XXXVI.-An Account of Carnot's Theory of the Motive Power of Heat;* with Numerical Results deduced from Regnault's Experiments on Steam. $\dagger$ By William Thomson, Professor of Natural Philosophy in the University of Glasgow.
(Read January 2, 1849.)

1. The presence of heat may be recognised in every natural object; and there is scarcely an operation in nature which is not more or less affected by its allpervading influence. An evolution and subsequent absorption of heat generally give rise to a variety of effects; among which may be enumerated, chemical combinations or decompositions; the fusion of solid substances; the vaporisation of solids or liquids; alterations in the dimensions of bodies, or in the statical pressure by which their dimensions may be modified; mechanical resistance overcome; electrical currents generated. In many of the actual phenomena of nature, several or all of these effects are produced together; and their complication will, if we attempt to trace the agency of heat in producing any individual effect, give rise to much perplexity. It will, therefore, be desirable, in laying the foundation of a physical theory of any of the effects of heat, to discover or to imagine phenomena free from all such complication, and depending on a definite thermal agency; in which the relation between the cause and effect, traced through the medium of certain simple operations, may be clearly appreciated. Thus it is that Carnot, in accordance with the strictest principles of philosophy, enters upon the investigation of the theory of the motive power of heat.
2. The sole effect to be contemplated in investigating the motive power of heat is resistance overcome, or, as it is frequently called, "nork performed," or " mechanical effect." The questions to be resolved by a complete theory of the subject are the following:
(1.) What is the precise nature of the thermal agency by means of which mechanical effect is to be produced, without effects of any other kind?

[^0](2.) How may the amount of this thermal agency necessary for performing a given quantity of work be estimated?
3. In the following paper I shall commence by giving a short abstract of the reasoning by which Carnot is led to an answer to the first of these questions; I shall then explain the investigation by which, in accordance with his theory, the experimental elements necessary for answering the second question are indicated; and, in conclusion, I shall state the data supplied by Regnault's recent observations on steam, and apply them to obtain, as approximately as the present state of experimental science enables us to do, a complete solution of the question.
I. On the nature of Thermal agency, considered as a motive power.
4. There are [at present known] two, and only two, distinct ways in which mechanical effect can be obtained from heat. One of these is by means of the alterations of volume which bodies may experience through the action of heat; the other is through the medium of electric agency. Seebeck's discovery of thermo-electric currents enables us at present to conceive of an electro-magnetic engine supplied from a thermal origin, being used as a motive power: but thi s discovery was not made until 1821, and the subject of thermo-electricity can only have been generally known in a few isolated facts, with reference to the electrical effects of heat upon certain crystals, at the time when Carnot wrote. He makes no allusion to it, but confines himself to the method for rendering thermal agency available as a source of mechanical effect, by means of the expansions and contractions of bodies.
5. A body expanding or contracting under the action of force, may, in general, either produce mechanical effect by overcoming resistance, or receive mechanical effect by yielding to the action of force. The amount of mechanical effect thus developed will depend not only on the calorific agency concerned, but also on the alteration in the physical condition of the body. Hence, after allowing the volume and temperature of the body to change, we must restore it to its original temperature and volume; and then we may estimate the aggregate amount of mechanical effect developed as due solely to the thermal origin.
6. Now the ordinarily-received, and almost universally-acknowledged, principles with reference to "quantities of caloric" and "latent heat," lead us to conceive that, at the end of a cycle of operations, when a body is left in precisely its primitive physical condition, if it has absorbed any heat during one part of the operations, it must have given out again exactly the same amount during the remainder of the cycle. The truth of this principle is considered as axiomatic by Carnot, who admits it as the foundation of his theory; and expresses himself in the following terms regarding it, in a note on one of the passages of his treatise.*

[^1]" In our demonstrations we tacitly assume that after a body has experienced a certain number of transformations, if it be brought identically to its primitive physical state as to density, temperature, and molecular constitution, it must contain the same quantity of heat, as that which it initially possessed; or, in other words, we suppose that the quantities of heat lost by the body under one set of operations are precisely compensated by those which are absorbed in the others. This fact has never been doubted; it has at first been admitted without reflection, and afterwards verified, in many cases, by calorimetrical experiments. To deny it would be to overturn the whole theory of heat, in which it is the fundamental principle. It must be admitted, however, that the chief foundations on which the theory of heat rests, would require a most attentive examination. Several experimental facts appear nearly inexplicable in the actual state of this theory."
7. Since the time when Carnot thus expressed himself, the necessity of a most careful examination of the entire experimental basis of the theory of heat has become more and more urgent. Especially all those assumptions depending on the idea that heat is a substance, invariable in quantity; not convertible into any other element, and incapable of being generated by any physical agency; in fact the acknowledged principles of latent heat; would require to be tested by a most searching investigation before they ought to be admitted, as they usually have been, by almost every one who has been engaged on the subject, whether in combining the results of experimental research, or in general theoretical investigations.
8. The extremely important discoveries recently made by Mr Joule of Manchester, that heat is evolved in every part of a closed electric conductor, moving in the neighbourhood of a magnet,* and that heat is generated by the friction of fluids in motion, seem to overturn the opinion commonly held that heat cannot be generated, but only produced from a source, where it has previously existed either in a sensible or in a latent condition.

[^2]In the present state of science, however, no operation is known by which heat can be absorbed into a body without either elevating its temperature, or becoming latent, and producing some alteration in its physical condition; and the fundamental axiom adopted by Carnot may be considered as still the most probable basis for an investigation of the motive power of heat ; although this, and with it every other branch of the theory of heat may ultimately require to be reconstructed upon another foundation, when our experimental data are more complete. On this understanding, and to avoid a repetition of doubts, I shall refer to Carnot's fundamental principle, in all that follows, as if its truth were thoroughly established.
9. We are now led to the conclusion that the origin of motive power, developed by the alternate expansions and contractions of a body, must be found in the agency of heat entering the body and leaving it; since there cannot, at the end of a complete cycle, when the body is restored to its primitive physical condition, have been any absolute absorption of heat, and consequently no conversion of heat, or caloric, into mechanical effect; and it remains for us to trace the precise nature of the circumstances under which heat must enter the body, and afterwards leave it, so that mechanical effect may be produced. As an example, we may consider that machine for obtaining motive power from heat with which we are most familiar-the steam-engine.
10. Here, we observe, that heat enters the machine from the furnace, through the sides of the boiler, and that heat is continually abstracted by the water employed for keeping the condenser cool. According to Carnot's fundamental principle, the quantity of heat thus discharged, during a complete revolution (or double stroke) of the engine must be precisely equal to that which enters the water of the boiler ;* provided the total mass of water and steam be invariable, and be restored to its primitive physical condition (which will be the case rigorously, if the condenser be kept cool by the external application of cold water, instead of by injection, as is more usual in practice), and if the condensed water be restored to the boiler at the end of each complete revolution. Thus, we perceive, that a certain quantity of heat is let down from a hot body, the metal of the boiler, to another body at a lower temperature, the metal of the condenser; and that there results from this transference of heat, a certain development of mechanical effect.
11. If we examine any other case in which mechanical effect is obtained from a thermal origin, by means of the alternate expansions and contractions of any substance whatever, instead of the water of a steam-engine, we find that a similar transference of heat is effected, and we may therefore answer the first question proposed, in the following manner:-

The thermal agency by which mechanical effect may be obtained, is the transference of heat from one body to another at a lower temperature.

[^3]II. On the measurement of Thermal Agency, considered with reference to its equivalent of mechanical affect.
12. A perfect thermo-dynamic engine of any kind, is a machine by means of which the greatest possible amount of mechanical effect can be obtained from a given thermal agency; and, therefore, if in any manner we can construct or imagine a perfect engine which may be applied for the transference of a given quantity of heat from a body at any given temperature, to another body, at a lower given temperature, and if we can evaluate the mechanical effect thus obtained, we shall be able to answer the question at present under consideration, and so to complete the theory of the motive power of heat. But whatever kind of engine we may consider with this view, it will be necessary for us to prove that it is a perfect engine; since the transference of the heat from one body to the other may be wholly, or partially, effected by conduction through a solid,* without the development of mechanical effect; and, consequently, engines may be constructed in which the whole, or any portion of the thermal agency is wasted. Hence it is of primary importance to discover the criterion of a perfect engine. This has been done by Carnot, who proves the following proposition :-
13. A perfect thermo-dynamic engine is such that, nhatever amount of mechanical effect it can derive from a certain thermal agency; if an equal amount be spent in norking it backnards, an equal reverse thermal effect will be produced. $\dagger$
14. This proposition will be made clearer by the applications of it which are given below ( $\$ 29$ ), in the cases of the air-engine and the steam-engine, than it could be by any general explanation; and it will also appear, from the nature of the operations described in those cases, and the principles of Carnot's reasoning, that a perfect engine may be constructed with any substance of an indestructible texture as the alternately expanding and contracting medium. Thus we might conceive thermo-dynamic engines founded upon the expansions

[^4]$\dagger$ For a demonstration, see § 29, below.
VOL. XVI. PART V.
and contractions of a perfectly elastic solid, or of a liquid; or upon thealterations of volume experienced by substances, in passing from the liquid to the solid state, 类 each of which being perfect, would produce the same amount of mechanical effect from a given thermal agency; but there are two cases which Carnot has selected as most worthy of minute attention, because of their peculiar appropriateness for illustrating the general principles of his theory, no less than on account of their very great practical importance ; the steam-engine, in which the substance employed as the transferring medium is water, alternately in the liquid state, and in the state of vapour ; and the air-engine, in which the transference is effected by means of the alternate expansions and contractions of a medium, always in the gaseous state. The details of an actually practicable engine of either kind are not contemplated by Carnot, in his general theoretical reasonings, but he confines himself to the ideal construction, in the simplest possible way in each case, of an engine in which the economy is perfect. He thus determines the degree of perfectibility which cannot be surpassed; and, by describing a conceivable method of attaining to this perfection by an air-engine or a steam-engine, he points out the proper objects to be kept in view in the practical construction and working of such machines. I now proceed to give an outline of these investigations.

## Carnot's Theory of the Steam-Engine.

15. Let $\mathrm{CDF}_{2} \mathrm{E}_{2}$ be a cylinder, of which the curved surface is perfectly impermeable to heat, with a piston also impermeable to heat, fitted in it; while the fixed bottom CD, itself with no capacity for heat, is possessed of perfect conducting power. Let K be an impermeable stand, such that when the cylinder is placed upon it, the contents below the piston can neither gain nor lose heat. Let $A$ and $B$ be two bodies permanently retained at constant temperatures, $\mathrm{S}^{0}$ and $\mathrm{T}^{0}$, respectively, of which the former is higher than the latter. Let the cylinder, placed on the impermeable stand, $K$, be partially filled with water, at the temperature $S$, of the body $A$, and (there being no air below it) let the piston be placed in a position E F, near the surface of the water. The

[^5]pressure of the vapour above the water will tend to push up the piston, and must be resisted by a force applied to the piston, * till the commencement of the operations, which are conducted in the following manner.
(1.) The cylinder being placed on the body A, so that the water and vapour may be retained at the temperature S , let the piston rise any convenient height $\mathbf{E} \mathrm{E}_{1}$, to a position $\mathrm{E}_{1} \mathrm{~F}_{1}$, performing work by the pressure of the vapour belom it during its ascent.
[During this operation a certain quantity, H , of heat, the amount of latent heat in the fresh vapour which is formed, is abstracted from the body $A^{2}$.]
(2.) The cylinder being removed, and placed on the impermeable stand K, let the piston rise gradually, till, when it reaches a position $\mathrm{E}_{2} \mathrm{~F}_{2}$, the temperature of the nater and vapour is $\mathbf{T}$, the same as that of the body $\mathbf{B}$.

#### Abstract

[During this operation the fresh vapour continually formed requires heat to become latent; and, therefore, as the contents of the cylinder are protected from any accession of heat, their temperature sinks.] (3.) The cylinder being removed from K , and placed on B , let the piston be pushed down, till, nhen it reaches the position $\mathrm{E}_{3} \mathrm{~F}_{3}$, the quantity of heat exolved and abstracted by B amounts to that which, during the first operation, was taken from A .

> [During this operation the temperature of the contents of the cylinder is retained constantly at $\mathrm{T}^{0}$, and all the latent heat of the vapour which is condensed into water at the same temperature, is given out to $B$.
(4.) The cylinder being removed from $B$, and placed on the impermeable stand, let the piston be pushed down from $\mathrm{E}_{3} \mathrm{~F}_{3}$ to its original position E F.
[During this operation, the impermeable stand preventing any loss of heat, the temperature of the water and air must rise continually, till (since the quantity of heat evolved during the third operation was precisely equal to that which was previously absorbed), at the conclusion it reaches its primitive valne, S , in virtue of Carnot's fundamental axiom.]
16. At the conclusion of this cycle of operations $\dagger$ the total thermal agency has been the letting down of H units of heat from the body $A$, at the temperature S , to B , at the lower temperature T ; and the aggregate of the mechanical effect has been a certain amount of nork produced, since during the ascent of the piston in the first and second operations, the temperature of the water and vapour, and therefore the pressure of the vapour on the piston, was on the whole higher than during the descent, in the third and fourth operations. It remains for us actually to evaluate this aggregate amount of work performed; and for this purpose the

[^6]following graphical method of representing the mechanical effect developed in the several operations, taken from Mons. Clapeyron's paper, is extremely convenient.
17. Let $O X$ and $O Y$ be two lines at right angles to one another. Along O X measure off distances $0 \mathrm{~N}_{i}, \mathrm{~N} \mathrm{~N}_{2}$, $\mathrm{N}_{2} \mathrm{~N}_{3}, \mathbf{N}_{3} \mathrm{O}$, respectively proportional to the spaces described by the piston during the four successive operations described above; and, with reference to these four operations respectively, let the following constructions be
 made :-
(1.) Along OY measure a length OA , to represent the pressure of the saturated vapour at the temperature $S$; and draw $\mathrm{A}_{1}$ parallel to OX , and let it meet an ordinate through $\mathrm{N}_{1}$, in $\mathrm{A}_{2}$.
(2.) Draw a curve $A_{1} P$ A such that, if $O N$ represent, at any instant during the second operation, the distance of the piston from its primitive position, N P shall represent the pressure of the vapour at the same instant.
(3.) Through $\mathrm{A}_{2}$ draw $\mathrm{A}_{2} \mathrm{~A}_{3}$ parallel to OX , and let it meet an ordinate through $\mathrm{N}_{3}$ in $\mathrm{A}_{3}$.
(4.) Draw the curve $A_{3} A$ such that the abscissa and ordinate of any point in it may represent respectively the distances of the piston from its primitive position, and the pressure of the vapour, at some instant during the fourth operation. The last point of this curve must, according to Carnot's fundamental principle, coincide with $A$, since the piston is, at the end of the cycle of operations, again in its primitive position, and the pressure of the vapour is the same as it was at the beginning.
18. Let us now suppose that the lengths, $\mathrm{ON}_{1}, \mathrm{~N}_{1} \mathrm{~N}_{2}, \mathrm{~N}_{2} \mathrm{~N}_{3}$, and $\mathrm{N}_{i j} \mathrm{O}$, represent numerically the volumes of the spaces moved through by the piston during the successive operations. It follows that the mechanical effect obtained during the first operation will be numerically represented by the area $A_{1} \mathrm{~N}_{1} \mathrm{O}$; that is, the number of superficial units in this area will be equal to the number of "footpounds" of work performed by the ascending piston during the first operation. The work performed by the piston during the second operation will be similarly represented by the area $A_{1} A_{2} N_{2} N_{1}$. Again, during the third operation a certain amount of work is spent on the piston, which will be represented by the area $A_{3} A_{3} N_{3} N_{2}$; and lastly, during the fourth operation, work is spent in pushing the piston to an amount represented by the area $\mathrm{A}_{3} \mathrm{AON}_{3}$.
19. Hence the mechanical effect (represented by the area $0 A_{1} \mathrm{~A}_{2} \mathrm{~N}_{2}$ ) which was obtained during the first and second operations, exceeds the work (represented by $N_{2} A_{2} A_{3} A 0$ ) spent during the third and fourth, by an amount represented by the area of the quadrilateral figure $\mathrm{AA}_{1} \mathrm{~A}_{2} \mathrm{~A}_{3}$; and, consequently, it
only remains for us to evaluate this area, that may determine the total mechanical effect gained in a complete cycle of operations. Now, from experimental data, at present nearly complete, as will be explained below, we may determine the length of the line $\mathrm{A} \mathrm{A}_{1}$ for the given temperature S , and a given absorption H , of heat, during the first operation ; and the length of $\mathrm{A}_{2} \mathrm{~A}_{3}$ for the given lower temperature $T$, and the evolution of the same quantity of heat during the fourth operation : and the curves $\mathrm{A}_{1} \mathrm{PA}_{2}, \mathrm{~A}_{3} \mathrm{P}^{\prime} \mathrm{A}$ may be drawn as graphical representations of actual observations.* The figure being thus constructed, its area may be measured, and we are, therefore, in possession of a graphical method of determining the amount of mechanical effect to be obtained from any given thermal agency. As, however, it is merely the area of the figure which it is required to determine, it will not be necessary to be able to describe each of the curves $\mathrm{A}_{1} \mathbf{P} \mathrm{~A}_{2} \mathrm{~A}_{3} \mathrm{P}^{\prime} \mathrm{A}$, but it will be sufficient to know the difference of the abscissas corresponding to any equal ordinates in the two; and the following analytical method of completing the problem is the most convenient for leading to the actual numerical results.
20. Draw any line $P P^{\prime}$ parallel to $O X$, meeting the curvilineal sides of the quadrilateral in P and $\mathrm{P}^{\prime}$. Let $\xi$ denote the length of this line, and $p$ its distance from $O X$. The area of the figure, according to the integral calculus, will be denoted by the expression
$$
\int_{p_{3}}^{p_{1}} \xi d p
$$
where $p_{1}$, and $p_{3}$ (the limits of integration indicated according to Fourier's notation) denote the lines OA , and $\mathrm{N}_{3} \mathrm{~A}_{3}$, which represent respectively the pressures during the first and third operations. Now, by referring to the construction described above, we see that $\xi$ is the difference of the volumes below the piston at corresponding instants of the second and fourth operations, or instants at which the saturated steam and the water in the cylinder have the same pressure $p$, and, consequently, the same temperature which we may denote by $t$. Again, throughout the second operation the entire contents of the cylinder possess a greater amount of heat by H units than during the fourth ; and, therefore, at any instant of the second operation there is as much more steam as contains $H$ units of latent heat, than at the corresponding instant of the fourth operation. Hen ce, if $k$ denote the latent heat in a unit of saturated steam at the temperature $t$, the volume of the steam at the two corresponding instants must differ by $\frac{H}{k}$. Now, if $\sigma$ denote the ratio of the density of the steam to that of the water, the volume $\frac{H}{k}$ of steam will be formed from the volume $\sigma \frac{\mathrm{H}}{k}$ of water; and, consequently, we have

[^7]VOL. XVI. PART V.
for the difference of volumes of the entire contents at the corresponding instants,

$$
\xi=(1-\sigma) \frac{\mathrm{H}}{k} .
$$

Hence the expression for the area of the quadrilateral figure becomes

$$
\int_{p_{3}}^{p_{1}}(1-\sigma) \frac{\mathrm{H}}{k} d p
$$

Now, $\sigma, k$, and $p$, being quantities which depend upon the temperature, may be considered as functions of $t$; and it will be convenient to modify the integral so as to make $t$ the independent variable. The limits will be from $t=\mathrm{T}$ to $t=\mathrm{S}$, and, if we denote by $M$ the value of the integral, we have the expression

$$
\begin{equation*}
\mathrm{M}=\mathrm{H} \int_{\mathrm{T}}^{\mathrm{S}}(1-\sigma) \frac{\frac{d p}{d t}}{k} d t \tag{1}
\end{equation*}
$$

for the total amount of mechanical effect gained by the operations described above.
21. If the interval of temperatures be extremely small; so small that $(1-\sigma) \frac{\frac{d p}{d t}}{k}$ will not sensibly vary for values of $t$ between $T$ and S , the preceding expresssion becomes simply

$$
\begin{equation*}
\mathrm{M}=(1-\sigma) \frac{\frac{d p}{d t}}{k} \cdot \mathrm{H}(\mathrm{~S}-\mathrm{T}) \ldots \ldots \tag{2}
\end{equation*}
$$

This might, of course, have been obtained at once, by supposing the breadth of the quadrilateral figure $\mathrm{AA}_{1} \mathrm{~A}_{2} \mathrm{~A}$ to be extremely small compared with its length, and then taking for its area, as an approximate value, the product of the breadth into the line $\mathrm{A}_{1}$, or the line $\mathrm{A}_{3} \mathrm{~A}_{2}$, or any line of intermediate magnitude.

The expression (2) is rigorously correct for any interval S-T, if the mean value of $(1-\sigma) \frac{d p}{k}$ for that interval be employed as the coefficient of $\mathrm{H}(\mathrm{S}-\mathrm{T})$. Carnot's Theory of the Air-Engine.
22. In the ideal air-engine imagined by Carnot four operations performed upon a mass of air or gas enclosed in a closed vessel of variable volume, constitute a complete cycle, at the end of which the medium is left in its primitive physical condition; the construction being the same as that which was described above for the steam-engine, a body A, permanently retained at the temperature $S$, and $B$ at the temperature $T$; an impermeable stand $K$; and a cylinder and piston, which, in this case, contains a mass of air at the temperature $S$, instead of
water in the liquid state, at the beginning and end of a cycle of operations. The four successive operations are conducted in the following manner :-
(1.) The cylinder is laid on the body $A$, so that the air in it is kept at the temperature S ; and the piston is allowed to rise, performing work.
(2.) The cylinder is placed on the impermeable stand $K$, so that its contents can neither gain nor lose heat, and the piston is allowed to rise farther, still performing work, till the temperature of the air sinks to T.
(3.) The cylinder is placed on $B$, so that the air is retained at the temperature T , and the piston is pushed down till the air gives out to the body B as much heat as it had taken in from $A$, during the first operation.
(4.) The cylinder is placed on $K$, so that no more heat can be taken in or given out, and the piston is pushed down to its primitive position.
23. At the end of the fourth operation the temperature must have reached its primitive value S , in virtue of Carnot's axiom.
24. Here, again, as in the former case, we observe that work is performed by the piston during the first two operations; and, during the third and fourth, work is spent upon it, but to a less amount, since the pressure is on the whole less during the third and fourth operations than during the first and second, on account of the temperature being lower. Thus, at the end of a complete cycle of operations, mechanical effect has been obtained; and the thermal agency from which it is drawn is the taking of a certain quantity of heat from A, and letting it down, through the medium of the engine, to the body $B$ at a lower temperature.
25. To estimate the actual amount of effect thus obtained, it will be convenient to consider the alterations of volume of the mass of air in the several operations as extremely small. We may afterwards pass by the integral calculus, or, practically, by summation, to determine the mechanical effect whatever be the amplitudes of the different motions of the piston.
26. Let $d q$ be the quantity of heat absorbed during the first operation, which is evolved again during the third; and let $d v$ be the corresponding augmentation of volume which takes places while the temperature remains constant, as it does during the first operation.* The diminution of volume in the third operation must be also equal to $d v$, or only differ from it by an infinitely small

[^8]quantity of the second order. During the second operation we may suppose the volume to be increased by an infinitely small quantity $\varphi$; which will occasion a diminution of pressure, and a diminution of temperature, denoted rerespectively by $\omega$ and $\tau$. During the fourth operation there will be a diminution of volume, and an increase of pressure and temperature, which can only differ, by infinitely small quantities of the second order, from the changes in the other direction, which took place in the second operation, and they also may, therefore, be denoted by $\varphi, \omega$, and $\tau$, respectively. The alteration of pressure, during the first and third operations, may at once be determined by means of Mariotre's law, since, in them, the temperature remains constant. Thus, if, at the commencement of the cycle, the volume and pressure be $v$ and $p$, they will have become $v+d v$ and $p \frac{v}{v+d v}$ at the end of the first operation. Hence the diminution of pressure, during the first operation, is $p-p \frac{v}{v+d v}$ or $p \frac{d v}{v+d v}$; and, therefore, if we neglect infinitely small quantities of the second order, we have $p \frac{d v}{v}$ for the diminution of pressure during the first operation; which, to the same degree of approximation, will be equal to the increase of pressure during the third. If $t+\tau$ and $t$ be taken to denote the superior and inferior limits of temperature, we shall thus have for the volume, the temperature, and the pressure at the commencements of the four successive operations, and at the end of the cycle, the following values respectively:-

| (1.) | $v$, | $t+\pi$, | $p ;$ |
| :--- | :--- | :--- | :--- |
| (2.) | $v+d v$, | $t+\tau$, | $p\left(1-\frac{d v}{v}\right) ;$ |
| (3.) | $v+d v+\varphi$, | $t$, | $p\left(1-\frac{d v}{v}\right)-\omega ;$ |
| (4.) | $v+\varphi$, | $t$, | $p-\omega ;$ |
| (5.) | $v$, | $t+\tau$, | $p$. |

Taking the mean of the pressures at the beginning and end of each operation, we find

$$
\begin{align*}
& p\left(1-\frac{d v}{\frac{1}{2}}\right)  \tag{1.}\\
& p\left(1-\frac{d v}{v}\right)-\frac{1}{2} \omega \tag{2.}
\end{align*}
$$

$$
\begin{equation*}
\text { (4.) } \quad p-\frac{1}{2} \omega, \tag{3.}
\end{equation*}
$$

which, as we are neglecting infinitely small quantities of the second order, will be
the expressions for the mean pressures during the four successive operations. Now, the mechanical effect gained or spent, during any of the operations, will be found by multiplying the mean pressure by the increase or diminution of volume which takes places; and we thus find

$$
\begin{align*}
& p\left(1-\frac{1}{2} \frac{d v}{v}\right) d v  \tag{1.}\\
& \left\{p\left(1-\frac{d v}{v}\right)-\frac{1}{2} \omega\right\} \varphi  \tag{2.}\\
& \left\{p\left(1-\frac{1}{2} \frac{d v}{v}\right)-\omega\right\} d v  \tag{3.}\\
& \left(p-\frac{1}{2} \omega\right) \varphi \tag{4.}
\end{align*}
$$

for the amounts gained during the first and second, and spent during the third and fourth operations; and hence, by addition and subtraction, we find

$$
\omega d v-p \varphi \frac{d v}{v}, \text { or }(v \omega-p \varphi) \frac{d v}{v},
$$

for the aggregate amount of mechanical effect gained during the cycle of operations. It only remains for us to express this result in terms of $d q$ and $\pi$, on which the given thermal agency depends. For this purpose, we remark that $\varphi$ and $\omega$ are alterations of volume and pressure which take place along with a change of temperature $\tau$, and hence, by the laws of compressibility and expansion, we may establish a relation* between them in the following manner.

Let $p_{0}$ be the pressure of the mass of air when reduced to the temperature zero, and confined in a volume $v_{0}$; then, whatever be $v_{0}$, the product $p_{0} v_{0}$ will, by the law of compressibility, remain constant; and, if the temperature be elevated from 0 to $t+\tau$, and the gas be allowed to expand freely without any change of pressure, its volume will be increased in the ratio of 1 to $1+\mathrm{E}(t+\tau)$, where E is very nearly equal to 00366 (the centigrade scale of the air-thermometer being referred to), whatever be the gas employed, according to the researches of Reqnault and of Magnus on the expansion of gases by heat. If, now, the volume be altered arbitrarily with the temperature continually at $t+\pi$, the product of the pressure and volume will remain constant; and, therefore, we have

Similarly

$$
\begin{gathered}
p v=p_{0} v_{0}\{1+\mathrm{E}(t+r)\} . \\
(p-\omega)(v+\varphi)=p_{0} v_{0}\{1+\mathrm{E} t\} .
\end{gathered}
$$

Hence, by subtraction, we have

$$
v \omega-p \varphi+\omega \varphi=p_{0} v_{0} \mathrm{E} \tau,
$$

or, neglecting the product $\omega \varphi$,

$$
v \omega-p \varphi=p_{0} v_{0} \mathrm{E} \tau
$$

[^9]Hence, the preceding expression for mechanical effect, gained in the cycle of operations, becomes

$$
p_{0} v_{0} \cdot \operatorname{Er} \cdot \frac{d v}{v},
$$

Or, as we may otherwise express it,

$$
\frac{\mathrm{E} p_{0} v_{0}}{v \frac{d q}{d v}} \cdot d q \cdot \tau
$$

Hence, if we denote by M the mechanical effect due to H units of heat descending through the same interval $\approx$, which might be obtained by repeating the cycle of operations described above, $\frac{\mathrm{H}}{d q}$ times, we have

$$
\begin{equation*}
\mathrm{M}=\frac{\mathrm{E} p_{0} \boldsymbol{v}_{0}}{v \frac{d q}{d \boldsymbol{v}}} \cdot \mathrm{H} \tag{3}
\end{equation*}
$$

27. If the amplitudes of the operations had been finite, so as to give rise to an absorption of $H$ units of heat during the first operation, and a lowering of temperature from $S$ to $T$ during the second, the amount of work obtained would have been found to be expressed by means of a double definite integral, thus ;*-
or

$$
\begin{align*}
& \mathrm{M}=\int_{0}^{\mathrm{H}} d q \int_{\mathrm{T}}^{\mathrm{S}} d t \cdot \frac{\mathrm{E} p_{0} v_{0}}{v \frac{d q}{d v}}  \tag{4}\\
& \mathrm{M}=\mathrm{E} p_{0} v_{0} \int_{0}^{\mathrm{H}} \int_{\mathrm{T}}^{\mathrm{S}} \frac{1}{v} \frac{d v}{d q} \cdot d t d q ;
\end{align*}
$$

this second form being sometimes more convenient.
28. The preceding investigations, being founded on the approximate laws of compressibility and expansion (known as the law of Mariotte and Boyle, and the law of Dalton and Gay-Lussac), would require some slight modifications, to adapt them to cases in which the gaseous medium employed is such as to present sensible deviations from those laws. Regnault's very accurate experiments shew that the deviations are insensible, or very nearly so, for the ordinary gases at ordinary pressures; although they may be considerable for a medium, such as

[^10]sulphurous acid, or carbonic acid under high pressure, which approaches the physical condition of a vapour at saturation; and therefore, in general, and especially in practical applications to real air-engines, it will be unnecessary to make any modification in the expressions. In cases where it may be necessary, there is no difficulty in making the modifications, when the requisite data are supplied by experiment.
29.* Either the steam-engine or the air-engine, according to the arrangements described above, gives all the mechanical effect that can possibly be obtained from the thermal agency employed. For it is clear, that, in either case, the operations may be performed in the reverse order, with every thermal and mechanical effect reversed. Thus, in the steam-engine, we may commence by placing the cylinder on the impermeable stand, allow the piston to rise, performing work, to the position $\mathrm{E}_{3} \mathrm{~F}_{3}$; we may then place it on the body B , and allow it to rise, performing work, till it reaches $\mathrm{E}_{2} \mathrm{~F}_{2}$; after that the cylinder may be placed again on the impermeable stand, and the piston may be pushed down to $\mathrm{E}_{1} \mathrm{~F}_{1}$; and, lastly. the cylinder being removed to the body $A$, the piston may be pushed down to its primitive position. In this inverse cycle of operations, a certain amount of work has been spent, precisely equal, as we readily see, to the amount of mechanical effect gained in the direct cycle described above; and heat has been abstracted from B , and deposited in the body A , at a higher temperature, to an amount precisely equal to that which, in the direct cycle, was let down from A to B. Hence it is impossible to have an engine which will derive more mechanical effect from the same thermal agency, than is obtained by the arrangement described above; since, if there could be such an engine, it might be employed to perform, as a part of its whole work, the inverse cycle of operations, upon an engine of the kind we have considered, and thus to continually restore the heat from $B$ to $A$, which has descended from $A$ to $B$ for working itself; so that we should have a complex engine, giving a residual amount of mechanical effect without any thermal agency, or alteration of materials, which is an impossibility in nature. The same reasoning is applicable to the air-engine; and we conclude, generally, that any two engines, constructed on the principles laid down above, whether steam-engines with different liquids, an air-engine and a steam-engine, or two air-engines with different gases, must derive the same amount of mechanical effect from the same thermal agency.
30. Hence, by comparing the amounts of mechanical effect obtained by the steam-engine and the air-engine from the letting down of the $H$ units of heat from A at the temperature $(t+\tau)$ to B at $t$, according to the expressions (2) and (3), we have

* This paragraph is the demonstration referred to above, of the proposition stated in $\S 13$; as it is readily seen that it is applicable to any conceivable kind of thermo-dynamic engine.

$$
\mathrm{M}=(1-\sigma) \frac{\frac{d p}{d \iota}}{k} \cdot \mathrm{H} \tau=\frac{\mathrm{E} p_{0} v_{0}}{v \frac{d q}{d v}} \cdot \mathrm{H} \tau \ldots . .(5)
$$

If we denote the coefficient of $\mathrm{H} \boldsymbol{\tau}$ in these equal expressions by $\mu$, which may be called " Carnot's coefficient," we have

$$
\begin{equation*}
\mu=(1-\sigma) \frac{\frac{d p}{d t}}{k}=\frac{\mathrm{E} p_{0} v_{0}}{v \frac{d q}{d v}} \tag{6}
\end{equation*}
$$

and we deduce the following very remarkable conclusions:-
(1.) For the saturated vapours of all different liquids, at the same temperature, the value of

$$
(1-\sigma) \frac{\frac{d p}{d t}}{k}
$$

must be the same.
(2.) For any different gaseous masses, at the same temperature, the value of

$$
\frac{\mathrm{E} p_{0} v_{0}}{v \frac{d q}{d v}}
$$

must be the same.
(3.) The values of these expressions for saturated vapours and for gases, at the same temperature, must be the same.
31. No conclusion can be drawn a priori regarding the values of this coefficient $\mu$ for different temperatures, which can only be determined, or compared, by experiment. The results of a great variety of experiments, in different branches of physical science (Pneumatics and Acoustics), cited by Carnot and by Clapeyron, indicate that the values of $\mu$ for low temperatures exceed the values for higher temperatures; a result amply verified by the continuous series of experiments performed by Regnault on the saturated vapour of water for all temperatures from $0^{\circ}$ to $230^{\circ}$, which, as we shall see below, give values for $\mu$ gradually diminishing from the inferior limit to the superior limit of temperature. When, by observation, $\mu$ has been determined as a function of the temperature, the amount of mechanical effect, M, deducible from $H$ units of heat descending from a body at the temperature $S$ to a body at the temperature $T$, may be calculated from the expression,

$$
\begin{equation*}
\mathrm{M}=\mathrm{H} \int_{\mathrm{T}}^{\mathrm{S}} \mu d t \tag{7}
\end{equation*}
$$

which is, in fact, what either of the equations (1) for the steam-engine, or (4) for the air-engine, becomes, when the notation $\mu$, for Carnot's multiplier, is introduced.

The values of this integral may be practically obtained, in the most convenient manner, by first determining, from observation, the mean values of $\mu$ for the successive degrees of the thermometric scale, and then adding the values for all the degrees within the limits of the extreme temperatures S and T.*
32. The complete theoretical investigation of the motive power of heat is thus reduced to the experimental determination of the coefficient $\mu$; and may be considered as perfect, when, by any series of experimental researches whatever, we can find a value of $\mu$ for every temperature within practical limits. The special character of the experimental researches, whether with reference to gases, or with reference to vapours, necessary and sufficient for this object, is defined and restricted in the most precise manner, by the expressions (6) for $\mu$, given above.
33. The object of Regnault's great work, referred to in the title of this paper, is the experimental determination of the various physical elements of the steam-engine ; and when it is complete, it will furnish all the data necessary for the calculation of $\mu$. The valuable researches already published in a first part of that work, make known the latent heat of a given weight, and the pressure, of saturated steam for all temperatures between $0^{\circ}$ and $230^{\circ}$ cent. of the air-thermometer. Besides these data, however, the density of saturated vapour must be known, in order that $k$, the latent heat of a unit of volume, may be calculated from Regnault's determination of the latent heat of a given weight. $\dagger$ Between the limits of $0^{\circ}$ and $100^{\circ}$, it is probable, from various experiments which have been made, that the density of vapour follows very closely the simple laws which are so accurately verified by the ordinary gases $; \ddagger$ and thus it may be calculated from Regnault's table giving the pressure at any temperature within those limits. Nothing as yet is known with accuracy as to the density of saturated steam between $100^{\circ}$ and $230^{\circ}$, and we must be contented at present to estimate it by calculation from Regnault's table of pressures; although, when accurate experimental researches on the subject shall have been made, considerable deviations from the laws of Boyle and Dalton, on which this calculation is founded, may be discovered.

[^11]34. Such are the experimental data on which the mean values of $\mu$ for the successive degrees of the air-thermometer, from $0^{\circ}$ to $230^{\circ}$, at present laid before the Royal Society, is founded. The unit of length adopted is the English foot; the unit of weight, the pound; the unit of work, a "foot-pound;" and the unit of heat that quantity which, when added to a pound of water at $0^{\circ}$, will produce an elevation of $1^{\circ}$ in temperature. The mean value of $\mu$ for any degree is found to a sufficient degree of approximation, by taking, in place of $\sigma, \frac{d p}{d t}$, and $k$; in the expression
$$
(1-\sigma) \frac{\frac{d p}{d t}}{k}
$$
the mean values of those elements; or, what is equivalent to the corresponding accuracy of aproximation, by taking, in place of $\sigma$ and $k$ respectively, the mean of the values of those elements for the limits of temperature, and in place of $\frac{d p}{d t}$, the difference of the values of $p$, at the same limits.
35. In Regnault's work (at the end of the eighth Mémoire), a table of the pressures of saturated steam for the successive temperatures $0^{\circ}, 1^{\circ}, 2^{\circ}, \ldots 230^{\circ}$, expressed in millimetres of mercury, is given. On account of the units adopted in this paper, these pressures must be estimated in pounds on the square foot, which we may do by multiplying each number of millimetres by $2 \cdot 7896$, the weight in pounds of a sheet of mercury, one millimetre thick, and a square foot in area.
36. The value of $k$, the latent heat of a cubic foot, for any temperature $t$, is found from $\lambda$, the latent heat of a pound of saturated steam, by the equation
$$
k=\frac{\mathrm{p}}{760} \cdot \frac{1+\cdot 00366 \times 100}{1+\cdot 00366 \times t} \cdot \times \cdot 036869 \cdot \lambda
$$
where $p$ denotes the pressure in millimetres, and $\lambda$ the latent heat of a pound of saturated steam ; the values of $\lambda$ being calculated by the empirical formula*
$$
\lambda=(606.5+0.305 t)-\left(t+\cdot 00002 t^{2}+0.000000 t^{3}\right)
$$
given by Regnault as representing, between the extreme limits of his observations, the latent heat of a unit weight of saturated steam.

[^12]
## Explanation of Table I.

37. The mean values of $\mu$ for the first, for the eleventh, for the twenty-first, and so on, up to the 231st* degree of the air-thermometer, have been calculated in the manner explained in the preceding paragraphs. These, and interpolated reresults, which must agree with what would have been obtained, by direct calculation from Regnault's data, to three significant places of figures (and even for the temperatures between $0^{\circ}$ and $100^{\circ}$, the experimental data do not justify us in relying on any of the results to a greater degree of accuracy), are exhibited in Table I.

To find the amount of mechanical effect due to a unit of heat, descending from a body at a temperature S to a body at T , if these numbers be integers, we have merely to add the values of $\mu$ in Table I. corresponding to the successive numbers.

$$
T+1, T+2, \quad . \quad . \quad . \quad . \quad S-2, S-1
$$

## Explanation of Table II.

38. The calculation of the mechanical effect, in any case, which might always be effected in the manner described in § 37 (with the proper modification for fractions of degrees, when necessary), is much simplified by the use of Table II., where the first number of Table I., the sum of the first and second, the sum of the first three, the sum of the first four, and so on, are successively exhibited. The sums thus tabulated are the values of the integrals

$$
\int_{0}^{1} \mu d t, \int_{0}^{2} \mu d t, \int_{0}^{3} \mu d t, \cdots \cdot \int_{0}^{231} \mu d t
$$

and, if we denote $\int_{0}^{t} \mu d t$ by the letter M, Table II. may be regarded as a table of the values of $M$.

To find the amount of mechanical effect due to a unit of heat descending from a body at a temperature S to a body at T , if these numbers be integers, we have merely to subtract the value of M , for the number $\mathrm{T}+1$, from the value for the number S , given in Table II.

[^13]Table I.* Mean Values of $\mu$ for the successive Degrees of the Air-Thermometer from $0^{\circ}$ to $230^{\circ}$.

|  | $\mu$ |  | $\mu$ |  | $\mu$ |  | $\mu$ |  | $\mu$ |

Note.-On the curves described in Clapeyron"s graphical method of exhibiting Carnot's Theory of the Steam-Engine.
39. At any instant when the temperature of the water and vapour is $t$, during the fourth operation (see above, § 16), the latent heat of the vapour must be precisely equal to the amount of heat that would be necessary to raise the temperature of the whole mass, if in the liquid state, from $t$ to S .* Hence, if $r^{\prime}$ denote the volume of the vapour, $c$ the mean capacity for heat of a pound of water between the temperatures S and $t$, and W the weight of the entire mass, in pounds, we have

$$
k v^{\prime}=c(\mathrm{~S}-t) \mathrm{W} .
$$

Again, the circumstances during the second operation are such that the mass of liquid and vapour possesses H units of heat more than during the fourth; and consequently, at the instant of the second operation, when the temperature is $t$, the volume $v$ of the vapour will exceed $v^{\prime}$ by an amount of which the latent heat is H , so that we have

$$
r=v^{\prime}+\frac{\mathrm{H}}{k}
$$

40. Now, at any instant, the volume between the piston and its primitive position is less than the actual volume of vapour by the volume of the water evaporated. Hence, if $x$ and $x^{\prime}$ denote the abscissæ of the curve at the instants of the second and fourth operations respectively, when the temperature is $t$, we have

$$
x=v-\sigma v, x^{\prime}=v^{\prime}-\sigma v^{\prime}
$$

and, therefore, by the preceding equations,

$$
\begin{align*}
& x=\frac{1-\sigma}{k}\{\mathrm{H}+c(\mathrm{~S}-t) \mathrm{W}\}  \tag{a}\\
& x^{\prime}=\frac{1-\sigma}{k} c(\mathrm{~S}-t) \mathrm{W} \tag{b}
\end{align*}
$$

These equations, along with

$$
\begin{equation*}
y=y^{\prime}=p \tag{c}
\end{equation*}
$$

enable us to calculate, from the data supplied by Regnault, the abscissa and ordinate for each of the curves described above ( $\$ 17$ ), corresponding to any as-

[^15]sumed temperature $t$. After the explanations of $\S \S 33,34,35,36$, it is only necessary to add that $c$ is a quantity of which the value is very nearly unity, and would be exactly so were the capacity of water for heat the same at every temperature as it is between $0^{\circ}$ and $1^{\circ}$; and that the value of $c(\mathrm{~S}-t)$, for any assigned values of S and $t$, is found, by subtracting the number corresponding to $t$ from the number corresponding to $s$, in the column headed "Nombre des unités de chaleur abandonnées par un kilogramme d'eau en descendant de $\mathrm{T}^{\circ}$ à $0^{\circ}$ ", of the last table (at the end of the Tenth Mémoire) of Regnault's work. By giving $S$ the value $230^{\circ}$, and by substituting successively $220,210,200$, \&c., for $t$, values for $x, y, x^{\prime}, y^{\prime}$, have been found, which are exhibited in the following Table:-

| Temperatures. | Volumes to be described by the piston, to complete the fourth operation. $x^{\prime}$ | Volumes from the primitive position of the piston to those occupied at instants of the second operation. <br> $\boldsymbol{x}$ | Pressures of saturated steam, in pounds on the square foot. $y=y^{\prime}=p$ |
| :---: | :---: | :---: | :---: |

| 230 | 0 | $x^{\prime}+\cdot 002643 . \mathrm{H}$ | $58376 \cdot 6$ |

## Appendix.

(Read April 30, 1849.)
41. In p. 30, some conclusions drawn by Carnot from his general reasoning were noticed; according to which it appears, that if the value of $\mu$ for any temperature is known, certain information may be derived with reference to the saturated vapour of any liquid whatever, and, with reference to any gaseous mass, without the necessity of experimenting upon the specific medium considered. Nothing in the whole range of Natural Philosophy is more remarkable than the establishment of general laws by such a process of reasoning. We have seen, however, that doubt may exist with reference to the truth of the axiom on which the entire theory is founded, and it therefore becomes more than a matter of mere curiosity to put the inferences deduced from it to the test of experience. The importance of doing so was clearly appreciated by Carnot; and, with such data as he had from the researches of various experimenters, he tried his conclusions. Some very remarkable propositions which he derives from his Theory, coincide with Dulong and Petit's subsequently-discovered experimental laws with reference to the heat developed by the compression of a gas; and the experimental verification is therefore in this case (so far as its accuracy could be depended upon) decisive. In other respects, the data from experiment were insufficient, although, so far as they were available as tests, they were confirmatory of the theory.
42. The recent researches of Regnault add immensely to the experimental data available for this object, by giving us the means of determining with considerable accuracy the values of $\mu$ within a very wide range of temperature, and so affording a trustworthy standard for the comparison of isolated results at different temperatures, derived from observations in various branches of physical science.

In the first section of this Appendix the Theory is tested, and shewn to be confirmed by the comparison of the values of $\mu$ found above, with those obtained by Carnot and Clapeyron from the observations of various experimenters on air, and the vapours of different liquids. In the second and third sections some striking confirmations of the theory arising from observations by Dulong, on the specific heat of gases, and from Mr Joule's experiments on the heat developed by the compression of air, are pointed out; and in con-
clusion, the actual methods of obtaining mechanical effect from heat are briefly examined with reference to their economy.
I. On the values of $\mu$ derived by Carnot and Clapeyron from observations on Air, and on the Vapours of various liquids.
43. In Carnot's work, p. 80-82, the mean value of $\mu$ between $0^{\circ}$ and $1^{\circ}$ is derived from the experiments of Delaroche and Berard on the specific heat of gases, by a process approximately equivalent to the calculation of the value of $\frac{\mathrm{E} p_{0} v_{0}}{v \frac{d q}{d v}}$ for the temperature $\frac{1^{\circ}}{}{ }^{\circ}$. There are also, in the same work, determinations of the values of $\mu$ from observations on the vapours of alcohol and water; but a table given in M. Clapeyron's paper, of the values of $\mu$ derived from the data supplied by various experiments with reference to the vapours of ether, alcohol, water, and oil of turpentine, at the respective boiling-points of these liquids, afford us the means of comparison through a more extensive range of temperature. In the cases of alcohol and water, these results ought of course to agree with those of Carnot. 'There are, however, slight discrepancies which must be owing to the uncertainty of the experimental data.* In the following table, Carnot's results with reference to air, and Clapeyron's results with reference to the four different liquids, are exhibited, and compared with the values of $\mu$ which have been given above (Table I.) for the same temperatures, as derived from Regnault's observations on the vapour of water.

| Names of the Media. | Temperatures. | Values of $\mu$ | Values of $\mu$ deduced from Regnault's Observations. | Differences. |
| :---: | :---: | :---: | :---: | :---: |
| Air, . | $0 \cdot 5$ | (Carnot) 4.377 | 4.960 | -383 |
| Sulphuric Ether, | (Boiling point) $35 \cdot 5$ | (Clapeyron) 4.478 | $4 \cdot 510$ | -032 |
| Alcohol, . | .............. $78 \cdot 8$ | ............ $3 \cdot 963$ | $4 \cdot 030$ | -671 |
| Water, | 100 | . $3 \cdot 658$ | $3 \cdot 837$ | $\cdot 179$ |
| Essence of Turpentine, | $156 \cdot 8$ | $3 \cdot 530$ | $3 \cdot 449$ | $-.081$ |

44. It may be observed that the discrepancies between the results founded on the experimental data supplied by the different observers with reference to water at the boiling-point, are greater than those which are presented between the results deduced from any of the other liquids, and water at the other temperatures; and we may therefore feel perfectly confident that the verification is com-

[^16]plete to the extent of accuracy of the observations.* The considerable discrepancy presented by Carnot's result, deduced from experiments on air, is not to be wondered at when we consider the very uncertain nature of his data.
45. The fact of the gradual decrease of $\mu$, through a very extensive range of temperature, being indicated both by Regnault's continuous series of experiments, and by the very varied experiments on different media, and in different branches of Physical Science, must be considered as a striking verification of the theory.

## II. On the Heat developed by the compression of Air.

46. Let a mass of air, occupying initially a given volume V , under a pressure $P$, at a temperature $t$, be compressed to a less volume V , and allowed to part with heat until it sinks to its primitive temperature $t$. The quantity of heat which is evolved may be determined, according to Carnot's theory, when the particular value of $\mu$, corresponding to the temperature $t$, is known. For, by equation § 30, equation (6), we have

$$
v \frac{d q}{d v}=\frac{\mathrm{E} p_{0} v_{0}}{\mu},
$$

where $d q$ is the quantity of heat absorbed, when the volume is allowed to increase from $v$ to $v+d v$; or the quantity evolved by the reverse operation. Hence we deduce

$$
\begin{equation*}
d q=\frac{\mathrm{E} p_{0} v_{0}}{\mu} \frac{d v}{v} . \tag{8}
\end{equation*}
$$

Now, $\frac{\mathrm{E} p_{0} v_{0}}{\mu}$ is constant, since the temperature remains unchanged; and therefore, we may at once integrate the second number. By taking it between the limits $V^{\prime}$ and $V$, we thus find

$$
\begin{equation*}
\varphi=\frac{\mathrm{E} p_{0} v_{0}}{\mu} \log \frac{\mathrm{~V} \dagger}{\mathrm{~V}^{\prime}} \tag{9}
\end{equation*}
$$

where $Q$ denotes the required amount of heat, evolved by the compression from V to $\mathrm{V}^{\prime}$. This expression may be modified by employing the equations $\mathrm{PV}=\mathrm{P}^{\prime} \mathrm{V}^{\prime}=p_{0} v_{u}(1+\mathrm{E} t)$; and we thus obtain

$$
\begin{equation*}
\mathrm{Q}=\frac{\mathrm{EPV}}{\mu(1+\mathrm{E} t} \log \frac{\mathrm{V}}{\overline{\mathrm{~V}}^{\prime}}=\frac{\mathrm{EP} \mathrm{P}^{\prime} \mathrm{V}^{\prime}}{(\mu(1+\mathrm{E} t)} \log \frac{\mathrm{V}}{\overline{\mathrm{~V}}^{\prime}} . \tag{10}
\end{equation*}
$$

[^17]$\dagger$ The Vapierian logarithm of $\frac{V}{V^{\prime}}$ is here understood.

From this result we draw the following conclusion :-
47. Equal volumes of all elastic fluids, when compressed to smaller equal volumes, disengage equal quantities of heat.

This extremely remarkable theorem of Carnot's was independently laid down as a probable experimental law by Dulong, in his "Recherches sur la Chaleur Spécifique des Fluides Élastiques," and it therefore affords a most powerful confirmation of the theory. ${ }^{*}$
48. In some very remarkable researches made by Mr Joule upon the heat developed by the compression of air, the quantity of heat produced in different experiments has been ascertained with reference to the amount of work spent in the operation. To compare the results which he has obtained with the indications of theory, let us determine the amount of work necessary actually to produce the compression considered above.
49. In the first place, to compress the gas from the volume $v+d v$ to $x$, the work required is $p d v$, or, since $p v=p_{0} v_{0}(1+\mathrm{E} t)$,

$$
p_{0} v_{0}(1+\mathrm{E} t) \frac{d v}{v}
$$

Hence, if we denote by $W$ the total amount of work necessary to produce the compression from V to $\mathrm{V}^{\prime}$, we obtain, by integration,

$$
\mathrm{W}=p_{0} v_{0}(1+\mathrm{E} t) \log _{\frac{\mathrm{V}}{}}^{\mathrm{V}},
$$

Comparing this with the expression above, we find

$$
\begin{equation*}
\frac{\mathrm{W}}{\mathrm{Q}}=\frac{\mu(1+\mathrm{E} t)}{\mathrm{E}} \tag{11}
\end{equation*}
$$

50. Hence we infer that
(1.) The amount of work necessary to produce a unit of heat by the compression of a gas, is the same for all gases at the same temperature.
(2.) And that the quantity of heat evolved in all circumstances, when the temperature of the gas is given, is proportional to the amount of work spent in the compression.

[^18]51. The expression for the amount of work necessary to produce a unit of heat is
$$
\frac{\mu(1+\mathrm{E} t)}{\mathrm{E}}
$$
and therefore Regnault's experiments on steam are available to enable us to calculate its value for any temperature. By finding the values of $\mu$ at $0^{\circ}, \mathbf{1 0}^{\circ}, \mathbf{2 0}$, \&c., from Table I., and by substituting successively the values $0,10,20, \& c$., for $t$, the following results have been obtained.

Table of the Values of $\frac{\mu(\mathbf{1}+\mathrm{E} t)}{\mathrm{E}}$,

| Work requisite to <br> produce a unit of <br> Heat by the com- <br> pression of a Gas. | Temperature of <br> the Gas. | Work requisite to <br> produce a unit of <br> Heat by the com- <br> pression of a Gas. | Temperature of <br> the Gas. |
| :---: | :---: | :---: | :---: |
| Ft.-lbs. | 0 | Ft.-lbs. |  |
| $1357 \cdot 1$ | 0 | $1446 \cdot 4$ | 120 |
| $1368 \cdot 7$ | 10 | $1455 \cdot 8$ | 130 |
| $1379 \cdot 0$ | 20 | $1465 \cdot 3$ | 140 |
| $1388 \cdot 0$ | 30 | $1475 \cdot 8$ | 150 |
| $1395 \cdot 7$ | 40 | $1489 \cdot 2$ | 160 |
| $1401 \cdot 8$ | 50 | $1499 \cdot 0$ | 170 |
| $1406 \cdot 7$ | 60 | $1511 \cdot 3$ | 180 |
| $1412 \cdot 0$ | 70 | $1523 \cdot 5$ | 190 |
| $1417 \cdot 6$ | 80 | $1536 \cdot 5$ | 200 |
| $1424 \cdot 0$ | 90 | $1550 \cdot 2$ | 210 |
| $1430 \cdot 6$ | 100 | $1564 \cdot 0$ | 220 |
| $1438 \cdot 2$ | 110 | $1577 \cdot 8$ | 230 |
|  |  |  |  |

Mr Joule's experiments were all conducted at temperatures from $50^{\circ}$ to about $60^{\circ}$ Fahr., or from $10^{\circ}$ to $16^{\circ}$ cent.; and, consequently, although some irregular differences in the results, attributable to errors of observation inseparable from experiments of such a very difficult nature are presented, no regular dependance on the temperature is observable. From three separate series of experiments, Mr Joule deduces the following numbers for the work, in foot-pounds, necessary to produce a thermic unit Fahrenheit by the compression of a gas.

$$
820,814,760 .
$$

Multiplying these by 18 , to get the corresponding number for a thermic unit centigrade, we find

1476,1465 , and 1368.
The largest of these numbers is most nearly conformable with Mr Joule's views of the relation between such experimental "equivalents," and others which he obtained in his electro-magnetic researches; but the smallest agrees almost perfectly with the indications of Carnot's theory; from which, as exhibited in the preceding Table, we should expect, from the temperature in Mr Joule's experiments, to find a number between 1369 and 1379 as the result.

## III. On the Specific-Heats of Gases.

52. The following proposition is proved by Carnot as a deduction from his general theorem regarding the specific heats of gases.

The excess of the specific heat* under a constant pressure above the specific heat at a constant volume, is the same for all gases at the same temperature and pressure.
53. To prove this proposition, and to determine an expression for the "excess" mentioned in its enunciation, let us suppose a unit of volume of a gas to be elevated in temperature by a small amount, r. The quantity of heat required to do this will be $A \tau$, if A denote the specific heat at a constant volume. Let us next allow the gas to expand without going down in temperature, until its pressure becomes reduced to its primitive value. The expansion which will take place will be $\frac{\mathrm{E} \tau}{1+\mathrm{E} t}$, if the temperature be denoted by $t$; and hence, by (8), the quantity of heat that must be supplied, to prevent any lowering of temperature,
will be

$$
\frac{\mathrm{E} p_{0} v_{0}}{\mu} \cdot \frac{\mathrm{E} \tau}{1+\mathrm{E} t}, \quad \text { or } \quad \frac{\mathrm{E}^{2} p}{\mu(1+\mathrm{E} t)^{2}} \tau
$$

Hence, the total quantity added is equal to

$$
\mathrm{A} r+\frac{\mathrm{E}^{2} p}{\mu(1+\mathrm{E} t)^{2}}
$$

But, since $B$ denotes the specific heat under constant pressure, the quantity of heat requisite to bring the gas into this state, from its primitive condition, is equal to $B_{r}$; and hence we have

$$
\begin{equation*}
\mathrm{B}=\mathrm{A}+\frac{\mathrm{E}^{2} p}{\mu(1+\mathrm{E} t)^{2}} . \tag{12}
\end{equation*}
$$

## IV. Comparison of the Relative advantages of the Air-Engine and Steam-Engine.

54. In the use of water-wheels for motive power, the economy of the engine depends not only upon the excellence of its adaptation for actually transmitting any given quantity of water through it, and producing the equivalent of work, but upon turning to account the entire available fall; so, as we are taught by Carnot, the object of a thermodynamic engine is to economize in the best possible way the transference of all the heat evolved, from bodies at the temperature of the source, to bodies at the lowest temperature at which the heat can be discharged. With reference then to any engine of the kind, there will be two points to be considered.
(1.) The extent of the fall utilised.
(2.) The economy of the engine, with the fall which it actually uses.
55. In the first respect, the air-engine, as Carnot himself points out, has a * Or the capacity of a unit of volume for heat.
vast advantage over the steam-engine; since the temperature of the hot part of the machine may be made very much higher in the air-engine than would be possible in the steam-engine, on account of the very high pressure produced in the boiler, by elevating the temperature of the water which it contains to any considerable extent above the atmospheric boiling point. On this account, a " perfect air-engine" would be a much more valuable instrument than a "perfect steam-engine." *

Neither steam-engines nor air-engines, however, are nearly perfect; and we do not know in which of the two kinds of machine the nearest approach to perfection may be actually attained. The beautiful engine invented by Mr StirLING of Galston, may be considered as an excellent beginning for the air-engine; $\dagger$ and it is only necessary to compare this with Newcomen's steam-engine, and consider what $W_{A T t}$ has effected, to give rise to the most sanguine anticipations of improvement.

## V. On the Economy of actual Steam-Engines.

56. The steam-engine being universally employed at present as the means for deriving motive power from heat, it is extremely interesting to examine, according to Carnot's theory, the economy actually attained in its use. In the first place, we remark that, out of the entire "fall" from the temperature of the coals to that of the atmosphere, it is only part-that from the temperature of the boiler to the temperature of the condenser-that is made available; while the very great fall from the temperature of the burning coals to that of the boiler, and the comparatively small fall from the temperature of the condenser to that of the atmosphere, are entirely lost as far as regards the mechanical effect which it is desired to obtain. We infer from this, that the temperature of the boiler ought to be kept as high as, according to the strength, is consistent with safety, while that of the condenser ought to be kept as nearly down at the atmospheric temperature as possible. To take the entire benefit of the actual fall, Carnot shewed that the " principle of expansion" must be pushed to the utmost. $\ddagger$

[^19]57. To obtain some notion of the economy which has actually been obtained, we may take the alleged performances of the best Cornish engines, and some other interesting practica cases as examples.*
(1.) The engine of the Foney Consols mine was reported, in 1845, to have given $125,089,000$ foot-pounds of effect, for the consumption of one bushel or 94 lbs . of coals. Now, the average amount evaporated from Cornish boilers, by one pound of coal, is $8 \frac{1}{2} \mathrm{lbs}$. of steam ; and hence, for each pound of steam evaporated 156,556 foot-pounds of work are produced.

The pressure of the saturated steam in the boiler may be taken as $3 \frac{1}{2}$ atmospheres $; \dagger$ and, consequently, the temperature of the water will be $140^{\circ}$. Now (Regnallt, end of Memoire X.), the latent heat of a pound of saturated steam at $140^{\circ}$ is 508 , and since, to compensate for each pound of steam removed from the boiler in the working of the engine, a pound of water, at the temperature of the condenser, which may be estimated at $30^{\circ}$, is introduced from the hot well; it follows that 618 units of heat are introduced to the boiler for each pound of water evaporated. But the work produced, for each pound of water evaporated, was found above to be 156,556 foot-pounds. Hence, $\frac{156556}{618}$, or 253 foot-pounds is the amount of work produced for each unit of heat transmitted through the Fowey Consols engine. Now, in Table II., we find 583.0 as the theoretical effect due to a unit descending from $140^{\circ}$ to $0^{\circ}$, and 143 as the effect due to a unit descending from $30^{\circ}$ to $0^{\circ}$. The difference of these numbers, or $440,{ }_{4}^{\dagger}$ is the number of foot-pounds of work that a perfect engine with its boiler at $140^{\circ}$, and its condenser at $30^{\circ}$ would produce for each unit of heat transmitted. Hence, the Fowey Consols engine, during the experiments reported on, performed $\frac{253}{420}$ of its theoretical duty, or $57 \frac{1}{2}$ per cent.
(2.) The best duty on record, as performed by an engine at work (not for merely experimental purposes), is that of Taylor's engine, at the United mines, which, in 1840, worked regularly, for several months, at the rate of $98,000,000$ footpounds for each bushel of coals burned. This is $\frac{98}{125}$, or $\cdot 784$ of the experimental

[^20]duty reported in the case of the Fowey Consols engine. Hence, the best useful work on record, is at the rate of 1983 foot-pounds for each unit of heat transmitted, and is $\frac{1993.3}{400}$, or 45 per cent. of the theoretical duty, on the supposition that the boiler is at $140^{\circ}$, and the condenser at $30^{\circ}$.
(3.) French engineers contract (in Lille, in 1847, for example) to make engines for mill power which will produce 30,000 metre-lbs., or 98,427 foot-lbs. of work for each pound of steam used. If we divide this by 618 , we find 159 footpounds for the work produced by each unit of heat. This is $36 \cdot 1$ per cent. of 440, the theoretical duty.*
(4.) English engineers have contracted to make engines and boilers which will require only $3 \frac{1}{2} \mathrm{lbs}$. of the best coal per horse-power per hour. Hence, in such engines, each pound of coal ought to produce 565,700 foot-pounds of work, and if 7 lbs . of water be evaporated by each pound of coal, there would result 80,814 foot-pounds of work for each pound of water evaporated. If the pressure in the boiler be $3 \frac{1}{2}$ atmospheres (temperature $140^{\circ}$ ) the amount of work for each unit of heat will be found, by dividing this by 618 , to be 130.7 foot-pounds, which is $\frac{130 \cdot 7}{4+10}$ or 29.7 per cent. of the theoretical duty. $\dagger$
(5.) The actual average of work performed by good Cornish engines and boilers is $55,000,000$ foot-pounds for each bushel of coal, or less than half the experimental performance of the Fowey Consols engine, more than half the actual duty performed by the United Mines engine in 1840 ; in fact about 25 per cent. of the theoretical duty.
(6.) The average performances of a number of Lancashire engines and boilers have been recently found to be such as to require 12 lbs . of Lancashire coal per horse-power per hour (i.e., for performing $60 \times 33,000$ foot-pounds) and of a number of Glasgow engines, such as to require 15 lbs. (of a somewhat inferior coal) for the same effect. There are, however, more than twenty large engines in Glasgow at present, $\ddagger$ which work with a consumption of only $6 \frac{1}{2}$ lbs. of dross, equivalent to 5 lbs. of the best Scotch, or 4 lbs. of the best Welsh coal, per horse-power

[^21]per hour. The economy may be estimated from these data, as in the other cases, on the assumption which, with reference to these, is the most probable we can make, that the evaporation produced by a pound of best coal is 7 lbs . of steam.
58. The following Tables afford a synoptic view of the performances and theoretical duties in the various cases discussed above.

In Table $A$ the numbers in the second column are found by dividing the numbers in the first by $8 \frac{1}{2}$ in cases (1.), (2.), and (5.), and by 7 in cases (4.), (6.), and (7.), the estimated numbers of pounds of steam actually produced in the different boilers by the burning of 1 lb . of coal.

The numbers in the third column are found from those in the second, by dividing by 618, in Table A, and 614 in Table B, which are respectively the quantities of heat required to convert a pound of water taken from the hot well at $30^{\circ}$, into saturated steam, in the boiler, at $140^{\circ}$ or at $121^{\circ}$.

With reference to the cases (3.), (4.), (6.), (7.), the hypothesis of Table B is probably in general nearer the truth than that of Table A. In (4.), (6.), and (.).), especially upon hypothesis $B$, there is much uncertainty as to the amount of evaporation that will be actually produced by 1 lb . of fuel. The assumption on which the numbers in the second column in Table $B$ are calculated, is, that each pound of coal will send the same number of units of heat into the boiler whether hypothesis A or hypothesis B be followed. Hence, except in the case of the French contract, in which the evaporation, not the fuel, is specified, the numbers in the third column are the same as those in the third column of Table A.

Table A. Various Engines in which the temperature of the Boiler is $140^{\circ}$, and that of the Condenser $30^{\circ}$.

Theoretical Duty for each Unit of Heat transmitted, 440 foot-pounds.

| Cases. | Work produced for each pound of coal consumed. | Work produced for each pound of water evaporated. | Work produced for each unit of heat transmitted. | Per centage of theoreti- cal duty. |
| :---: | :---: | :---: | :---: | :---: |
| (1.) Fowey Consols Experiment, reported in 1845, | Foot-Pounds. $1,330,734$ | Foot-Pounds. 156,556 | Foot-Pounds. 253 | 57.5 |
| $\left.\begin{array}{c}\text { (2.) Taylor's Engine at the United Mines, work- } \\ \text { ing in 1840, . . . }\end{array}\right\}$ | 1,042,553 | 122,6อ̃3 | 198.4 | $45 \cdot 1$ |
| (3.) French Engines, according to contract, . | * * * * | 98,427 | 159 | $36 \cdot 1$ |
| (4.) English Engines, according to contract, | 565,700 | 80,814 | $130 \cdot 8$ | $29 \cdot 7$ |
| (5.) Average actual performance of Cornish Engines, | 585,106 | 68,836 | $111 \cdot 3$ | $25 \cdot 3$ |
| $\left.\begin{array}{c}\text { (6.) Common Engines, consuming } 12 \text { lbs. of best } \\ \text { coal per hour per horse-power, }\end{array}\right\}$ | 165,000 | 23,571 | 38-1 | $8 \cdot 6$ |
| (7.) Improved Engines with Expansion Cylinders, consuming an equivalent to 4 lbs. of best coal per horse-power per hour, | 495,000 | 70,710 | 114.4 | 26 |

T'able B. Various Engines in which the Temperature of the Boilers is 121,* and that of the Condenser $30^{\circ}$.

Theoretical Duty for each Unit of Heat transmitted, 371 foot-pounds.

| Cases. | Work produced for each pound of coal consumed. | Work produced for each pound of water evaporated. | Work produced for each unit of heat transmitted. | Per centage of theoretical duty. |
| :---: | :---: | :---: | :---: | :---: |

[^22]
[^0]:    * Published in 1824, in a work entitled, " Réflexions sur la Puissance Motrice du Feu, et sur les Machines Propres à Déveloper cette Puissance. Par S. Carnor." An account of Carnot's Theory is also published in the Journal d'Ecole Polytechnique, vol. xiv., 1834, in a paper by Mons. Clapeyron.
    $\dagger$ An account of the first part of a series of researches undertaken by Mons. Regnault, by order of the late French Government, for ascertaining the various physical data of importance in the theory of the steam-engine, has been recently published (under the title, "Relation des Expériences," \&c.) in the Mémoires de l'Institut, of which it constitutes the twenty-first volume (1847). The second part of these researches has not yet been published.

[^1]:    * Carnot, p. 37.

[^2]:    * The evolution of heat in a fixed conductor, through which a galvanic current is sent from any source whatever, has long been known to the scientific world; but it was pointed out by Mr Joule that we cannot infer from any previously-published experimental researches, the actual generation of heat when the current originates in electro-magnetic induction; since the question occurs, is the heat which is evolved in one part of the closed conductor merely transferred from those parts which are subject to the inducing influence? Mr Joule, after a most careful experimental investigation with reference to this question, finds that it must be answered in the negative.-(See a paper "On the Calorific Effects of Magneto-Electricity, and on the Mechanical Value of Heat ; by J. P. Joule, Esq." Read before the British Association at Cork in 1843, and subsequently communicated by the Author to the Philosophical Magazine, vol. xxiii., pp. 263, 347, 435.)

    Before we can finally conclude that heat is absolutely generated in such operations, it would be necessary to prove that the inducing magnet does not become lower in temperature, and thas compensate for the heat evolved in the conductor. I am not aware that any examination with reference to the truth of this conjecture has been instituted; but, in the case where the inducing body is a pure electro-magnet (without any iron), the experiments actually performed by Mr Joule render the conclusion probable that the heat evolved in the wire of the electro-magnet is not affected by the inductive action, otherwise than through the reflected influence which increases the strength of its own current.

[^3]:    * So generally is Carnot's principle tacitly admitted as an axiom, that its application in this case has never, so far as I am aware, been questioned by practical engineers.

[^4]:    * When " thermal agency" is thus spent in conducting heat through a solid, what becomes of the mechanical effect which it might produce? Nothing can be lost in the operations of natureno energy can be destroyed. What effect then is produced in place of the mechanical effect which is lost ? A perfect theory of heat imperatively demands an answer to this question; yet no answer can be given in the present state of science. A few years ago, a similar confession must have been made with reference to the mechanical effect lost in a fluid set in motion in the interior of a rigid closed vessel, and allowed to come to rest by its own internal friction; but in this case, the foundation of a solution of the difficulty has been actually found, in Mr Joule's discovery of the generation of heat, by the internal friction of a fluid in motion. Encouraged by this example, we may hope that the very perplexing question in the theory of heat, by which we are at present arrested, will, before long, be cleared up.

    It might appear, that the difficulty would be entirely avoided, by abandoning Carnot's fundamental axiom; a view which is strongly urged by Mr Joule (at the conclusion of his paper "On the Changes of Temperature produced by the Rarefaction and Condensation of Air." Phil. Mag., May 1845, vol. xxvi.) If we do so, however, we meet with innumerable other difficulties-insuperable without farther experimental investigation, and an entire reconstruction of the theory of heat, from its fonndation. It is in reality to experiment that we must look-either for a verification of Carnot's axiom, and an explanation of the difficulty we have been considering; or for an entirely new basis of the Theory of Heat.

[^5]:    * A case minutely examined in another paper, to be laid before the Society at the present meeting.

[^6]:    * In all that follows, the pressure of the atmosphere on the upper side of the piston will be included in the applied forces, which, in the successive operations described, are sometimes overcome by the upward motion, and sometimes yielded to in the motion downwards. It will be unnecessary, in reckoning at the end of a cycle of operations, to take into account the work thus spent upon the atmosphere, and the restitution which has been made, since these precisely compensate for one another.
    $\dagger$ In Carnot's work some perplexity is introduced with reference to the temperature of the water, which, in the operations he describes, is not brought back exactly to what it was at the commencement ; but the difficulty which arises is explained by the author. No such difficulty occurs with reference to the cycle of operations described in the text, for which I ara indebted to Mons. Clapeyron.

[^7]:    * See Note at the end of this Paper.

[^8]:    * Thus, $\frac{d q}{d v}$ will be the partial differential coefficient, with respect to $v$ of that function of $v$ and $t$, which expresses the quantity of heat that must be added to a mass of air when in a "standard" state (such as at the temperature zero, and under the atmospheric pressure), to bring it to the temperature $t$, and the volume $v$. That there is such a function, of two independent variables $v$ and $t$, is merely an analytical expression of Carnot's fundamental axiom, as applied to a mass of air. The general principle may be analytically stated in the following terms :-If $\mathbf{M} d v$ denote the accession of heat received by a mass of any kind, not possessing a destructible texture, when the volume is increased by $d v$, the temperature being kept constant, and if $\mathrm{N} d t$ denote the amount of heat which must be supplied to raise the temperature by $d t$, without any alteration of volume; then $\mathrm{M} d v+\mathrm{N} d t$ must be the differential of a function of $v$ and $t$.

[^9]:    * We might also investigate another relation, to express the fact that there is no accession or removal of heat during either the second or the fourth operation; but it will be seen that this will not affect the result in the text; although it would enable us to determine both $\varphi$ and $\omega$ in terms of $\tau$.

[^10]:    * This result might have been obtained by applying the usual notation of the integral calculus to express the area of the curvilinear quadrilateral, which, according to Clapeyron's graphical construction, would be found to represent the entire mechanical effect gained in the cycle of operations of the air-engine. It is not necessary, however, to enter into the details of this investigation, as the formula (3), and the consequences derived from it, include the whole theory of the air-engine, in the best practical form ; and the investigation of it which I have given in the text, will probably give as clear a view of the reasoning on which it is founded, as could be obtained by the graphical method, which, in this case, is not so valuable as it is from its simplicity in the case of the steam-engine.

[^11]:    * The results of these investigations are exhibited in Tables I. and II. below.
    $\dagger$ It is, comparatively speaking, of little consequence to know accurately the value of of for the factor (1- $\sigma$ ) of the expression for $\mu$, since it is so small (being less than ${ }_{17} \frac{1}{\bar{\sigma} \overline{0}}$ for all temperatures between $0^{\circ}$ and $100^{\circ}$ ) that, unless all the data are known with more accuracy than we can count
    upon at present, we might neglect it altogether, and take $\frac{\frac{d p}{d t}}{k}$ simply, as the expression for $\mu$, without committing any error of important magnitude.
    $\ddagger$ This is well established, within the ordinary atmospheric limits, in Regnault's Études Météorologiques, in the Annales de Chimie, vol. xv., 1846.

[^12]:    * The part of this expression in the first vinculum (see Regnadlt, end of ninth Mémoire) is what is known as "the total heat" of a pound of steam, or the amount of heat necessary to convert a pound of water at $0^{\circ}$ into a pound of saturated steam at $t^{\circ}$; which, according to "Watt's law," thus approximately verified, would be constant. The second part, which would consist of the single term $t$, if the specific heat of water were constant for all temperatures, is the number of thermic units necessary to raise the temperature of a pound of water from $0^{\circ}$ to $t^{\circ}$, and expresses empirically the results of Regnault's experiments on the specific heat of water (see end of the tenth Mémoire), described in the work already referred to.

[^13]:    * In strictness, the 230th is the last degree for which the experimental data are complete; but the data for the 231 st may readily be assumed in a sufficiently satisfactory manner.

[^14]:    * The numbers here tabulated may also be regarded as, the actual values of $\mu$ for $t=\frac{1}{2}, t=1 \frac{1}{2}$, $t=2 \frac{1}{2}, t=3 \frac{1}{2}, \& c$.

[^15]:    * For, at the end of the fourth operation, the whole mass is liquid, and at the temperature $t$. Now, this state might be arrived at by first compressing the vapour into water at the temperature $t$, and then raising the temperature of the liquid to $S$; and however this state may be arrived at, there cannot, on the whole, be any heat added to or subtracted from the contents of the cylinder, since, during the fourth operation, there is neither gain nor loss of heat. This reasoning is, of course, founded on Carnot's fundamental principle, which is tacitly assumed in the commonly-received ideas connected with "Watt's law," the " latent heat of steam," and " the total heat of steam."

[^16]:    * Thus, from Carnot's calculations, we find, in the case of alcohol, $4 \cdot 035$; and in the case of water, $3 \cdot 648$, instead of $3 \cdot 963$, and 3.658 , which are Clapeyron's results in the same cases.

[^17]:    * A still closer agreement must be expected, when more accurate experimental data are afforded with reference to the other media. Mons. Regnault informs me that he is engaged in completing some researches, from which we may expect, possibly before the end of the present year, to be furnished with all the data for five or six different liquids which we possess at present for water. It is therefore to be hoped that, before long, a most important test of the validity of Carnot's theory will be afforded.

[^18]:    * Carnot varies the statement of his theorem, and illustrates it in a passage, pp. 52, 53, of which the following is a translation:-
    "When a gas varies in volume without any change of temperature, the quantities of heat absorbed or evolved by this gas are in arithmetical progression, if the augmentation or diminutions of volume are in geometrical progression.
    "When we compress a litre of air maintained at the temperature $10^{\circ}$, and reduce it to half a litre, it disengages a certain quantity of heat. If, again, the volume be reduced from half a litre to a quarter of a litre, from a quarter to an eighth, and so on, the quantities of heat successively evolved will be the same.
    " If, in place of compressing the air, we allow it to expand to two litres, four litres, eight litres, \&c., it will be necessary to supply equal quantities of heat to maintain the temperature always at the same degree."

[^19]:    * Carnot suggests a combination of the two principles, with air as the medium for receiving the heat at a very high temperature from the furnace; and a second medium, alternately in the state of saturated vapour and liquid water, to receive the heat, discharged at an intermediate temperature from the air, and transmit it to the coldest part of the apparatus. It is possible that a complex arrangement of this kind might be invented, which would enable us to take the heat at a higher temperature, and discharge it at a lower temperature than would be practicable in any simple air-engine or simple steam-engine. If so, it would no doubt be equally possible, and perhaps more convenient, to employ steam alone, but to use it at a very high temperature not in contact with water in the hottest part of the apparatus, instead of, as in the steam-engine, always in a saturated state.
    $\dagger$ It is probably this invention to which Carnot alludes in the following passage (p. 112):"Il a été fait, dit-on, tout recemment en Angleterre des essais heureux sur le développement de la puissance motrice par l'action de la chaleur sur l'air atmosphérique. Nous ignorons entièrement ne quoi ces essais ont consisté, si toutefois ils sont réels."
    $\ddagger$ From this point of view, we see very clearly how imperfect is the steam-engine, even after all Watt's improvements. For to "push the principle of expansion to the utmost," we must allow the

[^20]:    steam, before leaving the cylinder, to expand until its pressure is the same as that of the vapour in the condenser. According to "Watt's law," its temperature would then be the same as (actually a little above, as Regnault has shewn) that of the condenser, and hence the steam-engine worked in this most advantageous way, has in reality the very fault that Watt found in Newcomen's engine. This defect is partially remedied by Hornblower's system of using a separate expansion cylinder, an arrangement, the advantages of which did not escape Carnot's notice, although they have not been recognised extensively among practical engineers, until within the last few years.

    * I am indebted to the kindness of Professor Gordon of Glasgow, for the information regarding the various cases given in the text.
    $\dagger$ In different Cornish engines, the pressure in the boiler is from $2 \frac{1}{2}$ to 5 atmospheres; and, therefore, as we find from Regnallt's table of the pressure of saturated steam, the temperature of the water in the boiler must, in all of them, lie between $128^{\circ}$ and $152^{\circ}$. For the better class of engines, the average temperature of the water in the boiler may be estimated at $140^{\circ}$, the corresponding pressure of steam being $3 \frac{1}{2}$ temperatures.
    $\ddagger$ This number agrees very closely with the number corresponding to the fall from $100^{\circ}$ to $0^{\circ}$, given in Table II. Hence, the fall from $140^{\circ}$ to $30^{\circ}$ of the scale of the air-thermometer is equivalent, with reference to motive power, to the fall from $100^{\circ}$ to $0^{\circ}$.

[^21]:    * It being assumed that the temperatures of the boiler and condenser are the same as those of the Cornish engines. If, however, the pressure be lower, two atmospheres, for instance, the numbers would stand thus : The temperature in the boiler would be only 121. Consequently, for each pound of steam evaporated, only 614 units of heat would be required; and, therefore, the work performed for each unit of heat transmitted would be $160 \cdot 3$ foot-pounds, which is more than according to the estimate in the text. On the other hand, the range of temperatures, or the fall utilised, is only from 131 to 30 , instead of from 140 to $30^{\circ}$, and, consequently (Table II.), the theoretical duty for each unit of heat is only 371 foot-pounds. Hence, if the engine, to work according to the specification, requires a pressure of only 15 lbs. on the square inch (i. e., a total steam pressure of two atmospheres), its performance is $\frac{1003}{371}$, or $43 \cdot 2$ per cent. of its theoretical duty.
    $\dagger$ If, in this case again, the pressure required in the boiler to make the engine work according to the contract were only 15 lbs . on the square inch, we should have a different estimate of the economy, for which, see Table B, at the end of this paper.
    $\ddagger$ These engines are provided with separate expansive cylinders, which have been recently added to them by Mr M•Naught of Glasgow.

[^22]:    * Pressure 15 lbs . on the square inch.
