# a FIRST STUDY OF THE WEIGHT, VARIABILITY, AND CORRELATION OF THE HUMAN VISCERA, WITH SPECIAL REFERENCE TO THE HEALTHY AND DISEASED HEART. 

By M. GREENWOOD, Jonior.

1. During the last few years, thanks to many improvements in our methods of analysis, several of the biometric constants of the human body have been investigated. The coefficients of correlation of almost all the separate bones have been ascertained with some accuracy, and the suspected relationship between intellectual and physical characters has been closely sorutinised. Under these circumstances it is strange that so little work has been done on the weights and correlations of the viscera. Even such a simple measorement as the weight of the heart does not appear to have been calculated from any adequate series of observations. English text-books of anatomy give this weight on the authority of Reid and Peacock or on that of Clendinning. These two sets of observations are based upon very few cases. Peacock and Reid's results are drawn from 181 males and 110 females, and Clendinning's from 90 and 71 respectively*. It will be evident, therefore, that no great importance can be attached to them, even if we leave on one side the fact that they afford no materials for the study of correlation

Clearly, the only way to obtain data for the solution of problems concerning the absolute and relative weights of the viscera is to extract as large a series of observations as possible from the post-mortem department records of a large general hospital. The present memoir contains the preliminary analysis of such a series from the pathological data of the London Hospital

It might be supposed that post-mortem records would contain a very large number of available cases, and that the weights of the various organs would be found recorded with considerable accuracy. As a matter of fact, however, simple

[^0]measurements of this kind appear to be rather despised by post-mortom clerks, and the records are, from the quantitative point of view, very disappointing. Weights are frequently omitted altogether; sometimes we read "Spleen about 3 or 4 ozs."; at others, the ingenious writer appears to have given free play to his imagination, and we read of a man of forty-six years of age having a heart weighing one ounce ${ }^{*}$

It is much to be desired that, in future, more accurate methods of recording these simple observations should be adopted, so that large numbers of valuable facts may be rendered available for statistical inquiry. In my own research, after excluding the large majority of the examinations, there yet remained a considerable number of fairly trustworthy data suitable for tabulation, and this paper contains some of the results deduced therefrom, which it is hoped will not be without interest. I propose to divide my subject into four parts:

First. I sball discuss the average eizes, variabilities, and correlations of the heart, liver, spleen, and kidneys in the general population, dispased and normal, to be found within a London general hospital.

Secondly. I shall consider only cases in which the organs, were found healthy on post-mortom examination. We shall thus to some extent שe able to appreciate the influence of disease in modifying the biometric consta馬哣 of the organs in question.

Thirdly. I propose to deal with the influence of age on the biometric constants for the viscera in man.

And, lastly. I shall consider the influence of certain speciol diseases from the same standpoint. All the data dealt with in this memoif are for males, the number of females in my collection being very much smalfor. As far as I am aware, no investigation of this kind on the viscera has yet been undertaken, and mine does not profess in any respect to be more than a prễliminary study. Its ohject is to draw attention to the need of better post-mortein room records, und to indicate the wide field of valuable research which they open up, not only to the biometrician but to the physician $\dagger$.

## 2. The General Hospital Population.

In my first series of tables I have dealt, subject to certain limitations, with a random sample of a general hospital population. To avoid the extreme changes due to youthful growth or senile decay I have tabulated onfy cases between the

[^1]ages of 25 and 55 . Such a "random sample" is, of course, also a selection in that it consists solely of those patients who died in hospital, and upon whom a postmortem examination was held. Thus it is far from being a random sample of the "general population" of the country, many classes of which are never found in the wards of a general hospital at all.

Evidently the population of a general hospital will chiefly consist of, (i) persons acutely ill, (ii) those suffering from surgical injuries or diseases, (iii) sufferers from medical affections requiring special treatment. Chronic maladies of old age, such as bronchitis, indeed, any highly chronic disease, will be under-represented in comparison with the general death-rate. Similarly the number of cases of valvular heart disease and rarer disorders, such as Diabetes Mellitus or Insular Sclerosis and other nervous lesions, will be above the general average.

Now, as pneumonia and bronchitis, particularly the latter, form a considerable number of the so-called "terminal affections" responsible for a large majority of all adult deaths, a random thousand necropsies will not give us the information we require as to the quantitative relations of average viscera, post-mortem. The error resulting from too few cases of senile bronchitis will be lessened, if not minimised, by the fact that we have confined our attention to cases of less than 55 years of age. But even thus we have too many cases of valvular cardiac disease, and as this affection tends to produce hypertrophy of the heart, the average weight in the first three tables is probably a good deal higher than that of the ordinary population at death.

It is, of course, to be remembered that this "general hospital population" does not mean the "normal" or bealthy one. The above remarks are merely intended to show that a thousand deaths in hospital will not be due to exactly the same causes as a thousand deaths taken at random outside, and that therefore when we proceed to select sub-groups, such as "Normal Hearts," "Hearts in Pneumonis," etc., the material we have to select from is not what it wonld have been had we been able to start with 1000 random deaths in the population at large. And so, if we find that the average weight or variability of an organ is diminished when we proceed to special classes, we must bear in mind that possibly the change might not have been so striking if we had had a more representative sample to start from.

## General Hospital Population.

> TABLE I. Hearts with Livers Numbar 1388.
> Mean Heart 13.53 ozs. Standard Deviation 4.680 ozs. Mean Liver 63.01 ozs. Standard Deviation 13.314 ozs. Correlation of Heart and Liver $1931 \pm 0175$.
> TABLE II. Hearts with Spleens. Number 1303.
> Mean Heart 1307 ozs. Standard Deviation 4087.028 Mean Spleen 6.61 ors. Standard Deviation 3.345 ozs Correlation of Heart and Spleen $1827 \pm 0181$.

## TABLE III．Hearts with Kidnoya Number 1293.

| Mean Heart $13 \cdot 14$ ozs | Standard Deviation 4．134 ozs |
| :---: | :---: |
| Mean Kidneys 1868 ozs．$\quad$ Standard Deviation 3.125 ozs． |  |
| Correlation of Heart with Kidneys $2577 \pm 0175$. |  |

In this table the weight is that of the two kidneys taken together．To these results I add a table of the coefficients of variation＊，so as to obtain some ap－ preciation of the relative variability of the organs in question．

TABLE A．
Relative Variability in Weights．

| Organ |  | Coefflaient of Variation |  |  |
| :---: | :---: | :---: | :---: | :---: |
| Hearts with Livers | $\cdots$ | 34．69 |  |  |
| Hearts with Spleens | $\cdots$ | $31 \cdot 18\}$ | mean | 32．39\％ |
| Hearts with Kidneys | ．．． | $31 \cdot 47$ ） |  |  |
| Livers ．．． | ．．． | ．．． | ．．． | 81.18 |
| Spleans ．．．．．． | ．．． | ．．． | ．．． | $50.58{ }^{\text {a }}$ |
| Kidneys ．．．．．． | ．．． |  |  | 24．63¢ |

The substantial difference between the weights of the heart in the cases when livers were measured with hearts and the cases when eitherspleens or kidneys were measured is due to the fact that the 1382 cases of the former only in part cover the 1292 to 1303 cases of the latter，the additional cases ${ }_{3}^{3}$ amounting to three or four hundred，are due to entries in which only two or three weights were given． It seemed desirable to include all possible cases in order to utifise as much material as possible．But there has clearly been some special reason for measuring livers in the case of very large hearts which has not arisen in the case of spleens or kidneys．Thus with livers we have hearts up to 36 ozs ，but with either spleens or kidneys only up to 28 ozs ．

On the whole with respect to both mean and variability，We may consider the hearts with spleens or kidneys to give a more reasonable appreach to the biometric constants of the general hospital population than arises in thecase of hearts with livers，where there is evidence of much more selection．

We notice at once ：
（a）That the spleen is relatively much more variable then the heart，and the heart than the liver or kidneys．
（b）That the heart mean is considerably higher than ti⿱口⿰口口⿺辶 a usually given in anatomical text－books $\dagger$ ．
－The coefflcient of variation $=100 \times$ Standard Deviation $\div$ Mean．
$\dagger$ Peacook and Reid＇s result on 181 male hearts is a mean of 10.699 ozs．The coefficient of variation calculated from their flgures by Pearson is 19.825 ．For the liver，the mean（from 84 caseas）is $58 \cdot 48$ and the coofflaient of variation 14.32 （Pearson：op．cit．Val．1．p．B16）．It might，however，be better to compare these numbers with the resulta given later for the＂bealthy organs．＂Pearson eays that we may probably conelude from Peacook＇s own statements that he＂has cot off a considerable tail of really healthy hearts welghing over 12 oze．＂（op．cit．p．817）．
(c) That there are quite sensible correlations between the weight of the heart and that of the other organs.

## 3. The "Normal" Heart.

Let us now consider the "normal" heart. Evidently the ideal normal heart is hardly at present capable of measurement with respect to any character other than those related to its manner of performing its functions. Such an organ ought really to be measured during the life of its owner, and we cannot do this, as we are unacquainted with the exact relation subsisting between body weight and heart weight in the living subject. The following is, perhaps, the best approximation to the truth that we are in a position to make. Correlation tables have been constructed for pairs of organs found to be healthy post-mortorm. In any case in which I had the least reason to suspect the existence of disease, the measurements have been excluded.

The following results were reached:
Healthy Organs.
TABLE IV. Heart with Livers. Number 358.
Mean Heart 1104 oss. Standard Deviation 1923 ozs Mean Liver 80.44 ozs $\quad$ Standard Deviation $8-948$ ozs.

Correlation of Heart and Liver $\cdot 2780 \pm 0329$.
TABLE V. Hearts with Spleens. Number 517.
Mean Heart 11.25 ozs. Standard Deviation 2.073 ozs Mean Spleen 5.22 oss Standard Deviation 1.898 ozsh

Correlation of Heart and Spleen $2654 \pm 0876$.
TABLE VI. Hearts with Kidroys. Number 413.
Mean Heart 11.24 ozs $\quad$ Standard Deviation $1-846$ ozs Mean Kidney* 12.01 ozs. Standard Deviation 2.016 ozs.

Correlation of Heart and Kidneys $\mathbf{4 0 0 4} \pm 0279$.
Drawing up a table of coefficients of variation as before we have:
TABLE B.
Relative Variability of Healthy Organs.

| Organ |  | Coefficient of Varistion |  |  |
| :---: | :---: | :---: | :---: | :---: |
| Hearts with Livers | $\ldots$ | 17.42) |  |  |
| Hearts with Spleans | $\cdots$ | $18 \cdot 42$ | mean | 17.71 |
| Hearts with Kidneys | ... | 17.30) |  |  |
| Livers ... | ... | ... | ... | $14 \cdot 80$ |
| Spleens ... | ... | ... | ... | 38.21 |
| Kidneys ... ... | ... | ... | ... | $18 \cdot 80$ |

[^2]From these results we infer,
(a) That the average "healthy" organs are all lighter than those of the average general hospital population, and probably lighter than those of the general population as a whole. The weights are still, however, higher than those given by Peacock and Reid or by Clendinning.
(b) In passing from the mixed hospital population to the class of healthy organs, we find in every case the absolute variability is reduced, and by very large amounts indeed, the variability of the heart by over 50 p.c., and the other organs by amounts even 30 to 40 p.c. of their value.
(c) Relatively, the healthy spleen is still the most variable organ, and the heart comes second, but the kidneys are now close to the heart and the liver not very far behind. Disease appears to affect the weights of heart and spleen most, of livers and kidneys least.

We notice that onr value for the coefficient of variation of the healthy heart is now 17.7 as against the result deduced from Peacock and Reiề's measurement of 19.8 and for the liver 14.8 as against their $14.3^{*}$. We couldê̈̆hardly have anticipated such good agreement, and it certainly tends to confir $\frac{(1) ~ t h e ~ v a l u e ~ o f ~ t h e ~}{\text { a }}$ coefficient of variation as a fairly " steady" biometric constant.

## 4. Infuence of Age on the Weights of the Viscera.

I have first considered the change in the absolute weight of the adult male heart with age, and I have then investigated the influence of apon one set of correlations and variabilities, i.e those of heart and spleen.

Table VII. gives the correlation between age and weight of ${ }^{\text {beart }}$ in the case of health. We deduce the following values of the constants:

TABLE VII. Relationship of Weight of Healthy Hoart to Agẽ̛ Number 699.
Mean Heart $11 \cdot 13$ ozs. $\quad$ Standard Deviation 2015 ofa
Mean Age 40.23 years. Standard Deviation 8.500 years.
Correlation of Weight of Heart with $\Delta \mathrm{ge}=\cdot 1363 \pm 0950$.
There is thus a distinctly sensible increase of heart weight $\sum_{\substack{2}}$ health with age, the coefficient of correlation is more than five times its probable error. Still the correlation is smaller than what we might possibly have anticipated. Calculating the regression line we have, if $H_{p}$ be the probable weight of heart in ozs., and $A$ the age in years:

$$
H_{p}=9 \cdot 8322+0323 \mathrm{~A} .
$$

$$
\begin{aligned}
& \stackrel{\omega}{\check{0}} \\
& \stackrel{\rightharpoonup}{u}
\end{aligned}
$$

Thus the average henlthy heart gains about $\frac{1}{3}$ oz per ten years. For example we have:

[^3]Average weight of Heart at 20 years is 10.48 ozs.

| $"$ | $"$ | $"$ | 30 | $n$ | $"$ | 10.80 | $"$ |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| $"$ | $"$ | $"$ | 40 | $"$ | $"$ | 11.12 | $"$ |
| $"$ | $"$ | $"$ | 50 | $\prime$ | $"$ | 11.45 | $"$ |
| $"$ | $"$ | $"$ | 60 | $"$ | $"$ | 11.77 | $"$ |

As far as I am aware, the correlation between age and weight of body in adult males is unknown. We should $d$ priori expect it to be greater than the above, but it is always dangerous to judge without actual data The correlation between stature and age is known, and is actually negative; the stature of the adult male diminishing by about $\frac{f}{f}$ inch for ten years after his prime at 28 years $\dagger$. We thus conclude that while the stature decreases by $\frac{1}{f}$ unit, the heart increases by $\frac{f}{8}$ unit per ten years.

When we remember that the healthy heart is on the average much smaller than the heart in disease, and that sickness on the average increases continuously with age ${ }_{+}^{+}$, we shall probably lay less emphasis on the general $d$ priori idea that the weight of the adult heart increases very sensibly with age alone.

For my second inquiry I had unfortunately not sufficient material to divide my healthy hearts into three age groups and thus determine the influence of age on variability and correlation. I should have got less than 180 cases for each table. I was thus reluctantly compelled to deal with hearts in the general hospital population.

I divided them into three groups, ages $25-35,35-45$, and $45-55$. The following results were reached:

## Age Influence on Hearts and Spleens of General Hospital Population.

TABLE VIII. Hoarts and Splions. Ages 25-35. Number 358.
Mean Heart 11.91 ozs. Standard Deviation 3997 oses
Mean Spleen 7.45 ors. Standard Deviation 3.758 ozs. Correlation of Heart and Spleen $=0785 \pm 0384$.

TABLE IX. Hearts and Spleons. Ages 35-45. Number 530.
Mean Heart $13 \cdot 16$ 0zs. Standard Deviation 4018 ozs
Mean Spleen 6.60 ozs. Standard Deviation 3.428 ozs.
Correlation of Heart and Spleen $=\cdot 1817 \pm 0282$.
TABLE X. Hoarts and Sploens Ages 45-b5. Number 403.
Mean Heart 1365 ozzs Standard Deviation 4.425 oss Mean Spleen 6.21 ozs. Standard Deviation 3.120 ozs. Correlation of Heart and Spleen $=2518 \pm 0315$.

[^4]Forming as before a table of coefficients of variation，we have：

#### Abstract

TABLE $C$. Relative Variabilities of Genoral Hospital Population of Hearts and Spleons at different Ages．

| Organ | Coeflicient of Variation | Organ | Coeffloient of Variation |
| :---: | :---: | :---: | :---: |
| Heart，25－35 | 32.79 | Spleen，25－35 | 50.42 |
| Heart，35－45 | $30 \cdot 63$ | Spleen，35－45 | 51.97 |
| Heart，45－65 | 32.48 | Spleen，45－55 | $50 \cdot 24$ |

We can draw some important results from the above constanta．
（a）The heart in the general hospital population of adulto⿳亠丷厂彡⿱㇒⿻二亅㇒ increases far more rapidly with age than it does in the class of healthy hearts．＂On the other hand the weight of the spleen sensibly decreases．
$\stackrel{\stackrel{\rightharpoonup}{\circ}}{\stackrel{\rightharpoonup}{\circ}}$
（b）The absolute variability of the heart increases 10 per cent．，and the absolute variability of the spleen decreases 17 per cent．during thê period considered． These are quite sensible changes．Thus，while the heart tends to grow larger and more variable，the spleen tends to grow smaller and less varia
（c）If we deal with relative variation as judged by the coefficient of variation， we see that the changes referred to under（a）and（b）almastabalance each other． Or，the relative variabilities of both heart and spleen remain sensible constants with age and equal to the values found for the general hospital population of adults of all ages in Table A，p．66．This is further evidence of the real value of the coefficient of variation as a biometric measure of variability．
（d）The correlation between heart and spleen steadily increases with age．In the first period it is comparatively small，in the second peripd it has much the same value as in the general hospital population of adults（see p．65），and in the third period it approaches the value found for healthy adults．

These results are quite reasonable．As death below the age of 35 is generally aboormal＊，we ahould expect to find that the coefficient of correlation was low． Over the age of 45 years there is a slow deterioration of all ôrgans．There is no evidence to show that this degeneration is much more acute in any one of the organs we are considering than in any other．Therefore，although the absolute weights will differ from the normal，the correlation may be the same，and this we see that it actually is．

[^5]
## 5. Influence of Special Diseases on the Cardiac Biometric Constants.

We are now in a position to consider the effect of some special diseases on the weight and correlations of the heart. Unfortunately, scantiness of material and pressure on my time hindered my developing this most interesting branch of my subject very fully in the present paper. I shall hope to give it further consideration in another communication. I have confined my attention here to the heart and spleen weights, variabilities, and correlations in the case of two disease groups. First, Pneumonia (excluding tubercular disease); secondly, Valvular Disease of the Heart and Aortic Aneurism. I regret that the total number of cases available is small.

TABLE XL Hearts and Spleors. Casce of Prewmonica Number 177.
Mean Heart 18.50 ozs Standard Deviation 2.768 oss
Mean Splean 6.59 ozs. Standard Deviation 2.842 ozs Correlation of Heart and Spleen $=\cdot 1065 \pm 0501$.

TABLE XII. Hearts and Spleons. Casce of Valvular Disease and Aortic Aneurism. Number 168.
Mean Heart 19-08 oss Standard Deviation $5-950$ oss. Mean Spleen 8.57 ozs $\quad$ Standard Deviation 5.158 ozs, Correlation $=0558 \pm 0529$.
Forming as before a table for relative variabilities:
TABLE D.
Relative Variabilities of Heart and Spleen undor Special Diseases.

| Direase | Organ | Oomfficient of Variation |
| :---: | :---: | :---: |
| Pneumonia | Heart | $28 \cdot 15$ |
| Valvular Disease and Aortic Aneurism | Heart | $31 \cdot 18$ |
| Pneumonia $\quad . .$. | Spleen | $43 \cdot 18$ |
| Valvular Disease and Aortic Aneurism | Spleen | $60 \cdot 16$ |

From these values of the constants we may draw the following conclusions:
(a) In cases of pneumonia the mean weight of the heart is above that of the healthy heart ( p .67 ), but slightly below that of the general hospital population heart (p. 65). The weight of the spleen is somewhat above that of the healthy spleen ( p .67 ), and only about equal to that of the general hospital population spleen (p. 65). The absolute variabilities of both heart and spleen in pneumonia are far lower than the values in the general hospital population, and only slightly higher than their values in the case of healthy organs. The same remark applies to relative variabilities, which are in the case of this disease somewhat higher than the healthy values, but considerably below those of the general hospital population. We must therefore conclude that pneumonia does not influence in a marked degree the average values or the variabilities of either heart or spleen weights. As it
does raise the variability somewhat, ie. introduces disturbances in the relationship, we are not surprised to find that it weakens, although again not in a very marked degree, the correlation between weights of heart and spleen.
(b) On the other hand, Valvular Disease and Aortic Aneurism send up the weights of both heart and spleen not only vastly above their healthy values, but markedly above the values for the general hospital population. Further, their absolute variabilities are increased considerably above the general hospital population values, and a fortiori above the healthy values. The coefficients of variation of both are also far above the values in health, and that for the spleen above the general hospital values. In the case of the heart, the mean has been sent up so high that although the absolute variability is considerably greater, the relative variability remains much the same. The general effect of these heart diseases is to render the correlation between heart and spleen hardly sensible.

If we may judge by these two cases the general effect of disease is to increase the variability of affected organs and reduce their correlation. This is absolutely in keeping with the sensible, but of course less marked, changes we find when we pass from a population with healthy organs to the general ${ }^{\circ} \mathrm{Cospital}$ population, which of course contains much disease.

## 6. Genoral Conclusions.

The present paper is chiefly intended as an illustratiồn of how effective biometric methods might be from the standpoint of medical 8 cience if only there were a systenatic collection on a large scale of normal and pathological data. Some definite conclusions, however, may yet be drawn, and some suggestions made on the basis of our numbers. We see sensible, if moderate, Elorrelations between the weights of heart, liver, spleen, and kidneys.

It may be somewhat difficult to understand why the heatt-kidney correlation is higher than that of the heart with any of the other organs. That the kidney should be more closely associated with the heart than the liver is possibly owing to its more subordinate functions. The liver is the seat of 80 many important processes that its immediate connection with the heart is notso great as that of the heart with the kidney. The excretion of fluids is so closely bound up with physical changes in the vascular asstem, and conversely changees in renal structure react so markedly upon the heart and blood vessels that a very close physical relationship appears probable. No doubt the liver is great产y affected in many forms of cardiac disease, but on the other hand serious functiơnal disturbances or even acute inflammation of the liver do not produce heart chฐ̊nges with the same precision as analogous mischief in the kidney does. If this partially and imperfectly accounts for the higher heart-kidney correlation as compared with the heart-liver coefficient, it may perhaps serve as an argument in the case of the spleen. Heart mischief nearly always reacte on the spleen, but splenic trouble does not always affect the heart.

If we consider in braad lines the general results of our investigation, we should say that they may be summed up in the statement that both special diseases and the general want of bealth to be found in a hospital population tend in the same directions, namely, to increase the variability of the organs dealt with and to reduce their correlation $A_{8}$ we pass from the general hospital population to a healthy population we find that variability sinks and correlation rises. To what extent this is an antecedent or concomitant of the diseased state it might not be almays possible to assert.

In taking any population, low variabilities and high correlations are the two factors which measure closeness to type. As a general rule, under a given environment closeness to type is a condition of stability, we may almost say, of low selective death-rate. Hence we may look upon disease as less stringent approach to type, and high variability and low correlation as a sign of instability*.

Of course the capacity to vary absolutely and to alter the relationship of organs must exist, or a race will not be able to effect a change in type with a changing environment. Still, if we trust the theory of correlation by natural selection at all, death before senility os far as it is selective is the destruction of the less fit, ie. of those not approaching within certain limits the type suitable to the environment. Thus it comes about that we shall expect on the Darwinian theory to find the individuals who die of disease in adult life to be more variable and less highly correlated in their organs than the "healthy." This is precisely what we do find, and the post-mortem room provides direct evidence in favour of the action of natural selection in the case of man. Indeed, in a not very conscious way the medical world has been expressing these very truths of evolution in other words. The figures we have considered showing lowered correlation in the diseased state are a biometric illustration of the truth of Dr Sutton's aphorism, "Disease is absence of rhythmt." In the normal or healthy group we see a population possessing the characteristic marks of stability, small variability, and high correlation. In the two special and the general diseased groups we have conditions tending in the opposite sense. In the healthy class we get a closer quantitative relationship between the weights of the viscera, in the diseased there is greater variety of proportions. Indeed, to adopt a well-worn definition, "Among the diseased each organ has a life and growth of ite own, irrespective of the needs of the organism as a whole." Our biometric investigation shows us this independent life and growth leading to increased varisbility and to lessened correlation, shortly, to those deviatious from type which beyond certain limits are incompatible with survival under a given environment $\ddagger$.

[^0]:    * Clendinning's results are quoted in the English teat-books, and also in Grisolle's Traite de Puthologie Interne (9th Ed. p. 200, Vol. II.). See also, K. Pearson: "Varistion in Man and Woman" (Chances of Death and other Studies in Evolution, Vol. 1. p. B16); Peacook and Reid : London and Edinburgh Monthly Journal of Medical Science, 1848-6, 1854.

[^1]:    - L. H. Patk. Reports, 1899, No. 661.
    †"In ne fant jamais négliger de peser les órganes, surtont ceux qui sont atteints de lésions pathologiques; le poids foarnit souvent an effet des renseignements precieax sar le degré et sar l'importance des lesions; on n'oubliers pas cependant qu'il existe sur ce point des variations individuelles considérables....... Le poids total da enjet, la taille, l'áge, le sexe sont tout autant de conditions qui font varier le poids des organes enx-mênes." (Bard: Prteis d'dnat. Path. p. 736.)

[^2]:    *The mean value of the right kidney of 100 malas 80 to 65 years of age, as deduced by Pearson from Reid and Peacock's values, is $5 \cdot 57$ ozs.

[^3]:    * Pearson (The Chances of Death, Vol. 1. p. 818) gives $20-49$ for the coeffiejent of varistion of the right kidney as deduced from Peacock and Reld's measurements, as agsinst my values of 16.80 for healthy and $24 \cdot 68$ for general hospital weights of both kidneys.

[^4]:    * Clendinning gives, Ages 16-29, 81 oxs.; 80-60, 01 oxs.; 50-60,10t ozs. Med. Chirarg. Trans. 1888. See also Peacock and Reid, op. cit.
    $\dagger$ Biometrika, Vol. 1. pp. 46-9.
    $\ddagger$ Biometrika, Vol. I. pp. 260 et seq.

[^5]:    ＊By＂abnormal＂is meant bere a death due to disease；the result of an accident would be from this point of riew a normal death，as probably leaving the viscora＂bealthy＂onder port－morters record．

[^6]:    - In the evolution of subspecies it seems probable that the hardiest and most prolifio gronpa have the least coefficients of variation. Thus in an investigation recently made by Mr A. Bacot and the author on the variability of Spilosoma Urticae, it was found that in several series of broods the groaps Fith the largest coafficients of variation had the least net fertility.
    $\dagger$ Nedical Pathology, 1886, p. 95 et seq.
    $\ddagger$ I desire to take this opportunity of expressing my gratitude to Prof. Karl Pearson, to whose staff, among other acts of hindness, I owe the correction of many arithmetical slips in the above results. Anything of interest in this esaey is dae, either directly or indirectly, to him.
