old Town site along the Rose Canyon fault to 41% at the Mystic Lake site along the San Jacinto fault, to 44% at the Beteiha site along the DST. In contrast, 111 dates from Hog Lake (Rockwell et al., 2015) show that only about 15% of dates exhibit ages older than underlying strata, but most dates were on seeds contained in thin organic mat layers, all of which were in stratigraphic order. Hence, it is clear that chronologies constructed from single year growth samples substantially improve the accuracy of the ages of individual strata. Dates on lacustrine shells maye ven be worse in terms of reworking. We dated 32 samples of gastropods from a single lake sequence along the San Andreas fault and found that 90% exhibit age inheritance. Similarly, we dated 23 gastropod shells from two cores on the Colorado River delta that exhibited similar results. The percentage of reworked or older charcoal and Shell indicates that paleoseismic studies should consider dating twice as many samples as are expected to define an age sequence. Further, whenever possible, single-year growth samples, such as seeds and pine cones, should be dated to help constrain and anchor a chronologic model. These statistics have broad implications not only for paleoseismic studies, but for fire frequency and slip rate studies. Reliance on a single date to quantify processes or events appears to be quite risky.

Deformation History of the Pohang Basin in the Heunghae area, Pohang and Consideration on Characteristics of Coseismic Ground Deformations of the Pohang Earthquake, South Korea

Prof. Ji-Hoon Kang [1]

1. *Department of Earth & Environmental Sciences, College of Natural Science, Andong National University*

On November 15, 2017, a Mw 5.4 Pohang Earthquake occurred at about 4 km hypocenter in the Heunghae area, and caused great damages to Pohang city, South Korea. In the Heunghae area, which is the central part of Pohang Basin(PB), Cretaceous Gyeongsang Supergroup and Late Cretaceous to Early Paleogene Bulguksa igneous rocks as basement rocks, and Neogene Yeonil Group as fillings of PB, are distributed. In this paper, structural and geological researches on the crustal deformations(folds, faults, joints) in PB and the coseismic ground deformations(sand volcanoes, surface cracks, pup-up structures) of Pohang Earthquake were carried out, and the deformation history of PB and the characteristics of coseismic ground deformations were considered. The crustal deformations were formed through at least five stages before the Quaternary faulting: forming stages of the normal-slip(Gokgang fault) and sinistral strike-slip faults which strike (N)NE and dip at high angles, and the high-angle joints of E-W trend regionally recognized in Yeonil Group and the faults (sub)parallel to them, and the conjugate normal-slip faults(Heunghae Fault and Hyeongsan Fault) which strike E-W and dip at middle or low angles and the accompanying E-W folds, and the conjugate strike-slip faults dipped at high angles in which the (N)NW and E-W or NE striking fault sets show the (reverse) sinistral and dextral strike-slips, respectively, and the conjugate reverse-slip faults in which the NNE and NNW striking fault sets dip at middle angles. Sand volcanoes often exhibit linear arrangements (sub)parallel to surface cracks. The pop-up structures and surface cracks of N-S or (N)NE trend and surface cracks of E-W or (W)NW trending among the coseismic ground deformations were formed by the reverse-slip movement of the earthquake source fault and the accompanying buckling folding of its hanging wall due to the maximum horizontal stress of Pohang Earthquake source. These structural activities occurred extensively in the Heunghae area, Pohang, which is at the hanging wall of the earthquake source fault, causing enormous property damage here.

This research was supported by a grant (2022-MOIS62-001) of National Disaster Risk Analysis and Management Technology in Earthquake funded by Ministry of Interior and Safety (MOIS, Korea)

Recent improvement of the Active Fault Database of Japan

Dr. Takashi Azuma [1]

1. Geological Survey of Japan/AIST

Geological Survey of Japan/AIST has opened the Active Fault Database of Japan since 2005. It includes not only the active fault traces but also fault parameters obtained from field surveys by local governments, university groups as well as our institute. We started to improve this database recently and show detailed active fault maps for each segment, including fault traces and investigation sites. We also add several fault segments, which were included in the government reports. Accuracy of location of fault traces and investigation sites are improved in order to show them on the 1:50,000 scale map. In the detailed fault map, we add symbols to indicate the faulting sense (reverse, strike-slip, normal) and certainty of fault trace. We will open these new data for each fault segment one by one and will complete all segments by 2030FY in the current plan.

Active faulting in the eastern and central Mediterranean basin

Dr. Claudia Bertoni [1]***, Dr. Nicolo' Bertone*** [2]***, Dr. Lorenzo Bonini*** [2]***, Dr. Angelo Camerlenghi*** [3]***, Dr. Anna Del Ben*** [2]***, Dr. Andrew Madof*** [4]***, Ms. Michelle Vattovaz*** [2]***, Prof. Richard Walker*** [1]

1. *Department of Earth Sciences, University of Oxford,* ***2.*** *Department of Mathematics and Geosciences, University of Trieste,* ***3.*** *National Institute of Oceanography and Applied Geophysics OGS,* ***4.*** *Chevron*

We present an overview of results from the Leverhulme Trust 'NEPTUNE' project in which we combine observations of onshore and offshore active faulting in the eastern and central Mediterranean to build an overall appreciation of structural development, rates of deformation, and earthquake and tsunami hazard. We use compilations of seismic reflection data and EMOD bathymetry to identify basement faults, and to separate these few major features from more superficial deformation within and above the Messinian salt horizons. Since the late Miocene active faulting within the Mediterranean basin, and along its onshore eastern and northern margins, has had profound effects on the regional organisation of drainage networks that, in turn, affected the inputs of freshwater into the marine basin. Tectonic forcing of freshwater and clastic inputs has generated characteristic marker horizons and facies, such as the Messinian post-evaporitic clastic units, which are used to estimate long-term displacements and rates of faults, from the Messinian to present.

The Montereale basin: tectonic and sedimentation in a central Apennine intermontane depression.

Dr. Giuseppe Nirta [1], _Dr. Edi Chiarini_ [2], _Dr. Marco Nocentini_ [2], _Dr. Alessandra Sciortino_ [3], _Dr. Marco Spadi_ [3], _Prof. Marco Tallini_ [3]

__1.__ Italian Geological Survey - ISPRA, Rome, __2.__ Geological Survey of Italy - ISPRA, Rome, __3.__ Department of Civil, Construction-Architectural and Environmental Engineering, University of L'Aquila

The relationships between quaternary tectonic and sedimentation were investigated in the intermontane Montereale Basin (MB), in the axial sector of the central Apennine.
The quaternary faults interacting with the sedimentation of the MB basin are represented by the Capitignano Fault (CPF), bordering the basin to the NE, and the San Giovanni Fault (SGF) in the center of the SW sector of the basin. These tectonic elements guided the development of two distinct depocenters with differences in their evolution and thicknesses (the Capitignano and the Piedicolle sub-basins).
Despite the scarce exposure of the Quaternary deposits, the reconstruction of the stratigraphic record was possible by integrating field mapping with geophysical studies, core drillings, paleomagnetic analyses, and ^{14}C and ^{39}Ar/^{40}Ar dating. Obtained data suggest that in the first phase of the sedimentary evolution of the basin, the fault-related subsidence exceeded the sedimentation rate, allowing the persistence of lacustrine sedimentation. Subsequently, between the Early Pleistocene and the Middle Pleistocene, a slowdown in the activity of both the CPF and SGF allowed the threshold between the two depocenters to be overcome and consequently the establishment of a drainage pattern similar to the current one. Thus, the MB has followed the same evolutionary pattern recognized for other intermontane basins in the Central Apennines and it has been rather early integrated into the regional hydrographic system (Early-Middle Pleistocene transition?).
To verify the activity and quantify the slip rates of CPF and SPF during the late Pleistocene-Holocene a total of three paleoseismological trenches were dug. These allowed to estimate a slip-rate of about 0.3 to 0.4 mm/yr during the late Pleistocene-Holocene for the CPF and SGF.
Thus, despite the two faults can still be classified as active and capable, since the late Middle Pleistocene, alternating aggradation and erosive episodes, suggest that the tectonic subsidence was no longer able to compensate for the sedimentation rates and therefore the evolution of the basin was essentially controlled by external factors (e.g. lowering of base level).

Seismotectonics review and 3D rheological modelling of the Durres area (Albania)

Mr. Davide Russo [1], ***Dr. Massimiliano Maggini*** [1], ***Prof. Riccardo Caputo*** [1]

1. *University of Ferrara*

The Durres sector of the Adria-Eurasia collision was recently affected by the 2019 seismic sequence. The seismogenic volume belongs to the active portion of the accretionary wedge representing the external part of the Albanides fold-and-thrust belt. In this sector, the front is kinematically partitioned by the ENE-WSW Shkodra (to the North) and Lushnje (to the South) transfer faults (Caputo and Pavlides, 2013). This region shows a documented seismic activity (Baker et al., 1997; Louvari et al., 2001; Muco et al., 1994) associated to both thrust and back-thrust structures (Muceku et al., 2006; Roure et al., 2004; Skrami et al., 2001; Velaj et al., 2001), though the orientation of the causative source of the 26 November, 2019 Durres mainshock (Mw=6.4) is still debated. In order to better characterize the seismogenic sources recognised in the area (from GreDaSS database; Caputo and Pavlides, 2013), we performed a seismotectonic review and created a 3D rheological model for constraining their (maximum) seismogenic potential. The BDT (Brittle Ductile Transition) represents a good proxy of the seismic/aseismic transition and fundamentally corresponds to a mechanical boundary for coseismic rupture propagation processes (Maggini and Caputo, 2021). Close to this mechanical and behavioural transition, quasi-continuum deformation within the viscous crustal body generally induces elastic deformation within the contiguous elasto-brittle body; therefore, when sufficient energy is accumulated it is commonly released seismically. Following a similar approach by Maggini and Caputo (2020, 2021) for the broader Aegean Region, we compared the seismicity cut-off depth of the investigated sector with the modelled BDT depth, thus confirming that the rheological and seismological transitions are tightly correlated. Our model, based on dedicated MatLab scripts and proper calibrated input parameters, evidence the presence of different superposed brittle and ductile layers (clearly evident in transversal reconstructed 2D sections) within the modelled volume. The maximum seismogenic depth occurs at values ranging between 10 and 25 km. Finally, based on the inferred source parameters and applying appropriate empirical relationships (Wells and Coppersmith, 1994; Leonard, 2014), we estimate the maximum expected magnitude for each source and hence their contribution for the Seismic Hazard Assessment of the area.

Spatial evolution of warming across the Chinese Loess Plateau over the last deglaciation

Ms. Jingjing Guo [1], ***Ms. Louise Fuchs*** [1], ***Dr. Martin Ziegler*** [1], ***Prof. Youbin Sun*** [2], ***Dr. Francien Peterse*** [1]

1. *Utrecht University,* **2.** *State key laboratory of Loess and Quaternary Geology, Institute of Earth Environment, Chinese Academy of Sciences*

The East Asian Summer Monsoon (EASM) is driven by changes in the land-ocean thermal gradient, and is expected to strengthen in response to global warming. Previous studies suggest that peak EASM intensity gradually migrated northwestward over the Chinese Loess Plateau (CLP) over the last deglaciation. Since these studies are mostly based on proxy records that reflect a mixed signal of temperature and monsoon precipitation, it remains unclear whether warming has followed the same spatial and temporal evolution as EASM precipitation, or that EASM precipitation shows an increasingly delayed response to atmospheric warming towards the northwest.

Hence, we here assess the spatial evolution of warming over the last deglaciation by generating six quantitative temperature records based on soil bacterial membrane lipids (so-called 'brGDGTs') stored in loess-paleosol sequences along N-S and W-E transects across the CLP. Our records reflect a decrease in absolute temperatures from the SE to the NW, but the amplitude of deglacial warming increases from ~5 °C in Bailu in the SE to ~15 °C in Guojiapan in the NW of the CLP. Most importantly, the onset of warming in the NW lags that in the SE by up to 15 kyr, but overall leads changes in magnetic susceptibility in the same loess-paleosol sequence. This suggests that warming has followed the same spatial pattern as EASM precipitation, albeit offset in time. Presumably, warming first contributed to the waning of Northern Hemisphere ice sheets, after which the Siberian High could migrate north, allowing the EASM to gradually penetrate further inland towards the northwestern CLP.

Luminescence dated loess-palaeosol sequences in the eastern Carpathian Basin reveal variable Holocene climate

Dr. Zoran Perić [1], ***Prof. Slobodan Marković*** [2], ***Dr. Warren Thompson*** [3], ***Mr. Cathal Ryan*** [1], ***Ms. Milica Radaković*** [2], ***Mr. Rastko Marković*** [4], ***Prof. Helena Alexanderson*** [1]

Department of Geography, Faculty of Sciences, University of Niš, Višegradska 33, 18000 Niš, Serbia

Loess-palaeosol sequences (LPS) and loess like sediments are considered as some of the most significant terrestrial archives of climatic change and past atmospheric mineral dust activity. While these LPS have been widely used to investigate the immense climate disruptions of the last glacial period, relatively little attention has been directed toward the climate variability during the Holocene. The main reasons for this was the lack of LPS with a well-preserved Holocene record and more importantly, that the Holocene is generally considered a period of climatic stability. Loess in north-eastern Serbia drapes the westward slopes of the Carpathian-Balkan Mountain chain and provide a useful insight into climate dynamics, but until recently remained almost unexplored. Latest studies conducted on the Kisiljevo LPS and surrounding sites revealed that these LPS preserve some of the most extensive loess accumulations during the Holocene and MIS 2 thus far discovered in this part of Europe. This implies that the atmospheric mineral dust activity in this region during the last c. 12 ka was considerably higher than previously assumed and that the Holocene climate variations may have been larger and more frequent than current climate models suggest. To further investigate this, high-resolution, independent age models of additional well preserved Holocene loess are needed. Here we present initial OSL chronologies from LPS in north-eastern and eastern Serbia at a resolution capable of detecting even slight dust accumulation variations and hiatuses. Our dataset incorporates high-resolution Bayesian modelled chronostratigraphies with dust mass accumulation rates, grain size and magnetic susceptibility analyses.

Age-depth models indicate extremely high rates of dust accumulation during the Holocene; this has not been detected elsewhere in the wider region. The observed increase in atmospheric dust concentrations also generally coincides with at least one major Holocene cooling event for the Northern Hemisphere (9000–8000 cal. a. B.P). There were obviously phases of colder and drier climate during the Holocene which allowed a higher atmospheric dust flux and high accumulation rates in the eastern Carpathian Basin.

High resolution luminescence dating of the Süttő loess-paleosol sequence (MIS 6-2), Hungary: age depth model and mass accumulation rates

Dr. Novothny Ágnes [1], *Dr. György Sipos* [2], *Dr. Gábor Újvári* [3], *Mr. Dávid Filyó* [2], *Dr. Gergely Surányi* [4], *Mr. Tamás Végh* [1], *Dr. Diána Csonka* [1], *Dr. Tamás Bartyik* [2], *Mr. Gergő Magyar* [2], *Dr. Erzsébet Horváth* [1]

MTA-ELTE Geological, Geophysical and Space Sciences Research Group

Loess-paleosol sequences are among the most important and detailed terrestrial records of local/regional climate and environmental changes during the Pleistocene. The Carpathian Basin offers a unique opportunity to investigate temporal and spatial variations in dust accumulation, since 20-25% of its area is covered by loess with considerable thickness (80-90 m at max).

High-resolution numerical ages are available for some loess sections across the northern hemisphere (Jingbian, Sanbahuo, Toshan, Dunaszekcső) making it possible to develop reliable age-depth models and calculate precise mass accumulation rates (MARs), which are important input data of paleoclimate models. However, the mentioned chronologies and derived MARs are mostly limited to around 50 ka, as they are based on radiocarbon and/or quartz luminescence ages. In this project, more than 130 luminescence and some radiocarbon samples were collected in 2020-21 to investigate the 20 m thick loess-paleosol profile at Süttő, located in the northern part of the Carpathian Basin. A systematic sampling for porosity/density measurements was also carried out beyond the luminescence sampling.

The luminescence ages are calculated using the Optically Stimulated Luminescence signal of quartz for the younger part of the sequence and the post-Infrared IRSL signal of polymineral fine-grains for the >50 ka part of the sequence. The samples were collected from every 20 cm. All luminescence tests and measurements were carried out on primary samples. Secondary samples were measured using a shortened measurement routine to save measurement time thereby optimizing the use of resources.

Age-depth modelling is carried out using an R-package specifically developed for the Bayesian and inverse modelling of luminescence ages. Based on the constructed age-depth models and the already available datasets MARs were calculated for each MI stages.

The research was supported by the NKFIH project K 135509.

Late Pleistocene End-member Analysis and Its Environmental Significance on Grain Size of Loess in Central Shandong Mountainous region,China

As the product of dust transport and accumulation under the specific environment of Quaternary, Chinese loess is an important carrier to study the evolution information of Quaternary monsoon circulation and sedimentary environment. Loess Plateau is the most continuous and thick loess area in China, which has been widely concerned by scholars at home and abroad. In recent years, aeolian deposits outside the Loess Plateau have gradually become a hot research content. There are many loess deposits along the Muwen River in Hulinqian, and many ancient human activities have been found in the river terrace landform of the region. Therefore, the study of loess strata in the region has important implications for understanding the evolution of climate and environment for ancient human activities.In this study, the parameterized end-member modelling analysis of grain-size distributions is used to discuss the sedimentary characteristics, transport dynamics and environmental significance for a loess section in Hulinqian, Shandong Province.The results indicate that (1)The OSL ages of the Hulinqian section ranged from 2.26 to 77.91ka, suggesting that sediments were mostly deposited since the late Pleistocene.(2)The grain-size components of the sediments in this section were divided into four end members: EM1(first mode grain size 0.56μm) represents the mixed clay component of pedogenesis and transported sediment；EM2 (first mode grain size 6.32μm) represents the fine silt component transported by the high-level westerly wind over long distance. EM3 (first mode grain size 17.83μm) represents material that settles as floating dust; EM4(first mode grain size 35.57μm) represents the silt component transported via low-level suspension by the local wind systems.(3) According to the climatic proxies such as the grain-size end-member content, magnetic susceptibility and chromaticity, combined with the results of OSL, this effectively indicated the stage change and differences of the sedimentary environment in the Hulinqian section since the late Pleistocene and reflected the regional response to global climate change.

Loess, sand, wind and Ice: a Midwestern United States Late Wisconsin (MIS2) polygenetic Landscape and the formation of Paha

Mr. Phillip Kerr [1]

1. *Iowa Geological Survey*

Indicators of the long-term activity of the jet stream during the Last Glacial Maximum are found in Eastern Iowa, in the Midwest United States. This area is distinctive landform region called the Iowa Erosion Surface (IES) which formed during the Last Glacial Maximum, but not covered by ice during the Late Wisconsin (MIS 2) and has little to no loess cover. Surrounding regions, however, can have 10-20m of Peoria Formation loess on the uplands. Perplexingly, the IES also contains unique linear hills topped with 10m of loess, called paha. Their formation, timing, and relationship with the surrounding loess-free landscape has been debated for over a century.

To address this quandary, this study created a new polygenetic landscape framework using combination of extensive landform mapping, field data, and chronologic ages. Features mapped include dunes, paha, deflation troughs, linear loess-covered hillslopes, outwash-filled valleys, glacial margins, paleo-drainages, and periglacial erosional forms such as retrogressive thermokarst slump scars. Features formed from loess such as paha have an exceptionally uniform linear geometry which wind direction indicators found in dunes. The landforms indicate a uniform paleo-wind direction of ~300˚, west-northwest. AMS radiocarbon dating was conducted on organic materials collected in eolian sediments, paleosols, and debris flow deposits. Ages from charcoal collected from the in the Farmdale Geosol indicate the landscape was stable until ~27ka. Plant and wood collected from debris-filled valleys return ages of ~26ka, which indicate the start of widescale periglacial destabilization. However, radiocarbon ages from Succinea snail shells collected at the base of unleached loess indicate the onset of rapid loess deposition starts after periglacial erosion. Eolian sand was also active across the landscape and was able to be transported via the intense winds and flat topography due to periglacial erosion. which deflated loess except where topographic barriers blocked saltating sand. Paha formed because of this process. Loess was able to accumulate where there was an upwind impediment to deflating sand. The uniformity of these eolian features is likely due to the jet stream being locked onto the glacial margin during portions of the Last Glacial Maximum.

Magnetic susceptibility properties in loess- paleosol sequences over Eurasia

Because the magnetic susceptibilities of sediments are reported in various dimensions, and can be normalized to mass or volume, it is challenging to find truly compatible data from a suite of wide-spread localities. In this contribution, we compare magnetic enhancement as derived from magnetic susceptibility, and its frequency dependence from a variety of localities from western Europe to Asia. All data is measured with the same instrumentation and settings, providing true compatibility. Our comparison shows that full interglacial soils do not always reach the same degree of enhancement as well as different background susceptibilities which imply differences in dust sources. Furthermore, a suite of processes are acting on the magnetic properties, including magnetic enhancement as derived from magnetic susceptibility as well as wind vigor, and signal depletion by predominant occurrence of diamagnetic minerals.

We will present and discuss the result of a cluster analysis, and evaluate the usefulness of such an approach to our datasets. Further, we will exemplary explore the relationship between magnetic enhancement and (post-depositional) grain size variations.

Interplay pattern of monsoon and Westerlies in hyper-arid Asian interior since last deglaciation

Establishing the relationships between the behavior of monsoonal circulation and the behavior of the Westerlies in arid, continental climates represents an important problem of paleoclimatology, with significance for projecting arid-region water availability in a warming world. Using newly collected proxies in the Tarim Basin (TB) of interior Asia, together transient model simulations, we propose that a higher occurrence of rainstorms and an enhanced aridity coexisted in TB and surrounding mountains during the warmer time intervals over the past 15 kyrs. Insolation-gradient-driven weakening of the Northern Hemisphere summer monsoon was accompanied by an intensification and a southward displacement of the boreal Westerlies, leading to decreasing summer rainstorm events in basin and moistening the high-altitude mountains. These findings help refine our understanding of the effects of Westerlies and summer monsoon on the hyper-arid Asian interior hydroclimate and provide profound implications for understanding the cultural communications between east and west Asian ethnic groups.

Clay mineralogy of the Stari Slankamen (Serbia) loess-paleosol sequence during the last glacial cycle — Implications for dust provenance and interglacial climate

Clay minerals in loess-paleosol sequences carry important information on dust source and the regional paleoenvironments. However, relatively little is known about the origin and temporal variations of clay minerals in these deposits in the Serbian part of the Carpathian Basin and their paleoclimatic implications. Here we present the results of high-resolution XRD clay mineral analysis of the Stari Slankamen loess-paleosol sequence through the last glacial cycle, at a 10 cm-interval in paleosol and a 20 cm–interval in loess horizons.
The results show that illite (range of 27–63%, average of 42%) and smectite (range of 9–49%, average of 32%) dominate the clay fraction, while chlorite (range of 12–22%, average of 17%) and kaolinite (range of 6–13%, average of 9%) are less abundant for the 12.70-m thick section. The roughly constant composition of the clay minerals within the loess unit and most of the paleosol suggests that the clay minerals are of detrital origin and that pedogenic transformation has only occurred in the lower part of paleosol V-S1, which corresponds to the climatic optimum of Marine Isotope Stage (MIS) 5e. The smectite-rich characteristic of the glacial loess provides a diagnostic indicator for confirming local sources for the Carpathian Basin loess deposits, and that these sources made little contribution to the dust deposited in Greenland during the last glacial. The first application of illite crystallinity and the chlorite ratio to the Carpathian Basin loess-paleosol sequence suggests that they are more sensitive indicators than the clay mineral proxies previously used in European loess studies. The enhanced precipitation during MIS 5e indicated by the new proxies and the transformation of clay mineral potentially provide new insights into understanding the regional climatic response to future global warming.

Loess in Equatorial Peru

Dr. Gerilyn Soreghan **[1]*****, Mr. Steven Adams*** **[1]*****, Dr. Lily Pfeifer*** **[2]*****, Dr. Luzmila Davila*** **[3]**

1. *School of Geosciences, University of Oklahoma,* ***2.*** *Department of Geology, Rowan University,* ***3.*** *Instituto Nacional de Investigación en Glaciares y Ecosistemas de Montaña INAIGEM*

Loess occurs today in mid-high latitudes owing to silt generation via glacial grinding, and in subtropical deserts owing to non-glacial mechanisms of silt formation. But global maps depict an absence of loess in equatorial regions. Here we report particle-size and provenance data on inferred loess and associated sediments from the Cordillera Blanca, Peru, and discuss implications for loess formation.

The Cordillera Blanca forms a high-altitude (peaks >6 km) mountain range trending north-northwest in southern equatorial Peru (~8-10^{o}S), and is the glaciated footwall of a large detachment composed predominantly of the Cordillera Blanca batholith (12-5 Ma). Along the western slope of the range, glacial valleys incise transversely every 5-10 km and join the Rio Santa, which flows axially along the range before turning westward, ultimately debouching into the Pacific Ocean.

We sampled sediment from proglacial lakes, glacial moraines and eolian mantles of glacial valleys near and north of Huaraz, Peru, and from floodplain and loess of the Rio Santa along its course. Glacial sediment here is derived mostly from the relatively coarse-grained Cordillera Blanca granitoids. Sediment samples were processed for removal of organic and carbonate material before particle-size analysis of the <2000 µm fraction using a Malvern Mastersizer 3000 LPSA. Resulting PSD modes: glacial moraines: 40, 100 µm; proglacial lakes: ~18, 49 µm; eolian mantle at the head of a glacial valley: 40 µm; Rio Santo floodplain:~35-60 µm; loess: ~25 µm. Detrital zircon geochronology for the moraine exhibits a primary mode at 12 Ma, the same as the loess collected ~80 km downstream (north), although the loess includes a number of insignificant older age populations. The predominant age population of the moraine and loess match (12 Ma), indicating connectivity between proximal and distal deposits in this system. Older grains in the loess indicate downstream contributions from other sources along the Rio Santa system.

Glacial processes associated with this system are producing abundant fine-grained sediment with the potential to form loess, although few suitable areas for deflation and traps occur owing to the extraordinarily high relief.

Precipitation-dissolution dynamics of calcite and Silicate in the Tiefer See, Northeastern Germany

Dr. Ido Sirota [1]

1. *Section 4.3, 'Climate Dynamics and Landscape Evolution', GFZ German Research Centre for Geosciences, Potsdam, Germany*

The sensitivity of lakes to changes in environmental conditions make them excellent hydroclimatic recorders. However, the transfer of environmental signals into the lacustrine record is highly complex, involving diverse hydroclimatic-limnologic-sedimentologic processes on different time scales. To distinguish and quantify signal transfer processes in lakes, we developed a state of the art, intensive meteorological-limnological-sedimentological monitoring set-up at the Tiefer See, Northeastern Germany. Previous studies show that deposition rates peak during the spring-summer due to the spring diatoms bloom (March-May) followed by deposition (May-September). Here we follow variations in the Si, Ca and alkalinity concentrations along the water column as indicators for silicate and deposition/dissolution. These elements exhibit a seasonal cyclic behavior that corresponds the observed accumulation of silicate and in the sediment traps. During the spring-summer, the depleting concentration at the upper water column (depths <12 m), from 1.5 to 0.1 mg/l is concurrent with the increasing concentration at the bottom water column, from 1.5 to 2.5 mg/l. This indicates that diatoms formation during the spring is limited to the upper part of the water column. As diatoms settle to the lake floor, some are rapidly dissolved there. This is supported by the sediment trap data, showing that at most springs the diatoms flux at the shallow trap is larger than in the deep trap. The concentration shows a depletion in the epilimnion from ~85 to ~70 mg/l, a later smaller depletion in the metalimnion, from ~85 to ~75 mg/l and a more or less constant hypolimnion concentrations, ~85 mg/l. This indicates that form at the upper water column, following the consumption by the diatoms bloom and increasing pH, however, it does not dissolve at the hypolimnion. The degree of saturation of and silicate along the water column support the presented dynamics as is supersaturated ($0.8<\Omega<7.2$) at the hypolimnion or only slightly undersaturated, while silica is highly undersaturated ($0.01<\Omega<0.7$) at the hypolimnion throughout the entire year. These insights contribute to the understanding of and cycles in the lake and is crucial for the understanding of sediment distribution in lakes.

Pliocene-Pleistocene Paleohydrological reconstruction of the Tropical Andes of Colombia.

Dr. Lina Perez-Angel [1]***, Prof. James Russell*** [1]***, Dr. Julio Sepúlveda*** [2]***, Ms. Katie Eaman*** [3]

1. *Department of Earth, Environmental, and Planetary Sciences, Brown University,* ***2.*** *Institute of Arctic and Alpine Research, University of Colorado, Boulder CO,* ***3.*** *University at Buffalo, NY*

The Pliocene, from 5 to ~2.6 million years ago (Ma), is the last epoch when Earth's mean temperature was ~2.5-4°C warmer than today, and CO2 concentrations may have been higher than preindustrial levels. Although Pliocene warmth is well-know, there is a scarcity of Pliocene-Pleistocene records of terrestrial climatic and environmental change, particularly in the tropics, compared to marine records of mid- to high latitude change. This has resulted in considerable disagreement about the controls on tropical rainfall and temperature changes and uncertainty in future climate projections for this region. Whereas climate models generally predict rainfall increased in wet regions and decreased in dry regions in the Pliocene, existing proxy records indicate many discrepancies with these predictions. The Sabana de Bogotá in the Eastern Cordillera of Colombia offers unique sedimentary archives from the tropics (~4ºN), including sediment from an extinct lake preserved in the Funza-II core that dates to the late Pliocene. We measured hydrogen-isotopic composition of sedimentary plant waxes, C_{29} and C_{31}, along the Funza-II core to reconstruct past hydrological variability in the Sabana de Bogotá during the Pliocene-Pleistocene. We paired analyses of the hydrogen isotopic composition of terrestrial leaf waxes to reconstruct hydrological variability with branched glycerol dialkyl glycerol tetraethers (brGDGTs)-based temperature estimates that show that Pliocene temperatures were ~2°C warmer than mid-late Pleistocene temperatures. The plant wax isotope data test whether Pliocene warmth corresponds to a wetter climate than the mid-late Pleistocene.

Plio-Quaternary speleogenetic evolution of the Loza cave system based on the sedimentological record (Slavinski ravnik, W Slovenia)

Mrs. Astrid Švara [1]***, Mr. Šimon Kdýr*** [2]***, Dr. Petr Pruner*** [2]***, Prof. Pavel Bosák*** [2]***, Dr. Nadja Zupan Hajna*** [1]

1. *Karst Research Institute ZRC SAZU, Titov trg 2, SI-6230 Postojna,* ***2.*** *Institute of Geology of the Czech Academy of Sciences, Rozvojová 269, 165 00 Praha 6*

There are several contact karst areas in the NW part of the Dinaric karst. Slavinski ravnik corrosional plain is one of them, located south of the Postojna Basin, at the contact between impermeable flysch and karstified carbonates. As a result of multi-phase gradual regional tectonic uplift, climatic changes, erosion, and sedimentation, the evolution of the paragenetic Loza cave system can be observed. It consists of an intermittent ponor Markov spodmol, an epiphreatic cave Vodna jama v Lozi, an unroofed cave Brezstropa jama v Lozi, and several different bypass channels and shafts (e.g. Šimčev spodmol, Spodmol v Selški Lozi), representing side passages of the main unroofed cave. The multi-proxy approach allowed us to decipher the main factors of morphogenesis, speleogenesis, and changes in the karst underground hydrological zones in time. We studied several sedimentary sections of allogenic sediments, covered or intercalated with various speleothems, for mineralogical, paleontological, paleomagnetic, and U-series dating purposes. The mineral composition of allogenic sediments is consistent with transport from flysch of the Postojna Basin, which shows strong weathering at higher elevations. The paleomagnetic results of sampled sections reveal both normal and reverse polarities; some of them show an eastward counterclockwise rotation of more than 30°, which might represent the oldest allogenic sedimentation in this region. The distinct but contemporaneous sedimentation phases observed in the cave Šimčev spodmol reveal a more complex sedimentological and speleogenetic history than previously thought. Compared with previous research, the sedimentation of the Šimčev spodmol is older than the allogenic sedimentation in the Markov spodmol, while the formation of the unroofed cave Brezstropa jama v Lozi is the oldest. In summary, the location of the cave system, the interrelation of passages, and especially the sedimentological record show an evolution in all three karst hydrological zones reflecting the formation of the northern margin of the Slavinski ravnik corrosional plain within at least the last 5 million years. Therefore, the Loza cave system represents a unique, comprehensive study site with a complete speleogenetic evolution in a relatively small contact karst area, reflecting the Plio-Quaternary tectonic, climatic, and consequently hydrological and geomorphological changes of the karst system.

The Medieval Climate Anomaly in the Jakupica Massif (Republic of North Macedonia): evidence from Galubarnica cave

Climatic change is having a fundamental role in driving the fate of water resource availability in southern Europe, Mediterranean and Balkan regions. These regions accumulate most of their annual precipitation via migratory storms during November–April, which are in part controlled by the structure of North Atlantic atmospheric variability that controls storm tracks and usually described by the North Atlantic Oscillation variability (NAO).

The stable isotope composition of speleothem calcite is considered an effective proxy to reconstruct (qualitatively) paleohydrological variability over these regions and potentially NAO dynamics during the Holocene, and to give insights on future climate evolution of the region.. We present isotopic data supported by U/Th data from two stalagmites collected in the Galubarnica Cave (Republic of North Macedonia), which cover about the last 2000 yr. The $\delta^{18}O$ shows its lowest values - indicating wetter conditions - between ca. 60 and 370 AD, interrupted by an interval of distinctively drier conditions between ca. 110-140 AD. The climate then progressively moved towards drier conditions with the driest interval of the whole record recorded from ca. 900 to ca. 1160 AD. This interval, which appears to be the expression of the Medieval Climate Anomaly (MCA) in the region, terminates abruptly after the 1200 AD with a multidecadal event of wetter conditions. Drier conditions during the MCA are also supported by lake-level investigations at Prespa Lake confirming the regional significance of the speleothem $\delta^{18}O$ record.

A matter of time: towards internal chronological frameworks for Plio-Pleistocene U-Pb dated flowstones from the Cradle of Humankind

***Dr. Rieneke Weij* [1], *Dr. Tara Edwards* [1], *Mr. Sinethemba Ncetani* [2], *Dr. John Hellstrom* [3], *Prof. Russell Drysdale* [3], *Prof. Jon Woodhead* [3], *Dr. Robyn Pickering* [1]**

1. *Department of Geological Sciences & Human Evolution Research Institute, University of Cape Town,* ***2.*** *Department of Geological Sciences, University of Cape Town,* ***3.*** *School of Geography, Earth and Atmospheric Sciences, The University of Melbourne*

South Africa hosts some of the oldest hominid fossil remains, centered in the Cradle of Humankind. Climatic and environmental change played a pivotal role in the adaptation and diversification of our early prehuman relatives. However, the sedimentary and climatic archives in which their fossils are preserved are often discontinuous or difficult to date. Fortunately, calcite formations such as flowstones are ubiquitous across the Cradle caves and represent significantly wetter conditions in the past. They form the "golden standard" among palaeoclimatic archives as they can be precisely and accurately dated using U-Th and U-Pb dating techniques. It is, however, difficult to develop age-depth models for the Pliocene-Early Pleistocene U-Pb dated flowstones due to large and overlapping uncertainties of the individual U-Pb ages, hindering climatic proxy records to be anchored in time for this period. Therefore, here we focus on flowstones from just two carefully chosen cave sites, Gladysvale and Malapa. Two flowstone samples, GV01 and M9, are in macro appearance very similar to each other, even though they are from separate caves. Preliminary dating of GV01 shows it formed continuously between 344-337 ka (glacial maximum of MIS 10). The published U-Pb age for flowstone M9 is 2.026 ± 0.021 Ma[1]. This flowstone interval is of great significance as it forms the base of a sedimentary unit containing the fossil type specimens of *Australopithecus sediba*. We first establish an internal growth chronology for the younger U-Th dated GV01 flowstone by developing a tightly constrained age-depth model and using thin-section petrography, trace elements and visible layer counting. This record can then be used as a robust and well-understood analogue to build the first chronological framework for a high-resolution palaeoclimate proxy record for sample M9. This approach and model can eventually be applied to other, older Plio-Pleistocene Cradle flowstones, of which there are many.

The sedimentary sequence of the Račiška pečina cave represents chronostratigraphy and climate records from the late Pliocene to the Holocene. It is one of the best preserved cave records of paleoenvironmental changes during the last 3.4 Ma. The studied sedimentary sequence is mainly characterized by the deposition of calcite flowstone layers in a huge speleothem dome with long hiatuses in a cave environment. The deposition of calcite layers was interrupted by sedimentation of clayey to silty sediments originated from the surface above the cave. The interlayered clastic clays contained significant and representative Early and Late Pleistocene fauna (e.g. *Ursus* ex gr. *Spelaeus* dated older than about 72 ka, *Apodemus* cf. *atavus*, *Borsodia* sp., *Pliomys* sp., and *Clethrionomys* cf. *glareolus*) and probably the first known fossil subterranean gastropod (i.e. *Zospeum* sp.). In the upper part of the section, a soot material from three layers was radiocarbon dated to about 11 ka, 9 ka, and 3 ka. A detailed chronology of the section was established based on magnetostratigraphy and oxygen isotope stratigraphy and correlated with paleontological, U-series, and radiocarbon results. The part of the sequence correlated by the OIS was deposited from about 3.4 Ma to about 80 ka (MIS Km3 to MIS 5). Throughout the whole sequence, the transition from Pliocene to Pleistocene at 2.59 Ma, the presence of the Olduvai subchron between 1.78-1.925 Ma, and the Matuyama/Brunhes geomagnetic field reversal at about 777 ka are well recorded by magnetostratigraphy. The section also contains important information on climate changes through time. Paleoenvironmental changes associated with changes in sediment type and disconformities in sedimentation are also well expressed by changing of stable isotope values, indicating changes in the main factors that controlled environmental conditions in the region. Before the long hiatus at 2.6-2.5 Ma, the oxygen record was mainly shaped by regional Mediterranean factors, but after discontinuity, the record becomes more similar to the LR04 stack, indicating an increased influence of Atlantic Ocean factors. The research of the section has shown that speleothem domes may contain a range of different paleoproxy data that cannot be collected in a single borehole or stalagmite.

Isotope and trace element records from Sırtlanini Cave (Aydın, west central Turkey): Implications for the Little Ice Age and Medieval Climate Anomaly during the Byzantine and Ottoman periods

Dr. Ezgi Unal Imer [1], Prof. İsmail Ömer Yılmaz [1], Dr. M. Oruç Baykara [2], Dr. Matthew Jacobson [3], Dr. Guia Morelli [4], Prof. Jian-xin Zhao [5]

1. Middle East Technical University, 2. Pamukkale University, 3. University of Glasgow, 4. Italian National Research Council, 5. The University of Queensland

Anatolia (Turkey) served as a crossroad for early human migration and for the development of major empires such as the Hittites, Romans (Eastern provinces), Byzantines, and the Ottomans. It is geographically very susceptible to variations in available moisture, and as such climate has always had a major impact on the living patterns, organizations of its occupant societies, and agricultural productivity. An in-depth understanding of Holocene climate variability is thus critical to explore historical climate impacts in this spatially heterogenous region. Within this main objective, this study focuses on detailed mineralogical and geochemical (stable, radiogenic isotope and trace element) data sets obtained from a late Holocene stalagmite (SRT-5) from Sırtlanini Cave in western Turkey. Uranium-series age results reveal stalagmite growth between 0.111 ka and 1.825 ka with two possible hiatuses, corresponding to the Roman, Byzantine and Ottoman periods. Carbon and oxygen stable isotope profiles demonstrate substantial paleo-hydroclimatic variability through the Little Ice Age (LIA) and Medieval Climate Anomaly (MCA) between 900 and 1909 CE. These changes are comparable with documented drought and migration events in western Anatolia, primarily in the 19th century. The start of the LIA (~1400 CE) during the Ottoman rule becomes evident when a sudden decrease in growth rate is observed together with enrichments in stable isotopes ($\delta^{13}C$ and $\delta^{18}O$), clustering in Mg/Ca, Sr/Ca, Ti, Mn, Fe, Ni, and a marked increase in Hg at ~1500 CE. Although the Hg signature may reflect higher atmospheric Hg sourced from ancient mercury and/or gold-silver mining activities, trace element anomalies and increased Sr isotope ratios suggest elevated dust levels and prior calcite precipitations during the dry conditions of early LIA. Most metals (e.g., Pb, V) show similar variations starting from around 1250 CE (calculated variance of 57% using principal component analyses), pointing to a common environmental and/or geological factor effective in Sırtlanini Cave around this time. The need for further analyses (e.g., additional age and SEM studies) is recognized to investigate the uncertain periods of stalagmite growth and assess the possible influence of human activities in and around the cave.

Climate variability in the southwest of Europe during the beginning of the Middle Pleistocene based on flowstone records

In southeastern Spain, there are a series of cavities of considerable extension generated by mass movements of carbonates on a metapelitic substrates. The speleothems generated in these cavities provide information about the past climate in this semiarid area and the geological times after the generation of these landslides. A flowstone speleothem was studied from a wall of Sima del Saliente (Almería province, SE Spain), a cavity formed in a deep fracture (164 m deep) opened as a consequence of these movements. The variations in the δ18O and δ13C curves registered two cold and arid periods, although most of the record was formed during a more humid and warmer period. The U-series dating show that the core of the flowstone developed from MIS16 to MIS14. According to the dating and the comparisons with marine isotopic curves, the speleothem was formed from 635 to 532 kyr BP. The petrographic analysis of the textures and habits of the flowstone, together with the isotopic analysis, allow us to precisely define the climatic events recognized in the Sima del Saliente speleothem record.

Oxygen isotope composition of speleothem between Northern and Southern Italy during the Younger Dryas

The Younger Dryas (YD-12.9 to 11.7 ka), corresponding to GS1 in the Greenland ice record, was a period of rapid climate change occurring at the end of the Last Glacial Termination, with the strongest impacts apparent in the Northern Hemisphere (NH). Temperature over the Greenland Ice Sheet cooled by up to 10°C over periods of years to decades, and North Atlantic sea surface temperatures (SSTs) cooled by 1° to 7°C. Changes in the Atlantic Meridional Overturning Circulation, related to increased meltwater runoff from Greenland ice sheet, are believed to be a major contributor, causing also a reorganization in NH atmospheric circulation highlighted from Northern Europe temperature proxies and numerical simulations. The YD expression and timing in Southern Europe and the Mediterranean are still less explored, but their recognition is crucial to understand the intra-hemispheric propagation of abrupt high-latitudes changes. Here, we present a high-resolution speleothem stable isotope record from Bossea Cave (SW Italian Alps), covering the terminal part of the deglaciation and the Holocene onset. Across the 12.8 to 11.7 ka interval, the Bossea record shows an abrupt drop of $\delta^{18}O$ values. This suggests that changes in atmospheric condensation temperature were the main driver for the speleothem $\delta^{18}O$, with lower values related to cooling during the YD. The timing and pattern of this lowering of the $\delta^{18}O$ values agrees with increasing $\delta^{18}O$ values recorded by southern Italy speleothems, interpreted as the expression of drier conditions during this interval. This indicates the existence of a strong isotopic gradient across the Italian peninsula. The Bossea record provides additional evidence for a highly interconnected North Atlantic and Mediterranean climatic regime, with high-latitudes to European temperature changes coupled to Mediterranean hydrological fluctuations. It also highlights the existence of substantial differences in the same proxy at regional scale.

A speleothem record of climate variability in the southeastern Iberian Peninsula during the Roman period

Previous studies of lake sediments defined the Iberian Roman Humid Period (IRHP, 2600–1600 cal yr BP) as the most humid phase of the last 4000 yr in southern Spain. However, an increasing number of high-resolution paleoclimatic records suggest that sharp climate changes, including phases of persistent droughts, may have occurred during the IRHP. Here we present a novel $\delta^{18}O/\delta^{13}C$ stalagmite record from El Saliente Cave (Almería), spanning from ~4500 to ~800 yr BP and focus our investigation on the IRHP. During the early-IRHP (2600 to 2000 yr BP), the stalagmite growth rate was up to 34 times higher than during the late-IRHP (2000 to 1600 yr BP), indicating that a higher water seepage and wetter conditions prevailed during the early-IRHP. The $\delta^{18}O/\delta^{13}C$ records largely agrees with the observed growth rate changes. The $\delta^{18}O$ series is interpreted here as indicative of variations in the $\delta^{18}O$ of rainfall and precipitation amount, as a response to changes in the precipitation regimen and the predominant source of humidity, while the $\delta^{13}C$ record reflects changes in the vegetal coverage over the cave. According to the $\delta^{18}O$ series, the wettest period of the record (lower $\delta^{18}O$ values) occurred between 2400 and 2300 yr BP. Subsequently, conditions became gradually more arid until 2170 yr BP (the lowest $\delta^{18}O$ values of the series). Afterwards, during the late-IRHP, the $\delta^{18}O$ stabilized to values ~1‰ lower than during the early-IRHP, as consequence of relatively drier climate condition. The $\delta^{13}C$ record indicate that a denser and probably arboreal-based vegetation prevailed between 2400 and 2300 yr BP, which rapidly changed to steep-type vegetation by ~2100 yr BP. The observed isotopic variability during the entire IRHP closely follows the changes in the paleo-NAO indexes. This demonstrates that the paleo-hydroclimatic patters in SE Iberia were largely dominated by the interconnection between the North-Atlantic and the Mediterranean atmospheric realms.

In the central Mediterranean area, speleothem records covering the Last Glacial period and Termination I are scarce. Recently, stalagmite SA1 from Sant'Angelo Cave (Apulia region, southern Italy) has provided a record of the hydroclimate variability for this period based on high-resolution $\delta^{18}O$ data. Chrono-stages such as Greenland stadial/interstadial 2, Bølling-Allerød warm event and Younger Dryas cold event, as well as the Holocene onset, were identified through marked $\delta^{18}O$ shifts that agree in their timing with NGRIP.
SA1 was deposited from ca. 40 to 10 ka, and shows peculiar macro-morphological characteristics, such as i) diagenetic features at the bottom; ii) opaque layers interrupting translucent brownish layers; iii) a net diameter enlargement towards its top; iv) changes in the orientation of the growth axis.
A stalagmite morphologically looking very much like SA1 (named SA201) was recently sampled. Both stalagmites were found broken (by earlier visitors) in the same cave chamber. After slicing, SA201 shows the same internal structure as SA1. Importantly, the bottom and top U-Th dates of SA201 indicate that it encompasses the same time interval, from ca. 40 to 10 ka. SA201 is currently being analyzed for oxygen and carbon stable isotopes, by applying the same resolution (0.2 mm) as for SA1.
This study intends to compare the isotopic trend of these two stalagmites which form one speleothem generation. As a first step, the stable isotope profile of SA201 will be visually correlated to SA1 in order to construct a provisional synthetic chronology. In a second step, this age model will be tested by additional U-Th analyses. This study will thus explore to what extent coeval and morphologically similar stalagmites record the same isotopic trend. If this replication test is successful, the reliability of paleoclimate proxy timeseries from Apulian Caves will be greatly strengthened. Additionally, the two stalagmites will serve as key samples for future high-resolution quantitative temperature reconstructions by using analytical approaches which require a fairly high amount of sample material (i.e. fluid inclusion analyses).

Stalagmite-inferred precipitation record from northern Italy for the past 800 years and split westerlies over Europe in the early Little Ice Age

During the well-known "Little Ice Age" (LIA, ca. 1450–1850 C.E.), Europe experienced the coldest winters over the last ten thousand years. This interval was suggested to have been caused by major volcanic eruptions and periods of low solar activity. However, the detailed climate pattern in Europe remains unclear. By conducting high-precision radiometric U-Th dating and trace element analyses on a stalagmite collected from Bàsura Cave, northern Italy, the evolution of the westerly winds over the past 800 years in Europe and the Mediterranean realm was reconstructed. A comparison of the Bàsura record with previous published precipitation data shows that during the early LIA (1470–1610 C.E.) the westerly winds not only migrated southward, but also split into two branches away from mainland Europe. This strong decrease of moisture-delivering warm westerlies resulted in dry and cold winters in Europe. The splitting of the westerly winds could have been triggered by frequent high-pressure anomalies in northern Europe.

The speleological evolution of phereatic paleokarst of Ghar Kriz Cave, Jbel Chetlou (TellianTunisia).

The geomorphological study conducted in the Ghar Kriz cave, which is located in Jbel Chetlou, illustrates a model of the speleogenic evolution of the endokarst system especially, in the Tell region of Tunisia. The Ghar Kriz cave in Jbel Chetlou represents a ” phreatic paleokarst ” known particularly in the Tell region of Tunisia. This géomorphological study of Ghar kriz cave is based on the speleological exploration of the cave. The visual observations and the collection of samples are crucial to analyse the karstic environment and conceptualize the scenario of cave’s speleogenic formation. The carried out samples, mainly carbonate deposits (stalagmite concretion) and fine deposits (silty clay) have made it possible to specify two main speleogenic phases.
The first phase represents, the phreatic phase of the cave probably belonging to the pre-middle Pleistocene , as inferred from the evidence observed in the walls and ceilings of the cave. This phase is characterized by the presence of the ceiling pockets, the irregular shape of the walls as well as the insoluble pariental edges. Those patterns indicate the phreatic origin of the cave.
The second phase is the dewatring phase of the cave that started from the Middle Pleistocene (478823 ± 21,457 years BP) and up to the present day. This phase produces two generations of stalagmite concretions. The first generation (C 1) that is recorded in the middle to upper Pleistocene (from 478823 ± 21,457 years BP to 53162 ± 349 years BP) and the second generation (C2) that lasted from 10131 ± 315 years BP to 181 ± 11years BP. The latters are associated with significant periods of collapse related to the mechanical readjustement of the cave ceilings and walls.

Speleothems are cave carbonate deposits that can be precisely dated and efficiently record past climatic and environmental conditions, mostly throughout measurements of oxygen and carbon stable isotopes. The $\delta^{18}O$ variability recorded in Mediterranean speleothems is generally attributed to variations in cave drip water $\delta^{18}O$ (and precipitation $\delta^{18}O$), which are driven by changes in the hydrological cycle including variations in precipitation amounts and atmospheric circulation systems. Therefore, the $\delta^{18}O$ of Mediterranean speleothems is commonly used as a proxy of paleo-precipitation and paleo-hydrological reconstruction. However, evapotranspiration occurring in the soil and epikarst can modify the drip water $\delta^{18}O$, as well as complex flow paths due to karst hydrology that determine the mixing and homogenization of precipitation over several months or years. Moreover, the rainfall seasonality may shift the drip water $\delta^{18}O$ values towards the $\delta^{18}O$ signal of the season with the highest infiltration. Hence, the characterization of cave drip waters is crucial to identify the drips that have a clear relationship with the climatic signal and to interpret speleothem paleoclimate records properly. Monitoring studies on the $\delta^{18}O$ of precipitation and drip waters provide an understanding of climatic processes that control the rainfall isotopic variability and the transfer of the isotopic signal to cave waters, thus yielding more confident interpretations of past climate from speleothem records. Here, we provide the results from a two-year monitoring of the Renella Cave, a small shallow cave in the Apuan Alps (western Mediterranean), to understand the modern-day relationship between $\delta^{18}O$ of precipitation and $\delta^{18}O$ of drip waters. We collected monthly precipitation samples above the cave and monthly-integrated samples of three different drips, in addition to hourly monitoring of cave temperature and relative humidity. We recognized two groundwater flow systems feeding drips with different degrees of mixing and homogenization of waters. $\delta^{18}O$ variability of two drips was in the range of measurement error, unlike the wide precipitation isotopic variability, indicating a well-mixed system of waters infiltrated over long periods. The mean $\delta^{18}O$ of drips was more like the amount-weighted precipitation $\delta^{18}O$ than recharge-weighted precipitation $\delta^{18}O$, indicating the speleothem $\delta^{18}O$ as a proxy of paleo-precipitation.

Climate variability in southern Croatia from the end of MIS 5 through the last glacial period recorded in stalagmites from Mljet Island caves

Prof. Nina Lončar [1]***, Prof. Maša Surić*** [2]***, Dr. Miryam Bar-Matthews*** [3]***, Prof. Sanja Faivre*** [4]***, Dr. Avner Ayalon*** [3]

1. *University of Zadar,* ***2.*** *University of Zadar, Department of Geography,* ***3.*** *Geological Survey of Israel,* ***4.*** *University of Zagreb, Faculty of Science, Department of Geography*

This study presents oxygen (δ^{18}O) and carbon (δ^{13}C) stable isotope records of two U-Th dated stalagmites from Mljet Island caves in the southern part of the Croatian Adriatic. Speleothem MSM-1 from Mala špilja Cave recorded environmental changes during Marine Isotope Stage (MIS) 5 (119–101 ka and 91–81 ka BP), MIS 4 (60–54 ka BP), MIS 3 (43–35 ka BP). A short interval (18–13.5 ka BP) during the Last Glacial Maximum (MIS 2) is recorded in stalagmite VSM-1 from Velika špilja Cave. δ^{18}O and δ13C profiles display main climatic oscillations correlated within the age uncertainty with stadial–interstadial events recorded in North Greenland ice core (NGRIP) such as Dansgaard-Oeschger (DO) (25, 24, 17, 16, 15, 11, 10, 9, 8 and 7) and Heinrich event (HE) 1. The lowest δ18O (-7.02‰) and δ13C (-12.14‰) are recorded in speleothem VSM-1 during MIS 2. Speleothem MSM-1 recorded highest variations in both δ^{18}O and δ^{13}C during MIS 5. Consequently, this study confirms the assumption that changes in atmospheric and ocean circulation observed in Greenland and the North Atlantic during the last glacial, influenced the Mediterranean region and eastern Adriatic area. In addition, the timing of the VSM-1 deposition confirmed the hypothesis that during Last Glacial Maximum conditions in the Croatian part of the eastern Adriatic coast were favorable for the speleothem deposition.

Limited water availability during peak interglacials revealed by speleothem records from SE Spain

Dr. Michael Weber [1], _Dr. Alexander Budsky_ [2], _Ms. Viktoria Blumrich_ [1], _Dr. Hubert Vonhof_ [3], _Prof. Denis Scholz_ [1]

1. Johannes Gutenberg University Mainz, Institute for Geosciences, Mainz, Germany, 2. Landesmuseum Kärnten, Klagenfurt am Wörthersee, 3. Climate Geochemistry, Max Planck Institute for Chemistry, Mainz

The modern climate of southeastern Spain is characterised by a strong seasonality of precipitation, with annual rainfall totals usually not exceeding 300 mm. In addition, high summer temperatures lead to increased evapotranspiration, further limiting water availability. The combination of high temperatures and low precipitation amount will further enhance the threat of desertification in the future. Given the climate conditions, there is only a limited number of (high-resolution) speleothem records from this region. Cueva Victoria is one of the few caves with speleothem growth in SE Spain, and previous studies have revealed a high proxy sensitivity to past hydrological changes on millennial and orbital time scale. During the Holocene, there is limited growth of speleothems in Cueva Victoria and the near absence of modern calcite precipitates and active drip sites inside the cave highlights the sensitivity of this cave site to reconstruct past phases of limited water availability.

Here we present several flowstone and stalagmite records from Cueva Victoria covering Marine Isotope Stages (MIS) 11 – 5. Precise U-series dating shows growth during both glacial and interglacial periods, although speleothem growth is more prominent in interglacial phases. Interestingly, interglacial maxima do not show the most favorable conditions for speleothem growth, as the growth rate is significantly reduced. This change in growth rate is interpreted as limited water availability in Cueva Victoria due to increased evapotranspiration. Other proxy data, including initial ($^{234}U/^{238}U$) activity ratios, stable isotopes of carbon, oxygen and calcium, as well as $^{87}Sr/^{86}Sr$ and trace elements, confirm this interpretation. For example, in all speleothem samples examined, the highest Sr and Mg concentrations were found during MIS 11c, 9e, 7e and 5e, due to increased prior calcite precipitation (PCP). In contrast, MIS 11a and 9c proxy data show increased growth rates and generally wetter conditions. This shows, that during peak interglacials, speleothem growth was hampered by limited water availability similar to modern conditions. To better understand the underlying mechanisms, we will quantify the amount of PCP during different (peak) interglacials using Ca isotopes and aim to reconstruct the severity of droughts during the last 425 ka based on a multi-proxy approach.

Southwestern European temperature constrained by speleothem fluid inclusion water isotopes over the past 16,000 years

Mr. Juan Luis Bernal-Wormull [1], Dr. Ana Moreno [1], Prof. Christoph Spotl [2], Dr. Yuri Dublyansky [2], Dr. Miguel Bartolomé [1], Dr. Carlos Pérez-Mejías [3], Prof. R. Lawrence Edwards [4], Prof. Hai Cheng [3]

***1.** Pyrenean Institute of Ecology - CSIC, **2.** Department of Geology, University of Innsbruck, Austria, **3.** Xi'an Jiaotong University, **4.** Department of Earth Sciences, University of Minnesota*

Major and abrupt changes in the Atlantic Meridional Overturning Circulation (AMOC) during the last deglaciation in conjunction with latitudinal shifts of the polar jet stream had a major impact on the climate in the North Atlantic realm, including the Iberian Peninsula, a southern European region key to understanding Northern Hemisphere climate teleconnections. Recent studies used isotopic records of speleothems to reconstruct the climate history since the last deglaciation in northeastern Iberia (Bartolomé et al., 2015; Moreno et al., 2017; Bernal-Wormull et al., 2021, 2023; Pérez-Mejías et al., 2021). However, quantitative climate reconstructions for this region are still scarce. In this work, we present fluid inclusion water isotope data from several stalagmites obtained from two neighboring caves (Mendukilo and Ostolo) in the lowlands of Western Pyrenees. Combining these speleothems allows for the first time for this region to obtain a record of the isotopic composition of paleo-precipitation of the last 16,000 years with the main objective of quantifying major climate shifts on a regional scale.

The speleothem $\delta^{18}O$ and fluid inclusion water isotopes (δD) records follow closely the well-known hemispheric climate changes showing more negative values during GS-1 and H1, related to colder climates, while less negative values characterize GI-1 and the Early Holocene, pointing towards higher temperatures. The results indicate larger oscillations in the fluid inclusion isotopic composition during last deglaciation (ca. 16 to 11.7 ka BP) than during the Holocene (last 11.7 ka BP), as expected from calcite stable isotope and trace-element profiles. As an example, the dD shift at the GS2a-GI-1 boundary is 30 ‰, which would represent a warming by 8.5ºC if the modern T-rainfall isotope relationship is applied. During the Holocene, events such as the 8.2 ka are characterized by a dD amplitude of 10‰. This quantitative fluid inclusion-based paleotemperature record resembles Greenland air temperature and Mediterranean sea-surface temperature records and allows for the first time a continuous temperature reconstruction since the last deglaciation for continental southern Europe.

Pyrenean speleothems as Holocene archives of hydroclimate variability

***Dr. Miguel Bartolomé* [1], *Dr. Ana Moreno* [1], *Prof. Isabel Cacho* [2], *Prof. Heather Stoll* [3], *Dr. Negar Haghipour* [4], *Prof. R. Lawrence Edwards* [5], *Prof. Hai Cheng* [6]**

***1.** Pyrenean Institute of Ecology - CSIC, **2.** Universitat de Barcelona, **3.** Department of Earth Sciences, ETH Zürich, **4.** Geological Institute, ETHZ, Zurich, **5.** Department of Earth Sciences, University of Minnesota, **6.** Xi'an Jiaotong University*

Recent hydroclimate studies on the Iberian Peninsula have shown a complex regional pattern in timing and intensity of climate change spanning the Holocene associated to multifaceted interactions between climate variability that characterizes the Atlantic Ocean region and hydroclimatic processes associated with the Mediterranean climate. Speleothems from caves located at different altitudes in the Pyrenees constitute an exceptional source of detailed paleoclimate information yet unexplored for the Holocene period. This study combines high-resolution stable isotopes and trace elements analyzed in a total of thirteen stalagmites from five different caves in Central Spanish Pyrenees which have a robust chronology constrained by U-Th dates and 14C bomb peak identification. Speleothem data are later compared with lacustrine and marine records from the Iberian Peninsula. Carbon isotopic profiles are very different among the caves and providing a single reconstruction is not possible. Still, the organization of the caves in terms of altitude is evident, with less negative d13C values in caves located at higher altitude or under barren rock than those located under a well-developed soil. Combination of d18O profiles using *Iscam* software indicates a good overlapping among speleothems allowing to reconstruct rainfall isotopic variability at a regional scale. Thus, the onset of the Holocene is marked by a change to more negative values with the most negative ones attained at ca 10 ka BP, when we consider the Climatic Optimum in terms of precipitation. Later, during the second part of the Greenlandian and first part of Northgrippian (ca. 9-5 ka) a slight trend towards less negative values is observed. However, the main change occurs during the Meghalayan (4.2-0 ka BP) with in general less negative values and, in particular, the observation of two clear episodes with indications of dry climatic conditions, one at the onset of the period (4-5 ka) and the other one later on (at 2-3 ka). With this work we aim providing new knowledge on Holocene climate in NE Iberia and integrate it with previous marine and terrestrial records in order to get a coherent regional picture.

Sources of cave CO2 at Milandre cave, Switzerland constrained through multipool analysis of 14C and δ13C.

Ms. Sarah Rowan [1]***, Dr. Marc Luetscher*** [2]***, Prof. Sönke Szidat*** [3]***, Dr. Thomas Laemmel*** [4]***, Mr. Oliver Kost*** [5]***, Dr. Franziska Lechleitner*** [1]

Department of Chemistry, Biochemistry and Pharmaceutical Sciences, & Oeschger Centre for Climate Change Research, University of Bern, 5. Department of Earth Sciences, ETH Zürich

A detailed understanding of how carbon is cycled in karst environments is paramount to our knowledge of global carbon fluxes because karstic geology accounts for 15% of terrestrial lithology. However, the source and transportation pathway of subsurface CO_2 in karst systems is not well constrained. The classical cave carbon cycle model suggests that the dominant source of vadose CO_2 derives from the respiration of catchment soils. In contrast, several new studies have suggested the contribution comparatively older and deeper sources of cave CO_2.

During an ongoing two year monitoring campaign at Milandre cave, northern Switzerland, we evaluated the $^{14}CO_2$ and $\delta^{13}CO_2$ composition of the atmosphere in the cave catchment, catchment soil gas, well gas, and cave air. We found that the ^{14}C signature in cave gas samples is more depleted compared to soil and well gas. The $\delta^{13}C$ of cave and soil/well gas samples have similarly low $\delta^{13}C$ values, indicating a dominant contribution from biological respiration. This could either suggest a source of CO_2 from an aged deep reservoir contributing to the cave gas or substantial influence from degassing of ^{14}C fossil carbonate CO_2 from drip water. The effects of seasonality on cave ventilation dynamics can be observed in the ^{14}C and $\delta^{13}C$ of cave gas collected from two locations at opposing ends of the cave system. In addition, cave CO_2 ^{14}C and $\delta^{13}C$ from a high spatial resolution sample collection crossing the cave is presented. These results have implications for the understanding of the subterranean carbon cycle and the interpretation of speleothem carbon isotope records for paleoclimate studies.

Can we distinguish the vegetation and soil component of speleothem d13C?
