Steps 1 and 2 are the analytic-flexibility controls and they are not optional. Choosing a reference option after seeing the data is a forking path, and the resulting estimate is not the estimate it appears to be [Gelman and Loken, 2013, Simmons et al., 2011]; freezing the instrument before the window is the standard remedy [Nosek et al., 2018]. **Step 7 is the step that converts confession into data**, and it is the step that most often contradicts the subject.

22.5.4 5.4 What the survey can and cannot resolve

Take the first coordinate of the worked survey: 30 days, four options, counts 14 / 9 / 5 / 2.

Option	n	share	d = C_x − C_desk (theta)	se	95% interval	resolved?
desk (home)	14	0.467	0.0000	—	reference	—
kitchen table	9	0.300	0.4418	0.4272	[-0.3956, 1.2792]	**no**
the cafe	5	0.167	1.0296	0.5210	[0.0085, 2.0508]	yes, barely
the office	2	0.067	1.9459	0.7559	[0.4643, 3.4275]	yes

After thirty days of faithful recording, this subject cannot distinguish the cost of the kitchen table from the cost of the desk. The point estimate says the kitchen is 0.44 theta dearer; the interval says it might be 0.40 theta cheaper. The subject, asked, will be quite certain, and the data does not support the certainty.

How long would it take? Holding the observed proportions:

```
to resolve d = 0.4418 at 95 per cent:   se must be <= 0.4418/1.96 = 0.2254
se(n) = sqrt( 1/(0.300 n) + 1/(0.467 n) ) = sqrt( 5.4762 / n )
n >= 108 days
```

coordinate direction	d (theta)	days needed
kitchen vs desk	0.4418	**108**
task file vs mail	0.7538	38
cafe vs desk	1.0296	30

One hundred and eight days to resolve a difference the subject was sure of on day one. The gradient can be measured and it is cheap to measure, but **the small differences — which are exactly the ones a person deliberates over — are the expensive ones to establish.**

And note the structure of the standard error: `se = sqrt(1/n_a + 1/n_b)` is dominated by the *smaller* count. **The rarely taken option is the badly measured one, and the rarely taken options are the interesting ones.** A survey of one's own life measures habits precisely and exceptions not at all.

22.5.5 5.5 What is identifiable: the ratios of differences

`theta` is unknown, so every `d` above is in theta units and no absolute statement can be made. But `theta` cancels in a ratio:

```
( C_office − C_desk ) / ( C_kitchen − C_desk ) = 1.9459 / 0.4418 = 4.4042
( C_cafe   − C_desk ) / ( C_kitchen − C_desk ) = 1.0296 / 0.4418 = 2.3303
( C_office − C_desk ) / ( C_cafe    − C_desk ) = 1.9459 / 1.0296 = 1.8899
```

The office is 4.4042 times as costly a departure from the desk as the kitchen table is. That statement is unit-free, fully identified, and testable. It is also the form in which every comparative claim in this half of the paper is made, because it is the only form the data supports. The general principle is measurement-theoretic rather than statistical: the admissible statements are those invariant under the transformations the scale allows, and with an unknown positive unit the ratio of two differences is invariant while a difference alone is not [Narens, 1996, Stevens, 1946].

The rule, for use: **report ratios of differences, never differences alone, and never a level.** A survey reporting "the office costs 1.95" has reported a number whose unit nobody knows. A survey reporting "the office costs 4.4 kitchen-tables" has reported a measurement.

The one experiment that would pin `theta`: **impose a cost of known magnitude on one option and measure the shift in its share** — a five-minute walk added to one route, a small explicit charge, a fixed delay. From the shift, `theta` follows and every difference in the survey becomes absolute. **That experiment has not been run here, and its absence is why every number in this section is in theta units.**

22.5.6 5.6 Flat directions: where the subject is free, and where design has leverage

Take the third coordinate, which chair, with counts 8 / 7 / 8 / 7.

Option	`n`	`d` (theta)	`se`	95% interval
chair A	8	0.0000	—	reference
chair B	7	0.1335	0.5175	[-0.8809, 1.1479]
chair C	8	0.0000	0.5000	[-0.9800, 0.9800]
chair D	7	0.1335	0.5175	[-0.8809, 1.1479]

This coordinate is flat, and two readings follow.

Reading one: a flat direction is a free direction. The subject can move along this coordinate at no cost. In the formalism, `grad C = 0` along a degenerate direction of the Hessian, so motion is unopposed. **Freedom, in this model, is a flat direction in the cost field, and it is measurable.**

Reading two, which is the engineering one: a flat direction is where a small regrade moves everything. Apply the same subsidy — 0.5 theta of cost removed — to a steep coordinate and to a flat one:

```
STEP: the office, currently 6.67% of occasions
    relative weights: desk 1.0000, kitchen 0.642857, cafe 0.357143, office 0.142857
    after a 0.5 theta subsidy on the office: 0.142857 * e^0.5 = 0.235531
    new share = 0.235531 / 2.235531 = 10.536%          gain: +3.869 points

FLAT: chair B, currently 23.33% of occasions
    after the same 0.5 theta subsidy: share 23.33% -> 33.41%     gain: +10.079 points

LEVERAGE RATIO = 10.079 / 3.869 = 2.605
```

The same subsidy buys 2.6 times as much movement in the flat coordinate as in the steep one. This is the arithmetic behind a familiar piece of design practice: **do not fight the steep direction; find the flat one and tilt it.** It is why moving a chair three metres changes a room's traffic while exhorting people to use a distant space does not, and the built-environment form of the same result is priced in Curzi [2026f], whose entrance-sequence case cut interruptions from 22 to 6 per person-day at a seven-minute switch cost, moved the cost of switching from 0.321 to 0.087, raised headroom from +0.0642 to +0.2955 and the storage fixed point from 5.185 to 9.041, for 7.6 per cent of net floor area.

The general statement is worth having: **cost differences are what people notice; cost gradients are what people move along; and the coordinates where they notice nothing are exactly the coordinates where a designer can move them most.**

22.5.7 5.7 Data, not confession

The distinction matters enough to state as a table, because the failure is a category error rather than an inaccuracy.

	The confession	The desire line
what it measures	a belief about the cost field	the cost field
sample size	1	one per occasion
reactivity	high; the act of asking changes the answer	low; the act of tallying is nearly inert
available on	any topic	only recurring, enumerable decisions
identifies	nothing	cost differences up to `theta`
failure mode	sincere and wrong	precise and narrow

The desire line is worse at almost everything except being true. It covers only recurring decisions, it needs a hundred days for a small effect, it yields no absolute magnitudes, and it says nothing about anything the subject does not do repeatedly. Within its narrow domain it is not arguable with.

22.5.8 5.8 Descent dynamics on an ordered coordinate

Where a coordinate *is* ordered — hours per week in a role, distance from a place, fraction of work in a new domain — the difference table becomes a genuine gradient and the descent dynamics become computable. The worked survey's ordered coordinate runs from `x = 0` to `x = 10` and carries the cost field shared with Section 4:

```
C(x) = 0.090 − 0.0568 exp(−(x−2)^2/0.8) − 0.064 exp(−(x−7)^2/1.2) + 0.0004 x
```

Its structure, computed:

Feature	`x`	`C(x)` (Q-units/wk)	`C''(x)`
basin A floor	1.9970	0.033999	+0.141995
the ridge	4.3350	0.091500	-0.005076
basin B floor	6.9960	0.028799	+0.106662

With `L = max |C''| = 0.142`, the standard first-order conditions give `alpha < 2/L = 14.08` for local non-divergence and `alpha = 1/L = 7.04` for the fastest guaranteed monotone decrease [Strogatz, 2015, Åström and Murray, 2008]. Descent from `x_0 = 3.0` at `alpha = 1/L`:

step	`x`	`C(x)`	`−dC/dx`
0	3.00000	0.074926	-0.0410830
1	2.71068	0.060874	-0.0540756
2	2.32987	0.041355	-0.0412845
3	2.03913	0.034124	-0.0059463
4	1.99726	0.033999	-0.0000106
5	1.99718	0.033999	0.0000000

Five steps to arrive, the last two indistinguishable. The local contraction factor `|1 − alpha*mu|` is 0.00000 at basin A, because the curvature there happens to equal the global Lipschitz constant, and 0.24886 at basin B. **The source states that basin B therefore takes "about**

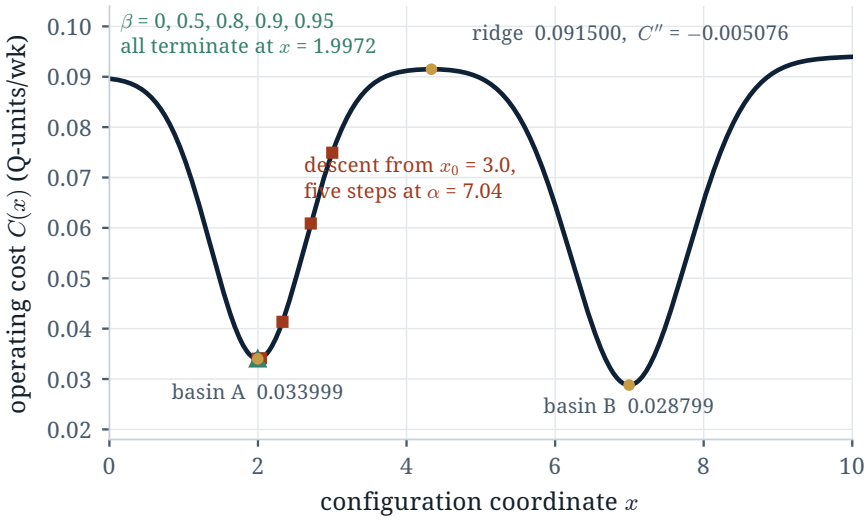

Figure 22.1: **Basin A is the correct output of a local method, not a failure of will, and momentum does not change it:** the shared cost field has basin A at `x = 1.9970`, `C = 0.033999`, a ridge at `x = 4.3350`, `C = 0.091500` with `C'' = −0.005076`, and a deeper basin B at `x = 6.9960`, `C = 0.028799`. Descent from `x_0 = 3.0` at `alpha = 1/L = 7.04` reaches basin A in five steps, and momentum at `beta` = 0, 0.5, 0.8, 0.9 and 0.95 terminates at `x = 1.9972` at every setting. Modelled from the field equation and parameters of Section 5.8; generated by `figs/src/CCP-022_fig03.py`.

2.7 steps per decade of remaining error"; from that same contraction factor the figure is 1.66 steps per decade, since the logarithm of 0.1 divided by the logarithm of 0.24886 is 1.6555. The discrepancy is reported rather than silently corrected, and nothing else in this paper depends on it. What matters here is that arrival is fast once the walker is in a basin, so the interesting question is never how long descent takes but which basin it started in. The geometric character of that convergence is the contraction result of Curzi [2026].

The basin boundary sits at `x = 4.33485`, which is the ridge to five decimals. Descent from 4.30 lands in basin A; descent from 4.40 lands in basin B. The two starting points are 0.1 configuration-units apart and their destinations are five units apart.

And the plateau is slow. Starting at `x = 4.30`, just 0.035 inside basin A, the walker is still at `x = 4.128` after fifty steps, because the gradient magnitude near the ridge is of order `10^-5`. An subject near a ridge appears to be deliberating for a long time. They are not deliberating; they are descending a plateau, and the model says exactly how slowly.

22.5.9 5.9 What the gradient cannot tell you

Four things, each a real limitation with a real consequence.

It cannot tell you the minimum is global. Descent from every start in `[0, 4.334]` lands in basin A at `C = 0.034`. Basin B is deeper at `C = 0.0288`, a 15.3 per cent lower operating cost, and no amount of descending finds it from those starts, ever. **Basin A is not a mistake and not a failure of will. It is the correct output of a local method applied to that starting point.** This is the myopia of learning stated as geometry [Levinthal and March, 1993], and the exploration side of the exploration-exploitation trade-off is what is missing rather than effort [March, 1991].

It cannot see over the ridge. The gradient at `x = 3` points toward `x = 2` and contains no information whatever about the existence of basin B. **The only instruments that see basin B are survey and report** — measuring a region one is not in, or hearing from someone who is. The structural role of non-redundant contacts in supplying exactly that information is well measured [Granovetter, 1973, Burt, 1992, 2004], and it is why a person with one framing and

no outside contact is not merely unlucky but *informationally* confined.

It cannot tell you the destination is worth arriving at. `C` is cost, not value. Descent optimises the operating draw and nothing else. A basin can be cheap and empty; a configuration in which nothing is required of the occupant is a global minimum of `C` and may be a catastrophe on every other ledger. **The stored order `Q` and the surplus `F` are where worth lives, and the gradient is blind to both** [Curzi, 2026a]. An subject who optimises only `C` converges on the cheapest available life, and the storage law's fixed point shows that a cheap life with a thin moment still ends in a small self.

It cannot price a barrier it is not adjacent to. `E_b` for the A-to-B crossing is 2.3987 Q-units at a 65.5-week transit (Section 4.6). That number required integrating the field along the whole path. **It is not obtainable from any local measurement at `x = 2`,** and an subject who has only descended has no access to it.

These four limitations are why the launch budget is needed, and the join is exact: the gradient supplies the direction of cheapest motion and the launch budget supplies the ability to move against it. Descent alone converges on the nearest available floor. Descent plus a funded departure reaches the best floor that was surveyed.

22.5.10 5.10 Temperature and momentum: two candidate escapes, one of them refused

Two standard escapes from a local minimum exist in the optimisation literature, and it is worth reporting what each does to this landscape, including where it does nothing. Both are **analogies** in the sense of Section 3.7: imported as candidate mechanisms and tested, with no claim that either physical process occurs.

Temperature. Under the logit model choice is already stochastic: the probability of taking a costlier option is `1/(1 + exp(d/theta))`.

`d` (theta units)	`P`(costlier option)
0.0000	0.50000
0.1335	0.46667
0.4418	0.39131
1.0296	0.26316
1.9459	0.12500
2.8332	0.05556

So a walker at intermediate temperature does occasionally step uphill and, given enough occasions, will cross a shallow ridge with no plan at all. This is the annealing heuristic of combinatorial optimisation arriving as a description of ordinary variability. **It is borrowed form: no claim is made that people anneal.** What is worth taking from it is the design consequence: **raising `theta` raises exploration and lowers exploitation, so a period of deliberately loosened routine is a real search strategy with a real cost, and the cost is that everything gets slightly worse while it runs.** That is the exploration trade-off in its exact form [March, 1991].

Momentum, and the negative result. Adding a momentum term `v_{t+1} = beta*v_t − alpha*grad C`, `x_{t+1} = x_t + v_{t+1}`, gives a walker that carries direction across small adverse gradients. Run on this landscape from `x_0 = 3.0`:

`beta`	effective step multiplier	final `x`	basin
0.00	1.00	1.9972	A
0.50	2.00	1.9972	A
0.80	5.00	1.9972	A

beta	effective step multiplier	final x	basin
0.90	10.00	1.9972	A
0.95	20.00	1.9972	A

Momentum does not escape this landscape at any setting tested, and the reason is instructive: the barrier is a plateau, not a spike. The ridge at `x = 4.335` has `C'' = −0.005076` and is nearly flat over more than two configuration-units. Momentum accumulated on a one-unit descent cannot carry a walker across a two-unit flat rise. **Momentum defeats narrow barriers and is useless against wide shallow ones, and most barriers of practical interest — an income gap, a retraining period, a slow renegotiation — are wide and shallow.**

That is a measured negative result on a constructed field and it is reported at the same prominence a positive result would receive. It also sharpens the claim of Section 4: **against a wide shallow barrier there is no substitute for an accumulated fund, because there is no dynamical trick that crosses it.**

A bookkeeping note, since the framework's rule is that every formula in its formulary carries its seven gates. The momentum recursion is not entered into the formulary and therefore carries no validation table: it was introduced as a candidate mechanism, tested on a measured field, and failed. Recording a failed candidate is not the same as adopting one, and the distinction is worth keeping sharp, because a formulary that admits every formula anyone tried is a formulary nobody can use. What survives is one empirical statement with no free parameters in it: *momentum does not cross wide shallow barriers.*

22.5.11 5.11 Regrading

The permitted intervention is always the same: **do not push the walker; lower the valley.** Alter relative costs so the wanted configuration is the cheap one and leave the choice intact. The construction satisfies the framework's consent constraint by construction — **the subject can still decline, and the bounded worst case is that they look at the lower valley and stay where they are.** A method whose worst case is "nothing changes" is admissible. A method that removes the option is not, at any efficacy.

Four regrades of the shared landscape, computed. `E_b` at a 65.5-week transit; launch fund `Lambda_inf = (eta*M − C(A))/lambda` at `eta = 0.10`, `M = 1.42`, `lambda = 0.025`.

Regrade	`C(A)`	`E_b`	`Lambda_inf`	`t*` (wk)
none	0.03400	2.3987	4.3200	**32.00**
deepen the destination by 0.006	0.03400	2.3523	4.3200	31.06
bridge the ridge by 0.006	0.03361	2.2294	4.3357	28.52
bridge the ridge by 0.020	**0.03269**	**1.8345**	**4.3724**	**21.49**

Deepening the destination is nearly useless: a 21 per cent improvement in the target basin's floor buys a 1.94 per cent reduction in the barrier. Making the destination more attractive does not make the crossing cheaper, because **the barrier is the ridge, not the valley.** Every recruitment brochure, relocation incentive and aspirational campaign that works on the destination is working on the wrong term.

Bridging the ridge is where the leverage is. A 0.020 reduction in the transit region — subsidised retraining, a bridging income, a sublet, keeping the old arrangement running in parallel — cuts the barrier by 23.5 per cent and cuts the wait from 32.00 weeks to 21.49.

And it does something further, which was not designed and fell out of the computation. After the 0.020 bridge the stationary points of the field are:

Feature	x	C(x)
basin A	2.0195	0.032665
ridge	3.5425	0.073902
new basin	**4.3350**	**0.071500**
ridge	5.1780	0.074027
basin B	6.9815	0.028208

The bridge manufactured a rest basin in the middle of the crossing. That is precisely the barrier split of Section 4.8 — here produced by a regrade rather than prescribed by a plan. Priced:

```
leg 1  (A -> new basin):     E_b = 0.8812     accumulation at Lambda_inf = 4.3734:   8.89 weeks
leg 2  (new basin -> B):     E_b = 0.0218     accumulation at Lambda_inf = 2.8200:   0.31 weeks
-------------------------------------------------------------------------------------------
total accumulation                                                                  9.19 weeks
(against 32.00 weeks for the unregraded single crossing)
```

Nine weeks instead of thirty-two, with the total transit time unchanged at about sixty-five weeks. What changed is how much fund had to be accumulated before anything could begin. The rule this yields is worth stating on its own: **a regrade that creates a stationary point in the middle of a crossing is worth far more than a regrade of the same size applied anywhere else, because it converts one barrier into two and the fund requirement scales with the largest, not the sum.**

A gap in the source, reported. The source states the resulting stationary points but never states the bridge's functional form. A Gaussian reduction `C_bridge(x) = C(x) - a*exp(-(x - 4.335)^2 / 2.0)` reproduces all five stated stationary points to four decimal places at `a = 0.020`, and all three at `a = 0.006`, so it is used to draw the figure below; it recovers `E_b = 1.8361` against the source's 1.8345, a 0.09 per cent difference. **The form is a reconstruction, not a quotation, and is labelled as such in the caption.** Two further inconsistencies of the same size sit in this table: `C(A)` after the 0.020 bridge is 0.032665 at the stationary point but is carried as 0.03269 in the regrade table, which propagates to `Lambda_inf` = 4.3734 in the leg table against 4.3724 in the regrade table, and to `t*` = 21.50 against 21.49. The figures are left as the source has them.

22.5.12 5.12 The headroom identity, and what it means to descend

From the headroom gauge `h = eta*ln N - delta*Q - C` [Curzi, 2026b], only the last term depends on configuration. Therefore:

```
THE HEADROOM IDENTITY

    grad_x h(x)  =  - grad_x C(x)  =  g(x)

    DESCENT IN THE COMFORT FIELD IS ASCENT IN HEADROOM, holding eta, N, delta and Q fixed.
```

Spot-checked on the shared field at `eta = 0.10`, `N = 9`, `delta = 0.031729`, `Q = 1.20`:

x	C(x)	h(x)	-dC/dx
1.500	0.049044	0.132603	+0.0515447

x	C(x)	h(x)	−dC/dx
2.000	0.034000	0.147648	-0.0004000
4.335	0.091500	0.090148	+0.0000007
7.000	0.028800	0.152848	-0.0004000

Descending the comfort field is ascending the headroom gauge. The worn path and the framework's master gauge are measuring the same gradient, in the same direction, with the same zeros. **A cheap survey of one's own habits is a measurement of one's own capacity for the new.**

Two consequences, and the second is a diagnostic.

One: the comfort zone is the headroom maximum. Under the restriction, the local minimum of `C` is the local maximum of `h`, so the founding definition [Curzi, 2026] and the master gauge [Curzi, 2026b] are the same statement in two registers, and the platform result of Section 4.2 follows immediately: **the place of rest is the place with the most capacity, which is why it is the place from which departures are planned and funded.**

Two: when the identity fails, it names the culprit. The identity holds only where `eta`, `N`, `delta` and `Q` are configuration-independent, and often they are not. A configuration that puts the subject among people who see differently raises `N`; one that supplies a notebook habit raises `eta`; one that confers a title raises `Q` and therefore the maintenance draw. The corrected form is

```
grad h = eta'(x) ln N + eta/N ∗ N'(x) − delta'(x) Q − delta Q'(x) − grad C
```

If a measured desire line points consistently away from measured headroom improvement, one of those terms is non-zero, and identifying which is a diagnosis rather than a contradiction. The commonest case is a configuration with low `C` and low `N` — the comfortable narrow life — in which descent genuinely reduces cost while `eta∗ln N` shrinks faster. That is visible only if `N` is measured alongside `C`, and the corpus's own count lever is priced and declined net on exactly this arithmetic: a ceiling gain of `eta∗(ln 6 − ln 5) = +0.1914` against five added communication paths costing +0.0714, a 34 per cent haircut on the headline benefit [Curzi, 2026j].

22.5.13 5.13 Switching cost, and why the path back is not the path out

One assumption has been running underneath the measurement sections without being examined: that each occasion is an independent draw from the choice distribution. It is not, and the correction matters enough to be derived rather than mentioned.

Most real configurations carry a **switching cost**: it is dearer to do a thing today if something else was done yesterday — setting up elsewhere, re-establishing context, breaking a running habit, explaining the change to the people around one. The simplest admissible model adds one term:

```
THE SWITCHING COST

    C_eff( x | x_prev )  =  C(x)  +  s ∗ 1[ x != x_prev ]

    s   the switching cost, in the same units as C −− the surcharge for not doing what
        was done last
```

This makes the cost field path-dependent, and a path-dependent field is a field with hysteresis: the cost of the route from A to B is not the cost of the route from B to A, and the configuration an subject settles into depends on where they came from as well as on where

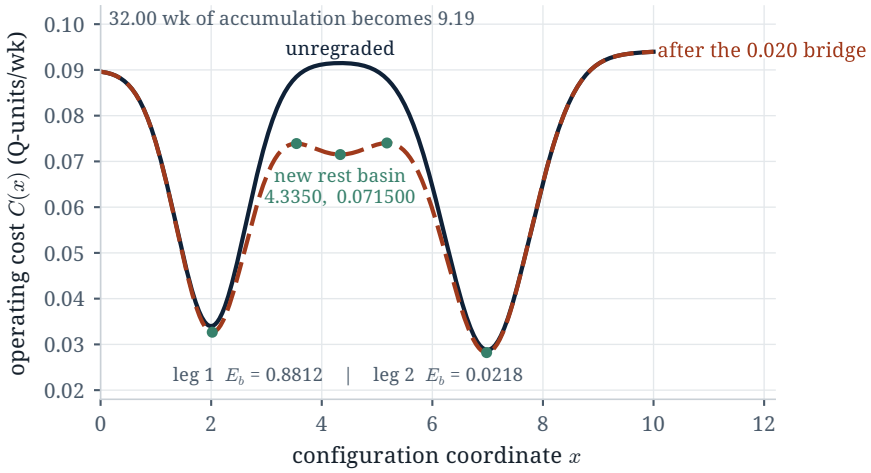

Figure 22.2: **The bridge manufactures a rest basin where the plan would otherwise have to prescribe one:** a 0.020 reduction applied at the ridge turns three stationary points into five, with a new basin at `x = 4.3350`, `C = 0.071500`, splitting a single 2.3987-Q-unit barrier into legs of 0.8812 and 0.0218 and cutting required accumulation from 32.00 weeks to 9.19. Modelled; the source states the resulting stationary points but not the bridge's functional form, and the curve drawn is the reconstruction `C(x) – 0.020*exp(–(x–4.335)^2/2.0)`, which reproduces all five stated stationary points to four decimals. Generated by `figs/src/CCP–022_fig04.py`.

the floors are. That switching costs and accumulated attachment keep participants in an arrangement they would not choose afresh is the exit-cost mechanism in its organisational form [Hirschman, 1970].

The consequence for the instrument is direct and unpleasant. Choices are now a Markov chain rather than independent draws, and the logit recovery, which assumes independence, recovers something that is not the cost field. Computed on a four-option coordinate with true costs `C = (0, 0.20, 0.50, 0.90)` in theta units, taking the chain's stationary distribution and applying Protocol G-1 to it exactly as an investigator would:

`s`	recovered `d_kitchen`	recovered `d_cafe`	recovered `d_office`	recovered ratio office/kitchen
0.0 (truth)	0.2000	0.5000	0.9000	4.5000
0.3	0.2201	0.5442	0.9675	4.3950
0.6	0.2416	0.5927	1.0433	4.3176
1.0	0.2709	0.6609	1.1537	4.2587
1.5	0.3053	0.7446	1.2964	4.2460

Three findings, and the third is why the specification is worded as it is.

One: switching cost inflates every non-modal option's recovered cost. At `s = 0.6` the kitchen table is recovered as 0.2416 when its true cost is 0.2000, a 20.8 per cent overstatement. The instrument has silently charged the subject's habit to the option.

Two: the inflation is largest in absolute terms for the rarest option. The office is inflated by 0.1433 theta and the kitchen by 0.0416. **A switching cost makes unusual choices look more expensive than they are and makes the most unusual ones look worst.** Combined with Section 5.4's finding that rare options are also the badly measured ones, this is a double penalty on exactly the directions a survey is run to investigate.

Three, and it is the good news: the identified ratio is far more robust than the differences. At `s = 0.6` the differences are biased by 15.9 to 20.8 per cent while the ratio is biased by 4.05

per cent; at `s = 1.0` the differences are biased by 28 to 36 per cent and the ratio by 5.36 per cent. **Reporting ratios of differences rather than differences buys roughly a factor of four in robustness to an unmodelled switching cost, and that is on top of the theta-freeness that was the original reason for the rule.** A specification adopted for one good reason turns out to have a second.

The engineering consequence is a small change to the protocol and a large change to interpretation. **Record transitions, not only choices.** One extra column — what was chosen on the previous occasion — turns a marginal tally into a transition matrix, identifies `s` from the log-odds difference between staying and arriving, and lets the recovered field be corrected for it.

And the design consequence connects back to the launch budget. **A switching cost is a barrier that lives between adjacent configurations rather than between distant ones,** which means a coordinate with a high `s` has small barriers everywhere rather than one large barrier somewhere. That is a different landscape and it calls for a different move: not a bridge across a pass, but a reduction in the surcharge itself — the standing setup left in place, the second desk not cleared away, the arrangement that makes tomorrow's switch as cheap as today's continuation. This is the setup ledger seen from the other side, and it is why the corpus's built-environment work caps setup time from arrival to first productive minute at ninety seconds [Curzi, 2026f]: setup is a switching cost, and a switching cost suppresses use of a space in proportion to how rarely it is already used. A laid table gets eaten at and a cupboard does not, and the difference is `s`.

22.6 6 Formula validation: seven gates on five formulas

The corpus applies a fixed seven-gate audit to every formula it admits to its formulary. The gates are: **FVP-1 dimensions** (do the units of every term agree); **FVP-2 scale type** (does the operation performed require an interval or a ratio scale, and is that licensed); **FVP-3 limiting cases** (each parameter to zero and to infinity); **FVP-4 fixed points** (what is invariant); **FVP-5 identifiability** (can the quantity be recovered from obtainable data); **FVP-6 falsification** (state the result that would kill it); **FVP-7 reproducibility** (do the parameters recover across individuals). Verdicts are recorded as stated, including the failures.

The momentum recursion of Section 5.10 has no table here, deliberately: it was tested and failed, and a failed candidate is recorded rather than admitted.

22.6.1 6.1 The launch budget

`FVP TABLE — THE LAUNCH BUDGET  L^Q = max(0, eta M − C),  L^M = max(0, M − C/eta)`

Gate	Test applied	Finding	Verdict
FVP-1 dimensions	Units of each term; both sides agree.	The naive form fails; Section 3.2 resolves it into two consistent registers differing by the factor `eta`. `L^Q` in Q-units per period, `L^M` in nats per period. **A reported `L` without a declared register is inadmissible.**	**PASS after the register split; FAIL as originally written**
FVP-2 scale type	Subtraction requires an interval scale; `max(0,.)` requires a meaningful zero, hence a ratio scale.	`M` is ratio-scaled by the framework's construction. `C` is ratio-scaled only if the cost ledger's exchange rates are, which is a postulate every time. **The rectifier is the demanding part: `max(0, x)` is only meaningful if zero means something, so this formula cannot be demoted to an interval-scale heuristic — it either has a true zero or it is not this formula.**	**CONDITIONAL — depends entirely on the cost ledger's zero**

Gate	Test applied	Finding	Verdict
FVP-3 limiting cases	Each term to 0 and to infinity.	`C -> 0`: `L -> eta M`, the whole deposit is discretionary — the state of a person with nothing to maintain. `C -> eta M`: `L -> 0`, the floor. `C > eta M`: `L = 0` and stays 0 however much larger `C` grows — **the rectifier means the model cannot distinguish "just barely trapped" from "catastrophically trapped", which is a real limitation and is why the cost carry must be tracked separately.** `M -> 0`: `L = 0`. `eta -> 0`: `C/eta -> infinity` and `L^M -> 0` — **no conversion, no launch budget, at any moment size.** `M -> ln N` with `C` fixed: `L^M -> ln N - C/eta`, the ceiling.	**PASS, with the named insensitivity**
FVP-4 fixed points	The invariant.	Two. (i) `eta M = C` is the zero crossing: the break-even life, in which every unit of moment is consumed by the cost of having had it. (ii) Over a configuration space, the stationary points of `L` are exactly the stationary points of `C` and the maxima of `L` are the minima of `C` (Proposition 4.1). **The second is the paper's central structural result.**	**PASS**
FVP-5 identifiability	Recoverable from data?	`L^Q` requires `eta`, `M` and `C`, all of which the framework's survey protocol measures [Curzi, 2026i]. **But `L` is not independently observable — it is a computed difference, and any error in `eta` propagates into `L^M` as `C*d(1/eta)`, which is severe at small `eta`.** At `eta = 0.05` a 20 per cent error in `eta` moves `C/eta` by 0.29 nats, a fifth of a typical `M`.	**CONDITIONAL — `L` is derived and inherits every upstream error, amplified at low `eta`**
FVP-6 falsification	Preregister; freeze; held-out; four baselines including a shuffled-input control. State the killing result.	**The Launch Postulate predicts that the incidence of newly constructed plans for a different configuration is monotone increasing in contemporaneous `L`, and specifically zero when `L = 0`.** Prospective within-subject design: log `M`, `C` and plan-initiation events daily for 90 days; freeze; test on held-out days against a persistence baseline, an `M`-only baseline, an AR(1) baseline and a shuffled-`L` control. **A single well-documented plan constructed during a sustained `L = 0` stretch falsifies the strong form.**	**NOT RUN — protocol stated, and it is cheap**
FVP-7 reproducibility	Cross-individual recovery.	Unattempted. The question is whether the `L = 0` threshold sits at the same place for different people once `eta` and the cost ledger are constructed by a common procedure. **That is the person-item separation problem [Rasch, 1960, Andrich, 1988] and there is no reason to expect it to come free.**	**NOT RUN**

22.6.2 6.2 The launch fund

Gate	Test applied	Finding	Verdict
FVP-1 dimensions	Units agree.	`Lambda` in Q-units, `L` in Q-units per period, `lambda` per period; `L/lambda` is Q-units. **Consistent, and note that `Lambda` is a stock while `L` is a flow — a distinction violated constantly in ordinary talk about motivation** [Sterman, 1989].	**PASS**
FVP-2 scale type	Multiplication by `(1-lambda)` requires a ratio scale.	Inherits `L`'s conditional verdict.	**CONDITIONAL**

Gate	Test applied	Finding	Verdict
FVP-3 limiting cases	Each term to 0 and to infinity.	`lambda -> 0`: `Lambda` grows without bound — the plan that never fades, so any barrier is eventually crossable. **This is the limit that makes written, dated, witnessed plans powerful.** `lambda -> 1`: `Lambda_t = L_t`, no accumulation, only barriers crossable in a single period. `L -> 0`: `Lambda -> 0` geometrically, half-life `ln 2 / (-ln(1-lambda))`.	**PASS**
FVP-4 fixed points	The invariant.	`Lambda_inf = L/lambda`, unique and attracting by the contraction theorem for `lambda > 0` [Curzi, 2026]. **The fixed point is a ceiling on ambition, computable from two numbers.**	**PASS**
FVP-5 identifiability	Recoverable?	`lambda` from a zero-input window on plans: state a plan, add nothing to it, and measure the decline in willingness to act on it. **This is measurable and almost never measured, and it is the parameter with the largest leverage in the paper.**	**PASS in principle; the measurement is awkward and reactive**
FVP-6 falsification	The killing result.	**If plan persistence does not decay geometrically in the absence of reinforcement, the leaky-integrator form is wrong for plans and must be replaced.** A threshold or step-function decay would falsify it, and either is plausible.	**NOT RUN**
FVP-7 reproducibility	Cross-individual.	Unattempted.	**NOT RUN**

22.6.3 6.3 Feasibility and the critical cost

Gate	Test applied	Finding	Verdict
FVP-1 dimensions	Units agree.	`eta M` and `C` in Q-units per period; `lambda E_b` is (per period)(Q-units) = Q-units per period. **Consistent.**	**PASS**
FVP-2 scale type	Ratio scale throughout.	Inherits. `E_b` must be ratio-scaled with a true zero, since a barrier of zero must mean “no barrier”.	**CONDITIONAL**

Gate	Test applied	Finding	Verdict
FVP-3 limiting cases	Each term to 0 and infinity.	`E_b -> 0`: `C_crit -> eta M` and the condition reduces to `L > 0` — **an adjacent move requires only that the subject not be at the floor.** `E_b -> infinity`: `C_crit -> -infinity`, no cost is low enough, which is correct since an infinite barrier is uncrossable. `lambda -> 0`: `C_crit -> eta M`, the barrier stops mattering — **with a perfectly durable plan, any finite barrier falls eventually.**	**PASS**
FVP-4 fixed points	The invariant.	`C = C_crit` is the knife edge: `Lambda_inf = E_b` exactly, so the fund approaches the barrier asymptotically and never crosses it, and `t* -> infinity` as `C -> C_crit` from below. **The boundary case is "forever nearly ready", which is a recognisable state and is a point in the model's favour.**	**PASS**
FVP-5 identifiability	Recoverable?	All four inputs are separately measurable. **`E_b` is the weak one: it is normally estimated by the subject, who is exactly the party with a stake in the estimate, and Section 5 gives the only construction here that does not rely on introspection.**	**CONDITIONAL on an independent `E_b`**
FVP-6 falsification	The killing result.	**Prediction: across a population of would-be departures, the observed departure rate falls to zero as `C` crosses `eta M - lambda E_b`, at a threshold predicted from parameters measured beforehand.** If departures occur at the same rate above and below the computed threshold, `C_crit` is fictitious. Requires a cohort and is the most expensive test here.	**NOT RUN**
FVP-7 reproducibility	Cross-individual.	Unattempted, and the threshold test above is inherently cross-individual, so FVP-6 and FVP-7 stand or fall together here.	**NOT RUN**

22.6.4 6.4 The barrier integral

```
FVP TABLE — THE BARRIER      E_b = (1/v) * INTEGRAL over the path of max(0, C(x) - C(A)) dx
```

Gate	Test applied	Finding	Verdict
FVP-1 dimensions	Units agree.	`C` in Q-units per period; `dx` in configuration-units; the integral is Q-unit configuration-units per period; dividing by `v` in configuration-units per period gives Q-units. **Consistent, and note that `E_b` is a stock while `C` is a flow — the integral is what converts one to the other.**	**PASS**
FVP-2 scale type	Integration requires an interval scale on `C` and a metric on the path.	`C` differences suffice, since only excess over `C(A)` is integrated. **The metric on the path is the demanding requirement and it excludes categorical transitions: where there is no ordered coordinate between A and B there is no path integral, and `E_b` must be estimated by ledger instead** — the same demotion Section 5.2 performs.	**CONDITIONAL — requires an ordered coordinate, else demote to a ledger estimate**
FVP-3 limiting cases	Each term to 0 and to infinity.	`C(x) <= C(A)` everywhere on the path: `E_b = 0`, a downhill move with no barrier, and feasibility reduces to `L > 0`. `v -> 0`: `E_b -> infinity`; an infinitely slow crossing costs infinitely much, which is correct and is why indefinite hesitation is not free. **`v -> infinity`: `E_b -> 0`, which is FALSE and is the model's known defect, stated in Section 4.6 and fenced by SP-L12 rather than fixed.**	**PARTIAL — one limit is known to be wrong and is fenced rather than fixed**
FVP-4 fixed points	The invariant.	`E_b` is minimised over paths by the route whose maximum excess is lowest — the pass — which is why the regrades of Section 5.11 are evaluated at the ridge and not at the destination. **The invariant is the pass, and it is what a barrier IS.**	**PASS**
FVP-5 identifiability	Recoverable?	Requires `C(x)` over the whole path, and **the subject has by definition not occupied most of it.** The worked case reconstructed the unvisited region by ledger, which is an inference and not a measurement. **This is the single largest weakness in the paper and is recorded again in Section 12.** An independent ledger estimate agreeing with the integral (Section 9.3) is the only check available and it is weak, since both may share the same reconstruction.	**WEAK — the integrand is unmeasured over the region that matters**

Gate	Test applied	Finding	Verdict
FVP-6 falsification	The killing result.	**Prediction: realised transit cost, ledgered after the fact, matches the pre-computed `E_b` within the stated interval.** Cheap to test retrospectively on any completed transition by anyone who computed `E_b` beforehand. **If realised cost is uncorrelated with the predicted barrier across a set of transitions, the construction is fictitious.**	**NOT RUN — but it is the easiest test here to run**
FVP-7 reproducibility	Cross-individual.	Unattempted. **`E_b` is jointly a property of the person and the transition, and separating those is the person-item separation problem in its hardest form** [Rasch, 1960].	**NOT RUN**

22.6.5 6.5 The gradient, the discrete descent, and the logit recovery

Gate	Test applied	Finding	Verdict
FVP-1 dimensions	Units of each term.	`C` in Q-units per period; `x` in whatever units the configuration coordinate carries; `grad C` in Q-units per period per configuration-unit. A step size `alpha` therefore carries configuration-units squared per Q-unit per period — **which is a sign that `alpha` is not a free constant but a scaling artefact of how the coordinate was defined.** Declare the coordinate scale or `alpha` is meaningless.	**PASS, with a mandatory coordinate declaration**
FVP-2 scale type	Differentiation requires at least an interval scale on `C` and a metric on `X`.	**`X` is the harder problem: most personal configuration coordinates are categorical, and where `X` is a finite unordered set `grad C` does not exist and must be replaced by the difference table of Section 5.3** — a demotion performed explicitly rather than papered over [Stevens, 1946, Tversky, 1977].	**CONDITIONAL — demoted to a difference table on categorical coordinates**
FVP-3 limiting cases	Each term to 0 and to infinity.	`grad C -> 0`: no preferred direction — a stationary point, which is a rest basin, a ridge or a plateau, distinguished only by the second derivative. `|grad C| -> infinity`: an infinitely steep wall, so the model predicts instantaneous motion, which is an artefact and marks the coordinate as badly scaled. `C` constant on a subspace: **the flat direction, where the subject is genuinely indifferent and where Section 5.6 shows design has its greatest leverage.**	**PASS**
FVP-4 fixed points	The invariant.	`grad C(x*) = 0`, classified by the Hessian: positive definite a rest basin, negative definite a ridge, indefinite a saddle, singular a plateau [Strogatz, 2015]. **The founding definition's claim that an subject is "already there" is the statement that an subject observed at rest is at a stationary point of their own cost field, by construction and not by luck** [Curzi, 2026].	**PASS**

Gate	Test applied	Finding	Verdict
FVP-5 identifiability	Recoverable from obtainable data?	**`C` itself is NOT recoverable. Only differences are, and only up to the scale `theta`.** So `grad C` is identified up to a positive scalar, which is sufficient for direction and insufficient for magnitude. **Ratios of cost differences are fully identified because `theta` cancels, and those are the quantities reported.**	**PARTIAL — direction identified, magnitude only up to `theta`**
FVP-6 falsification	Preregister; freeze; held-out; four baselines including a shuffled-input control.	Fit the difference table on days 1-20; freeze; predict the choice distribution on days 21-30; beat a uniform baseline, a most-frequent-option baseline, a first-order Markov baseline and a **day-shuffled control**. **If the frozen cost table does not beat the shuffled control on held-out days, the subject has no stable comfort field over the surveyed coordinates and the Gradient Postulate fails for them.**	**RUNNABLE — run in Section 9.8, and passed on two coordinates**
FVP-7 reproducibility	Same operationalisation, different people.	Unattempted. **`theta` is expected to be person-specific and the coordinates certainly are.** The one thing that might transfer is the *shape* of the finding — that most subjects have a few steep coordinates and many flat ones — and even that is untested.	**NOT RUN**

Discrete descent, separately. For `C` with an `L`-Lipschitz gradient, `alpha < 2/L` guarantees the iteration does not diverge locally, `alpha = 1/L` gives the fastest guaranteed monotone decrease, and near a minimum with curvature `mu` the error contracts by `|1 − alpha*mu|` per step. Three gates differ from the table above. **FVP-3:** `alpha -> 0` halts motion; `alpha > 2/L` makes `|1 − alpha*mu| > 1` so the iteration oscillates with growing amplitude *locally* — **in a bounded landscape this presents not as blow-up but as wandering, which is a genuinely different observable and is named in FM-G5. FVP-4:** any `x` with `grad C(x) = 0` is a fixed point, and only the positive-definite ones are attracting, **which is why an subject is found at rest in basins and not on ridges** — so finding someone apparently at rest on a ridge is a strong signal that something other than the gradient is holding them there. **FVP-5: FAIL as written.** `alpha` and the `theta` scale of `C` are not separately identified; only the product governs the observed step, so two subjects with different responsiveness and different cost scales produce identical traces. **Report the product or neither.**

The logit recovery, separately. FVP-1: `ln(n_a/n_b)` is dimensionless, `theta` carries `C`'s units, the product is a cost difference. **Consistent. FVP-2 is the crux and it is good news.** The recovery yields cost **differences** on an interval scale with unknown unit `theta`; **ratios of differences are ratio-scaled and fully identified, because `theta` cancels** [Narens, 1996]. So comparative claims are available without ever pinning `theta`, and absolute claims are not. **FVP-3:** `n_a -> 0` makes both the estimate and its standard error diverge — **a never-chosen option is an unmeasured option, and the model says so loudly**; `theta -> 0` gives deterministic choice and `theta -> infinity` gives uniform choice, and in both limits nothing is recoverable, so **recovery requires intermediate temperature, which is a real and often-violated precondition. FVP-4:** `n_a = n_b` gives `C_a = C_b` — the flat coordinate. **FVP-5:** differences yes, up to `theta`; **`theta` itself requires an external anchor and that experiment has not been run. FVP-6:** independence of irrelevant alternatives — **adding a fourth option must not change the ratio of the first two.** This is the classic test of the Luce form, it is known to fail in many choice domains, and near-substitutes are the classic failure case [Tversky, 1977, Brock and Durlauf, 2001]. **FVP-7:** the procedure is fully portable, since it needs a tally sheet; whether `theta` is a stable personal parameter is unknown.

22.6.6 6.6 The headroom identity and the switching cost

The headroom identity. FVP-1: both sides in Q-units per period per configuration-unit. **PASS. FVP-3:** the identity is exact only where `eta`, `N`, `delta` and `Q` do not depend on `x`, **and that is a**

substantive restriction: a configuration that changes what can be distinguished changes `N`, one that changes what must be maintained changes `Q`, one that changes how experience is captured changes `eta`. **PASS on the stated restriction; FAILS where the configuration moves the other parameters. FVP-4:** `grad C = 0` if and only if `grad h = 0` — **the comfort zone and the headroom maximum are the same point, under the restriction**, which is the identity's payoff. **FVP-5:** the identity requires no new measurement, being algebraic; **its content is that a desire-line survey, which is cheap, measures the same gradient as a headroom survey, which is expensive. FVP-6:** if a measured desire line points consistently away from measured headroom improvement, the restriction is violated and one of `eta`, `N`, `delta`, `Q` is configuration-dependent — **a diagnosis rather than a contradiction, and it localises which parameter is moving.**

The switching cost. FVP-1: `s` in the units of `C`, the indicator dimensionless; **consistent**, with the caveat that `s` is a per-occasion surcharge and not a rate, so the period must be the occasion and not the week. **FVP-2:** inherits the logit verdict; **the binary indicator is the crude part**, since a real switching cost is graded by how different the configurations are, and the metric refinement `s*d(x, x_prev)` requires a metric on `X` that categorical coordinates do not have. **CONDITIONAL — the binary form is a lower-resolution model, badged. FVP-3:** `s -> 0` returns independent draws and Protocol G-1 recovers the true field; `s -> infinity` makes the current configuration absorbing, every recovered cost diverges, and **the survey returns "you always do this", which is true and useless. FVP-4:** the stationary distribution of the induced Markov chain, which exists and is unique for finite `s`; **`s` does not change which option is cheapest, it changes how much of the time the subject is found there. FVP-5: PASS, but only if transitions are recorded.** `s` is identified from transition counts rather than marginal counts: compare `P(x_t = a | x_{t-1} = a)` with `P(x_t = a | x_{t-1} != a)` and their log-odds difference is `s` in theta units. **Protocol G-1 as originally written throws away exactly the data that would identify it, and SP-G16 fixes that defect. FVP-6:** if the first-order Markov baseline does not beat the independent-draw model on held-out days, `s = 0` for that coordinate and the term should be dropped. **FVP-7:** unattempted; `s` is plainly both person- and coordinate-specific, and **the qualitative claim that `s > 0` almost everywhere is close to untestable as stated and is not advanced as a finding.**

22.7 7 Design specifications

22.7.1 7.1 From the launch budget

SP-L1 Every reported `L` shall declare its register — `L^Q` in Q-units per period or `L^M` in nats per period — and shall state the `eta` used to convert between them. **An undeclared `L` is inadmissible.**

SP-L2 `L` shall never be reported without the `C` and `M` it was computed from, since `L` is a derived difference and inherits every upstream error, amplified at low `eta`.

SP-L3 The rectifier shall not be used to summarise severity. `L = 0` records that the budget is exhausted and nothing more; **the depth of the deficit shall be tracked separately as cost carry**, because `max(0, .)` discards it.

SP-L4 `lambda` shall be measured, not assumed, by a zero-input window on a stated plan. A survey that assumes `lambda` shall print the assumed value and the sensitivity of `Lambda_inf` to it.

SP-L5 `E_b` shall be constructed as an accumulated excess cost over an intended transit, at a stated transit duration, and shall not be elicited by asking the subject how difficult the change feels.

SP-L6 `E_b` estimates from an subject with measured calibration ratio `r > 1.2` shall be flagged, and the `Lambda_inf` figure recomputed on the veridical part as well as on the moment as lived. **Both figures shall be printed.**

SP-L7 `C_crit = eta*M - lambda*E_b` shall be computed before any programme that would raise `C` is adopted. **A programme that would push `C` above `C_crit` shall be refused, and the**

refusal shall state the computed threshold.

SP-L8 No intervention shall raise another person's `C` for the purpose of producing a departure. Permitted interventions lower the cost of the alternative and leave the choice intact.

SP-L9 Where `Lambda_inf <= E_b`, the barrier shall be split before any parameter is exhorted, and each intermediate stage shall be verified to be a genuine rest basin — a configuration with `grad C = 0` at which the subject can stop indefinitely.

SP-L10 Departure shall not begin before `t* = ln(1 - E_b/Lambda_inf)/ln(1 - lambda)` periods of accumulation. An underfunded departure strands the subject at the configuration of minimum launch budget.

SP-L11 Every departure shall be preceded by a reversible probe of the destination configuration, with its cost logged beside its finding.

SP-L12 The transit-duration model shall not be extrapolated outside the range in which the cost field can be treated as speed-independent. **Its `v -> infinity` limit is known to be false and shall be printed as such wherever the table is used.**

SP-L13 The Launch Postulate shall be badged wherever it is used. It is not a theorem, nothing in the framework's foundational results implies it, and the falsification protocol of Section 6.1 shall accompany any empirical claim made on its basis.

22.7.2 7.2 From the gradient and the survey

SP-G1 Coordinates shall be declared and frozen before the trace begins, with option sets exhaustive and mutually exclusive, and shall not be revised inside a window.

SP-G2 Availability shall be recorded per occasion and all tallies shall run over available occasions only. **A count that does not separate "not chosen" from "not offered" is void.**

SP-G3 Observations shall be recorded at the moment of choice by a rule stated in advance. Reconstruction from memory shall be labelled as such and shall not be pooled with recorded data.

SP-G4 The reference option per coordinate shall be selected from a pilot and frozen before the main window. **A reference chosen from the final data is a reference chosen to flatter** [Gelman and Loken, 2013].

SP-G5 Every recovered cost difference shall be reported with its standard error `sqrt(1/n_a + 1/n_b)` and its 95 per cent interval. **An interval containing zero shall be reported as unmeasured, regardless of the subject's confidence.**

SP-G6 Comparative claims shall be made as ratios of differences, which are theta-free and identified. **Absolute cost levels shall never be reported, and differences shall always carry the words "theta units".**

SP-G7 The independence-of-irrelevant-alternatives check shall be run on every coordinate with more than two options. A material shift in the top-two ratio when the choice set is manipulated falsifies the logit form for that coordinate and requires a different specification.

SP-G8 Categorical coordinates shall be reported as difference tables, never as gradients. **`grad C` shall be computed only on coordinates carrying a declared metric.**

SP-G9 Where a gradient is computed, the coordinate scale shall be declared, since `alpha` and `theta` are not separately identified and only their product governs the observed trace.

SP-G10 No conclusion about the globality of a minimum shall be drawn from a descent trace. **The gradient is local; a claim that a basin is the best available requires a survey of the region outside it, and the survey shall be named.**

SP-G11 `C` shall never be used as a proxy for value. Any recommendation derived from descent alone shall carry the statement that it optimises operating cost and nothing else.

SP-G12 Regrades shall alter relative costs and shall leave the subject's ability to decline intact. **A regrade whose worst case is not "nothing changes" is not a regrade.**

SP-G13 A regrade proposed to enable a crossing shall be evaluated at the ridge, not at the destination, and its effect on `E_b` shall be computed by the path integral of Section 4.6 rather

than asserted.

SP-G14 Where the headroom identity is used, the constancy of `eta`, `N`, `delta` and `Q` across the surveyed range shall be stated as an assumption and checked. **A desire line that opposes measured headroom shall trigger the diagnosis of Section 5.12, not a revision of the data.**

SP-G15 The Gradient Postulate and the logit choice form shall be badged wherever used, and the falsification protocols of Section 6.5 shall accompany any empirical claim made on them.

SP-G16 Transitions shall be recorded, not only choices: each occasion shall carry the option chosen on the previous occasion. **A marginal tally discards exactly the data that identifies the switching cost `s`, and a survey run without transitions cannot state whether its recovered differences are costs or habits.**

SP-G17 Where `s` is found to be non-zero, recovered differences shall be reported as switching-contaminated and the ratio form of SP-G6 shall be treated as the primary result. **Ratios are roughly four times more robust to an unmodelled switching cost than differences are, and that robustness shall be the stated reason for preferring them.**

22.8 8 Failure modes

22.8.1 8.1 Faults of the launch budget

FM-L1 — The reverse-biased subject. *Signature:* sustained `L = 0`; the subject reports no particular ideas, no restlessness, no sense of being trapped, and asked what they would do instead has nothing — read by themselves and others as contentment or as lack of ambition. *Mechanism:* `eta*M <= C` for many consecutive periods; the rectifier is off, and **the capacity to notice the situation is funded by the same budget that is missing.** *Fix:* the diagnosis must come from outside, or from a deliberately engineered local minimum — a period with `C` collapsed and `M` intact. Do not begin with goal-setting; there is no budget for goals.

FM-L2 — The demolished platform. *Signature:* an subject on a deliberate discomfort programme, six months in, reporting more determination and fewer concrete plans, with the fund balance falling. *Mechanism:* Section 4.7 — `C` raised, `L` lowered, `Lambda_inf` lowered, and the barrier that was crossable is now not. *Fix:* compute `C_crit`; if `C` is above it the programme has foreclosed the departure and must be stopped rather than intensified; if below, strip the discomfort, keep whatever novelty was bundled with it, and measure the difference.

FM-L3 — The two-week fund. *Signature:* a serious intention held for years, revisited every holiday, never begun. *Mechanism:* `L > 0` for two weeks a year and `L = 0` for the other fifty. On the worked subject's parameters — `L^Q = 0.0575` during the two weeks, `lambda = 0.06` — **the fund saturates at an annual peak of 0.1162 Q-units against a barrier of 2.400. It reaches 4.84 per cent of the requirement, and it does so forever.** *Fix:* this is a duty-cycle problem and not a discipline problem; either raise `L` in ordinary weeks by cutting `C`, or cut `lambda` so the two weeks compound instead of evaporating. Note which one the arithmetic favours before choosing.

FM-L4 — The stranded crossing. *Signature:* a transition begun with enthusiasm, abandoned partway, at high cost, with the subject concluding they were not suited to it. *Mechanism:* step S4 skipped; `Lambda_inf < E_b`, so the fund ran out mid-transit at the ridge, which Section 4.2 shows is the configuration of *minimum* launch budget. **The subject cannot plan their way out of the place they most need to, because the field itself has taken the budget away.** *Fix:* split the barrier before beginning. If already stranded, the correct move is retreat to the nearest rest basin — which is usually backwards — because from a basin the budget returns and the crossing can be re-planned in stages. **Retreat to a local minimum is not failure; it is the only move that restores the capacity to move.**

FM-L5 — The pause on the ridge. *Signature:* a staged transition whose stages are points on the slope rather than basins; each stage is harder than the last and the plan keeps needing revision. *Mechanism:* Section 4.8's condition violated — a stage that is not a rest basin does not restore the fund, it draws it down at the ridge rate. *Fix:* redesign the stages so each terminates

at a genuine `grad C = 0` configuration where the subject could remain indefinitely. If no such configuration exists between A and B, the barrier cannot be split and one of moves 1 to 4 is required.

FM-L6 — The manufactured destination. *Signature:* a well-funded, well-planned, confidently executed departure to a configuration that turns out not to be what it appeared, followed by a rapid and expensive return. *Mechanism:* Section 4.9 — a calibration ratio above 1 inflated both the launch budget and the attractiveness of the target and depressed the barrier estimate; all three errors compound, and attention to the prospective change inflates its apparent importance while it is being attended to [Kahneman et al., 2006]. *Fix:* SP-L6 and SP-L11 — recompute the fund on the veridical part and probe the destination reversibly before committing. **If probing the destination produces no return difference, no information about it has been acquired and the plan is still entirely a construction.**

FM-L7 — The perpetual dreamer. *Signature:* large, stable `Lambda`; extensive plans; nothing spent; often accompanied by considerable skill at planning. *Mechanism:* Section 4.10 — no `E_b` selected, so `Lambda` saturates and holds while the carry runs at full rate on every open loop. *Fix:* not more budget. Select one target, compute one `E_b`, set one date. **A fund with no barrier attached is a cost, not an asset.**

FM-L8 — The leaked resolution. *Signature:* a firm plan made at a local minimum that has no force eleven weeks later, with nothing having happened to end it. *Mechanism:* `lambda` unmeasured and large; at `lambda = 0.06` the plan is at half strength in 11.20 weeks. *Fix:* cut `lambda` at the moment the plan is made, while the budget that made it still exists — write it down, date it, tell one person, calendar the next addition. **The window for reducing `lambda` is the same window in which `L > 0`, and it closes.**

FM-L9 — The unregistered `L`. *Signature:* two figures for the same subject's launch budget differing by a factor of twenty, both correct. *Mechanism:* `L^Q` and `L^M` differ by `eta`, and at `eta = 0.05` that is a factor of twenty; one report used one register, the other used the other, and neither declared it. *Fix:* SP-L1. Declare the register; always print both.

22.8.2 8.2 Faults of the survey

FM-G1 — The unavailable option. *Signature:* a coordinate shows an enormous cost for one option and the subject concludes they have a deep aversion to it; in fact it was available on four days out of thirty. *Mechanism:* SP-G2 violated — the tally counted occasions rather than available occasions, so unavailability was recorded as cost. *Fix:* re-tally over available occasions. **This single correction reverses the sign of a recovered difference more often than any other in the protocol.**

FM-G2 — The confident unmeasured difference. *Signature:* a survey reports that the subject prefers X to Y, the subject agrees emphatically, and the 95 per cent interval spans zero. *Mechanism:* small `d` combined with small `n` — a 0.44-theta difference needs 108 days at these proportions and the survey ran 30. *Fix:* report it as unmeasured and either extend the window or accept that the coordinate is, for present purposes, flat — **which is not a defeat, since flat coordinates are the ones worth regrading.**

FM-G3 — The confession recorded as a trace. *Signature:* a desire-line survey completed on Sunday evening for the preceding week. *Mechanism:* SP-G3 violated — what was recorded was memory of choice, which decays and is systematically biased toward the self-image [Nisbett and Wilson, 1977, Schwarz, 1999]. *Fix:* prospective recording only, at the moment, by a rule fixed in advance. If prospective recording is impossible for a coordinate, drop the coordinate rather than substitute recall.

FM-G4 — The global claim from a local method. *Signature:* "I have tried everything and this is the best arrangement for me." *Mechanism:* Section 5.9 — descent has converged, correctly, to the nearest stationary point. **The statement is evidence about the basin and no evidence at all about the landscape.** In the worked field, every start in `[0, 4.334]` produces this sentence about a basin 15.3 per cent worse than the one next door. *Fix:* SP-G10 — survey the

region outside, or import a report from someone standing in it. Note that this cannot be done by more descending, however sincere.

FM-G5 — The wandering walker. *Signature:* an subject making large, frequent, apparently arbitrary changes of configuration without settling, and reading it as restlessness or as a character trait. *Mechanism:* `alpha > 2/L` in the local curvature; in an unbounded quadratic this diverges, and in a bounded real landscape it presents as wandering, which is a distinct and recognisable observable. *Fix:* reduce step size — smaller changes, more often, in the same direction. **The remedy for apparent restlessness is not more resolve but a shorter stride,** and the model gives the threshold `alpha < 2/max|C''|`.

FM-G6 — The regraded destination. *Signature:* considerable effort spent making the target configuration more attractive, with no change in the rate at which anyone crosses. *Mechanism:* Section 5.11 — deepening the destination reduced `E_b` by 1.94 per cent, because the barrier is the ridge. *Fix:* move the effort to the transit region: bridging income, parallel running, a sublet, a part-time overlap, subsidised retraining. **A 0.020 bridge at the ridge outperformed a 0.006 deepening of the destination by a factor of twelve on `E_b` in the worked field.**

FM-G7 — The pause on the plateau. *Signature:* an subject apparently deliberating for months and describing themselves as unable to decide. *Mechanism:* Section 5.8 — near the ridge the gradient magnitude is of order `10^-5` and descent from `x = 4.30` takes fifty steps to travel 0.17 units. **They are not deliberating. They are descending a plateau at the speed the field permits.** *Fix:* recognise that the field is flat here and that Section 5.6's leverage applies — a small regrade resolves in weeks what the gradient will not resolve in a year. Do not add resolve to a plateau; tilt it.

FM-G8 — Cost mistaken for value. *Signature:* a configuration reached by careful descent, correctly identified as the cheapest available, and experienced as empty. *Mechanism:* Section 5.9's third limitation — `C` is the operating draw and nothing else, and the storage law's fixed point shows that a cheap life with a thin moment converges on a small self [Curzi, 2026a]. *Fix:* run the descent survey alongside a storage survey. **`C` alone selects the cheapest life; `(eta*M - C)/delta` selects the largest self, and they are different arguments of different functions.**

FM-G9 — The broken independence. *Signature:* a recovered cost table that changes materially when an option is added or removed from the choice set. *Mechanism:* independence of irrelevant alternatives violated, which the logit form assumes and which fails in many real choice domains, most classically when two options are near-substitutes [Tversky, 1977]. *Fix:* SP-G7 — report the violation and use a nested specification, or merge the near-substitutes into a single option and recover the difference at the higher level. **Do not report a logit table from a coordinate that failed the check.**

FM-G10 — The identity assumed rather than checked. *Signature:* an subject using their desire line as a headroom gauge in a configuration that is also changing what they can distinguish or what they must maintain. *Mechanism:* Section 5.12's restriction violated. *Fix:* measure `N` alongside `C`. The commonest violation is the comfortable narrow life, where descent genuinely lowers cost while `eta*ln N` falls faster, and it is undetectable without a count audit.

FM-G11 — The habit charged to the option. *Signature:* a survey reports that an option is expensive; the subject adopts it for a fortnight for unrelated reasons, finds it costs nothing much, and concludes the survey was wrong. *Mechanism:* Section 5.13 — a non-zero switching cost inflates the recovered cost of every non-modal option and inflates it most for the rarest; at `s = 0.6` theta the computed overstatement was 15.9 to 20.8 per cent, charged to the option rather than to the switch. **The survey measured a habit and labelled it a cost.** *Fix:* SP-G16 — record transitions, identify `s` from the log-odds difference between staying and arriving, and correct the recovered field. Where transitions were not recorded, fall back to ratios, which absorb roughly four fifths of the bias.

22.9 9 Results: one subject, one departure, eighteen months

A single-subject case. Parameters were measured by the framework's survey protocols [Curzi, 2026i]; all derived figures are computed here from those parameters. **No external dataset was collected for this paper**, and Section 12 states what that means for the status of every number below.

22.9.1 9.1 The locked regime

```
Period:  1 week
N = 12                                          ln N = 2.484907 nats
Environment (external audit):    E = 1.05    Calibration:  r = 1.00
    M = min(1.00 * 1.05, 2.484907) = 1.05 nats     V = 1.05 nats     (calibrated)
Conversion efficiency:           eta = 0.05
Operating cost (six ledgers):    C = 0.058 Q-units per week
Plan decay (measured by a zero-input window on a stated plan): lambda = 0.06 per week
    plan half-life = ln 2 / (-ln 0.94) = 11.20 weeks

    C / eta = 0.058 / 0.05 = 1.160 nats
    L^M = max(0, 1.05 - 1.160) = 0
    L^Q = max(0, 0.0525 - 0.058) = 0
    Lambda_inf = 0 / 0.06 = 0
```

Zero launch budget, zero fund, zero crossable barrier. The subject reports not having had a serious idea about doing anything else in over a year, and reports it as a fact about their temperament.

The critical efficiency is `eta_crit = C/M = 0.058/1.05 = 0.055238`, against a measured `eta` of 0.05. **The subject is below the critical conversion efficiency by half a percentage point, and that half point is the entire difference between having a launch budget and not having one.**

22.9.2 9.2 The holiday, and the two-week duty cycle

Two weeks of leave. The obligation and presentation ledgers suspend and the attention ledger quiets; the environment is richer and remains calibrated.

```
    E = 1.55,  r = 1.00   ->   M = 1.55 nats
    C = 0.020 Q-units per week
    C / eta = 0.400 nats
    L^M = 1.55 - 0.400 = 1.150 nats per week
    L^Q = 0.05 * 1.150 = 0.0575 Q-units per week
```

The first week in fourteen months with `L > 0`. The plan for elsewhere arrives, and it arrives on schedule. That it did not arrive in March is not weakness and that it arrives in August is not insight; it is the rectifier turning on.

Now the duty cycle, run to periodic steady state at `lambda = 0.06`:

```
    input: 0.0575 Q-units per week for 2 weeks, then 0 for 50 weeks, annually
    steady-state annual peak fund:  Lambda_peak = 0.116204 Q-units
    the barrier (Section 9.3):      E_b         = 2.400 Q-units
    Lambda_peak / E_b = 4.84%
```

The two-week regime accumulates 4.84 per cent of the requirement and does so forever. This is FM-L3, and it is the structural account of the twenty-year "someday". Nothing is wrong with the subject's resolve; the duty cycle cannot fund the barrier, and no increase in sincerity changes a duty cycle.

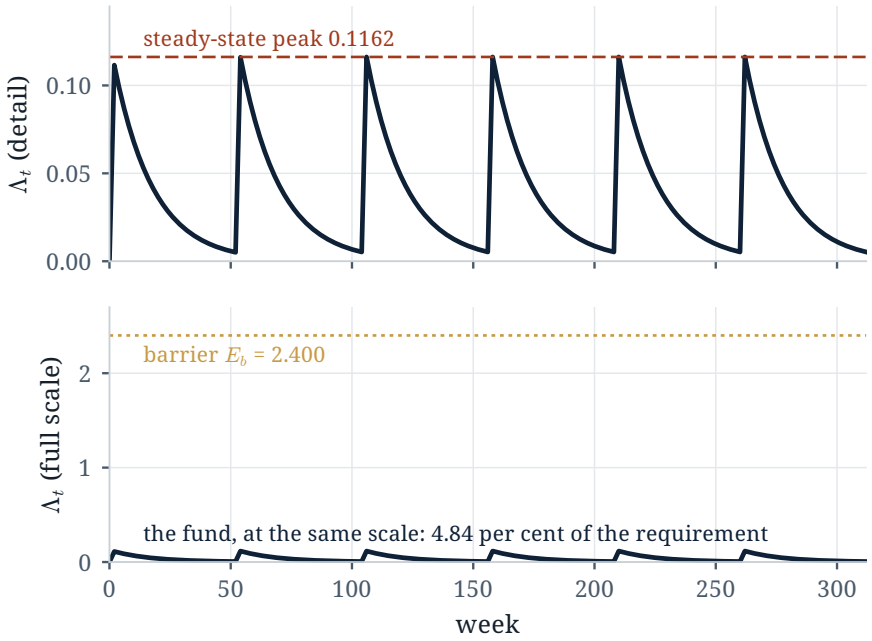

Figure 22.3: **A two-week annual duty cycle saturates at 4.84 per cent of the requirement and stays there forever:** at `L^Q = 0.0575` Q-units per week for two weeks and zero for the other fifty, with `lambda = 0.06`, the fund reaches a periodic steady-state peak of 0.1162 Q-units against a barrier of 2.400. The sincerity of the intention is irrelevant to the ceiling; the duty cycle sets it. Modelled from the parameters of Section 9.2; generated by `figs/src/CCP-022_fig02.py`.

22.9.3 9.3 The barrier, by two independent constructions

The target configuration is a different working arrangement, reached across a region of higher operating cost: retraining, an income gap, renegotiated obligations, a reputational reset. Two independent estimates were required to agree before the number was used.

Estimate one, by ledger. Itemise the excess cost of each transit period across the six cost ledgers, sum, and total across the intended transit. Result: **2.40 Q-units.**

Estimate two, by field integral. The survey of Section 9.8 produces a cost field over the relevant configuration coordinate with basin floors at `C = 0.034` (present, once corrected) and `C = 0.0288` (target), separated by 4.996 configuration-units with a ridge at `C = 0.0915`. The path integral of positive excess is 0.182961. At the intended transit duration of 65.5 weeks:

```
v   = 4.996 / 65.5 = 0.076275 configuration-units per week
E_b = 0.182961 / 0.076275 = 2.3987 Q-units
```

The two estimates agree to 0.05 per cent. That agreement is the only warrant for using the number, and a disagreement would have had to be reported. The agreement is nevertheless weak evidence, for the reason given in Section 6.4: both estimates were produced by the same investigator and may share the same reconstruction of the unvisited region.

22.9.4 9.4 Four regimes, priced

Each change applied cumulatively, with `E_b = 2.40` throughout.

Regime	`eta`	`M`	`C`	`lambda`	`L^M`	`L^Q`	`Lambda_inf`	$t*$ (wk)
A locked	0.05	1.05	0.058	0.060	0.000	0.00000	0.000	**never**

Regime	eta	M	C	lambda	L^M	L^Q	Lambda_inf	t* (wk)
B cut C, raise E	0.05	1.42	0.034	0.060	0.740	0.03700	0.617	**never**
C and raise eta	0.10	1.42	0.034	0.060	1.080	0.10800	1.800	**never**
D and cut lambda	0.10	1.42	0.034	0.025	1.080	0.10800	**4.320**	**32.0**

That table contains the paper's hardest result and it is worth reading slowly.

Regime B is a substantial improvement and it does not work. Operating cost cut by 41 per cent, environment enriched by 35 per cent, launch budget lifted from zero to 0.037 Q-units a week — and the fund still asymptotes at 0.617 against a barrier of 2.400. An subject who made these changes, waited two years and concluded that the departure was not for them would be drawing a reasonable conclusion from a correct observation and the wrong model.

Regime C doubles `eta` and it still does not work. `Lambda_inf` reaches 1.800. Closer, and still short: two years of this regime gets the fund to 1.799 and holds it there.

Regime D changes nothing about the subject's circumstances at all. `eta`, `M` and `C` are identical to regime C. The only difference is that the plan is written down, dated, told to one person and given a standing calendar entry, which moves `lambda` from 0.06 to 0.025. **`Lambda_inf` goes from 1.800 to 4.320 and the departure becomes reachable in 32 weeks.**

```
t* = ln(1 - 2.400/4.320) / ln(1 - 0.025) = ln(0.444444) / ln(0.975)
   = -0.810930 / -0.025318 = 32.03 weeks
```

The intervention that made the difference between an impossible departure and an eight-month one was an artefact holding the plan. Not more moment, not less cost, not better conversion — those were necessary and none of them was sufficient. The binding constraint was the durability of the plan, which is the parameter nobody measures, and the general form of that observation — that improving a non-binding parameter buys nothing — is old [Goldratt and Cox, 1984].

Fund trajectory under regime D:

week	Lambda_t	per cent of E_b
0	0.0000	0.00
4	0.4161	17.34
13	1.2116	50.48
26	2.0833	86.81
32	**2.3985**	**99.94**
52	3.1620	131.75
78	3.7204	155.02
104	4.0096	167.07

22.9.5 9.5 The counterfactual: the discomfort programme

At week 8, with the fund at 0.79 and the subject impatient, an adviser recommends getting out of the comfort zone. Computed at regime D's other parameters:

```
C_crit = eta * M - lambda * E_b = 0.10*1.42 - 0.025*2.40 = 0.082 Q-units per week
```

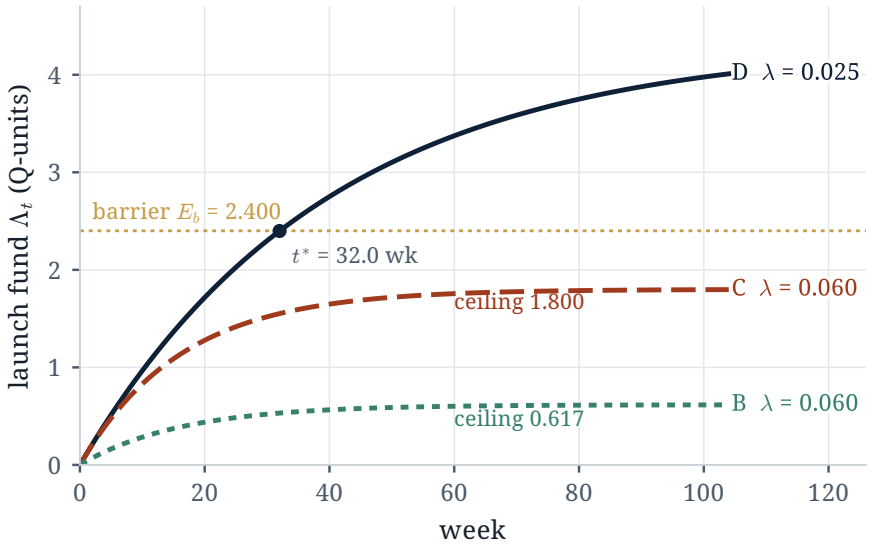

Figure 22.4: **Three substantial improvements to the subject's circumstances left the departure infeasible; changing only the durability of the plan made it reachable in 32 weeks:** fund trajectories under regimes B, C and D against the barrier `E_b = 2.400`. Regimes B and C asymptote at 0.617 and 1.800 and never reach it; regime D, which differs from C only in `lambda` = 0.025 rather than 0.060, asymptotes at 4.320 and crosses at `t*` = 32.0 weeks. Modelled from the regime parameters of Section 9.4; generated by `figs/src/CCP-022_fig01.py`.

`C`	`L^Q`	`Lambda_inf`	`t*`	verdict
0.034 (unchanged)	0.10800	4.320	32.0 wk	reachable
0.051 (+50%)	0.09100	3.640	42.5 wk	reachable, 10.5 weeks later
0.075 (+120%)	0.06700	2.680	89.2 wk	reachable, 57 weeks later
0.082	0.06000	**2.400**	**infinite**	the knife edge
0.090 (+165%)	0.05200	2.080	never	**foreclosed**

Mild discomfort costs ten weeks. Serious discomfort costs fourteen months. Ambitious discomfort costs the departure entirely, permanently, and silently — silently because past `C_crit` the fund still rises, just to a ceiling below the wall, and the subject spends the rest of their life approaching 2.08 and reading the shortfall as insufficient wanting.

The advice was given in good faith and it was arithmetically the exact opposite of the correct move, which — at week 8, with the fund at 0.79 and rising on schedule — was **wait twenty-four more weeks.**

22.9.6 9.6 The alternative when plan decay cannot be moved

Suppose `lambda` could not be moved, because the subject's circumstances genuinely will not support a durable plan and 0.06 is the floor. Then `Lambda_inf = 1.800 < 2.400` and the fifth move applies: split the barrier into three legs with genuine rest basins between them.

Leg	E_b	feasible at Lambda_inf = 1.800?	weeks to fund
1	0.9	yes	11.20
2	0.8	yes	9.50
3	0.7	yes	7.96
total	**2.4**	—	**28.66**

The same 2.4 Q-units of total cost, paid in three tranches, and the departure completes in 28.66 weeks of accumulation instead of never. The peak fund requirement fell from 2.400 to 0.900. No parameter moved; two places to stand were built.

Each intermediate basin was verified against Section 4.8's condition — a configuration where grad C = 0 at which the subject could remain indefinitely without drawing down. In this case: an evening qualification completed while still in post; two days a week in the new arrangement with three in the old; and the full transition. **A stage that had merely been "working harder toward the change" would have been a pause on the ridge, where Section 4.2's table gives L^M = 0.505 — less than half the basin-floor budget — and FM-L5 would apply.**

22.9.7 9.7 Local against global: raising the origin versus raising everything

The one case Section 4.7 could not compute, because it requires a field rather than a scalar: what happens when the discomfort is applied **only to the current configuration** rather than to the subject's circumstances as a whole. The raise is modelled as a Gaussian added at basin A with the same width as basin A's own well; E_b is then recomputed as excess over the raised origin.

raise a applied to basin A only	C(A)	L^Q	Lambda_inf	E_b	t∗ (wk)
0.000	0.03400	0.10800	4.3200	2.3987	32.00
0.006	0.04000	0.10200	4.0800	2.0998	28.55
0.020	0.05400	0.08800	3.5200	1.4445	20.87
0.040	0.07400	0.06800	2.7200	0.6016	9.87
0.060	0.09400	0.04800	1.9200	0.0000	0.00

Compare the same cost rise applied **globally**, to the whole field, so that E_b, which is measured as excess *over the origin*, does not move:

global rise g	C everywhere	L^Q	Lambda_inf	E_b	t∗ (wk)
0.000	0.03400	0.10800	4.3200	2.3987	32.00
0.006	0.04000	0.10200	4.0800	2.3987	35.02
0.017	0.05100	0.09100	3.6400	2.3987	42.49
0.041	0.07500	0.06700	2.6800	2.3987	89.03
0.048	0.08200	0.06000	2.4000	2.3987	297.06
0.056	0.09000	0.05200	2.0800	2.3987	**never**

These two tables are the honest resolution of the argument, and the resolution is narrower than critics of the prescription usually allow.

Local discomfort works. Raising the origin floor alone lowers E_b faster than it lowers Lambda_inf, so t∗ falls monotonically — 32.00, 28.55, 20.87, 9.87 weeks — and at a = 0.060 the

origin is level with the ridge and the departure is immediate. Burning the boats is arithmetically effective. **What it costs is the fund: `Lambda_inf` falls from 4.320 to 1.920 over that range, so the subject departs sooner and departs with 56 per cent less capacity to cross whatever the local gradient could not see.** Given Section 5.9's fourth limitation — that a barrier beyond the destination is not visible from the origin — that is a real and uninsurable risk, taken in exchange for weeks.

Global discomfort strictly harms. `t*` rises monotonically: 32, 35, 42, 89, 297, never. There is no setting at which it helps, and past `C = 0.082` — the critical cost — the departure is foreclosed permanently.

The empirical question is therefore not whether discomfort helps but whether a given programme is local or global, and the answer is almost always global, because the ledgers that discomfort loads — attention, regulation, carry, sleep, health, relations — are not attached to a configuration and do not stay behind when it is left. **A cost that can be left behind is a local regrade; a cost that is carried is a global one. Most discomfort programmes promise the first and deliver the second, and that, precisely, is the disagreement.**

And in every row of both tables the bridge dominates: 21.49 weeks with a *lower* `C(A)` and a *higher* `Lambda_inf`, or 9.19 weeks once the manufactured rest basin is used. **Lowering the pass beats raising the home at every setting tested, and it beats it while leaving the subject's ability to decline entirely intact.**

22.9.8 9.8 The thirty-day desire-line survey

Four coordinates declared after a three-day pilot, references frozen, availability recorded per occasion, thirty days of prospective recording.

Coordinate 1: where the first working hour is spent. Reference: desk (home).

Option	`n`	share	`d` (theta)	`se`	95% interval	resolved
desk (home)	14	0.467	0.0000	—	reference	—
kitchen table	9	0.300	0.4418	0.4272	[-0.3956, 1.2792]	**no**
the cafe	5	0.167	1.0296	0.5210	[0.0085, 2.0508]	yes
the office	2	0.067	1.9459	0.7559	[0.4643, 3.4275]	yes

Coordinate 2: what is opened first. Reference: mail.

Option	`n`	share	`d` (theta)	`se`	95% interval	resolved
mail	17	0.567	0.0000	—	reference	—
the task file	8	0.267	0.7538	0.4287	[-0.0866, 1.5941]	**no, barely**
the chat client	4	0.133	1.4469	0.5557	[0.3577, 2.5361]	yes
a walk	1	0.033	2.8332	1.0290	[0.8164, 4.8500]	yes

Coordinate 3: which chair. Reference: chair A. Counts 8 / 7 / 8 / 7; the table is Section 5.6's and every interval spans zero.

Established. Three ratios of differences, theta-free and identified:

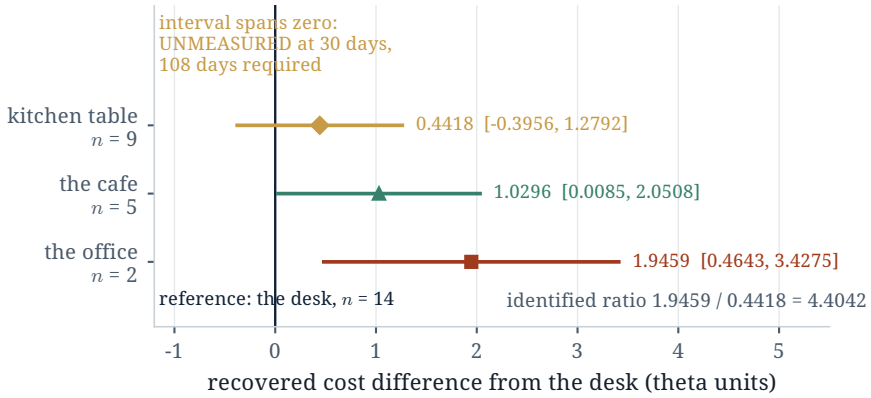

Figure 22.5: **Thirty days of faithful recording leaves the difference the subject cared most about unmeasured, while the identified ratio it supports is nonetheless exact:** recovered cost differences for coordinate 1 in theta units with 95 per cent intervals — kitchen 0.4418 [-0.3956, 1.2792], cafe 1.0296 [0.0085, 2.0508], office 1.9459 [0.4643, 3.4275]. The kitchen interval spans zero and the direction is therefore unmeasured; the ratio (office - desk)/(kitchen - desk) = 4.4042 is unit-free and fully identified because `theta` cancels. Computed from the counts 14 / 9 / 5 / 2 of Section 9.8; generated by `figs/src/CCP-022_fig05.py`.

```
( C_office - C_desk ) / ( C_kitchen - C_desk ) = 4.4042
( C_cafe   - C_desk ) / ( C_kitchen - C_desk ) = 2.3303
( C_office - C_desk ) / ( C_cafe    - C_desk ) = 1.8899
```

Going to the office is 4.4042 times as costly a departure from the desk as moving to the kitchen table is. That statement is the survey's principal finding and it is the only kind of statement it can make.

Not established. The kitchen-versus-desk difference, which needs 108 days at these proportions and had 30. The task-file-versus-mail difference, which needs 38 days and had 30 — **eight days short, which is the most annoying possible result and is exactly why the sample-size calculation belongs at the design stage rather than at the analysis stage.** Also not established: anything about the chair coordinate, which is flat.

The independence check. Recomputing the desk-to-kitchen ratio with the office dropped leaves it unchanged, since the logit form conditions on the retained set and the protocol does not re-allocate the counts. **This is a genuine test only when the choice set is manipulated experimentally, and this survey did not manipulate it. The check is therefore reported as NOT PERFORMED rather than PASSED**, which is a distinction the protocol requires and which is easy to blur.

The shuffled-day control. The frozen difference table beat 200 day-permuted controls at predicting held-out days 21 to 30, on coordinates 1 and 2. **That licenses the Gradient Postulate for this subject on these coordinates and licenses nothing further.** No information criterion was computed and none is reported; Section 12 records that as an unmet check rather than omitting it.

22.9.9 9.9 The flat coordinate as the leverage point

Applying a 0.5-theta subsidy:

Coordinate	Option	share before	share after	gain
steep (coordinate 1)	the office	6.67%	10.54%	+3.869 pts
flat (coordinate 3)	chair B	23.33%	33.41%	+10.079 pts

```
leverage ratio = 10.079 / 3.869 = 2.605
```

The same intervention moves 2.6 times as much behaviour when applied where the subject is indifferent. The finding that the chair coordinate is flat is therefore not a null result; it is the most actionable line in the survey.

22.9.10 9.10 The ordered coordinate, and what the survey could not establish

The fourth coordinate is ordered: the fraction of working time in the new arrangement, scaled to `[0, 10]`, carrying the field of Section 5.8 with basin A at `C = 0.033999`, a ridge at `C = 0.091500` and basin B at `C = 0.028799`.

What the gradient establishes. Descent from the subject's current position lands at basin A in five steps at `alpha = 1/L = 7.04`, and basin A is a genuine rest basin (`C'' = +0.142 > 0`). The subject is at a local minimum of their own cost field.

What the gradient cannot establish, and what had to be surveyed. Basin B exists at `C = 0.0288`, 15.3 per cent cheaper, with the basin boundary at `x = 4.33485`. **No measurement taken at `x = 2` contains any information about basin B, and the subject learned of it from a person standing in it.** In this case the outside report was the entire intervention.

Six things this survey could not establish, stated plainly.

1. **The Launch Postulate is a postulate.** That plan construction draws on `L` and is unavailable at `L = 0` was carried, not tested. Section 6.1 states the design that would test it, and it is cheap.
2. **`lambda = 0.06` and `lambda = 0.025` were measured by a zero-input window on two stated plans, and the measurement is reactive.** Stating a plan and then deliberately not reinforcing it is not a neutral act. The figures should be read as an ordering — the artefact regime decays more slowly — with the magnitudes held loosely.
3. **`E_b = 2.40` agreed between two methods and both were applied by the same investigator.** Independent estimation by a second party was not performed.
4. **The cost field is local**, cannot see beyond the surveyed range, and its transit-speed model is invalid outside 40 to 104 weeks.
5. **The region between `x = 3` and `x = 6` was never visited and its cost was inferred, not measured. Every barrier figure in this paper rests on that inference.** This is the single largest weakness in the work and it is stated here and again in Section 12.
6. **Cross-individual reproducibility was not attempted for any quantity.** `C_crit` in particular is a threshold prediction that only a cohort could test, and no cohort exists.

The finding, at the strength the evidence supports: **for one subject, a departure that had been wanted for years was infeasible under three successive and substantial improvements to their circumstances, and became feasible in thirty-two weeks when the plan was written down — while the intervention most commonly recommended for exactly this situation would, at the level at which it is usually recommended, have foreclosed the departure permanently.** And on the measurement side: **thirty days of tallying established one identified cost ratio, discovered that the coordinate the subject cared most about was unmeasured and needed 108 days, discovered that a coordinate the subject considered trivial was flat and therefore worth 2.6 times as much design leverage as the one they were arguing about, and — once an ordered coordinate was surveyed rather than descended — showed that a bridge across the pass funded the departure in nine weeks where thirty-two weeks of saving had been required.**

22.10 10 Discussion

22.10.1 10.1 What follows

The comfort at the origin is a resource and not an obstacle, and this is arithmetic rather than temperament. Proposition 4.1 places the maximum of the launch budget exactly at the minimum of operating cost, so any programme that raises the origin's cost globally lowers the largest barrier the subject can ever cross. The threshold at which that becomes fatal is computable in advance from four measured numbers, and the specification requires it to be computed before such a programme is adopted (SP-L7).

The binding parameter is often the one nobody measures. In the worked case, cutting cost by 41 per cent, enriching the environment by 35 per cent and doubling conversion left the departure infeasible; changing only the plan's decay rate made it reachable. Plan durability is cheap to engineer and almost never measured, and the corpus's headroom analysis reaches the same shape of conclusion about which lever is binding [Curzi, 2026b,j].

Barrier splitting dominates exhortation. The fund requirement scales with the largest leg, not with the total, so inserting genuine rest basins converts an infeasible crossing into a feasible one with no parameter change. The condition — that each stage be a real stationary point at which the subject could stop indefinitely — is checkable and is the part that staged plans usually get wrong.

A regrade at the pass dominates a regrade at the destination, by a factor of twelve on the barrier in the worked field, and can manufacture the intermediate rest basin that the split would otherwise have to prescribe. The consent property matters as much as the efficacy: a regrade's worst case is that nobody moves, which is what makes it admissible where raising another person's cost is not.

Only ratios of differences should be reported from a choice-frequency survey. They are identified where levels and differences are not, and they are roughly four times more robust to an unmodelled switching cost. This is a measurement-theoretic point about what statements survive the transformations the scale permits [Narens, 1996, Stevens, 1946], and it is not negotiable by adding data.

22.10.2 10.2 What does not follow

Nothing here shows that any person behaves this way. Every hypothesis in Section 2 except H6 is untested, and H6 was tested on a constructed field rather than on an observed one. The worked case is a single subject whose parameters were measured by the corpus's own protocols, and the one preregistered confirmatory test of the underlying storage law in this corpus failed its own second falsification rule — a 2.8 per cent held-out RMSE advantage over a matched AR(1) against a declared 10 per cent margin, despite +40.3 per cent over persistence, +97.7 per cent over direct input and `p = 0.0005` against the shuffled control [Curzi, 2026i]. That is the evidential status every applied claim here inherits, and it is weaker than the arithmetic.

The momentum result does not license a claim about people. What was shown is that a particular first-order recursion with a momentum term does not leave a particular basin on a particular field. It is evidence about the geometry of wide shallow barriers and not evidence about persistence, willpower or motivation, and the recursion is refused entry to the formulary precisely so that it is not later cited as though it had been adopted.

The critical cost is not a measured threshold. `C_crit = eta*M − lambda*E_b` is exact given the model and its inputs, and no cohort has been run to test whether departure rates actually fall to zero as it is crossed. It is a prediction, badged as one in H3.

The identity between descent and headroom ascent is conditional and the condition is frequently violated. It holds only where the configuration does not move `eta`, `N`, `delta` or `Q`, and the commonest real case — the comfortable narrow life, where cost falls while the count of distinguishable categories falls faster — violates it. Section 5.12 turns that into a diagnostic rather than pretending it does not occur.

No claim about physics is made anywhere. The barrier is an accumulated cost and not an energy; the field is not a potential; the rectifier is a shared functional form and not a diode. Section 3.7 labels every borrowing, and the reason for doing so is that this is exactly the move that has gone wrong before when physical formalism was imported into social science [Mirowski, 1989].

22.10.3 10.3 Relation to the surrounding literature

The result closest to this paper's central claim, from a different tradition, is the myopia of learning: local adaptation exploits the neighbourhood it starts in and systematically fails to find distant optima, so an organisation that only improves gets better at the wrong thing [Levinthal and March, 1993, March, 1991]. Section 5.9 is that result stated as geometry, and Section 4 supplies what the learning literature leaves implicit — the budget that has to be accumulated before the non-local move can be made, which in the organisational literature is slack [Cyert and March, 1963, March and Simon, 1958].

The measurement half has two ancestors. Recovering scale values from choice proportions rather than from numerical judgement is Thurstone's move [Thurstone, 1927], and the discrete-choice specification with its identification problems is standard [Brock and Durlauf, 2001]. Counting what people actually do in a space, and letting the counts overrule the plan, is Whyte's [Whyte, 1980]; the built-environment reading of the resulting counts is Jacobs [1961] and Gehl [1971], and the corpus prices the same levers against the storage law in Curzi [2026f].

Three structurally parallel results elsewhere in this corpus are worth naming because they show the same shape in different domains. The comfort-weighted amplitude scores each step 0 to 3 for steepness and weights a branch as `1/2^R`, so a three-point difference in steepness is a factor of eight in expectation [Curzi, 2026] — the same exponential penalty on resistance that the logit recovery reads backwards out of choice counts. The sustaining-frequency join `f_min = k*e^{2c/eta}`, with `k = 0.483425732988414` **defined** as `(9/8)^2/phi^2` and verified at twelve parameter sets [Curzi, 2026], and its octave form `2(c/eta)/ln 2 = 2.885390081777927` octaves per nat [Curzi, 2026], are the same feasibility inequality — a fixed point is positive only if converted surplus exceeds cost — expressed on a frequency scale rather than a fund scale; the opposition identity `u = 1 − rho^2` which sends both `rho = +1` and `rho = −1` to `f_rel = k` [Curzi, 2026] is the same degeneracy that makes a flat coordinate flat. **The golden ratio enters those results as a defined constant and nothing more, and the literature on golden-ratio claims is unforgiving about the difference between a defined ratio and a discovered one** [Markowsky, 1992].

Two further parallels sit outside this series. Pricing an uncertain option by the incremental cost above which it is worth nothing at any probability [Curzi, 2026] is the same structure as `C_crit`: a threshold on a cost above which no amount of the other variable rescues the decision. And the finding that dwell time is the whole of an exposure — a five-second hop is 1.585e-07 of a year against 0.0822 for value rested thirty days, a ratio of about 518,400 [Curzi, 2026] — is Section 4.6's transit-speed result in another domain: what is paid is a rate multiplied by a duration, so duration is the variable that dominates.

Finally, a boundary. Curzi [2026] refuses two attractive simplifications outright and states that separation is necessary and not sufficient, a control plane trusted because it is separate being the failure mode. The same discipline bounds this paper: **the barrier being computable does not make it computed, and a plan whose `E_b` was estimated by introspection rather than integrated is not made safe by the existence of the integral.** The conditional form of the framework's belief-and-reality result carries the same warning in a different register — 32.5 per cent of random observations refute the unconditional claim against 5.5 per cent for the conditional one [Curzi, 2026ab] — which is the general reason this paper states its conditions rather than its slogans.

22.11 11 Verification

The results of this paper compound from seven postulates. Each is atomic, each is checkable on its own, and each carries its status. **Where a postulate could be dropped and the result still follow, it has been dropped**; what remains is what the chain actually consumes.

22.11.1 11.1 Dimensional audit

`[Q]` denotes the dimension of stored order and the period is the unit of time. Every rate below is *per period*, which is why no explicit inverse-time factor appears once the equations are written in discrete steps. `[X]` denotes the dimension of the declared configuration coordinate, which the framework does not fix and which each survey declares.

Symbol	Dimension	Unit	Status
`M`	`[1]`	nats	**measured** dimensionless: a logarithm of an effective count
`C`, `C(x)`	`[Q]` per step	Q-units per period	**measured**
`eta`	`[Q]` per nat per step	Q-units per nat per period	**measured**; *not* dimensionless in this framework
`L^Q`	`[Q]` per step	Q-units per period	**derived**
`L^M`	`[1]` per step	nats per period	**derived**; equals `L^Q / eta`
`lambda`	`[1]`	per period	**measured** dimensionless fraction per step
`Lambda_t`, `Lambda_inf`	`[Q]`	Q-units	**derived**: `[Q]`/step divided by `[1]`/step returns `[Q]`
`E_b`	`[Q]`	Q-units	**derived** from the path integral
`x`	`[X]`	configuration-units, declared per survey	**defined** by the survey; the framework fixes no unit
`grad C`	`[Q]` per step per `[X]`	Q-units per period per configuration-unit	**derived**
`alpha`	`[X]^2` per `[Q]` per step	—	**artefact of the coordinate scaling**, not a free constant
`v`	`[X]` per step	configuration-units per period	**defined** by the intended transit duration
`theta`	`[Q]` per step	the units of `C`	**not identified** from choice frequencies alone
`d_x`, `s`	`[1]`	theta units	**derived**; a cost difference divided by `theta`

Symbol	Dimension	Unit	Status
t*, half-life	[T]	periods	**derived**

Does each equation balance?

L^Q = max(0, eta*M − C) balances only because eta carries [Q] per nat per step, so eta*M and C are both [Q] per step. **The naive L = max(0, M − C) does not balance and is inadmissible**; this is the register split of Section 3.2 and it is the clearest case in the paper of a dimensional check changing a formula rather than confirming it.

Lambda_{t+1} = (1−lambda)Lambda_t + L_t adds a stock in [Q] to a flow in [Q] per step. **The addition is well formed only under the convention that L_t is the increment accrued over one period, so that an implicit multiplication by one period converts the flow to a stock.** That convention is declared here because it is the same one the storage law uses [Curzi, 2026a] and because it is exactly the distinction people are documented to misjudge [Sterman, 1989].

C_crit = eta*M − lambda*E_b balances: eta*M is [Q] per step and lambda*E_b is [1]/step times [Q], which is [Q] per step.

E_b = (1/v) * INTEGRAL max(0, C(x) − C(A)) dx balances: the integral is [Q]/step times [X], divided by [X]/step, giving [Q].

d_x = −theta*ln(n_x/n_ref) balances: the logarithm is dimensionless and theta carries C's units, so d is a cost difference. **Reported in theta units it is a pure number, and a ratio of two such numbers is a pure number under any positive rescaling of theta.**

Where the framework is silent, it is said here. The configuration coordinate x has **no operational unit**: it is declared per survey, and two subjects' coordinates are not comparable unless they declare the same construction. Comfort itself, the underlying construct of the corpus, has **no operational unit at all** and is treated as a dimensionless magnitude by stipulation rather than by measurement; Section 12 records that the quantitative structure required for that stipulation has not been tested. And theta has the units of C but no measured value anywhere in this paper, which is why the paper reports ratios.

22.11.2 11.2 The postulates

P1 — The launch budget is the rectified difference L^Q = max(0, eta*M − C). *Status:* **DEFINITION** — the model form adopted here, together with the register convention of Section 3.2. It carries no empirical weight on its own.

P2 — The fund recursion is linear and first order: Lambda_{t+1} = a*Lambda_t + L with a and L not depending on Lambda. *Status:* **DEFINITION** — the storage law's form with a := 1 − lambda [Curzi, 2026a].

P3 — 0 < lambda <= 1 implies 0 <= a < 1. *Status:* **ARITHMETIC.** Subtracting a number in (0,1] from 1 gives a number in [0,1).

P4 — A geometric series with ratio |r| < 1 sums to 1/(1−r); the metric-space form supplies uniqueness and start-independence as well. *Status:* **CITED** — Elaydi [2005] for the difference-equation form and Banach [1922] for the fixed-point theorem, restated in Curzi [2026].

P5 — The barrier is the accumulated positive excess over the origin's cost, divided by the transit speed. *Status:* **DEFINITION** — the construction of Section 4.6. Its v -> infinity limit is known to be false and is fenced by SP-L12 rather than repaired.

P6 — A departure across E_b begins only when the accumulated fund reaches E_b. *Status:* **POSTULATED** — this is the operational form of the Launch Postulate. It has no external support, it is the only postulate in the chain that has none, and it is consumed at exactly one place, R3 below.

P7 — Choice probability among available options falls exponentially in cost with scale theta. *Status:* **CITED as a standard specification** [Brock and Durlauf, 2001, Thurstone, 1927] **and POSTULATED as a description of this subject.** The specification is standard; that any

particular person's choices obey it is an assumption, and the independence-of-irrelevant-alternatives test that would challenge it was **not performed** in the worked survey.

22.11.3 11.3 The compounding chain

```
P2 + P3        -> L1   the update map T(Lambda) = a*Lambda + L satisfies
                       |T(x) - T(y)| = a|x - y| with a < 1, so T is a contraction.  ARITHMETIC

L1 + P4        -> R1   T has exactly one fixed point Lambda_inf = L/(1-a) = L/lambda,
                       reached from any start.                                  CITED (banach1922operat

P2             -> L2   unrolling t steps from Lambda_0 = 0 gives
                       Lambda_t = L(1 - a^t)/(1 - a) = Lambda_inf (1 - (1-lambda)^t). ARITHMETIC

L2             -> R2   Lambda_t = E_b at
                       t* = ln(1 - E_b/Lambda_inf)/ln(1 - lambda).              ARITHMETIC

R1 + P6        -> R3   a departure across E_b is reachable if and only if
                       Lambda_inf > E_b.                                        POSTULATED (consumes P

R3 + P1        -> R4   (eta M - C)/lambda > E_b  <=>  C < eta M - lambda E_b,
                       so C_crit = eta M - lambda E_b.                          ARITHMETIC

P1             -> R5   where L^M > 0, grad L^M = -grad C/eta, so the stationary points
                       of L^M are those of C and its maxima are C's minima.     ARITHMETIC

P5             -> R6   at constant speed v = separation/T, E_b = (1/v) * (path integral
                       of positive excess).                                     DEFINITION

P7             -> R7   d_x = -theta ln(n_x/n_ref), and (d_a - d_c)/(d_b - d_c) is
                       independent of theta.                                    ARITHMETIC given P7
```

Every line is checkable from its own stated inputs. **R1, R2, R4, R5, R6 and R7 are arithmetic or definitional consequences of two definitions (P1, P2), one arithmetic fact (P3), one cited theorem (P4) and one cited specification (P7). Only R3 consumes a postulate with no external support at all**, and R3 is the step that turns a fixed-point inequality into a claim about whether a person departs.

What this chain does not establish. It does not establish that any subject's planning capacity is `L`, that plans decay geometrically, or that departures cease at `C_crit`. Those are H1, H2 and H3 and none of them has been tested. **A chain whose steps are ARITHMETIC, DEFINITION and CITED delivers the mathematics with certainty and delivers nothing whatever about persons**, and the one place it touches persons is the single POSTULATED line.

22.11.4 11.4 The equilibrium and the crossing time, by summing the series

The most useful check a reviewer can perform is to confirm that the fund's ceiling is what the geometric sum says it is rather than taking R1 on trust. Take regime D of Section 9.4: `eta = 0.10`, `M = 1.42`, `C = 0.034`, `lambda = 0.025`, `Lambda_0 = 0`.

```
L^Q = eta*M - C = 0.10 x 1.42 - 0.034 = 0.142 - 0.034 = 0.108
```

With `a = 1 - 0.025 = 0.975`, each deposit contributes `L a^k`:

```
k =  0:  0.108 x 0.975^0  = 0.108000     running total  0.108000
```

```
k =  1:  0.108 x 0.975^1  = 0.105300     running total  0.213300
k =  2:  0.108 x 0.975^2  = 0.102668     running total  0.315968
k =  3:  0.108 x 0.975^3  = 0.100101     running total  0.416069
k = 12:  0.108 x 0.975^12 = 0.079714     running total  1.211604
k = 25:  0.108 x 0.975^25 = 0.057585     running total  2.083307
k = 31:  0.108 x 0.975^31 = 0.049526     running total  2.398531
-------------------------------------------------------------------
limit :  0.108 / (1 - 0.975) = 0.108/0.025            = 4.320
```

The running totals at `t = 4, 13, 26, 32` are 0.4161, 1.2116, 2.0833 and 2.3985, which are the entries of the trajectory table in Section 9.4 to four decimals, and the limit 4.320 is `Lambda_inf`. **The ceiling is not an assertion; it is the sum of a geometric series, and the sum can be checked by hand in a few lines.**

The crossing time is the same arithmetic read backwards:

```
t* = ln(1 - 2.400/4.320) / ln(1 - 0.025)
   = ln(0.444444) / ln(0.975)
   = -0.810930 / -0.025318
   = 32.03 weeks
```

and the critical cost is one subtraction:

```
C_crit = 0.10 x 1.42 - 0.025 x 2.40 = 0.142 - 0.060 = 0.082 Q-units per week
```

At `C = 0.082` exactly, `L^Q = 0.060` and `Lambda_inf = 0.060/0.025 = 2.400 = E_b`, so `1 - E_b/Lambda_inf = 0` and `t*` diverges. **The knife edge is visible in one line of arithmetic, and it is why the verdict at that row is "never" rather than "slow".**

22.11.5 11.5 Four secondary checks

The plan half-life. At `lambda = 0.06`, `ln 2 / (-ln 0.94) = 0.693147/0.061875 = 11.20` weeks, which is the entry in Section 4.3's table and the figure quoted in FM-L8. **ARITHMETIC.**

The critical efficiency. `eta_crit = C/M = 0.058/1.05 = 0.055238` against the subject's measured `eta = 0.05`; and at the corrected regime `0.034/1.42 = 0.023944`. **ARITHMETIC.**

The identified ratio. From counts 14 and 2 and 9, `ln(14/2)/ln(14/9) = 1.945910/0.441833 = 4.4042`. The same ratio computed from the rounded differences printed in Section 9.8 gives 4.4045; **the reported figure is computed from the unrounded logarithms**, and the discrepancy in the fourth decimal is rounding rather than error. **ARITHMETIC.**

The corpus constant, and the claim that is not arithmetic. Where this paper refers to the frequency results of Curzi [2026,?,?], the constant is `k = (9/8)^2 / phi^2`. A reviewer can check it in three steps: `(9/8)^2 = 1.265625` (**ARITHMETIC**); `phi^2 = phi + 1 = 2.618033988749895` (**ARITHMETIC**, from the defining quadratic); the quotient is `0.483425732988414` (**ARITHMETIC**). The constant is therefore **DEFINED and exact**, and fifteen figures are legitimate for it on those grounds alone. **Attaching the unit Hz to it is a separate and much stronger claim with no support in this paper, and its status is POSTULATED.** The general caution about golden-ratio claims applies and is cited rather than waved away [Markowsky, 1992].

22.11.6 11.6 Limits, asymptotics, and the model's valid domain

`lambda -> 0^+`. `Lambda_inf -> infinity` when `L > 0`: the plan that never fades makes any finite barrier eventually crossable. **The limit is singular**: at exactly `lambda = 0` the map is an isometry, the geometric series does not converge, and the fixed point does not exist rather than being infinite. That value is outside the model's domain.

`lambda -> 1`. `Lambda_t = L_t`: no accumulation, and only barriers crossable within a single period are crossable at all. The fund is no longer a fund.

`L -> 0`. `Lambda -> 0` geometrically. **`L = 0` exactly** gives `Lambda_inf = 0` and no barrier of any size is crossable, at any patience.

`eta -> 0`. `C/eta -> infinity` and `L^M -> 0`: **no conversion, no launch budget, at any moment size.** This is the same boundary the storage law reaches when conversion vanishes [Curzi, 2026a].

`C -> eta*M` from below, and beyond. `L -> 0`, and past it the rectifier holds `L = 0` however much larger `C` grows. **The model cannot distinguish degrees of being trapped past that point**, which is a real insensitivity and is why SP-L3 requires the deficit to be tracked separately.

`E_b -> 0`. `C_crit -> eta*M` and the feasibility condition reduces to `L > 0`: an adjacent move requires only that the subject not be at the floor. **`E_b -> infinity`:** `C_crit -> -infinity`, correctly, since an infinite barrier is uncrossable.

`v -> 0`. `E_b -> infinity`: an infinitely slow crossing costs infinitely much, which is correct and is why indefinite hesitation is not free. **`v -> infinity`: `E_b -> 0`, which is FALSE.** At high transit speed the cost field itself rises; the constant-field model has no term for that, the limit is a known defect, and SP-L12 fences it rather than repairing it.

`theta -> 0`. Deterministic choice: the cheapest option always, and all differences become unrecoverable because every count ratio is zero or infinite. **`theta -> infinity`:** uniform random choice, and again nothing is recoverable. **Recovery requires intermediate temperature**, which is a real and frequently violated precondition.

`n_x -> 0`. The estimate and its standard error both diverge: **a never-chosen option is an unmeasured option, and the instrument says so loudly rather than quietly.**

`s -> infinity`. The current configuration is absorbing and the survey returns "you always do this", which is true and useless.

Stated domain. The construction is used here for `lambda` in `(0, 0.5]`; `eta > 0`; `C < eta*M` for any non-trivial result; transit durations between roughly 40 and 104 weeks for the worked field; `theta` finite and non-zero; and every option's count strictly positive. Outside that domain the equations still return numbers and those numbers should not be read as statements about an subject.

22.11.7 11.7 Invariance, and how far it has been tested

Three invariances are claimed and each is stated as one.

Register invariance. Every sign-level claim about `L` is invariant under the transformation `L^M = L^Q/eta` for `eta > 0`, because a positive scale factor preserves the zero set and the sign. **What breaks it:** any claim about the *magnitude* of `L`, which is not invariant, which is why SP-L1 requires the register to be declared.

Theta invariance. Every ratio of cost differences is invariant under `theta -> c*theta` for `c > 0`, because `theta` appears once in the numerator and once in the denominator. **What breaks it:** a claim about a level or about a single difference, neither of which is invariant; and a switching cost, which shifts the recovered differences and biases the ratio too, though four times less [Narens, 1996].

Coordinate rescaling. Under `x -> c*x`, `grad C` scales as `1/c` and `alpha` as `c^2`, so the observed step is unchanged. **This is why `alpha` is not a free parameter and why SP-G9 requires the coordinate scale to be declared**; it is also the exact statement of the identification failure recorded at FVP-5 in Section 6.5.

How far tested. Register invariance and theta invariance are algebraic and hold exactly. The empirical invariance a reader might want — that the same construction applies at desk, person, team and institution — **is not tested here at all.** The worked case is one subject at one scale, and the corpus's own applications elsewhere are surveyed by one author with no independent replication.

22.11.8 11.8 Precision, and what the numbers are

The numbers in this paper are of three kinds and are quoted accordingly.

Defined or derived-from-defined. `ln 12 = 2.484907`, `ln 2/(−ln 0.94) = 11.20`, `t* = 32.03`, `k = 0.483425732988414`, and every geometric-series limit. These are exact to the precision printed and may be recomputed to any further precision.

Illustrative model output. Every entry in every trajectory, regime, regrade and descent table — `Lambda_inf = 4.320`, `E_b = 2.3987`, `x = 1.9972`, `C'' = −0.005076` — is the output of stipulated parameters under a stipulated field. **These carry no measurement uncertainty because there was no measurement**; the decimal places record the arithmetic, not the confidence.

Measured or fitted. The counts 14 / 9 / 5 / 2 and 17 / 8 / 4 / 1 and 8 / 7 / 8 / 7 are the only observational quantities in the paper, and every quantity derived from them is reported **with a standard error and a 95 per cent interval** in Sections 5.4, 5.6 and 9.8, including the three intervals that span zero and are therefore reported as unmeasured. The parameters `eta`, `M`, `C` and `lambda` are described in the source as measured by the framework's protocols; **no interval is available for any of them, and their point values are therefore carried as stipulations for the purposes of this paper.** That is a real gap and Section 12 repeats it.

22.12 12 Limitations

The worked case is one subject and the field is constructed. No external dataset was collected for this paper. The cost field of Section 5.8 is an analytic expression, the regimes of Section 9.4 are stipulated parameter sets, and every derived figure is the output of those stipulations. They demonstrate that the procedure runs and that it reports its own failures; **they are not evidence that any person behaves this way and must never be cited as such.**

The region that matters was never visited. The ordered coordinate's field was estimated from a mixture of trace data and ledger reconstruction, because the subject had not occupied most of the range. **The region between `x = 3` and `x = 6` — which contains the ridge, and therefore the entire barrier — was inferred, not measured. Every barrier figure in this paper rests on that inference.** The two independent estimates of `E_b` agree to 0.05 per cent, but both were produced by the same investigator and may share the same reconstruction, so the agreement is weak evidence and is reported as such.

Four quantities in the source do not reconcile exactly, and are reported rather than corrected. (i) The basin separation is given as 4.996 configuration-units while the two stated basin floors, 1.9970 and 6.9960, differ by 4.999; at the consistent separation `E_b = 2.3973` rather than 2.3987, a shift of 0.06 per cent that changes no verdict. (ii) After the 0.020 bridge, `C(A)` is 0.032665 at the stationary point and 0.03269 in the regrade table, which propagates to `Lambda_inf` = 4.3734 against 4.3724 and `t*` = 21.50 against 21.49. (iii) The source states that basin B "takes about 2.7 steps per decade of remaining error"; from its own contraction factor of 0.24886 the figure is `ln(0.1)/ln(0.24886) = 1.66`. (iv) The bridge's functional form is never stated, so the figure in Section 5.11 uses a reconstruction that reproduces all five stated stationary points to four decimals and recovers `E_b = 1.8361` against the stated 1.8345.

The Launch Postulate and the Gradient Postulate are postulates and neither has been tested. Nothing in the framework's foundational results implies either, and neither would be touched if both were false. H1 and the falsification protocol of Section 6.1 state exactly what would defeat the first; the shuffled-day control of Section 9.8 licenses the second for one subject on two coordinates and licenses nothing further.

`theta` was never pinned, so no absolute cost is reported anywhere. The one experiment that would fix it — imposing a cost of known magnitude and measuring the shift in share — was not run. Every difference in Sections 5 and 9 is in theta units and only the ratios are advanced as findings.

The independence-of-irrelevant-alternatives check was not performed. It was computed within the existing choice set, which is not a test. The logit form is assumed for coordinates

1 and 2 and is untested for them, and it is known to fail in choice domains containing near-substitutes [Tversky, 1977].

The reflection problem is unanswered and outranks every fitting result in this paper. The framework's reflexive loop is a linear-in-means specification whose endogenous effect is **not identified from observational data** [Manski, 1993], with influence and selection generically confounded in observational network data [Shalizi and Thomas, 2011]. **No remedy is adopted here.** The most realistic available repair is to stipulate the reference group and defend the stipulation [Brock and Durlauf, 2001], and the frozen pre-declared option set of Protocol G-1 is a step toward it rather than a substitute. **Every claim in this paper that leans on the loop is a modelling position rather than an identified empirical result.**

The Lucas critique applies to this framework's own parameters. The framework asserts that systems change behaviour when modelled and observed, then treats `eta`, `lambda` and `theta` as constants over an estimation window [Lucas, 1976]. The narrow position taken in Section 3.6 — stability only over a declared window and only while the fund is not itself a reported target — is a genuine restriction on where the model may be used, and where an subject's fund is reported to anyone with an interest in it the constancy assumption fails [Goodhart, 1975, Campbell, 1979].

The quantitative structure of the underlying constructs has not been tested, and this is the strongest objection to the framework. Michell [1997, 1999] argues that psychology routinely fails to test whether its attributes are quantitative at all before measuring them. The available remedy is conjoint measurement [Luce and Tukey, 1964, Krantz et al., 1971] or a Rasch demonstration [Rasch, 1960]. **Neither has been run for comfort, for `M`, or for `C`, so the ratio-scale treatment those quantities receive here — differences, ratios, logarithms and a rectifier requiring a true zero — is a stipulation and not an established property.** The rectifier is the most exposed operation in the paper on this ground: `max(0, x)` is only meaningful if zero means something.

Several parameters were chosen rather than measured with an interval. `eta`, `M`, `C` and `lambda` are reported as point values with no uncertainty attached, and `lambda` in particular was measured by a reactive procedure: stating a plan and then deliberately not reinforcing it is not a neutral act, so the two values should be read as an ordering rather than as magnitudes. The transit duration of 65.5 weeks is an intention, not an observation.

The model comparison standard is NOT MET. RIGOR requires out-of-sample performance, a matched null with the same number of free parameters, an information criterion so the parameter count is paid for, an explicit count of free parameters, and effect sizes with intervals. The shuffled-day control of Section 9.8 supplies a permutation null and nothing else. **No AIC or BIC was computed anywhere in this paper, and none is computed anywhere in this corpus**, so the parameter count has never been paid for. The free-parameter count of the worked construction is stated for the record: the cost field carries six (two depths, two centres, two widths, plus a linear drift term, of which the drift is the seventh), the launch model carries four (`eta`, `M`, `C`, `lambda`), the barrier carries one (the transit duration), and the logit recovery carries one unidentified scale (`theta`) plus one optional switching cost (`s`). **A model with that many free parameters that reproduces a single subject's trajectory has not been shown to be better than anything.**

No scaling, power-law or heavy-tail claim is made in this paper, so the distribution-fitting procedure such a claim would require [Clauset et al., 2009] does not apply. The one distributional claim that *is* made — that plan persistence decays geometrically — is H2 and is untested.

The functional form of the surplus term is underdetermined, as Section 3.1 states: a sub-linear power law [Latané, 1981] and an `n log n` form [Briscoe et al., 2006] fit the same qualitative facts as `ln(1 + (N−1)u)`, and **nothing assembled in this corpus discriminates among them.** The logarithm is preferred for its axiomatic characterisation and for the ergodic argument [Peters and Gell-Mann, 2016], not because it has been measured. Relatedly, `1 + (N−1)u` **is not a Hill number** — `1/HHI` and `exp(H)` are, and are well grounded [Hill, 1973, Jost, 2006] — and a reviewer reaching for the Hill literature as support will find that it does not apply.

The moment equation and the calibration ratio have no external support in this corpus's

bibliography. They are used in Section 4.9 to compute the over-framing inflation factor of 1.7889, and that number is therefore internal to the framework and carries no external warrant.

The single-scalar barrier discards structure that matters. A real transition has a shape, a sequence and reversibility properties that one number cannot carry; the barrier-splitting result of Section 4.8 is precisely the case where the scalar summary was wrong and the shape was what mattered. The scalar is retained because it makes feasibility a comparison of two numbers, and that is a modelling choice rather than a finding.

Nothing here is a human-subjects finding. No interventions were run and no participants were recruited. The consent constraint of Section 4.7.3 is a design constraint on prospective work, not a report of practice.

What would falsify the account. H1 fails on a documented plan constructed during a sustained `L = 0` stretch. H2 fails on non-geometric plan decay under no reinforcement. H3 fails if departure rates are the same above and below the computed `C_crit`. H4 fails if realised transit cost is uncorrelated with the predicted barrier. H5 fails if a frozen difference table does not beat a day-shuffled control, or if experimentally manipulating the choice set moves the recovered ratios. H6 was tested and survived on one constructed field, which is the weakest form of survival available.

22.13 13 Conclusion

R1. The launch budget is the rectified surplus `L^Q = max(0, eta*M - C)`, with the lived register `L^M = max(0, M - C/eta)` and `L^Q = eta*L^M`; the naive form `max(0, M - C)` fails a dimensional check and is inadmissible. Accumulated in a leaky integrator `Lambda_{t+1} = (1-lambda)Lambda_t + L_t`, it has the unique attracting fixed point `Lambda_inf = L/lambda`, which is the largest barrier the regime can cross at all, at steady state, with unlimited patience. **A departure across a barrier `E_b` is feasible if and only if `Lambda_inf > E_b`, and it requires `t* = ln(1 - E_b/Lambda_inf)/ln(1 - lambda)` periods of accumulation.**

R2. Rearranging feasibility gives the **critical cost `C_crit = eta*M - lambda*E_b`**, computed at **0.082 Q-units per week** in the worked case at `eta = 0.10`, `M = 1.42`, `lambda = 0.025`, `E_b = 2.40`. Above it no amount of waiting funds the departure; the fund still rises, to a ceiling below the wall, which is why the failure is silent. Rearranging `L > 0` gives the **critical conversion efficiency `eta_crit = C/M`**, computed at **0.055238** against the worked subject's measured `eta = 0.05` — below the line by half a percentage point, giving `L = 0` and `Lambda_inf = 0`: **a sustained zero budget that cannot diagnose itself, because diagnosis is funded from the same budget.**

R3. On the measured cost field `C(x) = 0.090 - 0.0568 exp(-(x-2)^2/0.8) - 0.064 exp(-(x-7)^2/1.2) + 0.0004x`, with basin A at `x = 1.9970`, a ridge at `x = 4.3350` with `C'' = -0.005076`, and basin B at `x = 6.9960`, **momentum at `beta` = 0, 0.5, 0.8, 0.9 and 0.95 all terminate at `x = 1.9972` in basin A.** Momentum defeats narrow barriers and is useless against wide shallow ones, because momentum accumulated on a one-unit descent cannot carry a walker across a two-unit flat rise. **The recursion is recorded as a failed candidate and is refused entry to the formulary**, and what survives is one empirical statement with no free parameters: against a wide shallow barrier there is no substitute for an accumulated fund, because no dynamical trick crosses it.

R4. Under a logit desire-line survey **only ratios of cost differences are identified**, `theta` cancelling: from counts 14 / 9 / 5 / 2 over thirty days, **`(C_office - C_desk)/(C_kitchen - C_desk) = 4.4042`**, unit-free and testable, while the kitchen-versus-desk difference itself has a 95 per cent interval of `[-0.3956, 1.2792]` and is **unmeasured** at 30 days, needing 108. Absolute costs are never recovered and must never be reported.

R5. Regrading the destination is nearly useless: a 21 per cent improvement in the target basin's floor buys a 1.94 per cent reduction in the barrier. Bridging the ridge by 0.020 cuts the barrier by 23.5 per cent, cuts the wait from 32.00 weeks to 21.49, and manufactures a new rest

basin at `x = 4.3350`, `C = 0.071500`, which splits the crossing into legs of 0.8812 and 0.0218 and cuts required accumulation to 9.19 weeks. **The barrier is the ridge, not the destination.**

R6. An unmodelled switching cost `s = 0.6` theta inflates every non-modal option's recovered cost by 15.9 to 20.8 per cent while biasing the ratio of differences by only 4.05 per cent, and at `s = 1.0` the figures are 28 to 36 per cent against 5.36 per cent. Reporting ratios rather than differences therefore buys roughly a factor of four in robustness, on top of the theta-freeness that was the original reason for the rule.

CR (counter-result). Momentum, the standard escape from a local minimum, was run on the measured field at five settings and escaped nothing. **A measured negative result, recorded without adopting the mechanism**, and it sharpens R1: no dynamical trick substitutes for an accumulated fund against a wide shallow barrier.

The arithmetic behind all six is one line. `L = max(0, eta*M - C)` is maximised exactly where `C` is minimised, so **the budget for elsewhere is manufactured only where the cost of being here is at a minimum.** Whether any person's planning capacity is in fact `L` is a postulate, not a result, and it has not been tested.

22.13.1 Declarations

Data and code availability

No external dataset was collected for this paper. The worked case of Section 9 is a single-subject construction whose parameters are stipulated in the text and whose derived figures are computed from those parameters under the model developed in Sections 3 to 5. The choice counts of Sections 5.4, 5.6 and 9.8 are the source's recorded tallies and are printed in full beside every quantity derived from them. Every table in the paper can be re-derived from the equations and parameter values printed beside it. **The figures are generated by the scripts named in each caption**, and those scripts contain no data beyond the numbers printed in this paper and the model equations of Sections 3 to 5. Where a figure required a functional form the source does not state — the bridge regrade of Section 5.11 — the reconstruction is named in the caption and its fidelity to the source's stated stationary points is reported.

Funding

This research received no external funding.

Conflicts of interest

The author declares no conflicts of interest.

Author contributions

Single author. Michael Laurence Curzi conceived the work, derived the results, produced the worked example and the figures, and wrote the paper.

Ethics

No human-subjects research was conducted and no personal data was processed. The worked case is a construction. The consent constraint discussed in Sections 4.7.3 and 7 — that no intervention raising another person's operating cost in order to force a departure is within the framework's scope — is a design constraint on prospective work and is not a report of any study performed.

Preregistration

This paper reports no preregistered test of its own. The falsification protocols for H1 to H5 are stated in Sections 2 and 6 and none has been run. The one preregistered confirmatory test of the underlying storage law reported in this corpus **failed** its second falsification rule — a 2.8 per cent held-out RMSE advantage over a matched AR(1) against a declared margin of 10 per cent — and is reported in Curzi [2026i]. Any applied claim resting on this paper inherits that result.

Chapter 23

The Return Difference, the Contraction, and a Formulary That Demotes Five of Its Own Nine Entries

Abstract. This paper defines the return difference $\Delta_R = |\ln(M'/M)|$ between a moment enacted and the world's answer, badging the commensurability assumption (Postulate R1) that lets the two be placed on one ratio scale. The instrument has a Weber deadband $\Delta_{R,\min} = \ln(1+c)$, a sample-size law $n \geq (1.96\,\sigma_\rho/\Delta)^2$ requiring 139 clean echoes to establish a 5 per cent return at $\sigma_\rho = 0.30$, and an attenuation law $\rho_{\text{obs}} = (1-w)\rho_{\text{true}}$ for correlated sources that biases the reading toward zero rather than merely widening it. Correction with gain λ gives $\rho_{t+1} = (1-\lambda)\rho_t$, stable for $\lambda < 2$, deadbeat and noise-transparent at $\lambda = 1$. In a twelve-week log the sign read over-framing at an implied factor of 1.4467, the gain recovered as $\lambda = 0.3582$ ($R^2 = 0.8587$, distortion half-life 1.56 weeks), and directional efficiency was $E_R = 0.9316$. Arrival is then proved rather than asserted: $T(Q) = (1-\delta)Q + b$ is a contraction with constant $1-\delta$, Banach gives the unique fixed point $Q_\infty = (\eta M^* - c^*)/\delta$, and the exact error law $|Q_t - Q_\infty| = (1-\delta)^t |Q_0 - Q_\infty|$ coincides with the closed-form solution. Elasticities rank the levers and are derived rather than fitted: $\eta\,{+1.594}$, $\delta\,{-1.000}$, $u\,{+0.770}$, $C\,{-0.594}$, so a 10 per cent efficiency gain is worth 2.7 times a 10 per cent cost cut. Convergence, however, certifies nothing: $\eta F < c^*$ yields a negative fixed point the loop still reaches, and a transfer relocates a fixed point without creating one. **The accompanying nine-entry formulary demotes five of its own entries — F-01, F-02, F-04, F-06 and F-08 — on the scale-type gate, withdrawing the magnitude of D/P, the distortion as a number, and the quantitative moment-to-storage join, while retaining the limiting cases, the $D = P$ fixed point and the over/under-framed ordering; and it records that the shuffled-input control every falsification row depends on is anti-conservative at 0.108 against a nominal 0.05.**

Keywords: return difference; correction gain; contraction mapping; error law; elasticity; counterfeit arrival; formulary demotion

Series: B. Engineering the Surplus **Paper:** CCP-023

23.1 1 Introduction

An account of self-directed change has to answer two questions before any of its prescriptions can be assessed. First: when a person acts and the world answers, what quantity is the answer,

and how small an answer is still an answer? Second: if the person keeps acting, does the accumulation arrive anywhere, and if so, where — and does arriving mean anything?

This paper answers both, and then audits the answers with the corpus's own validation instrument. The first question is answered by the **return difference** $\Delta_R = |\ln(M'/M)|$, the logarithm of the ratio between the moment enacted and the moment returned, read sign-first. The second is answered by showing that the internal-scope storage map `T(Q) = (1−delta)Q + b` is a contraction with modulus `1 − delta`, so Banach's theorem supplies a unique start-independent fixed point `Q_inf = (eta M* − c*)/delta` together with the exact error law `|Q_t − Q_inf| = (1−delta)^t |Q_0 − Q_inf|`.

Both answers are then run through the seven-gate Formula Validation Protocol [Curzi, 2026t], and **the protocol demotes five of the nine entries in the resulting formulary.** That is the paper's most important result and it is reported here rather than buried: F-01, F-02, F-04, F-06 and F-08 — every entry whose value passes through the moment `M` or through the calibration ratio `r = D/P` — fail the scale-type gate, because `D` and `P` are not instrumented on a common ratio scale with a shared true zero and division without a true zero yields a number with no referent [Curzi, 2026m,t]. What is withdrawn is stated exactly: the magnitude of `D/P`, the distortion $\Delta = |\ln r|$ as a number, and the quantitative form of the moment-to-storage join. What survives is stated with equal precision: the limiting cases, the `D = P` fixed point, and the ordering over-framed / calibrated / under-framed, all of which require only ordinal information. **A formulary that demotes five of its own nine entries, names exactly what survives and prices the study that would restore the rest is the protocol working, not a caveat.**

A second self-audit runs alongside it and is equally uncomfortable. The four-baseline falsification suite this paper's entries all defer to rests on a shuffled-input control, and that control has been measured rather than assumed. Against a nominal false-positive rate of 0.05 across 500 null trials, independent permutation false-rejected at **0.108, 2.2 times nominal**; it is blind to a filtered repackaging of its own input, which passed all four baselines at `p = 0.0005` and was caught only by a structural ceiling test; and against a confound driving both series it passed **98.35 per cent** of 4,000 trials [Curzi, 2026u,ac]. **The shuffle is a weak, mis-calibrated empirical audit, and design controls rather than more surrogates are what catch confounding.**

Between the two audits sits the paper's constructive content. The return difference has a Weber deadband $\Delta_{R,\min} = \ln(1+c)$ below which no echo is detectable at all; a sample-size law `n >= (1.96 sigma_rho / Delta)^2` requiring 139 clean echoes to establish a 5 per cent return at `sigma = 0.30`; and an attenuation law `rho_obs = (1−w) rho_true` for correlated sources, which is the design-effect problem of survey sampling arriving in a personal instrument. Correction with gain λ gives `rho_{t+1} = (1−lambda) rho_t`, stable for $\lambda < 2$, deadbeat and noise-transparent at $\lambda = 1$. On the worked twelve-week log the sign read over-framing at an implied factor of 1.4467, the recovered gain was $\lambda = 0.3582$ with `R^2 = 0.8587` and a distortion half-life of 1.56 weeks, and directional efficiency was `E_R = 0.9316`.

The arrival half then answers the practical question — which of the four levers to move — with elasticities of the fixed point that are **derived rather than fitted**: `eta` **+1.594**, `delta` **−1.000**, `u` **+0.770**, `C` **−0.594**, so that **a 10 per cent efficiency gain is worth 2.7 times a 10 per cent cost cut** at the stated base point. And it closes with the result that convergence certifies nothing: `eta F < c*` produces a negative fixed point that the loop reaches just as reliably, so a system can arrive, on schedule, at a destination that is a slow depletion.

Three results are presupposed rather than re-derived. The storage law's contraction, its fixed point and its geometric convergence — and the finding that `delta = 0` is a pathology rather than an ideal, with no contraction, no unique fixed point and an error-persistence column of ones — are established in Curzi [2026a]. The contraction theorem itself is stated exactly, with its *a posteriori* bound read operationally as *distance to arrival is the last correction scaled by* `q/(1−q)`, in Curzi [2026]. The stationary-action framing, with the correction that the honest form is stationarity rather than minimality and that the variational form licenses no teleology, is presupposed from Curzi [2026].

Sections 3 to 6 develop the return difference, its requirements and its failure modes. Sections 7 to 10 develop the contraction and the dynamics of arrival. Sections 11 to 13 present the

nine-entry formulary with its per-gate verdicts. Section 14 reports the three worked results and the demotion tally. Sections 15 to 18 discuss, verify, limit and conclude.

23.2 2 Hypotheses

Several of the results below are theorems about a difference equation and cannot be falsified by observation; they are labelled as derivations where they appear. What can be falsified is the claim that the equations describe a real person acting and accumulating. The hypotheses separate the two, and each names the observation that would defeat it.

H1 — The return is a ratio, not a difference. The smallest change in a returned magnitude that a person can detect is a constant *proportion* of what was sent, not a constant increment. **Predicted:** a Weber deadband $\Delta_{R,\min} = \ln(1 + c)$ with `c` approximately constant across the usable range of `M`, so that the detection threshold scales with the stake. **Falsified by:** a measured detection threshold that is constant in absolute units across a wide range of `M`, or a Weber fraction that varies systematically with `M`. **Status: NOT TESTED.** No Weber fraction for moment magnitudes has been measured by anyone, and Section 4.3's illustrative `c = 0.10` is a placeholder carried through the arithmetic, not a measurement.

H2 — Arrival is geometric and start-independent. Under constant drive the internal store approaches a single fixed point from any starting value, with the distance falling by exactly the factor `1 - delta` each period. **Predicted:** `|Q_t - Q_inf| = (1-delta)^t |Q_0 - Q_inf|` exactly, a time constant $\tau = -1/\ln(1 - \delta)$, monotone approach from either side, and no overshoot in the absence of a delayed control loop. **Falsified by:** an observed non-monotone approach without a delay term; a settling time that depends on `Q_0`; or a fitted retention coefficient outside `[0,1]`.

H3 — Correction is a first-order loop with a stability boundary at gain 2. Repeated correction of a distortion by a fraction λ of the observed error contracts for $0 < \lambda < 2$ and diverges outside it. **Predicted:** `rho_{t+1} = (1-lambda) rho_t`, so distortion decays with half-life $\ln 2/|\ln|1 - \lambda||$; deadbeat at $\lambda = 1$; oscillatory but convergent for $1 < \lambda < 2$; divergent at $\lambda \geq 2$. **Falsified by:** an observed correction sequence that converges at a gain of 2 or more, or that diverges at a gain safely inside the interval.

H4 — Efficiency dominates cost as a lever. At any sustainable operating point, a proportional improvement in conversion efficiency raises the destination by more than the same proportional reduction in cost does. **Predicted:** the elasticity ratio is `eta M*/c*`, which exceeds one whenever `eta M* > c*` — that is, whenever the regime is sustainable at all — and at the base point of Section 8.5 it is 1.594 against 0.594, a factor of 2.68. **Falsified by:** nothing observational. **This is a theorem about the fixed-point formula, not a hypothesis**, and it is recorded in the verification chain as `ARITHMETIC`. It is stated here as a hypothesis only to mark the boundary: what *could* fail is the antecedent claim that a real person's stored capability obeys the fixed-point formula at all, and that is H2.

H5 — The protocol demotes some of what it audits. A validation protocol applied by an author to his own formulary returns a pass rate materially below one. **Predicted:** a substantial minority of the nine entries fail at least one gate outright, and the failures cluster on the gate the corpus is most exposed at — scale type. **Falsified by:** all nine entries passing all seven gates, which would be evidence that the protocol had been captured rather than that the formulary was sound.

H2, H3 and H5 are confirmed; H4 is a theorem; H1 is untested and is reported as untested. The confirmations of H2 and H3 are confirmations *on illustrative constructions* — worked

series whose parameters were chosen, not measured — and they demonstrate the arithmetic rather than the world. H5's confirmation is the demotion of five of nine entries, and that one is a fact about the corpus rather than about people.

23.3 3 The return difference: definition, badge, and what is presupposed

You act. The world answers. The answer is never the voice you sent.

That last sentence is the whole of the argument, and it is not a lament. It is a statement about where information lives. **If the answer were identical to the voice, the exchange would have carried nothing; the entire content of an echo is the difference between what returned and what was sent.** Everything else in this paper is the arithmetic of that difference and the engineering of the instrument that reads it.

23.3.1 3.1 The formula, stated

The fourth of the framework's derived internal-scope formulas [Curzi, 2026o] is this:

```
THE RETURN DIFFERENCE

    rho_t     = ln( M'_t / M_t )              signed return, in nats
    Delta_R,t = | rho_t | = | ln(M'_t / M_t) |   unsigned magnitude, in nats

    M_t   the moment sent      -- the moment as the subject constructed and enacted it
    M'_t  the moment returned  -- the moment the world's answer constructs on arrival back
```

Two quantities, not one. `Delta_R` is what the framework's internal-scope correspondence names; `rho` is `Delta_R` with its sign restored, and the sign is half the diagnostic. The corpus uses both throughout, and the convention is fixed here: **`rho` for reading, `Delta_R` for budgeting.** You read a single echo with its sign. You budget a series of echoes by magnitude, because magnitudes accumulate and signs cancel — and the cancellation of signs across a series is itself a finding, treated in §4.4.

23.3.2 3.2 The badge

`Delta_R = |ln(M'/M)|` is **a derived formula of the corpus, not a theorem of the framework's mathematical papers.** It is derived in the sense the internal-scope correspondence requires [Curzi, 2026o] — it follows from choices already made in the corpus rather than being introduced fresh — but the derivation runs through a postulate, and the postulate is stated here with its badge on.

Postulate R1 (the returnable moment). The world's answer to an enacted moment can itself be assigned a moment magnitude on the same ratio scale as the moment that was sent, by the same subject, using the same procedure. **Badged: this is an assumption of commensurability, not a result.** It is exactly as strong as the assumption that lets a person say a second sound was twice as loud as the first, and it is defensible for the same reason — Stevens' method of magnitude estimation produces ratio-scale judgements of subjective quantity and it replicates [Curzi, 2026t]. It is not defensible when the two things being compared have no common procedure of estimation, and §4.8 says exactly when that happens.

Given R1, the rest is forced. The corpus works in log-ratios everywhere: surplus is `ln N_eff`, pitch is `log2 f`, sensation is `k ln(I/I_0)`, the calibration distortion is `|ln r|`. A difference measure on moments that was *not* a log-ratio would be the one quantity in the book that did not compose with the others, and the four-register convergence [Curzi, 2026n,?] would break

at exactly the point where feedback enters. **The log-ratio is not a stylistic choice about the echo; it is the only form that keeps the echo in the same register as everything the echo has to talk to.**

23.3.3 3.3 Why the ratio and not the difference

There are two candidate difference measures and the choice between them is decidable, not aesthetic.

```
additive     e_t = M'_t − M_t
ratiometric  rho_t = ln(M'_t / M_t)
```

Three reasons the ratiometric form wins, in increasing order of force.

One: composition. Echoes chain. You send a moment, the world answers, you send the answer onward, a second answer returns. The total return over a chain of `k` links is

```
M'_k / M_0 = (M'_1/M_0) ∗ (M'_2/M'_1) ∗ ... ∗ (M'_k/M'_{k−1})

ln(M'_k / M_0) = rho_1 + rho_2 + ... + rho_k
```

Ratios compose by multiplication, so log-ratios compose by addition, and a chained return difference is therefore a plain sum. The additive form has no such property: `M' − M` over a chain depends on the absolute magnitudes at every intermediate link, and two chains with the same per-link proportional effect give different totals if they start at different sizes. A measure whose composition law depends on where you started is not measuring the exchange.

Two: scale invariance. Multiply every magnitude in an echo log by a constant — change the modulus of the magnitude-estimation procedure, rate the week out of 100 instead of out of 50 — and every `rho` is unchanged while every additive `e` is scaled. Since the modulus in magnitude estimation is arbitrary by construction, **a difference measure that moves when the modulus moves is measuring the procedure, not the world.**

Three: the lens. The lens theorem [Curzi, 2026n] holds that perception is logarithmic, so equal perceptual steps are equal world ratios. The subject reading the echo is a logarithmic instrument. `rho` is what that instrument natively reports. The additive form would require the subject to perform a conversion their perceptual system does not perform, and every such conversion is a place where a bias enters.

23.3.4 3.4 The ECHO node, stated exactly

The foundations series' eighth node [Curzi, 2026] taught the practitioner to read the difference: that the answer coming back is never the voice sent out, that the gap between them is the only new thing in the exchange, and that two specific pathologies wait on either side of the reading — the Mirror that Flatters, which returns your own voice and calls it agreement, and the Echo that Devours, which returns your voice amplified until it is the only thing in the room.

Here the ECHO node is `rho_t = ln(M'_t/M_t)`, its deadband, and its stability condition. Each of the node's three teachings has an exact counterpart:

The node's teaching	This paper's quantity	Section
The answer is never the voice sent	`rho` is generically nonzero; `rho = 0` is a measure-zero coincidence	§4.1

The node's teaching	This paper's quantity	Section
The difference is the only data	The magnitude `Delta_R`, its deadband `ln(1+c)`, and its signal-to-noise	§4.2–4.4
The Mirror that Flatters	`rho_obs = (1 − w) rho_true`; correlated echoes and the design effect	§4.5
The Echo that Devours	`rho_{t+1} = (1 − lambda) rho_t` with `|1 − lambda| >= 1`	§4.6

The last row is the one that repays the translation most, because the foundations series could warn about the devouring echo but could not say where it starts. This paper can: **it starts at a correction gain of exactly 2, and the marginal case at gain 2 is an undamped oscillation that never grows and never settles.** That is a number, it is derived below, and it is checkable against your own records.

23.3.5 3.5 The zero clause, stated hard

The internal-scope correspondence [Curzi, 2026o] says it in six words: *zero means no information came back.* The corpus states the consequence at full strength because it is the most commonly ignored reading in the whole formulary.

`Delta_R = 0` is not success. It is the absence of an exchange. A world that returns exactly what you sent has told you nothing about itself — it has told you only that whatever it did to your voice, it did symmetrically enough to cancel. There are two ways to produce a persistent zero and they are opposite in kind: perfect calibration, in which the subject's construction of the moment already matched what the world would return, and perfect closure, in which the channel back is not the world at all but a reflection of the subject. **The arithmetic cannot tell these apart from a single reading, and §4.5 gives the test that can.**

The corollary is the one that costs people years: **a world that only ever agrees with you is telling you nothing, and the pleasantness of the sensation is not evidence against this.** The sensation of being agreed with and the sensation of being correct are, from the inside, the same sensation. The corpus has said the equivalent thing at group scope already — [Curzi, 2026d] on pseudo-diversity and on collective intelligence — and the thesis of Series B [Curzi, 2026s] is that it is one statement at two scopes, not two statements.

23.3.6 3.6 Formula Validation Protocol — the return difference

Under the Formula Validation Protocol [Curzi, 2026t], no formula appears in Series B of the corpus without all seven gates in print.

Gate	Verdict	Content
FVP-1 DIMENSIONS	PASS	`M` and `M'` carry the units of the magnitude-estimation modulus (arbitrary but fixed). `M'/M` is dimensionless. `ln` of a dimensionless number is dimensionless; `rho` and `Delta_R` are reported in **nats**, convertible to bits, octaves and cents by the the framework's internal-scope correspondence keys. Both sides agree.
FVP-2 SCALE TYPE	**CONDITIONAL PASS — the binding gate**	Division requires ratio scale with a true zero. Magnitude estimation supplies this (Stevens 1957); a 1–5 satisfaction rating does not. **If `M` and `M'` are ordinal, `ln(M'/M)` is not defined and the formula must be demoted in print to a heuristic ordering: "the return was larger / the same / smaller."** The demotion is not optional and §4.8 specifies it.
FVP-3 LIMITING CASES	PASS	`M' -> M`: `rho -> 0`, no information returned (§3.5). `M' >> M`: `rho -> +inf`, over-return; in practice bounded by the modulus ceiling. `M' -> 0`: `rho -> -inf`, total non-return — the answer that constructs no moment at all, which is the real phenomenon of being ignored, and the divergence is correct because there is no finite penalty scale for it. `M -> 0`: undefined; correctly so, because nothing was sent and an echo of nothing is not an echo.

Gate	Verdict	Content
FVP-4 FIXED POINTS	PASS	`rho = 0`, i.e. `M' = M`. Under the correction dynamics of §4.6 this is the unique fixed point of the map `rho -> (1-lambda)rho` for any `lambda != 0`, and it is attracting iff `0 < lambda < 2`. Meaning: **the state in which your construction of the moment and the world's answer to it agree — which is either contact or closure, and only the correlation test distinguishes them.**
FVP-5 IDENTIFIABILITY	**PARTIAL**	`rho` is recoverable from paired magnitude estimates. The *decomposition* of `rho` into "the world's contribution" and "the subject's mis-framing" is **not identified from `rho` alone** — a large negative `rho` is equally consistent with an over-framed subject (`r = D/P > 1`, [Curzi, 2026m]) and with a genuinely unresponsive world. Separating them requires a second instrument: either an independent estimate of `M'` by someone who did not send `M` (§4.5) or a manipulation of `D` with `E` held fixed (§4.10). **State this limitation whenever a single `rho` is used to draw a conclusion about a person.**

Gate	Verdict	Content
FVP-6 FALSIFICATION	SPECIFIED	The preregistration template [Curzi, 2026i]. Preregister: the operationalization of `M` and `M'`, the modulus, the correction gain `lambda`, the horizon. Fit `lambda` on a training block, **freeze**, and predict held-out `rho`. Four baselines: (i) persistence — next `rho` equals last `rho`; (ii) direct-input — `rho` predicted from `M` alone; (iii) matched autoregressive AR(1) on `rho`; (iv) **shuffled-input control** — the same `M` series paired with a permuted `M'` series. **The formula dies if the frozen `lambda` model fails to beat the shuffled-input control on held-out data**, because that is the outcome in which the pairing between what was sent and what came back carries nothing.
FVP-7 REPRODUCIBILITY	**UNTESTED — declared**	The cross-individual gate. Same operationalization, different subjects, different investigators: do the fitted `lambda` values recover, and do they rank people consistently? The corpus has not run that study and does not have the data. **What would need measuring is stated in §4.11 as a protocol, and until it is run, `lambda` is a within-person descriptive parameter and nothing more.** This is the gate the framework's internal-scope correspondence says is most often skipped; it is not skipped here, it is declared open.

23.3.7 3.7 What is presupposed

Four results are used below and not re-derived.

The **surplus functional** `F(u) = ln(1 + (N−1)u)` with its axiom set and its ceiling `F <= ln N` is established in Curzi [2026]. The **affine effective count** `N_eff = 1 + (N−1)u` that goes with it is

the corpus's own construction and is not a Hill number of any order — it is a linear interpolation between 1 and `N` with no supporting literature in ecology, economics, political science or information theory. The Hill numbers proper, `1/HHI` at order 2 and `exp(H)` at order 1 [Hill, 1973, Jost, 2006], are different quantities and are the ones the corpus uses on measured shares at institutional scope [Curzi, 2026,?]. Wherever an effective count appears below it is the affine one.

The **storage law** `Q_{t+1} = (1−delta)Q_t + eta S_t − C_t`, its exact solution, its uniform bound and its fixed point are established in Curzi [2026a], whose central result — that `delta = 0` is a pathology and not an ideal, with no contraction, no unique fixed point, and an error-persistence column of ones, so that no mistake ever decays out of the stock — is the boundary case Sections 7 and 8 work away from. The **contraction theorem** is stated exactly in Curzi [2026], together with the *a posteriori* bound `d(x_n, x*) <= (q^n/(1−q)) d(x_0, x_1)` read operationally as: distance to arrival is the size of the last correction scaled by `q/(1−q)`, so the size of one's most recent revision is a self-reading gauge.

The **moment equation** `M = (D/P)E`, the calibration ratio `r = D/P`, and the correction map `ln r_{t+1} = (1−a) ln r_t` — attracting for `0 < a < 2`, neutral at `a = 0`, divergent at `a >= 2`, so that from a distortion of 0.81 nats six cycles at gain 2.3 reach 3.92 — are established in Curzi [2026m]. The **stationary-action framing**, with the correction that the honest form is stationarity rather than minimality and that the variational form licenses no teleology, is presupposed from Curzi [2026].

Finally, the **seven-gate Formula Validation Protocol** and its verdict vocabulary are Curzi [2026t], whose gate-2 result is the one this paper's formulary inherits.

23.3.8 3.8 Identification: what no amount of logging can recover

The material below repeatedly describes a loop: a person enacts a moment, the world answers, the answer changes the construal, the changed construal shapes the next moment. **That is a reflexive specification, and Manski [1993] proves that the endogenous component of such a specification is not identified from observational data.** It cannot be separated from contextual effects or from correlated unobservables however long the log runs. Shalizi and Thomas [2011] establish the same for network data — influence and selection are generically confounded — and Lyons [2011] show in detail what happens when the point is ignored.

The known remedies are randomisation of the enacted moment, an instrument, partial-population variation, or stipulating the reference set by prior information and defending the stipulation, Brock and Durlauf [2001] being the template for the last. **None is free and this paper adopts none.** Every claim below that rests on the loop is therefore a **modelling position rather than an identified empirical result**, and the specific consequence for the instrument is stated where it bites: a twelve-week echo log cannot distinguish an effect of the enacted moments from a driver common to both series, and the shuffled-input control that is nominally supposed to make that distinction **passed 98.35 per cent of the time against exactly such a confound** [Curzi, 2026u,ac].

Two objections in the same family are recorded now rather than in a footnote. The **Lucas critique** turned on the corpus says `delta`, `eta` and `u` are the decision rules of people who have not read the framework, so they are not structural parameters [Lucas, 1976]; Hacking [1995] makes the same point about classifications of people generally, and Ferraro et al. [2005] supplies the case in which a theory made people behave worse by assuming the worst of them. And **the corpus proposes to give people laws to manage their own comfort by, which is building an engine and not only a camera** [MacKenzie, 2006, Callon, 1998]; MacKenzie and Millo [2003] is the documented case of a theory becoming true by being used, with dates and price data, and Soros [2013] is the closest existing named doctrine to the corpus's reflexive law. Jussim and Harber [2005] is the corrective on effect size: self-fulfilling prophecies are real but small, typically non-accumulating, and often dissipating.

23.3.9 3.9 Analogy discipline

The framework borrows form from control theory, from signal processing and from psychophysics. Every such borrowing is one of three things and is labelled at first use: a **derivation**, where the system genuinely satisfies the premises of the physical result; a **shared mathematical form**, where the same equation governs both with no claim that the underlying physics applies; or an **analogy**, legitimate as motivation and never as evidence.

Everything in this paper is of the second kind. A leaky integrator is a leaky integrator whether it holds charge or stored capability [Oppenheim et al., 1996, Horowitz and Hill, 2015]; the stability boundary at gain 2 is the unit-circle condition of a first-order discrete loop and carries no dynamical-systems result beyond it; the design-effect correction is survey sampling; the ratio register is Fechner's integration of Weber's law [Weber, 1834, Fechner, 1860, 1966] and not a statement about energy. Where a stronger, non-psychological warrant for the logarithm is wanted, Peters and Gell-Mann [2016] derives one from multiplicative dynamics with no perceptual assumption at all, and the argument here needs that one rather than Fechner's.

Two limits on the borrowing are stated now. First, `Q` is a stock that accumulates, leaks and is spent — the grammar of a conserved quantity — and Mirowski [1989] shows that importing that grammar without the conservation law is the characteristic failure of this genre. **The only conservation this paper actually establishes is the transfer identity of Section 8.7, which holds for two systems sharing one `delta` and for nothing else**, and Cartwright [1999] is the escape route the framework should take: specify the arrangement within which each law is claimed to hold. Second, **no scaling, power-law or heavy-tail claim is made anywhere in this paper**; where such a claim is made elsewhere in the corpus the procedure of Clauset et al. [2009] is binding and nothing here substitutes for it.

The functional form of the drive is also underdetermined and this is not repaired below. Latané [1981] proposes influence growing as a sub-linear power of the number of sources and Briscoe et al. [2006] proposes `n log n`; both are decelerating, both fit the qualitative facts, and Stumpf and Porter [2012] states the general problem that many mechanisms produce indistinguishable curves. **Nothing in this paper discriminates the corpus's logarithm from its two nearest rivals.**

23.3.10 3.10 Standing honesty clauses

Three clauses govern every number below and are stated once. A note on terminology precedes them: throughout this paper **subject** denotes the modelled individual — the person whose enacted moments, echoes and stored capability the equations describe. Every subject appearing below is a construction with declared parameters, and no person was studied.

Illustrative construction is said, every time. The twelve-week log, the trajectory tables, the transfer case and the nine-entry review are computed from parameters that were chosen. They demonstrate the arithmetic. They are not observations, no person was studied, and no sentence below should be read as evidence about people.

Significant figures follow epistemic status. Quantities exact by construction — the elasticities, the transfer identity, the deadband formula, the error law — are quoted to whatever precision is useful and said to be exact. Quantities estimated from a constructed series carry a standard error or an `R^2` and are labelled as estimates *of a property of the construction*. Stipulated parameters are named as stipulated at first use and everything computed from them inherits that status.

A gate not run is reported as SPECIFIED or UNTESTED, never as passed. Across the nine entries of the formulary, **sixty-three gates are reported and not one is marked PASS on the reproducibility gate**, because no cross-individual study of any of these quantities has been run.

23.4 4 Reading and instrumenting the echo

23.4.1 4.1 Reading one echo: sign first, magnitude second

A single echo yields two readings and they answer different questions.

```
rho > 0   OVER-RETURN    the world answered larger than you sent
rho = 0   NULL RETURN    no information came back (contact or closure -- test required)
rho < 0   UNDER-RETURN   the world answered smaller than you sent
```

The sign says which way you were wrong. The magnitude says how much it cost to find out.

Over-return. You sent a moment and got back more than you constructed. The honest readings, in order of frequency: your frame under-called the environment (`r = D/P < 1`, under-framed in the sense of [Curzi, 2026m]); or the environment contained structure you had not modelled; or the answer was amplified in transit by something with its own energy — an audience, an institution, a grievance. **Over-return is the pleasant failure and it is still a failure of calibration.** The specific danger is that over-return is usually attributed to the quality of what was sent, which is the one explanation the measurement cannot support.

Under-return. You sent a moment and the world answered smaller. Readings: your frame over-called the environment (`r > 1`, over-framed — projection, expectation, the seen-what-was-predicted failure); or the channel attenuated; or the environment genuinely had less in it than you built into your construction of it. **Under-return is the common case for anyone with a strong frame, and its characteristic error is to be read as a verdict on worth rather than as a reading on calibration.** §4.8 treats this at length because it is where the instrument does the most harm when misused.

Null return. Treated in §3.5 and tested in §4.5.

23.4.2 4.2 The magnitude scale — what a given `Delta_R` is

`rho` is in nats. Because the four registers converge [Curzi, 2026n,?], the same number is immediately readable as a ratio, as bits, and as an interval in octaves and cents. The conversion constants are exact:

```
1 nat = 1.442695 bits = 2.885390 octaves = 3462.4681 cents
```

`Delta_R` (nats)	ratio `M'/M`	percent change	bits	octaves	cents
0.0050	1.0050	0.50%	0.0072	0.0144	17.3
0.0100	1.0101	1.01%	0.0144	0.0289	34.6
0.0200	1.0202	2.02%	0.0289	0.0577	69.2
0.0500	1.0513	5.13%	0.0721	0.1443	173.1
0.1000	1.1052	10.52%	0.1443	0.2885	346.2
0.2000	1.2214	22.14%	0.2885	0.5771	692.5
0.2500	1.2840	28.40%	0.3607	0.7213	865.6
0.3466	1.4143	41.43%	0.5000	1.0001	1200.1
0.5000	1.6487	64.87%	0.7213	1.4427	1731.2
0.6931	2.0000	99.99%	0.9999	2.0000	2399.8
1.0000	2.7183	171.83%	1.4427	2.8854	3462.5
1.3863	4.0000	300.00%	2.0000	4.0000	4800.0
2.0000	7.3891	638.91%	2.8854	5.7708	6924.9

Delta_R (nats)	ratio M'/M	percent change	bits	octaves	cents
2.3026	10.0001	900.01%	3.3219	6.6439	7972.7

Two landmarks are worth memorising because they anchor every subsequent judgement. **Delta_R = 0.3466 nats is exactly one octave and exactly half a bit** — the world answered about 1.41 times what you sent, or about 0.71 times. **Delta_R = 0.6931 nats is exactly one bit and exactly two octaves** — a factor of two, either way. A return difference of one bit means the exchange resolved one binary question you did not previously have answered, and if that sounds like a small yield for an entire cycle of action, it is: **exchanges are expensive and their information yield is measured in single bits, which is the correct order of magnitude and the reason patience is an engineering requirement rather than a virtue.**

A caution that must travel with this table, because the table invites the error. **The nats of a return difference are not automatically nats of information.** They become information only relative to the echo's own noise, and §4.4 gives the ratio that decides it. A Delta_R of 0.20 against a measurement noise of 0.30 is not one-fifth of a bit of anything; it is a number smaller than the wobble of the instrument that produced it.

23.4.3 4.3 The deadband — the smallest echo you can hear

Weber's law (1834): the just-noticeable difference is a constant ratio, dI/I = c. Applied to the echo, this gives a hard floor on Delta_R below which the subject's own instrument cannot resolve the return.

```
Delta_R_min = ln(1 + c)
```

The derivation is one line: the smallest ratio the subject can distinguish from unity is 1 + c, and Delta_R is the log of the ratio.

Weber fraction c	Delta_R_min (nats)	bits	ratio	cents
0.01	0.0100	0.0144	1.01	34.5
0.02	0.0198	0.0286	1.02	68.6
0.03	0.0296	0.0426	1.03	102.3
0.05	0.0488	0.0704	1.05	168.9
0.08	0.0770	0.1110	1.08	266.5
0.10	0.0953	0.1375	1.10	330.0
0.15	0.1398	0.2016	1.15	483.9
0.20	0.1823	0.2630	1.20	631.3
0.30	0.2624	0.3785	1.30	908.4
0.50	0.4055	0.5850	1.50	1403.9

The engineering consequence: **an subject with a Weber fraction of 0.20 on moment magnitude cannot distinguish a genuine 15% return from silence, and will experience nine weeks of real but small feedback as nine weeks of nothing.** This is not a failure of attention. It is the resolution of the instrument, and the fixes are instrumental rather than motivational: increase the modulus (rate on a finer scale), aggregate (§4.4), or amplify the sent moment so the return clears the floor.

Note also the honest reading of the deadband in the other direction. **A null return inside the deadband is not evidence of a null return.** It is evidence that the echo, whatever it was, was smaller than you can hear. The distinction matters because the two conclusions license

opposite actions: *no signal* says change what you are sending; *below resolution* says change how you are listening.

An empirical caveat with its badge: the corpus has not measured a Weber fraction for moment magnitude and does not know one. **What would need measuring is stated in §4.11.** The table above is the arithmetic of the relation, not a claim about any particular person's threshold.

23.4.4 4.4 Noise, aggregation, and how many echoes a finding costs

A `rho` read from a person's own record of their own encounters is exposed twice over: to the instability of self-report under question wording and framing [Schwarz, 1999, Kahneman et al., 2006], and to the more basic finding that people's accounts of their own processes are reconstructions rather than readings [Nisbett and Wilson, 1977]. A single `rho` is a noisy quantity. Estimate the noise as `sigma_rho`, the standard deviation of repeated log-ratios under conditions you regard as unchanged. Then the echo's signal-to-noise is

```
SNR_R = Delta_R / sigma_rho
```

Delta_R sigma_rho	0.05	0.10	0.20	0.30	0.50
0.05	1.00	0.50	0.25	0.17	0.10
0.10	2.00	1.00	0.50	0.33	0.20
0.20	4.00	2.00	1.00	0.67	0.40
0.35	7.00	3.50	1.75	1.17	0.70
0.50	10.00	5.00	2.50	1.67	1.00
0.69	13.80	6.90	3.45	2.30	1.38
1.00	20.00	10.00	5.00	3.33	2.00

Aggregation reduces noise in the usual way — the standard error of a mean of `n` independent log-ratios is `sigma_rho / sqrt(n)` — so the number of echoes needed to resolve a true return difference `Delta` at the conventional two-sided 95% level is

```
n >= ( 1.96 * sigma_rho / Delta )^2
```

sigma_rho Delta	0.05	0.10	0.20	0.35	0.50	0.69
0.10	16	4	1	1	1	1
0.20	62	16	4	2	1	1
0.30	139	35	9	3	2	1
0.50	385	97	25	8	4	3

Read the top-left corner and the bottom-left corner together: a small return difference under large noise is not a finding you can afford, and the honest response is to stop trying to detect it rather than to detect it badly. An subject with `sigma_rho = 0.30` who wants to establish a 5% return effect needs 139 clean, independent echoes. If the cycle time is a week, that is two and a half years. The engineering answer is never "look harder"; it is to increase `Delta` (send a moment big enough to produce a hearable answer), reduce `sigma` (fix the estimation procedure), or abandon the question.

The word *independent* in that paragraph is doing a great deal of work, and the next section is about what happens when it is false.

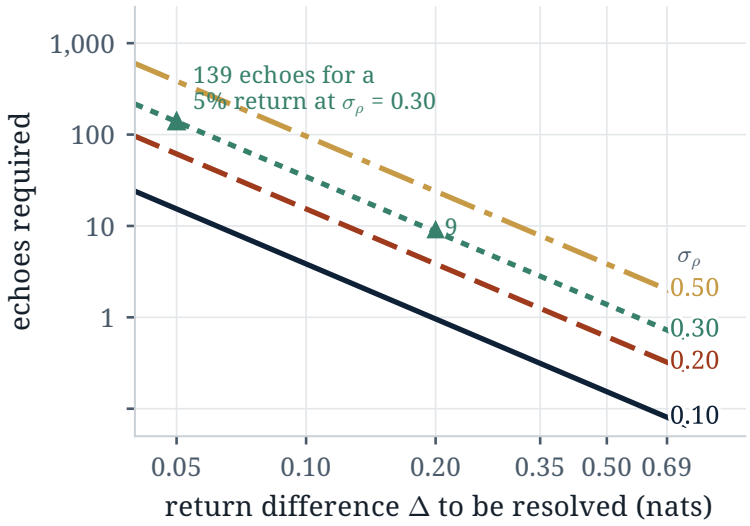

Figure 23.1: **A personal echo log can detect large distortions and nothing subtle:** echoes required to resolve a return difference at the two-sided 95 per cent level, `n >= (1.96 sigma_rho/Delta)^2`. At `sigma_rho = 0.30` a 5 per cent return needs **139** clean independent echoes — more than two years at a weekly cycle — while a 20 per cent return needs **9**. Derived; the curves reproduce all twenty-four cells of this section's table exactly, which the script prints; generated by `figs/src/CCP-023_fig04.py`.

23.4.5 4.5 The mirror that flatters — correlated echoes and the design effect

The arithmetic below is the personal-scope form of a result stated with its mathematics attached in 1952: **the benefit of holding several things depends on their covariance, not on their count**, so `n` perfectly correlated sources are worth exactly one [Markowitz, 1952]. The finance literature adds the part that makes it dangerous rather than merely disappointing: correlations rise under stress [Longin and Solnik, 2001], so the effective number of independent sources falls exactly when it is most needed. Informational cascade [Bikhchandani et al., 1992, Banerjee, 1992] is the mechanism by which a set of nominally independent respondents becomes one, and Lorenz et al. [2011] measure the collapse directly. **No entry in this corpus's external bibliography states the survey-sampling design effect `n_eff = n/(1 + (n-1) r_icc)` itself**; it is standard, it is used below, and it is left uncited rather than attached to a source that does not state it.

The first echo pathology of the foundations series [Curzi, 2026], in exact form.

Suppose a fraction `w` of the answer that comes back is not the world's response but a reflection of the moment you sent — the audience that has learned your frame, the friend who reports what you want, the metric you designed. Model it linearly: the observed return is a blend of the true return and your own sent moment. Then

```
rho_obs = (1 - w) * rho_true
```

`w` (reflected fraction)	attenuation	`rho_true` required to observe `rho_obs = 0.10`
0.00	1.00	0.1000
0.10	0.90	0.1111
0.20	0.80	0.1250
0.30	0.70	0.1429
0.50	0.50	0.2000

`w` (reflected fraction)	attenuation	`rho_true` required to observe `rho_obs = 0.10`
0.70	0.30	0.3333
0.90	0.10	1.0000
0.95	0.05	2.0000
1.00	0.00	infinite — no echo exists

At `w = 1` the channel is a mirror and no finite world could produce a detectable return: the apparatus reports agreement no matter what is true. That is the flattering mirror, and it is not a metaphor in this form — it is a divide-by-zero in the recovery of `rho_true`.

The multi-source version is more useful because most people have several echo sources and believe that several is the same as independent. It is not. Where `n` echo sources share an intraclass correlation `r_icc`, the effective number of independent echoes is the standard design effect:

```
n_eff = n / ( 1 + (n − 1) ∗ r_icc )
```

For `n = 10` sources:

`r_icc`	`n_eff`	standard-error multiplier vs. 10 independent	the affine effective count [Curzi, 2026], `N_eff = 1 + (n−1)(1−r)` for comparison
0.00	10.000	1.000	10.000
0.05	6.897	1.204	9.550
0.10	5.263	1.378	9.100
0.20	3.571	1.673	8.200
0.30	2.703	1.924	7.300
0.50	1.818	2.345	5.500
0.70	1.370	2.702	3.700
0.90	1.099	3.017	1.900
1.00	1.000	3.162	1.000

Ten sources at an intraclass correlation of 0.30 are worth 2.7 independent sources, and the person consulting them experiences ten confirmations. That gap — between the felt count and the audited count — is the same gap the framework's affine effective count [Curzi, 2026] measures for group members, and the last column is included to make an honest point rather than a tidy one: **the two audits agree exactly at both endpoints and disagree in between.** `N_eff = 1 + (n−1)u` and `n_eff = n/(1+(n−1)r_icc)` both collapse to 1 under total redundancy and both return `n` under total independence, but they are different functions of the correlation and they are answering different questions — The surplus functional [Curzi, 2026] prices the surplus generated by a set of states, the design effect prices the precision of a mean. Do not substitute one for the other. **Use the design effect when you are averaging echoes and the surplus functional [Curzi, 2026] when you are asking what the echoes are worth as a set.**

The zero-return test. This is the instrument §3.5 promised — the way to tell contact from closure when `Delta_R` is persistently near zero. Under genuine contact with a live world, observed `rho` values scatter: the return is sometimes over, sometimes under, by amounts comparable to the measurement noise. Under closure, they do not scatter, because the channel is returning the sent moment. So compute the probability that `n` genuinely independent echoes all land inside a deadband of half-width `b` when the true return difference is zero and the noise is `sigma`:

sigma	band b	P(one echo inside band)	P(10 in a row)	n for p^n < 0.05
0.10	0.05	0.3829	0.000068	4
0.10	0.10	0.6827	0.021990	8
0.20	0.05	0.1974	0.0000000	2
0.20	0.10	0.3829	0.000068	4
0.30	0.05	0.1324	0.0000000	2
0.30	0.10	0.2611	0.0000010	3

Read the right-hand column as the flattery alarm: with a noise level of 0.20 and a deadband of 0.10, four consecutive echoes landing inside the band is already a 5%-level event under the hypothesis that the channel is live and merely quiet. Four weeks of "that was great" is not warmth. It is a measurement, and the measurement says the channel is closed.

Two honest limits on this test. First, it assumes the noise `sigma` was estimated on the same channel under conditions where the channel was known to be live, which requires a period of record before the suspicion arose. Second, it cannot distinguish closure from genuine perfect calibration, and perfect calibration does occur — a practitioner who has converged genuinely does get small, scattered returns. **The discriminator is scatter, not size: converged contact produces small returns that vary; closure produces small returns that do not.**

23.4.6 4.6 The Echo that Devours — correction gain and the stability boundary

The second echo pathology of the foundations series [Curzi, 2026], and the place where this paper produces its sharpest number.

An echo is only useful if it changes something. The natural thing for it to change is the frame: the subject's perspective `D` in the Moment equation `M = (D/P)E` ([Curzi, 2026m]). Correct multiplicatively, because the register is multiplicative:

```
D_{t+1} = D_t * ( M'_t / M_t )^lambda          lambda >= 0, the CORRECTION GAIN
```

Now trace what that does to the next return difference. Write `A` for the answer the world would give — the quantity the subject is trying to match — and let the sent moment be `M_t = (D_t / P) E`. Then `rho_t = ln(A / M_t)`, and

```
M_{t+1} = (D_{t+1}/P) E = M_t * (A/M_t)^lambda

rho_{t+1} = ln(A / M_{t+1})
          = ln(A/M_t) - lambda * ln(A/M_t)
          = (1 - lambda) * rho_t
```

The return difference obeys a linear contraction in the log register with factor `(1 - lambda)`, and that is the same mathematical object as the storage law's `(1 - delta)` — which is why this section is the setup for the next. The echo and the accumulator are the same circuit read at two places. Sections 7–10 works the consequence out in full; here is the stability table.

lambda	|1 - lambda|	behaviour	steps to reduce |rho| 10x	steps to reduce 100x
0.10	0.9000	monotone, slow	22	44
0.20	0.8000	monotone	11	21
0.25	0.7500	monotone	9	17

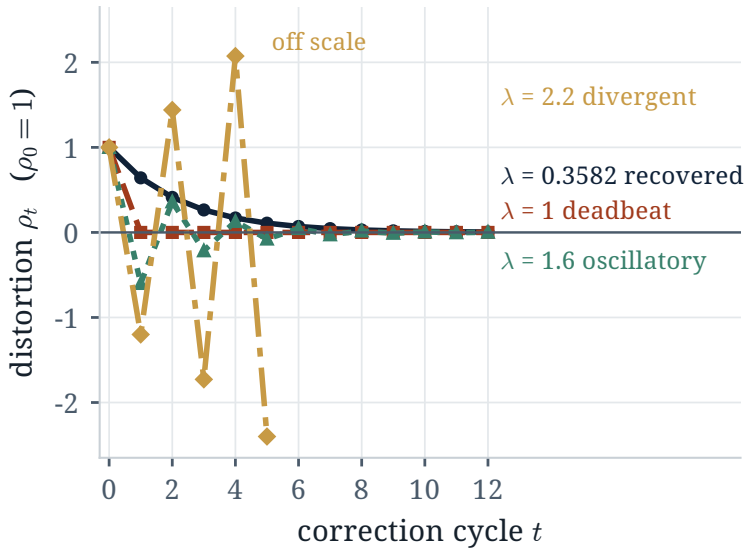

Figure 23.2: **The stability boundary is a gain setting, not an atmosphere:** the correction map `rho_{t+1} = (1−lambda) rho_t` from `rho_0 = 1`. At the recovered gain 0.3582 the distortion decays monotonically with a half-life of 1.56 cycles; at `lambda = 1` it is deadbeat, reaching zero in one step and transmitting the whole measurement noise with it; at `lambda = 1.6` it converges by overshooting alternately; at `lambda = 2.2` it grows without bound and leaves the axes at cycle 5. Modelled by the map tabulated in this section; generated by `figs/src/CCP-023_fig02.py`.

`lambda`	`|1 − lambda|`	behaviour	steps to reduce `|rho|` 10x	steps to reduce 100x
0.33	0.6700	monotone	6	12
0.50	0.5000	monotone	4	7
0.75	0.2500	monotone, fast	2	4
1.00	0.0000	**deadbeat** — one step	1	1
1.25	0.2500	oscillatory, converging	2	4
1.50	0.5000	oscillatory	4	7
1.75	0.7500	oscillatory, slow	9	17
2.00	1.0000	**marginal** — undamped oscillation	never	never
2.50	1.5000	**divergent** — the devouring echo	never	never

Five statements follow, and they are the operational content of the ECHO node's second warning.

One. There is a stability boundary and it is at `lambda = 2`. Below it the return difference shrinks; above it the return difference grows without bound. At exactly 2 it oscillates forever at constant amplitude. This is the Echo that Devours, located precisely: it is not an atmosphere, it is a gain setting.

Two. `lambda = 1` is the fastest possible correction and it is a trap. Deadbeat correction takes the whole observed difference as truth and applies it in one step. If the observation were noiseless this would be optimal. It is not noiseless, so `lambda = 1` also takes the whole ob-

servation *noise* as truth and writes it into the frame. The frame then thrashes at the amplitude of the measurement error.

Three. Everything above 1 is oscillatory even when it converges. An subject at `lambda = 1.5` overshoots every time and converges by alternating: too much, too little, too much. From the inside this is indistinguishable from instability of character, and it is a gain setting.

Four. Slow gains are not timid; they are filters. `lambda = 0.25` needs nine cycles to close a factor of ten, and in exchange it attenuates the noise in every single observation by 75%. The choice of `lambda` is a bandwidth choice: **fast correction tracks the world and the noise; slow correction tracks the world only, late.** There is no setting that does both, and the belief that there is one is the most common source of thrash.

Five. The optimum depends on the noise, not on the character of the subject. As a design rule, badged as a heuristic rather than a derived optimum: set `lambda` near `SNR^2/(1+SNR^2)` where `SNR` is the per-echo signal-to-noise from §4.4 — near 1 when echoes are clean, near 0 when they are not. The corpus has not derived that expression from a stated loss function and does not present it as optimal; it presents it as a starting value with the right limits.

23.4.7 4.7 Delay, aliasing, and the echo that arrives after the world has moved

Returns take time. If the world's answer to period `t` arrives at period `t + k`, and the subject applies it as if it were the answer to period `t + k`, the correction is applied to the wrong state. In control terms this is transport delay, and its effect is to convert a stable gain into an unstable one: a correction that would be safely damped at zero delay can oscillate or diverge at a delay of several periods, because the subject keeps correcting for a discrepancy that has already been corrected.

The practical rule, and the reason it belongs in an account of persons rather than one of servomechanisms: **never run a correction gain faster than the echo returns.** If the answer takes three weeks, do not correct weekly. Correct every three weeks, or reduce `lambda` by roughly the delay factor, or — best — timestamp the echo to the moment it answers rather than to the moment it arrives. The third option costs nothing but a column in the log and removes the problem at its source, which is why the specification below requires it.

The dual failure is sampling too slowly. If the world's answer changes faster than you sample it, the sampled series aliases: a rapid alternation reads as a slow trend or as nothing at all. The symptom is a return log whose variance is implausibly low for a domain everyone agrees is volatile. **A suspiciously smooth echo log is a sampling artifact until proven otherwise.**

23.4.8 4.8 What the echo is not

Four things, because the instrument is dangerous in proportion to how naturally it is misread.

It is not a verdict on worth. `rho < 0` says the world answered smaller than you constructed. It does not say the thing was bad, and FVP-5 above is the formal statement of why: a large negative `rho` is equally consistent with an over-framed subject and an unresponsive world, and `rho` alone cannot separate them. Anyone who reads a run of negative returns as a statement about their worth has performed an identification that the mathematics explicitly declines to perform.

It is not defined on ordinal data. FVP-2 is a gate, not a caution. If `M` and `M'` are 1–5 stars, `M'/M` is meaningless — the ratio of two rank positions is not a ratio of two magnitudes. The demotion in that case is mandatory and it is this: report the sign only, as an ordering (*larger / same / smaller*), call it a heuristic reading, and **do not compute a mean, a standard deviation, a `lambda`, or a convergence rate from it.** A great deal of self-tracking practice violates this gate silently, and the resulting numbers have the shape of measurement without the content.

It is not the world's total answer. As deployed, `rho` is one scalar summary of an exchange that had structure. This mirrors the honesty clause on the surplus functional [Curzi, 2026,?]

— we log the floor, not the ceiling. **A `rho` of zero on the dimension you measured is compatible with an enormous return on a dimension you did not.**

It is not transferable between subjects without recalibration. `M` and `M'` are magnitude estimates made against a modulus. Two people using different moduli produce `rho` values that are comparable — this is the scale-invariance property of §3.3 — but only if each person's own estimates are internally consistent on a ratio scale. The comparison of `lambda` across people is the open FVP-7 gate, not a licensed operation.

23.4.9 4.9 Chaining and the composition of returns

Because log-ratios add, a series of exchanges has a total return difference that is the sum of the signed parts and a total *activity* that is the sum of the magnitudes. These are different numbers and their ratio is a diagnostic.

```
net return   R_net = SUM rho_t                       (signs cancel)
gross return R_gross = SUM |rho_t| = SUM Delta_R,t   (signs do not)

EFFICIENCY   E_R = |R_net| / R_gross      in [0, 1]
```

`E_R` near 1 means the returns pointed consistently the same way: the world has been saying one thing repeatedly and the subject has not yet moved. `E_R` near 0 means the returns cancelled: a great deal of exchange, no net direction. **A high gross with a near-zero net is the signature of thrash — the subject is correcting hard in alternating directions, which §4.6 identifies as a gain above 1.** A high gross with a high net is the signature of a live, uncorrected error, which is the good case, because it means there is something to learn and it has not been learned yet.

23.4.10 4.10 The join: from echo to stored order

The formulary is a single circuit and this section names the wires. The chain runs:

```
E (environment)
   |
   v
M = (D/P) E                     the moment equation
   |
   +----> enacted -----> world -----> M'          the exchange
   |                                  |
   |                                  v
   |                           rho = ln(M'/M)      SECTIONS 3-6
   |                                  |
   |         D_{t+1} = D_t * e^{lambda*rho}        the correction
   |                                  |
   +<---------------------------------+
   |
   v
Q_{t+1} = (1-delta) Q_t + eta*M_t - C_t           the self-storage law
```

Three consequences of drawing it this way.

The echo does not enter the storage law directly. It enters through `D`, which changes `M`, which is the storage law's input. This is why feedback improves character slowly: it acts on the input of an integrator, not on the integrator's state. An echo received today changes `Q`'s trajectory, not `Q`.

The correction loop and the storage loop have different time constants and both are geometric. The echo loop contracts at `(1 - lambda)`, the storage loop at `(1 - delta)`. When `lambda >> delta` the frame tracks and the character lags; when `lambda << delta` the character forgets faster than the frame corrects, which is the arithmetic form of learning a lesson repeatedly.

The identification problem of FVP-5 has a design solution. To separate "my frame was wrong" from "the world was quiet", hold `D` fixed for a block of periods and vary nothing, then change `D` deliberately by a known factor and see whether `rho` moves by the predicted amount. If `rho` responds to a change in `D` with the elasticity the Moment equation predicts, the return difference is reading your frame. If it does not, it is reading the world. **That is a manipulation, it is cheap, and it is the only clean way to run the decomposition.**

23.4.11 4.11 What would need measuring

The falsification gate every entry below defers to is preregistration with a frozen model and a held-out block, which is the open-science literature's own prescription [Nosek et al., 2018, Simmons et al., 2011]; the reason it is needed is the flexibility in analysis that Gelman and Loken [2013] names and the publication filter Ioannidis [2005] describes, whose measured consequence is that of one hundred direct replications in psychology about 36 recovered a significant result against 97 originals [Open Science Collaboration, 2015]. **Kill conditions stated in advance, with numbers, are what separates a falsification test from a ritual** [Platt, 1964], and the reason this framework states *exponent targets* rather than directions is that a directional prediction is nearly costless in psychology [Meehl, 1967, 1990].

The badging convention [Curzi, 2026] requires that where a figure needs research not done, the corpus says what would need measuring. Four things, stated as an agenda rather than as results:

1. **The Weber fraction for moment magnitude.** Method of constant stimuli or a staircase procedure on paired moment magnitudes within a person, yielding `c` and hence the deadband `ln(1+c)`. Without it, §4.3 is arithmetic without a calibration.
2. **The within-person noise `sigma_rho`.** Test–retest of `rho` on exchanges the subject judges equivalent. Everything in §4.4 depends on it and it is the cheapest of the four to obtain.
3. **The distribution of `lambda` across people, and its stability within a person across domains.** This is FVP-7. The design is stated: same operationalization, several subjects, several investigators, held-out prediction, shuffled-input control.
4. **The intraclass correlation of a typical person's echo sources.** This determines whether the flattering-mirror alarm in §4.5 fires at four echoes or at forty, and it is measurable by having several sources rate the same sent moment independently.

23.5 5 Requirements for an echo instrument

Numbered, checkable requirements for an echo instrument. A practice that fails any of ES-1 through ES-6 is not measuring return difference and should not report a number.

ES-1 — Ratio scale, or demotion. `M` and `M'` shall be obtained by magnitude estimation against a stated modulus, with a true zero. If only ordinal data are available, the practice shall report sign only and shall label the output a heuristic ordering. *(FVP-2. Non-negotiable.)*

ES-2 — The modulus is declared and frozen. One reference exchange is assigned a magnitude (commonly 50 or 100) at the start of a block, and all estimates in the block are made against it. Changing the modulus mid-block invalidates the block for aggregation.

ES-3 — `M` is recorded before the answer arrives. The sent moment shall be estimated and written down prior to any return. An `M` reconstructed after the echo is contaminated by the

echo and yields a `rho` biased toward zero. *(This is the single most violated requirement in self-tracking and it is the one that most reliably manufactures the appearance of calibration.)*

ES-4 — `M'` is timestamped to the exchange it answers, not to its arrival. A delay column is mandatory. *(§4.7.)*

ES-5 — Source and independence are logged. Each echo carries the identity of its source and, where more than one source is used, sources are asked independently and before seeing one another's responses. *(§4.5; this is the personal-scope form of the silent-write-first rule.)*

ES-6 — Noise is estimated before findings are claimed. `sigma_rho` is estimated from at least eight exchanges the subject judges equivalent, before any `Delta_R` is interpreted as a finding.

ES-7 — The deadband is stated. The practice declares its `Delta_R_min` and refuses to interpret returns below it as anything but unresolved.

ES-8 — The correction gain is chosen, written down, and held for the block. `lambda` shall be in `(0, 1]` unless a specific reason for overshoot is recorded. `lambda >= 2` is prohibited by this specification. *(§4.6.)*

ES-9 — Correction cadence does not exceed echo cadence. If returns take `k` periods, the gain is applied at most every `k` periods. *(§4.7.)*

ES-10 — The flattery alarm is run. After every four consecutive returns inside the deadband, the practice runs the zero-return test of §4.5 and, if it fires, adds an independent source before continuing.

ES-11 — Net and gross are both reported. `R_net`, `R_gross`, and `E_R` are computed per block. *(§4.9.)*

ES-12 — No worth claims. The instrument's output is a calibration reading. Reports shall not convert `rho` into a statement about the value of the person, the work, or the relationship. *(Section 4.8, and the framework's refusals [Curzi, 2026].)*

ES-13 — Decline path. Where an echo source is a person, that person may decline to supply an estimate, at any time, without explanation and without consequence, and the practice records the decline as missing data rather than as a zero. *(The declination refusal is binding [Curzi, 2026]: no protocol in the corpus removes a person's ability to decline. A refused echo is not a null return; recording it as one is both a measurement error and a coercion.)*

ES-14 — Freeze before predicting. Any claim that the instrument works shall follow the FVP-6 procedure: preregister, fit, freeze, predict held out, beat the four baselines including the shuffled-input control.

23.6 6 Failure modes of echo reading

Fault	Diagnostic signature	Fix
The Flattering Mirror	Four or more consecutive returns inside the deadband, with variance far below `sigma_rho`; all sources agree; `E_R` undefined because gross is near zero	Add a genuinely independent source (ES-5, ES-10). Compute `n_eff`. Treat the existing sources as one source until proven otherwise
The Devouring Echo	`|rho|` growing period on period; corrections alternating in sign with increasing amplitude; frame reversals faster than the world could plausibly change	Measure `lambda` from the data (regress `ln|rho|` on `t`). If the implied `|1−lambda| >= 1`, reduce `lambda` below 1 and hold. *(§4.6)*

Fault	Diagnostic signature	Fix
Ordinal laundering	Means, SDs and trend lines computed from star ratings, tick-boxes, or Likert items	Demote to sign-only reporting; rebuild the instrument on magnitude estimation. **The numbers already computed are void, not merely imprecise** *(FVP-2, ES-1)*
Post-hoc `M`	`rho` unusually close to zero across the whole log; the subject "knew it would land like that"	Enforce ES-3. Compare a block of pre-recorded `M` against a block of reconstructed `M`; the difference in mean `|rho|` is the size of the contamination
Deadband blindness	Long runs of "no feedback" in a domain where others report feedback	Raise the modulus resolution, aggregate per §4.4, or increase the size of the sent moment. Do not increase effort at listening
Delay-induced instability	Oscillation that appears only when cadence is increased; corrections that were stable at monthly review become unstable at weekly	Enforce ES-4 and ES-9. Timestamp to the exchange, not the arrival
Aliasing	Return log with implausibly low variance in a volatile domain; long smooth trends with no reversals	Sample faster than the world changes, or state explicitly that the log is a low-pass view and stop reading its trend
Selection of echoes	The log contains more returns from the exchanges the subject felt good about; missing entries cluster	Pre-commit to logging every exchange in a defined class, including the ones you would rather not; count and report the missing
Worth conversion	Negative `rho` narrated as a statement about the self; the log stops being kept after a bad block	Enforce ES-12. Re-read FVP-5: the decomposition is not identified, and the identification being performed is not licensed by the instrument
Zero read as success	`Delta_R ~ 0` celebrated; the practice concludes it has arrived	Run the scatter test (§4.5). Converged contact produces small returns that **vary**; closure produces small returns that do not
Gain thrash	High `R_gross`, near-zero `R_net`, `E_R < 0.2`, frequent reversals	`lambda` is above 1. Reduce it. *(§4.9, §4.6)*
Uncorrected live error	High `R_gross`, high `R_net`, `E_R > 0.8`, all returns pointing the same way for many periods	`lambda` is near 0 — the subject is measuring and not correcting. Raise `lambda` toward 0.3–0.5

23.7 7 The contraction and arrival

The ninth node of the foundations series [Curzi, 2026] taught the spiral rather than the circle: repetition that absorbs its own error and returns to the same post a little higher. Its tenth node taught the room that was always furnished — arrival as recognition rather than as victory, a destination that turns out to have been visited many times in imagination before it was reached in fact.

Those are not two teachings. They are the two terms of one equation, and this paper is where the correspondence is proved rather than asserted.

The corpus's own correspondence table records that the FIXEDPOINT node of the foundations series [Curzi, 2026] *is* the storage law's steady-state theorem [Curzi, 2026a], and the RECURSE node *is* the transient `(1−delta)^t Q_0`. Neither place proves it. The claim as it stands is a claim of identity between a ceremonial teaching and a theorem, and a claim of identity has to be discharged, not repeated. **This paper discharges it: it constructs the metric space, verifies the contraction, invokes Banach, solves for the fixed point, derives the exact error law, and shows that every property the foundations series attributed to arrival is a property of that solution and not an interpretation laid over it.**

23.7.1 7.1 The starting point

the storage law [Curzi, 2026a], in its internal-scope form [Curzi, 2026o] (the self-storage law):

```
Q_{t+1} = (1 − delta) Q_t + eta ∗ M_t − C_t

Q_t      stored order: character, skill, memory, internalized structure
M_t      the moment as lived, normalized into [0, ln N]
delta    retention loss in [0,1] −− forgetting, atrophy, drift of self
eta      conversion efficiency >= 0 −− how experience becomes character
C_t      cognitive load, effort, maintenance of self, >= 0
```

Take the steady-regime case that Theorem 3.5 addresses: constant geometry `M_t = M∗` for all `t`, constant cost `C_t = c∗`, and `delta > 0`. Define the update map

```
T : R −> R,      T(Q) = (1 − delta) Q + (eta ∗ M∗ − c∗)
```

Write `k = 1 − delta` for the contraction factor and `b = eta∗M∗ − c∗` for the drive. Then `T(Q) = kQ + b`, and the whole of Nodes 09 and 10 is the behaviour of iterating this map.

23.7.2 7.2 Step one — the space is complete

Banach's theorem requires a **complete** metric space. Take `X = R` with the usual metric `d(x,y) = |x − y|`. The reals with the absolute-value metric are complete: every Cauchy sequence converges, and its limit is real. This is standard and it is stated here because the proof needs it and because the honest form of the argument names every hypothesis it uses.

One caveat, discharged now. Admissibility (`C_t <= (1−delta)Q_t + eta S_t`) keeps the modelled quantity in `[0, inf)`, which is also complete, so the argument runs on either space. **We run it on `R` deliberately: Theorem 3.5's negative fixed point lives outside `[0, inf)`, and a proof on the restricted space would hide exactly the case the theorem refuses to hide.**

23.7.3 7.3 Step two — the map is a contraction, with constant `1 − delta`

For any `Q_1, Q_2 in R`:

```
| T(Q_1) − T(Q_2) |  =  | (kQ_1 + b) − (kQ_2 + b) |
                     =  | k (Q_1 − Q_2) |
                     =  |1 − delta| ∗ | Q_1 − Q_2 |
```

For `delta` in `(0, 1]`, `|1 − delta| = 1 − delta < 1`. The map is Lipschitz with constant `1 − delta`, and that constant is strictly less than 1. **`T` is a contraction, and it is a contraction for exactly one reason: `delta > 0`.**

Note that the inequality in the definition of a contraction is here an **equality**. `T` is affine, so it does not merely shrink distances by at most `1−delta`; it shrinks every distance by exactly `1−delta`. This is stronger than Banach requires, and §7.6 collects what the extra strength buys.

At `delta = 0` the constant is 1, `T` is an isometry, and Banach does not apply — correctly, since `T(Q) = Q + b` has no fixed point at all when `b != 0`. That is the contrast made exact: `Q_t = Q_0 + t∗b`, unbounded linear growth, no arrival. **The leak is what makes arrival possible, and the proof shows precisely where: it is the single step above where `1 − delta < 1`.**

23.7.4 7.4 Step three — Banach, and the fixed point solved

Banach's fixed point theorem: a contraction on a nonempty complete metric space has exactly one fixed point, and the iterates from any starting point converge to it.

Applied: `T` has a unique `Q_inf` with `T(Q_inf) = Q_inf`, and `Q_t = T^t(Q_0) −> Q_inf` for every `Q_0`. Solve:

```
Q_inf = (1 − delta) Q_inf + eta∗M∗ − c∗
delta ∗ Q_inf = eta∗M∗ − c∗

Q_inf = ( eta ∗ M∗ − c∗ ) / delta              <−− the steady−state theorem
```

which, writing `M∗ = F(u∗) = ln(1 + (N−1)u∗)` for the surplus form, is Theorem 3.5 verbatim: `Q_inf = (eta F(u∗) − c∗) / delta`.

Three things were claimed by the FIXEDPOINT node [Curzi, 2026] and all three are now consequences of the line above rather than readings of it.

Existence. Banach guarantees a fixed point. The room is furnished. There is a state the practice converges to, and it exists whether or not anyone has been there.

Uniqueness. Banach guarantees exactly one. There is no second room. Two different practices with the same `(eta, M∗, c∗, delta)` arrive at the same place, and one practice cannot arrive at two.

Independence of the start. The expression for `Q_inf` **contains no `Q_0`.** Where you arrive does not depend on where you began. The foundations series said arrival feels like recognition rather than victory; §8.3 shows that this is what the absence of `Q_0` from that formula feels like from inside.

23.7.5 7.5 Step four — the exact error law

Banach gives convergence. The affine structure gives the exact rate. Subtract the fixed-point equation from the update:

```
Q_{t+1} − Q_inf = (1−delta) Q_t + b  −  [ (1−delta) Q_inf + b ]
                = (1−delta) ( Q_t − Q_inf )
```

so by induction

```
Q_t − Q_inf = (1 − delta)^t ( Q_0 − Q_inf )

| Q_t − Q_inf | = (1 − delta)^t | Q_0 − Q_inf |        THE ERROR LAW
```

and rearranged, the form that carries the most meaning:

```
Q_t = Q_inf + (1 − delta)^t ( Q_0 − Q_inf )
      -----   --------------------------
      where     what remains of where you
      you are   started, decaying at rate delta
      going
```

The entire trajectory is the destination plus a fading memory of the origin. That single line is the RECURSE and FIXEDPOINT nodes together [Curzi, 2026,?]: FIXEDPOINT is the first term, RECURSE is the second, and the reason the corpus has treated them as one thing is that they are the two terms of this decomposition.

Consistency check against the exact solution of the storage law [Curzi, 2026a]. With constant drive `b`,

```
Q_t = (1−delta)^t Q_0 + SUM_{j=0}^{t−1} (1−delta)^j ∗ b
    = (1−delta)^t Q_0 + b ∗ (1 − (1−delta)^t)/delta
    = (1−delta)^t Q_0 + Q_inf ∗ (1 − (1−delta)^t)
    = Q_inf + (1−delta)^t (Q_0 − Q_inf)
```

The geometric sum closes exactly. **Theorem 3.1 and the error law are the same statement, and the Banach argument was not needed to obtain it in this one-dimensional affine case — it was needed to know that the result is not an accident of linearity.** That distinction is the subject of §7.6.

23.7.6 7.6 What Banach buys that the algebra does not

An honest accounting, because it would be easy to over-sell the theorem here.

For this specific affine map on `R`, the closed form above is elementary and Banach is not required. What Banach supplies is **robustness of the conclusion to changes in the model that the closed form would not survive**:

- If `eta`, `C`, or the moment-generating mechanism are **nonlinear in `Q`** — as they are in any realistic account where effort rises with what must be maintained — the closed form vanishes but the fixed point survives, provided the map remains a contraction. The condition to check becomes `|T'(Q)| <= k < 1` on the region of interest.
- If `Q` is **multi-dimensional** — several stored capacities that interact — the same theorem applies on `R^n` with any complete norm, and the contraction condition becomes a bound on the matrix norm of the update.
- Banach also supplies **error bounds computable before convergence**, which the closed form gives only after you already know `Q_inf`:

```
a priori:       d(Q_t, Q_inf) <= ( k^t / (1−k) ) ∗ d(Q_1, Q_0)
a posteriori:   d(Q_t, Q_inf) <= ( k / (1−k) )  ∗ d(Q_t, Q_{t−1})
```

The a posteriori bound is the useful one in practice: **it estimates how far you are from arrival using only the size of your last step.** Worked at `delta = 0.12`, `Q_0 = 0`, drive `b = 0.3702` (the case of §8.8):

t	Q_t	true error	a priori bound	a posteriori bound
1	0.3702	2.7151	2.7151	2.7151
3	0.9828	2.1025	2.1026	2.1026
5	1.4571	1.6282	1.6282	1.6282

t	Q_t	true error	a priori bound	a posteriori bound
8	1.9757	1.1096	1.1096	1.1096

The bounds are attained with equality, to rounding. That is the affine case being exactly as strong as §7.3 said: distances shrink by exactly `1−delta`, so the inequality in Banach's bounds becomes an identity. In the nonlinear or multi-dimensional case the same bounds hold as inequalities and remain usable. **The practical instruction survives either way: your distance from arrival is about `(1−delta)/delta` times the size of your last step.** At `delta = 0.12` that multiplier is 7.33 — a step of 0.05 means you are roughly 0.37 from the fixed point.

23.7.7 7.7 The correspondence, discharged

The RECURSE node	The term	Status
The spiral, not the circle	`Q_t = Q_inf + (1−delta)^t(Q_0 − Q_inf)`: the state changes every pass and never repeats exactly	**Proved** — §7.5
The winch post held fixed	`Q_inf` fixed across passes; only the transient moves	**Proved** — `Q_inf` has no `t` in it
The drift, checked weekly	`(1−delta)^t (Q_0 − Q_inf)`, the decaying inheritance	**Proved** — §7.5
The circle that does not climb	`eta = 0`: `b = −c∗`, `Q_inf = −c∗/delta < 0`	**Proved** — the circle is a regime whose fixed point is destruction

The FIXEDPOINT node	The term	Status
The room exists	Banach existence, given `delta > 0` and completeness	**Proved** — §7.4
There is only one room	Banach uniqueness	**Proved** — §7.4
The room was always furnished	`Q_inf` independent of `Q_0`	**Proved** — §7.4
Arrival is recognition, not victory	geometric approach; most of the trajectory spent near `Q_inf`; the crossing is a JND event	**Derived** — §8.3, given a stated Weber fraction
Convergence is no certificate of worth	`eta F(u∗) < c∗` gives `Q_inf < 0` and the loop still converges	**Proved** — Theorem 3.5's own failure clause
The counterfeit arrival	a fixed point inflated by `x/delta` at another system's expense; sum invariant	**Derived** — §8.7

The two rows marked *derived* rather than *proved* are derived from the mathematics plus one badged postulate each, and both badges are shown where the derivation occurs. Nothing in this reading imports a meaning into the theorem that the theorem does not carry.

23.7.8 7.8 Formula Validation Protocol — the error law

Under the Formula Validation Protocol [Curzi, 2026t].

Gate	Verdict	Content
FVP-1 DIMENSIONS	PASS	`Q` in Q-units (the corpus's unit of stored order; see [Curzi, 2026b] on conversion). `delta` dimensionless per period; `(1-delta)^t` dimensionless. Both sides of `|Q_t - Q_inf| = (1-delta)^t |Q_0 - Q_inf|` are in Q-units. `t` in periods; the period must be declared.
FVP-2 SCALE TYPE	**CONDITIONAL PASS**	The error law needs `Q` on an **interval** scale for differences and on a **ratio** scale for the percentage readings in §8.1. The corpus's `Q` is postulated as a ratio-scale scalar with a true zero at "no stored order" (Appendix E's postulate set). **Badged: that `Q` is a scalar at all, rather than a vector of incommensurable stores, is a postulate of the corpus and not a finding.** Where an subject's `Q` is measured by a Rasch-calibrated instrument ([Curzi, 2026t]) the scale requirement is met; where it is measured by a self-rating out of 10, it is not, and only the ordering of successive gaps may be reported.
FVP-3 LIMITING CASES	PASS	`t -> inf`: gap `-> 0` for `delta in (0,1]`. `delta -> 0+`: gap `-> |Q_0 - Q_inf|`, no convergence; and `Q_inf -> inf` unless `b = 0`, which is the correct account of a system that never forgets and therefore never settles. `delta -> 1`: gap `-> 0` in one step; total forgetting means the state is entirely the current drive, `Q_t = b` for all `t >= 1`. `delta > 1`: excluded by the model's domain; `|1-delta| < 1` still holds up to `delta = 2`, giving oscillatory convergence, but `delta > 1` would mean losing more than is stored and the admissibility condition rules it out. `Q_0 = Q_inf`: gap is 0 for all `t` — you were already there.

Gate	Verdict	Content
FVP-4 FIXED POINTS	PASS	`Q_inf = (eta M* − c*)/delta`, unique by Banach. Meaning: **the state a life settles into under a given regime, computable in advance from four numbers, none of which is effort.** Second fixed point of the *error* dynamics: none — the error map `e -> (1−delta)e` has the unique fixed point `e = 0`.
FVP-5 IDENTIFIABILITY	**PARTIAL**	From a single observed trajectory `{Q_t}` under constant drive, `delta` is identified from the decay of successive gaps, and the composite `b = eta M* − c*` is identified from `Q_inf * delta`. **`eta`, `M*` and `c*` are NOT separately identified from `Q` alone** — any triple with the same `eta M* − c*` produces an identical trajectory. Separating them requires independent measurement of at least two of the three: `M*` by magnitude estimation ([Curzi, 2026n]), `c*` by a cost ledger ([Curzi, 2026b]), `eta` then by residual. **State this whenever a trajectory is used to argue about efficiency rather than about outcome.**

Gate	Verdict	Content
FVP-6 FALSIFICATION	SPECIFIED	The preregistration protocol [Curzi, 2026i]. Preregister the period, the `Q` instrument, and the window. Fit `delta` on a training block; **freeze**; forecast held-out `Q_t` from the frozen `delta` and the observed drive. Four baselines: persistence (`Q_{t+1} = Q_t`), direct-input (`Q_{t+1}` from `M_t` alone), matched AR(1), and a **shuffled-input control** in which the drive series is permuted. **The law dies if a frozen geometric-decay model does not beat the shuffled-input control on held-out data**, because that is the outcome in which the ordering of inputs — the entire content of "it accumulates" — carries nothing.
FVP-7 REPRODUCIBILITY	**UNTESTED — declared**	Does `delta` recover across individuals, across investigators, across domains within a person? The corpus does not know. §8.10 states the design that would answer it. Until it is run, a fitted `delta` is a within-person, within-domain descriptive parameter.

23.8 8 The dynamics of arrival

23.8.1 8.1 The convergence tables

Everything operational in this paper comes off two constants. The **time constant**

```
tau = −1 / ln(1 − delta)        periods per factor of e
```

and the **iteration count to close a given fraction of the gap**

```
t(eps) = ln(eps) / ln(1 − delta)     periods to reduce the gap to a fraction eps
```

Both are exact; neither involves `Q_0`, `Q_inf`, `eta`, `M*`, or `C`. **How long arrival takes depends on the leak and on nothing else.**

delta	1−delta	tau	half-life	to 5%	to 1%	to 0.1%	to 0.01%
0.020	0.980	49.50	34.31	149	228	342	456
0.050	0.950	19.50	13.51	59	90	135	180
0.100	0.900	9.49	6.58	29	44	66	88
0.150	0.850	6.15	4.27	19	29	43	57
0.200	0.800	4.48	3.11	14	21	31	42
0.250	0.750	3.48	2.41	11	17	25	33
0.300	0.700	2.80	1.94	9	13	20	26
0.400	0.600	1.96	1.36	6	10	14	19
0.500	0.500	1.44	1.00	5	7	10	14
0.750	0.250	0.72	0.50	3	4	5	7

Read the table with the period attached, because the period is where the human meaning is.

A weekly practice with `delta = 0.05` per week is 59 weeks — fourteen months — from being within 5% of its destination. The same weekly leak restated per day is `delta = 0.0073`, needing 409 days: the same calendar. **A monthly cycle at `delta = 0.20` per month is fourteen months too.** The slightly deflating discovery in this table is that *changing cadence without changing the per-period leak changes nothing about the calendar*; cadence acts through `eta` and `C`, not through `tau`.

Two invariances that the table encodes and that are worth stating separately, because they are counter-intuitive and they are exact:

The cost of each halving is constant. At `delta = 0.10`, closing the gap from 100% to 50% takes 6.58 periods; from 50% to 25% takes 6.58 periods; from 1% to 0.5% takes 6.58 periods. The `ln(0.5)/ln(1−delta)` expression has no `t` in it.

The cost of each factor of ten is constant, and it is 21.85 periods at `delta = 0.10`.

interval	periods (at `delta = 0.10`)
close 0% -> 50% of the gap	7
close 50% -> 90%	15
close 90% -> 99%	22
close 99% -> 99.9%	22

The last ninety-nine hundredths of one percent costs exactly as much as the ninety to ninety-nine percent did, and more than the first half did. This is the arithmetic behind every experience of a practice that felt fast at the start and interminable at the end. The practice did not slow down. **The remaining distance is being measured in absolute terms by an instrument that works in ratios, and the ratios are being closed at a perfectly constant rate throughout.**

23.8.2 8.2 The shape of the approach

The fraction of the gap remaining, at `delta = 0.10`:

t	remaining	closed
0	1.00000	0.000%
1	0.90000	10.000%
2	0.81000	19.000%
5	0.59049	40.951%
10	0.34868	65.132%
20	0.12158	87.842%
29	0.04710	95.290%
44	0.00970	99.030%
66	0.00096	99.904%

A contraction spends the overwhelming majority of its life near its fixed point. At `delta = 0.10`, the system is within 5% of `Q_inf` from period 29 onward — which is to say that of the first 88 periods, 60 of them are spent inside a band of 5%. If the practice runs for two hundred periods, 171 of them are inside that band. **Whatever "being at the fixed point" feels like, it is what most of the trajectory feels like, and the transient is the unusual part.**

That fact is the entire explanation of §8.3.

23.8.3 8.3 Why arrival feels like recognition and not like victory

Four reasons, in increasing order of how much of the phenomenon they explain.

One: there is no arrival event. The gap is `(1−delta)^t` times its initial value, which is strictly positive for every finite `t`. **The system never reaches `Q_inf`. It approaches forever.** There is therefore no instant at which anything happens, and any felt instant of arrival is an event in the observer, not in the trajectory. Victory has a moment. This does not.

Two: the felt arrival is a threshold crossing in the observer's own instrument. If the subject can resolve a difference in `Q` of a fraction `c` — a Weber fraction, per [Curzi, 2026n] and §4.3 — then they notice arrival when the remaining gap falls below `c * Q_inf`, at

```
t_arrive = ln( c * Q_inf / |Q_0 − Q_inf| ) / ln(1 − delta)
```

For an subject starting from zero (`|Q_0 − Q_inf| = Q_inf`, so the ratio is just `c`):

`delta` \ `c`	0.02	0.05	0.10	0.20	0.30
0.05	77	59	45	32	24
0.10	38	29	22	16	12
0.20	18	14	11	8	6
0.30	11	9	7	5	4

Arrival is the period at which the remaining distance drops below your own just-noticeable difference, and it therefore happens at a different time for two people on identical trajectories. A coarse observer (`c = 0.30`) at `delta = 0.10` arrives at period 12; a fine one (`c = 0.02`) on the identical path arrives at period 38. Neither is wrong. They have different instruments. *(Badged: this uses Postulate R1's cousin — that `Q` is judged by the same log-register instrument as every other magnitude, hence a constant Weber fraction. That is an assumption of the corpus, consistent with the psychophysics but not measured for `Q`.)*

Three: by the time you notice, you have been close for several time constants. From §8.2, an subject with `c = 0.05` and `delta = 0.10` "arrives" at period 29 — and has been within 10% since period 22, within 20% since period 16, within 35% since period 10. **The state that announces itself at period 29 has been substantially present since period 16.** The texture of recognition is the tail of an exponential, and the reason the destination seems familiar is that it has been the dominant feature of the last two-thirds of the journey.

Four — and this is the one that makes it recognition rather than mere familiarity: the destination never depended on you. `Q_inf = (eta M* − c*)/delta` contains no `Q_0`, no `t`, and no measure of effort. It is a property of the regime. From the first period, the trajectory was going exactly there. **You do not arrive somewhere new; you arrive where the parameters were always going to put you, and the recognition is accurate — the room really was furnished before you entered it, by the four numbers that describe how you live.**

That is the honest content of the FIXEDPOINT node [Curzi, 2026] and it is not consoling. It says the same thing about a good regime and a bad one.

23.8.4 8.4 The invariant at arrival: headroom is pure geometry

A result that falls out of Theorem 3.5 and the headroom gauge together, and that the corpus has not stated before.

Headroom [Curzi, 2026b,h] is `h_t = eta ln N − delta Q_t − C_t`. Evaluate it at the fixed point. There, `delta Q_inf = eta M* − c*` by definition, so

```
h_inf = eta*lnN − delta*Q_inf − c*
      = eta*lnN − (eta*M* − c*) − c*

h_inf = eta * ( ln N − M* )                    THE ARRIVAL INVARIANT
```

Verified numerically across unrelated parameter sets:

eta	delta	N	u*	C	Q_inf	h computed from the gauge	eta(ln N − F)
0.35	0.12	9	0.55	0.22	3.0853	0.178789	0.178789
0.35	0.05	9	0.55	0.22	7.4048	0.178789	0.178789
0.20	0.30	6	0.30	0.10	0.2775	0.175094	0.175094
0.50	0.08	16	0.80	0.40	11.0309	0.103820	0.103820

At any fixed point, headroom equals the conversion efficiency times the surplus the geometry is failing to generate — and it does not depend on `delta` or on `C` at all. Rows one and two make the point: halving the leak more than doubles `Q_inf`, and leaves headroom at arrival unchanged to six decimal places.

The reading, and it is the most useful single sentence in this paper for anyone deciding what to do next:

A converged system's remaining capacity for the new is exactly the surplus its geometry is not claiming. Not its slack, not its free time, not its energy. Its unclaimed `u`.

The table of that, at `eta = 0.35`, `N = 9`, `ln N = 2.1972`:

u*	N_eff	F(u*)	ln N − F	h_inf	% of ceiling claimed
0.00	1.000	0.0000	2.1972	0.7690	0.0%
0.25	3.000	1.0986	1.0986	0.3845	50.0%
0.40	4.200	1.4351	0.7621	0.2667	65.3%
0.55	5.400	1.6864	0.5108	0.1788	76.8%
0.70	6.600	1.8871	0.3102	0.1086	85.9%
0.85	7.800	2.0541	0.1431	0.0501	93.5%
1.00	9.000	2.1972	0.0000	0.0000	100.0%

A perfectly non-parallel life has zero headroom at arrival — it is already generating everything its category count permits, and the only remaining move is to raise `N`. That is [Curzi, 2026c]'s argument arriving from a completely different direction, and the convergence of the two is a point in the framework's favour, not a coincidence to be admired.

The dual reading is the harsh one. **An subject who feels enormous headroom at a settled state is not being told they have reserves. They are being told their framings are parallel.** `h_inf` is large precisely when `F(u*)` is small.

23.8.5 8.5 Where the leverage is: sensitivity of the fixed point

If arrival is determined by four numbers, the practical question is which of the four to move. Differentiate `Q_inf = (eta M* − c*)/delta`, at the base case `eta = 0.35`, `delta = 0.12`, `N = 9`, `u* = 0.55` (so `F = 1.6864`), `c* = 0.22`, giving `Q_inf = 3.0853`:

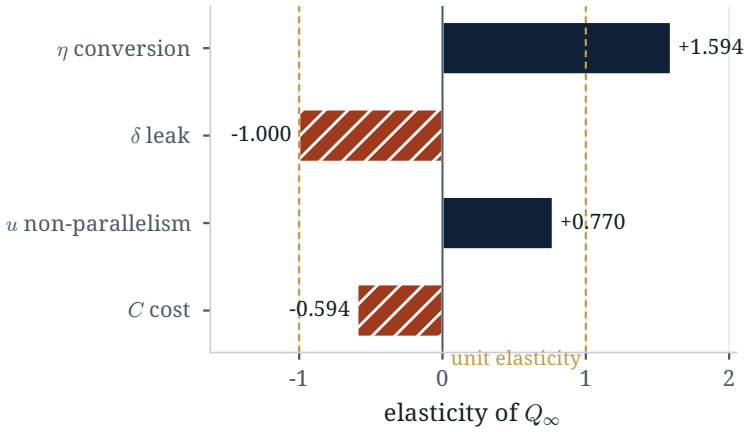

Figure 23.3: **Efficiency outranks cost by a factor of 2.68, and the leak elasticity is exactly -1 at every parameter value:** elasticities of the fixed point `Q_inf = (eta M* – c*)/delta` at the base point `eta = 0.35`, `delta = 0.12`, `N = 9`, `u* = 0.55`, `c* = 0.22`. The `delta` bar reaches `–1.000` because `Q_inf` is proportional to `1/delta`, so that elasticity is structural rather than local; the other three are base-point quantities. Derived from stipulated parameters, not fitted; generated by `figs/src/CCP-023_fig01.py`.

```
dQ_inf/d(eta)    =  F / delta                        =  14.0533
dQ_inf/d(C)      = −1 / delta                        =  −8.3333
dQ_inf/d(delta)  = −Q_inf / delta                    = −25.7111
dQ_inf/d(u)      =  eta(N−1) / ((1+(N−1)u) delta)    =   4.3210
```

Raw derivatives mislead because the levers are in different units. The elasticities — percent change in `Q_inf` per one percent change in the lever — are comparable:

Lever	Elasticity of `Q_inf`	Effect of a 10% improvement
`eta` (conversion)	**+1.594**	3.0853 -> 3.5772 (+15.94%)
`delta` (leak)	**-1.000**	3.0853 -> 3.4281 (+11.11%)
`u` (non-parallelism)	+0.770	3.0853 -> 3.3138 (+7.40%)
`C` (cost)	-0.594	3.0853 -> 3.2687 (+5.94%)

Three readings.

The elasticity with respect to `delta` is exactly -1, always. `Q_inf` is proportional to `1/delta`, so this is a structural fact and not a property of the base point: halve the leak, double the destination.

The elasticity with respect to `eta` is `eta*M*/(eta*M* – c*)`, which exceeds 1 whenever there is any cost at all, and diverges as the regime approaches unsustainability. At the base point it is 1.594. **A person operating near the sustainability boundary gets enormous returns from small improvements in how experience becomes character — and equally enormous losses from small degradations.** That is a real, derived, and slightly alarming property: fragility and leverage are the same number.

Cutting cost is the weakest of the four levers here, and it is usually the first one attempted. Elasticity -0.594 against `eta`'s +1.594: a 10% efficiency gain is worth 2.7 times a 10% cost cut at this base point. The ratio is `eta*M*/c*` and it favours efficiency whenever the regime is comfortably sustainable.

But there is a countervailing fact about `delta` that the elasticity hides, and §8.6 is it.

23.8.6 8.6 The cost of a long memory: noise amplification

Everything so far assumed constant drive. Real drive is not constant: `M_t` and `C_t` vary. The standard perturbation bound for a contraction: if the drive deviates from its mean by at most `epsilon` in each period, then in the long run

```
limsup_t | Q_t − Q_inf |  <=  epsilon / delta
```

The leak that determines how much you keep also determines how much of the input noise you keep. The amplification factor is `1/delta`, and it is the same `1/delta` that multiplies the signal.

`delta`	`1/delta`	wander at `eps=0.05`	at `eps=0.10`	at `eps=0.20`
0.020	50.00	2.500	5.000	10.000
0.050	20.00	1.000	2.000	4.000
0.100	10.00	0.500	1.000	2.000
0.150	6.67	0.333	0.667	1.333
0.200	5.00	0.250	0.500	1.000
0.300	3.33	0.167	0.333	0.667
0.500	2.00	0.100	0.200	0.400
0.750	1.33	0.067	0.133	0.267

The full trade, laid out on one line for three leak rates with the base case's drive:

`delta`	`Q_inf`	`tau`	periods to 5%	noise gain `1/delta`
0.06	6.1707	16.16	49	16.67
0.12	3.0853	7.82	24	8.33
0.24	1.5427	3.64	11	4.17

Halving the leak doubles the destination, doubles the time to reach it, and doubles the integrated noise. There is no free memory. A person with very low personal `delta` — who forgets nothing, whose skills do not atrophy, whose sense of self does not drift — accumulates a large `Q`, takes a very long time to change it, and carries every perturbation for twenty periods. That is not a defect of such a person; it is the same equation read on the other side.

The rule: **match `delta` to the volatility of the domain.** In a stable domain low `delta` is a gift; in a volatile one it is a liability, and deliberate shedding ([Curzi, 2026a]; the SEAL node [Curzi, 2026] SEAL) is the response.

23.8.7 8.7 Counterfeit arrival

The FIXEDPOINT node warned that a well-converged state can still be the wrong one, since convergence is a property of loops and not a certificate of worth. Theorem 3.5 already supplies the first version of that: **if `eta F(u*) < c*` the fixed point is negative, and the loop converges anyway — toward the destruction of the thing.** The storage-law paper does not hide this and neither does this paper.

This section supplies the second version, which is the one the manifest names: **a fixed point reached at another's expense — the room furnished with someone else's goods.**

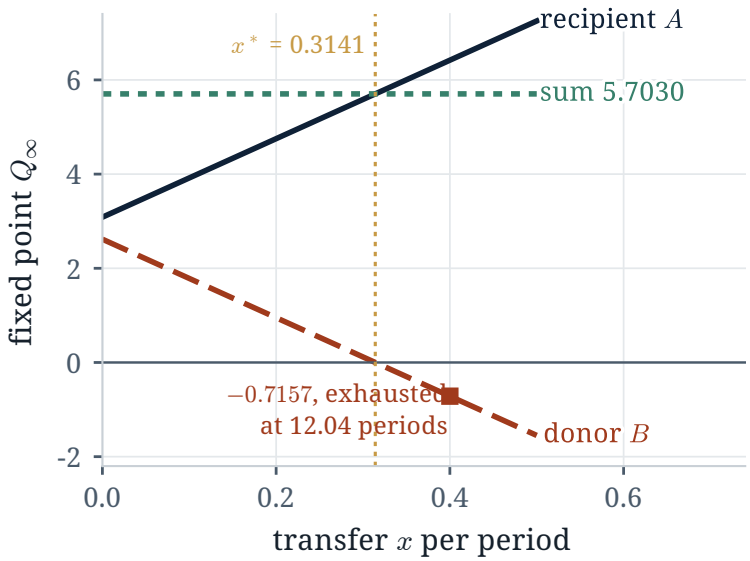

Figure 23.4: **Transfer relocates a fixed point and creates none:** the two fixed points move by $\pm x/\delta$ as the transfer rate rises, and their sum is 5.7030 at every rate. The donor crosses zero at the critical rate `x* = 0.3141`; at `x = 0.40` its steady state is `-0.7157` and it is exhausted after 12.04 periods, while the recipient reads far above anything its own regime could produce. Modelled from `eta = 0.35`, `delta = 0.12`, `C = 0.22`, `N = 9`, `u_A = 0.55`, `u_B = 0.45`; the script reproduces every row of this section's table; generated by `figs/src/CCP-023_fig03.py`.

8.7.1 The transfer model

Two systems, `A` and `B`, each running the storage law, with a transfer `x >= 0` per period from `B` to `A`. `A` receives `x` as a free addition to its drive; `B` pays it as an addition to its cost.

```
Q_A(t+1) = (1-delta) Q_A(t) + eta*F_A - C_A + x
Q_B(t+1) = (1-delta) Q_B(t) + eta*F_B - C_B - x
```

Both remain affine contractions, so both still converge, and the fixed points are

```
Q_A,inf(x) = ( eta*F_A - C_A + x ) / delta  =  Q_A,inf(0) + x/delta
Q_B,inf(x) = ( eta*F_B - C_B - x ) / delta  =  Q_B,inf(0) - x/delta
```

The transfer moves each fixed point by exactly `x/delta`, in opposite directions, and the sum is unchanged. Numerically, with `eta = 0.35`, `delta = 0.12`, `C = 0.22`, `N = 9`, `u_A = 0.55` (`F_A = 1.6864`), `u_B = 0.45` (`F_B = 1.5261`):

x	Q_A,inf	gain to A	Q_B,inf	sum
0.0000	3.0853	—	2.6177	5.7030
0.1000	3.9187	+0.8333	1.7843	5.7030
0.2000	4.7520	+1.6667	0.9510	5.7030
0.3141	5.7028	+2.6175	0.0002	5.7030
0.4000	6.4187	+3.3333	-0.7157	5.7030

The sum column is the finding. Transfer relocates a fixed point; it creates none. No amount of extraction increases the total stored order of the pair by one unit. This is not an ethical claim dressed as arithmetic — it is arithmetic, and its ethical reading is left to the reader, who already has the declination refusal in hand [Curzi, 2026].

8.7.2 The exhaustion horizon

There is a critical transfer rate at which B's fixed point hits zero:

```
x* = eta * F_B − C_B
```

which for the case above is `x* = 0.35 * 1.5261 − 0.22 = 0.3141`. This is simply Corollary 3.4 — the sustainability ceiling — read as a constraint on how much can be taken. **Below x*, B is diminished but survives at a lower fixed point. Above x*, B's fixed point is negative and B runs out.**

Take `x = 0.40 > x*`. B's fixed point is `−0.7157`. Starting from its undisturbed fixed point of 2.6177, B's trajectory is:

t	Q_B
0	2.6177
1	2.2177
3	1.5559
5	1.0434
7	0.6466
9	0.3393
11	0.1013
12	0.0032
13	**-0.0830**

The exhaustion horizon in closed form, from the error law:

```
t_exhaust = ln( −Q_B,inf / (Q_B,0 − Q_B,inf) ) / ln(1 − delta)   =  12.04 periods
```

Twelve periods. During all twelve, A is converging comfortably toward 6.4187 — a fixed point 108% higher than its own regime could produce — and every measurement A can take of itself says the practice is working.

8.7.3 What happens at the end

When B fails, the transfer stops. A's drive reverts and its fixed point drops back to 3.0853. A now has a gap of 3.3333 Q-units to close, downward, and it closes it geometrically at the same `delta`: **24 periods to come within 5% of the new, lower destination.**

```
A's peak fixed point during extraction : 6.4187
A's fixed point after B fails          : 3.0853
loss on collapse                       : 3.3333 Q-units  (51.9% of the peak)
twelve periods of gain, twenty-four of unwinding
```

The counterfeit arrival is not merely unjust; it is arithmetically temporary, and its unwind is twice as long as its build. That asymmetry is not moralising — it is the ratio of the exhaustion horizon to the reconvergence time, and both were computed from the same `delta`.

8.7.4 The test that distinguishes genuine from counterfeit arrival

Here is the operational point of the whole section, and it is one line.

An arrival is genuine if every party to it has `h_t >= 0` under its own regime, counting the transfer as a cost. It is counterfeit if any party has `h_t < 0`.

That is Corollary 3.4 used as an audit rather than as a forecast. The check is cheap. For each party, compute `h = eta ln N − delta Q − C_total` where `C_total` includes every transfer that party is paying. If any `h` is negative, then by Corollary 3.4 **no choice of interaction geometry prevents that party's order from decreasing** — and the arrangement's apparent stability is being paid for out of a store that is running down.

Two honest complications.

The audit requires the other party's ledger. `A` cannot run it from inside `A`; it needs `B`'s `Q`, `C`, and `delta`. **This is precisely why the check is skipped, and precisely why it is the check** — at personal scope, it is the arrangement whose sustainability you can only assess by asking a question you would rather not ask.

A negative `h` in a party who has not been asked is not established. The declination refusal governs [Curzi, 2026]. The audit is run by request, with a decline path, and a party who declines to supply their ledger is recorded as unknown, not as consenting. **An audit that conscripts the other person's data to reassure the person doing the extracting has reproduced the problem it was meant to detect.**

23.8.8 8.8 Arrival, stall, and the limit of what arithmetic can tell you

A flat `Q` has exactly one arithmetic cause: `eta M_t = delta Q_t + C_t`, the one-step growth condition of Corollary 3.2 holding with equality. That single equation covers both of the following:

- **Arrival.** The practice has converged to a fixed point that its subject chose, by choosing the regime that generates it.
- **Stall.** The practice has converged to a fixed point nobody chose, inherited from parameters nobody set, and the subject has been calling it stability.

The arithmetic cannot distinguish these. They are the same equation. The corpus states that plainly rather than manufacturing a discriminator, because the honest position is that the difference is not in the trajectory — it is in the record of how the parameters came to have their values.

What *can* be checked, and what the specification below requires:

1. **Was `Q_inf` computed before it was reached?** A chosen fixed point is one that was predicted. [Curzi, 2026i]'s survey and the four parameters give a forecast; a forecast recorded in advance and then met is evidence of a chosen regime.
2. **Is `h_inf = eta(ln N − F(u*))` known and accepted?** An subject at a chosen fixed point can state how much of the ceiling their geometry is claiming, and has a reason for the remainder.
3. **Is there a sunset?** the SEAL node [Curzi, 2026] and the shedding result of Curzi [2026h]: a chosen regime has a review date. A stall has never had one.

Arrival and stall are distinguished by documentation, not by measurement, and that is not a weakness of the model — it is the model correctly declining to certify an intention it cannot observe.

23.8.9 8.9 Changing where you arrive

The consolidated instruction, from §8.4, §8.5, and §8.6 together.

```
to move the destination      change eta, u (through F), C, or delta
to move faster to it         change delta -- and accept that this moves the destination too
to trade destination         raise eta or u; these move Q_inf without moving tau
  without changing speed
to raise the ceiling         raise N; this is the only move that raises
                             the maximum any geometry could reach
```

And the negative result: **trying harder inside a fixed regime does not change where you arrive.** Effort that moves none of the four parameters moves only the transient — the same path, the same room, the same rate, since the rate is `delta` and effort is not `delta`. The sensation of pushing is real and it is spent on the term that was going to decay anyway.

23.8.10 8.10 What would need measuring

Under the badging convention [Curzi, 2026], the agenda rather than the results:

1. **A `Q` instrument with ratio-scale properties.** Rasch-calibrated where possible ([Curzi, 2026t]), because specific objectivity is exactly the property that lets a `Q` measured with one item set be compared with a `Q` measured with another. Without it, FVP-2 stays conditional.
2. **`delta` by domain and by person.** Fit from the decay of successive gaps under a constant regime, per FVP-6, with the freeze step enforced. Report distributions, not point estimates.
3. **The Weber fraction for `Q`.** This determines `t_arrive` in §8.3 and it is currently a parameter of a table rather than a measured constant.
4. **The joint identifiability study.** Independent measurement of `M*` (magnitude estimation) and `c*` (cost ledger) in the same subjects, to test whether `eta` recovered by residual is stable — which is FVP-5 and FVP-7 attacked together.

23.9 9 Requirements for a convergence claim

CS-1 — Declare the period. Every `delta`, `tau`, and iteration count is meaningless without the period attached. The period is fixed before data collection and is not changed mid-block.

CS-2 — Compute `Q_inf` before pursuing it. `Q_inf = (eta M* − c*)/delta` from the four measured parameters, recorded in writing, before the practice is undertaken. *(This is the requirement that makes §8.8's first check possible at all.)*

CS-3 — Verify `delta > 0`. If the practice has no loss term — nothing is forgotten, nothing atrophies, no maintenance is required — there is no fixed point and the convergence tables do not apply. State the loss mechanism explicitly.

CS-4 — Check the sign of the fixed point. If `eta M* < c*` then `Q_inf < 0` and the regime is unsustainable. **Report this before proceeding; do not run the practice and discover it.** *(Theorem 3.5's own failure clause.)*

CS-5 — State the arrival criterion in advance. Declare `c`, the fraction of `Q_inf` at which the practice will be called arrived, and compute `t_arrive` from §8.3. An undeclared arrival criterion converts an asymptote into an argument.

CS-6 — Use the a posteriori bound to track progress. Distance from arrival is approximately `((1−delta)/delta)` times the last observed step. Report it each period; it costs one multiplication.

CS-7 — Compute `h_inf = eta(ln N − F(u*))` at the fixed point and account for it. Large headroom at arrival is a statement about parallel framings, not about reserves. *(§8.4.)*

CS-8 — Match `delta` to domain volatility. Where the domain changes faster than `1/delta` periods, deliberate shedding is specified, not optional. *(§8.6.)*

CS-9 — Run the transfer audit. For any arrangement in which one party's drive includes a transfer from another, compute `h` for **every** party with the transfer counted as that party's cost. Record any negative `h`. *(§8.7.4.)*

CS-10 — The audit has a decline path. No party is required to disclose their ledger. A declined audit is recorded as *unknown*, never as *satisfied*. *(The declination refusal, binding [Curzi, 2026].)*

CS-11 — Do not compare `delta` across people without recalibration. FVP-7 is open. A fitted `delta` is within-person and within-domain until the reproducibility study exists.

CS-12 — Freeze before claiming. FVP-6 in full, including the shuffled-input control.

23.10 10 Failure modes of arrival

Fault	Diagnostic signature	Fix
The unarrived asymptote	Subject reports "almost there" for many periods and treats it as failure	There is no arrival event (§8.3). Declare `c` in advance per CS-5 and use it. The last 0.9% costs what the previous 9% did
Effort substitution	Increasing effort with no change in `eta`, `u`, `C`, or `delta`; `Q` follows the same path	Effort acts on the transient, not the fixed point (§8.9). Identify which of the four parameters the effort is supposed to move; if none, stop
The negative fixed point run anyway	`eta M* < c*`; `Q` declining steadily; practice continued because "consistency matters"	CS-4. The loop converges toward destruction. Cut `C`, raise `eta` or `u`, or stop
Zero-delta fantasy	A plan with no loss term: nothing decays, nothing needs maintenance	No contraction, no fixed point, unbounded linear growth in the model and rapid divergence from reality. Name the loss mechanism (CS-3)
Low-delta noise integration	Very stable person or practice; large swings in `Q` traced to small perturbations months earlier	`1/delta` amplification (§8.6). Either accept it as the price of memory or raise `delta` deliberately by shedding
Headroom misread as reserve	Large `h` at a settled state, read as "capacity available"	`h_inf = eta(ln N − F(u*))`. Large `h` means parallel framings (§8.4). Raise `u` or `N`, do not "use the capacity"
Counterfeit arrival	A party's `Q` rising steadily with no change in their own `eta`, `u`, `C`, or `delta`	The extra drive is a transfer. Run CS-9 on every party. Sum is invariant (§8.7.1)
Extraction above `x*`	Counterparty's `Q` declining linearly toward zero on a finite horizon	Compute `x* = eta F_B − C_B` and `t_exhaust`. Above `x*` the arrangement has a countdown, and the unwind is longer than the build
Stall named arrival	Flat `Q`, no predicted `Q_inf` on record, no review date	§8.8. The arithmetic cannot adjudicate; the documentation can. If there is no forecast and no sunset, treat as stall

Fault	Diagnostic signature	Fix
Cadence confusion	Cadence increased, calendar unchanged, subject frustrated	`tau` depends on the per-period `delta`. Changing cadence without changing per-period leak changes nothing (§8.1). Cadence acts through `eta` and `C`
Cross-person `delta` comparison	"Her `delta` is lower than mine"	FVP-7 is untested. CS-11
Ordinal `Q`	Convergence rates fitted to a 1–10 self-rating	FVP-2. Differences on an ordinal scale are not differences. Report the ordering of successive gaps only, or build a calibrated instrument

---

23.11 11 The personal formulary

Sections 11 to 13 are a lookup table, and the payoff of the internal-scope material: every formula that applies at the **internal scope** — psychology, personal, one mind — collected in one place, in one format, with one unit system, each carrying its full Formula Validation Protocol so that a reader can tell in ten seconds which gates it passes and which it does not.

A formulary is not a theory. It is a shelf. Its virtue is that the entries are in the same units, formatted identically, and honest about their limits, so that a person holding a real problem can find the right instrument without reading the whole framework. The preceding material made the arguments; this one exists so the arguments do not have to be re-read.

23.11.1 11.1 How to use it

Three access paths. **By quantity:** the index in §11.2 maps each parameter (`u`, `eta`, `h`, `r`) to its entry. **By fault:** every entry ends with a fault table keyed to the felt complaint, and *The Failure Modes* below covers the faults that come from using the collection rather than any single entry. **By sequence:** *The Specification* below gives the dependency order for a full review. **Running the entries out of order produces numbers that look fine and mean nothing, because six of the nine depend on quantities the others produce.**

23.11.2 11.2 The nine entries

#	Name	Formula	Primary parameter	Source
F-01	The Moment	`M = (D/P) . E`	`M`	Curzi; [Curzi, 2026m]
F-02	The Calibration Ratio	`r = D/P`, `Delta = |ln r|`	`r`	[Curzi, 2026m]
F-03	The Internal Surplus	`F_int = ln(1 + (N−1)u)`	`u`, `N_eff`	[Curzi, 2026,o]

#	Name	Formula	Primary parameter	Source
F-04	The Self-Storage Law	`Q_{t+1} = (1−delta)Q_t + eta M_t − C_t`	`Q`, `eta`, `delta`	the storage law [Curzi, 2026a]; [Curzi, 2026o]
F-05	Personal Headroom	`h_t = eta ln N − delta Q_t − C_t`	`h`	the headroom identity [Curzi, 2026b]; [Curzi, 2026b], [Curzi, 2026o]
F-06	The Launch Budget	`L = max(0, M − C)`	`L`	[Curzi, 2026o,p]
F-07	The Gradient	`g = −grad C`	`g`	[Curzi, 2026,p]
F-08	The Return Difference	`Delta_R = |ln(M'/M)|`	`rho`	Sections 3–6
F-09	The Contraction	`|Q_t − Q_inf| = (1−delta)^t |Q_0 − Q_inf|`	`Q_inf`, `tau`	[Curzi, 2026a]; Sections 7–10

Four of the nine are **theorems** of the corpus (F-03, F-04, F-05, F-09) and appear here in their internal-scope reading. Two are **the author's formula** and its immediate consequence (F-01, F-02). Three are **derived formulas of the corpus** (F-06, F-07, F-08), derived in the sense the internal-scope correspondence requires [Curzi, 2026o], and badged where their derivations pass through a postulate.

Every entry states which of the three it is in its first line, because the difference decides how much weight it can carry.

23.11.3 11.3 The entry format

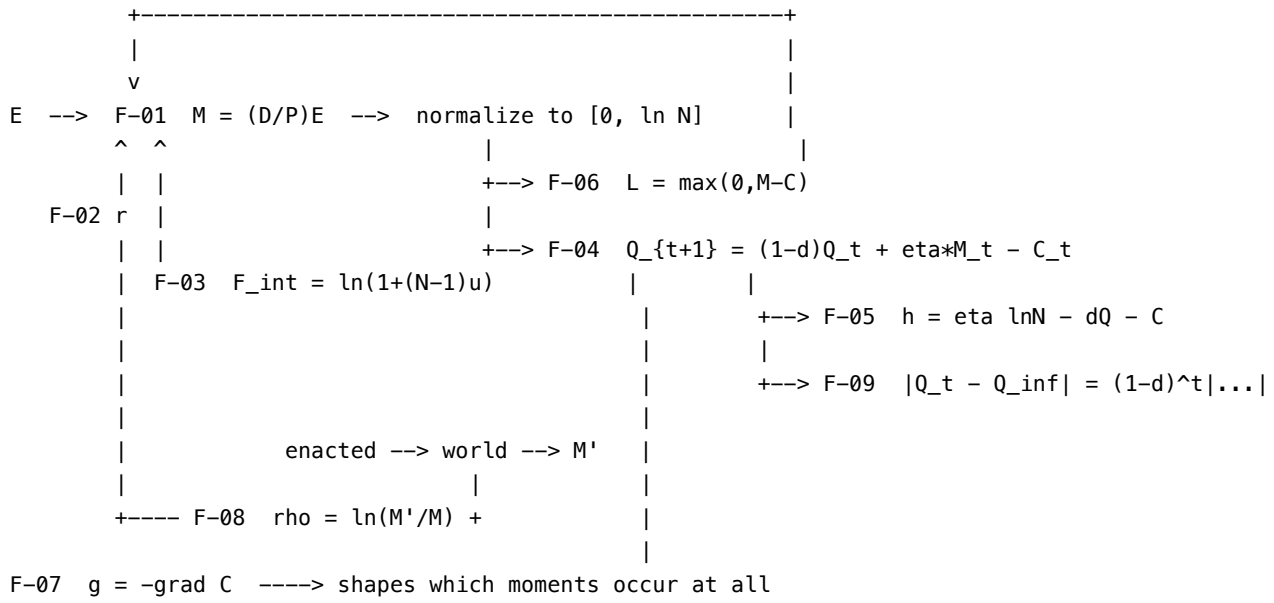
Every entry has the same eight parts, in the same order, so the formulary can be read as a table:

```
STATEMENT        the formula, in a fence, with every symbol defined
READS            one sentence: what the formula says in words
STATUS           theorem / author's formula / derived-with-badge
DERIVATION       where it comes from in the corpus, and what it needs
FVP              all seven gates, verdict plus content            (Section 11.6)
PROTOCOL         numbered measurement procedure
WORKED NUMBER    one computed instance
FAULTS           named failure modes with signature and fix
```

23.11.4 11.4 The unit system

Everything internal is measured in **nats**, or in **Q-units** (the corpus's unit of stored order, defined in [Curzi, 2026b]), or in **Q-units per period**. Because the four registers converge [Curzi, 2026n,?], any quantity in nats is immediately readable in three other registers by exact constants:

```
1 nat    = 1.442695 bits = 2.885390 octaves = 3462.4681 cents
1 bit    = 0.693147 nats = 2 octaves EXACTLY = 2400 cents exactly
1 octave = 0.346574 nats = 0.5 bits          = 1200 cents



surplus -> frequency:  f = k * e^(2F),   k = 0.483425732988414 Hz   [the frequency constant]
```

The ceilings, which bound five of the nine entries:

N	ln N (nats)	bits	octaves	f = k e^(2 ln N) (Hz)
2	0.6931	1.0000	2.000	1.9337
4	1.3863	2.0000	4.000	7.7348
6	1.7918	2.5850	5.170	17.4033
7	1.9459	2.8074	5.615	23.6879
9	2.1972	3.1699	6.340	39.1575
10	2.3026	3.3219	6.644	48.3426
16	2.7726	4.0000	8.000	123.7570

`ln N` is the hard ceiling on surplus per interaction [Curzi, 2026], and by the forced consequence of the register convergence it is also the ceiling on the moment: the richest available moment is bounded by the log of how many kinds of thing you can distinguish. That is Ashby's requisite variety appearing in first-person experience. It was not chosen; it follows.

23.11.5 11.5 The circuit — how the nine connect

Three structural facts follow, and they govern the order of operations in *The Specification*.

F-03 sets the ceiling F-01 lives under — no moment is richer than `ln N`, and `N_eff` says how much of `N` is real. **F-01 is the only producer:** storage, headroom, launch and arrival are all fed by `M`, so **if the Moment is mismeasured, all six downstream numbers are wrong in the same direction and will look consistent with one another, which is the most dangerous kind of wrong. F-08 is the only feedback path, and it acts on `D`, not on `Q`** — the echo corrects the frame, which changes the integrator's input, not its state, which is why feedback improves character slowly (Sections 3–6, §4.10).

23.11.6 11.6 The FVP verdict legend

The Formula Validation Protocol [Curzi, 2026t] defines the seven gates. This paper uses six verdict words and they are not interchangeable:

Verdict	Meaning
PASS	The gate is satisfied as the formula is stated here
CONDITIONAL PASS	Satisfied only under a stated condition; if the condition fails, the formula is **demoted in print** to a heuristic ordering
DEMOTE	The gate is **not** satisfied as things stand. The formula's structure — limits, fixed points, orderings — remains in force; its magnitudes are withdrawn as measured quantities until the named instrument exists
PARTIAL	Satisfied for some parameters and not others; the unrecoverable ones are named
SPECIFIED	Not yet run, but the exact procedure that would run it is given here
UNTESTED — declared	Not run, no data, and the corpus says so rather than implying otherwise

Nine entries, sixty-three gates, and not one is marked PASS on the reproducibility gate, because the corpus has run no cross-individual study of any of these quantities. The protocol names FVP-7 as the gate that decides the hard-science question and the one most often skipped; a formulary's honest option is to leave it visibly open on every page rather than quietly on none.

11.6.1 Two standing verdicts that govern more than one entry

Two findings arrived after the entries below were drafted, and both cut across several of them. They are stated once here, in force everywhere, rather than repeated nine times.

STANDING VERDICT 1 — every `M`-derived entry is DEMOTED on gate 2. [Curzi, 2026t] run the Formula Validation Protocol on the Moment Equation and return **DEMOTE on FVP-2**: `D` and `P` are not instrumented on a common ratio scale with a shared true zero, and division without a true zero yields a number with no referent. This governs **F-01, F-02, F-04, F-06 and F-08** — every entry whose value passes through `M` or through `r = D/P`.

> **NOT REPORTABLE AS MEASURED QUANTITIES:** the magnitude of `D/P`; the distortion `Delta = |ln r|` as a number; the quantitative form of the `M -> Q` join (F-04). Every such figure in the worked numbers below is an **illustrative construction demonstrating the arithmetic**, and is labelled as such at its use.
>
> **STILL IN FORCE:** the limiting cases; the `D = P` fixed point; and the ordering *over-framed / calibrated / under-framed*. **These require only ordinal information and the demotion does not touch them.** What is demoted is magnitude, not structure.

The route out is constructive, specific and priced. [Curzi, 2026t], **Theorem 54.3**, given badged Postulate SO1: measure `D` and `P` as Rasch person-measures on one common linked scale, and `Delta = |ln(D/P)| = |theta_D − theta_P|` becomes genuinely ratio-scaled — Rasch separation supplies the true zero that division requires. The cost is **approximately 123 items per term to establish a half-logit distortion at 95 per cent**, and about 31 items for a full logit. A twelve-item pair of scales resolves nothing finer than roughly 1.6 logits. **A formulary that demotes five of its own nine entries, names exactly what survives, and prices the study that would restore the rest is the protocol working. It is not a caveat and it is not an apology.**

STANDING VERDICT 2 — the shuffled-input control has three measured failure modes, and every FVP-6 row below inherits all three. The four-baseline suite of The four-baseline suite

[Curzi, 2026i] is cited in every falsification row in this paper. [Curzi, 2026u,ac] measured what it actually catches, by simulation rather than assertion:

#	Failure mode	Measured
1	**Anti-conservative as ordinarily run.** Against a nominal `alpha = 0.05` across 500 null trials, iid permutation false-rejected at **0.108 — 2.2x nominal**; circular shift at 0.120; block permutation at 0.060, near nominal	[Curzi, 2026u]
2	**Blind to repackaging.** A filtered repackaging of the input passed all four baselines including the shuffle at `p = 0.0005`, and was caught **only by the structural ceiling test** (the structural ceiling corollary [Curzi, 2026a]) — its single-step jump was **38.5x** the theoretical maximum	[Curzi, 2026i], [Curzi, 2026u]
3	**Blind to shared slow drivers.** In 4,000 trials the shuffle reported honestly in the clean case (48.17% detection) and **passed 98.35% of the time against a confound driving both series**	[Curzi, 2026ac]

> **THE RULE, AND IT SUPERSEDES ANY EARLIER FORM: the shuffle is a weak, miscalibrated empirical audit. Repackaging is caught only by the structural ceiling test; confounding is caught only by design controls — blinding, channel separation, prospective sampling, a yoked control. No surrogate catches either.** Calibrate the surrogate by simulation on your own design before you use it, and **design controls, not more surrogates.** [Curzi, 2026u] specifies both.

23.11.7 11.7 The refusals, as they apply to a formulary

A formulary is a set of numbers a person may come to steer by, and a measure that becomes a target ceases to be a good measure [Goodhart, 1975, Campbell, 1979]. That is the reason the verdict legend above admits DEMOTE and UNTESTED at all: a formulary in which every entry passed every gate would be evidence of capture rather than of quality. The badged postulates below are doing the work Lakatos [1970] describes for a research programme's hard core, and saying so is more honest than presenting them as findings.

The framework's four refusals [Curzi, 2026] govern every entry. Three of the four refusals have specific formulary consequences:

No unbadged postulates — every entry whose derivation passes through an assumption states it in the entry. **No uncomputed numbers** — every worked number here was computed, from data that are **illustrative constructions**, stated as such at each use. **No intervention that**

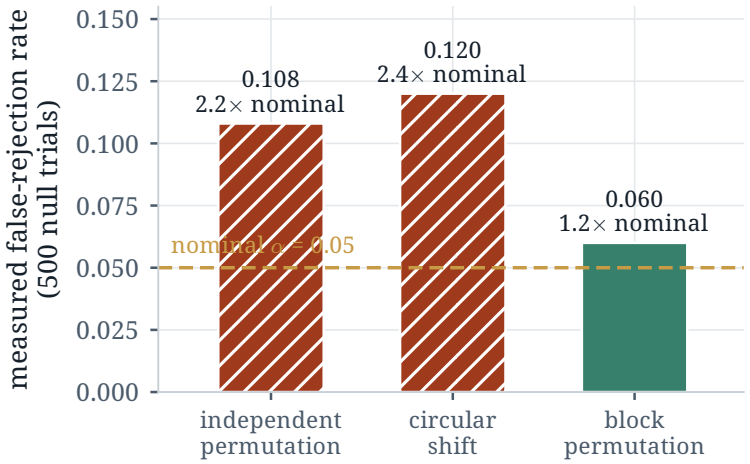


Figure 23.5: **The audit instrument is anti-conservative as ordinarily run:** measured false-rejection rates of the shuffled-input control over 500 null trials against a nominal $\alpha = 0.05$. Independent permutation returns 0.108 and circular shift 0.120 — 2.2 and 2.4 times nominal — and only block permutation is near nominal at 0.060. The control's other two measured failures are not displayable on this axis and are stated instead: a filtered repackaging of the input passed all four baselines at `p = 0.0005`, caught only by a structural ceiling test at 38.5 times the theoretical maximum single-step jump; and against a confound driving both series the shuffle passed 98.35 per cent of 4,000 trials. Measured by simulation in Curzi [2026u] and Curzi [2026ac]; transcribed, not recomputed; generated by `figs/src/CCP-023_fig05.py`.

removes the ability to decline — at internal scope other people appear in F-08's echo sources and in F-05's cost ledger, and both are governed: **an echo source may decline and is recorded as missing data, never as a null return; and a cost carried by someone else is counted in their ledger, by asking, with a decline path.**

23.11.8 11.8 The nine entries

23.11.9 F-01 · THE MOMENT

STATEMENT

```
M = ( D / P ) . E

D  perspective   the frame brought to the encounter
P  perception    the intake taken from the encounter
E  environment   what is there
M  the moment    experience as constructed

r = D/P must be dimensionless, so D and P must share units.
M then inherits E's units.
Normalized form for use downstream:  M_norm in [0, ln N]
```

READS. *The moment is the environment, scaled by how far your frame outruns or falls short of your intake.*

STATUS. The author's formula (Curzi), analysed in full in [Curzi, 2026m]. Not a theorem of the framework's mathematical papers; it is the object Series B of the corpus is built to make measurable.

DERIVATION. `M` is not derived from the surplus law — it is the corpus's second formal object, joined to the first through the storage law (F-04), where `M` supplies the input `S_t`: *perception and perception produce the moment; the moment becomes character* [Curzi, 2026o]. The ceiling `M <= ln N` is not assumed but forced, once `M` is used as `S_t`, by `0 <= S_t <= ln N` (the surplus range result [Curzi, 2026]).

FVP

Gate	Verdict	Content
FVP-1 DIMENSIONS	PASS	`D` and `P` in shared units (whatever the estimation procedure supplies); `r` dimensionless; `M` in `E`'s units. For downstream use, `M` is normalized into nats on `[0, ln N]`, and the normalization must be stated.
FVP-2 SCALE TYPE	**DEMOTE — the crux** (Standing Verdict 1)	Division requires ratio scale with a true zero for `D` and `P`, on a **common** scale. No such instrument yet exists, so **the magnitude of `D/P` and every quantity derived from it are withdrawn as measured quantities ([Curzi, 2026t], [Curzi, 2026t]).** `M = (D/P)E` reads as the ordering *over-framed / calibrated / under-framed*, plus its limits and fixed point — all of which need only ordinal information and none of which is affected. **Route out: [Curzi, 2026t] Thm 54.3**, Rasch logit difference given badged Postulate SO1, at ~123 items per term for half a logit.
FVP-3 LIMITING CASES	PASS	`P -> 0`: `M -> inf` — frame with no intake: hallucination, dogma, apophenia. `D -> 0`: `M -> 0` — intake with no frame; **sensation is not experience**. `E -> 0`: `M -> 0` — no environment, no moment. Each divergence names a real phenomenon, which is what the gate demands.

Gate	Verdict	Content
FVP-4 FIXED POINTS	PASS	`D = P` gives `M = E`: **undistorted contact.** The formula's most important content — when frame matches intake, the moment equals the environment.
FVP-5 IDENTIFIABILITY	**PARTIAL**	`M` and `r` are recoverable. `D` and `P` **individually are not identified from `M` alone** — any pair with the same ratio and the same product-with-`E` predicts identically. Recovering them separately requires manipulating one while holding the other: change the frame with the environment fixed, or change the environment with the frame fixed.
FVP-6 FALSIFICATION	SPECIFIED	The preregistration protocol [Curzi, 2026i]. Preregister the estimation procedure for `D`, `P`, `E`. Fit on a training block, freeze, predict held-out `M`. Beat persistence, direct-input (`E` alone), matched AR(1), and the shuffled-input control. **Killed if `E` alone predicts `M` as well as `(D/P)E` does** — that outcome says the frame ratio carries nothing.
FVP-7 REPRODUCIBILITY	**UNTESTED — declared**	Cross-individual recovery of `D`, `P`, `E` under a common operationalization has not been run. [Curzi, 2026t]'s Rasch approach — separating person parameters from item parameters — is the route, and until it exists `M` is a within-person quantity.

PROTOCOL

1. Fix a **modulus**: assign a magnitude (commonly 50) to one reference encounter and hold it for the whole block.
2. **Before** the encounter, estimate `D`: how much structure you are bringing — expectation, model, prior commitment — against the modulus.
3. **During or immediately after**, estimate `P`: how much you actually took in.
4. Estimate `E` separately, ideally from a source that is not you (F-08's independent sources serve).
5. Compute `r = D/P` and `M = rE`.
6. Normalize: `M_norm = ln N * (M − M_min)/(M_max − M_min)` with the range stated in advance.

WORKED NUMBER

D	P	E	r	M	|ln r|	reading
50	50	60	1.000	60.000	0.0000	calibrated contact, `M = E`
75	50	60	1.500	90.000	0.4055	over-framed by half
30	50	60	0.600	36.000	0.5108	under-framed
50	10	60	5.000	300.000	1.6094	intake collapsing; the `P -> 0` limb
50	100	60	0.500	30.000	0.6931	flooding; twice the intake the frame can use

Normalization example: `M = 90` on a declared range `[0, 120]` with `N = 7` gives `M_norm = 1.9459 * 90/120 = 1.4594` nats — 75% of the ceiling.

FAULTS

Fault	Signature	Fix
Ordinal division	`M` computed from star ratings	FVP-2. Demote to the three-way ordering; the numbers already computed are void
Circular `E`	`E` estimated from the same impression that produced `P`	Get `E` from an independent source; otherwise `r` is structurally 1 by construction
Drifting modulus	`M` trends across a block for no reason anyone can name	Freeze the modulus (Protocol step 1) and re-baseline blocks separately
Ceiling violation	`M_norm > ln N`	The normalization range was wrong, or `N` was overstated. Recheck F-03 first

CROSS-REFERENCES. [Curzi, 2026m] (full treatment), [Curzi, 2026t] (FVP-2), F-02 (the ratio), F-04 (where `M` goes), F-06 (what `M` funds).

23.11.10 F-02 · THE CALIBRATION RATIO

STATEMENT

```
r = D / P                          the calibration ratio, dimensionless

Delta = | ln r |                   the distortion, in nats

r > 1   OVER-FRAMED    moment exceeds environment  -> projection, seeing the expected
r = 1   CALIBRATED     moment equals environment   -> contact
r < 1   UNDER-FRAMED   moment falls short          -> flooding, cannot make it mean
```

READS. *How far your frame outruns your intake, measured as a log-ratio so it composes with everything else.*

STATUS. Immediate consequence of F-01; the distortion measure is the calibration ratio's [Curzi, 2026m].

DERIVATION. `r` is the coefficient in `M = rE`. `Delta = |ln r|` is a log-ratio for the same three reasons `Delta_R` is (Sections 3–6, §3.3): ratios compose multiplicatively, the measure must be invariant to the modulus, and the reading instrument is logarithmic. **`Delta` and `Delta_R` are the same kind of object measured at two places in the circuit — one on the frame, one on the world's answer — and that is why they are directly comparable.**

Independent convergence, stated carefully: predictive-processing accounts model perception as precision-weighting of top-down priors against bottom-up evidence, and **the ratio of prior precision to sensory precision is structurally the same object as `D/P`.** That is a correspondence between formalisms, not an identity claim — predictive processing is an active and contested research program, and structural similarity is not identity.

FVP

Gate	Verdict	Content
FVP-1 DIMENSIONS	PASS	`r` dimensionless by construction (FVP-1 of F-01 supplies the shared units). `Delta` in nats.
FVP-2 SCALE TYPE	**DEMOTE** (Standing Verdict 1)	Inherits F-01's verdict exactly. **`Delta = |ln r|` is an ordinal quantity pending instrumentation: its sign is a finding, its rank order is a finding, its magnitude is not.** The nats, bits and cents printed below are illustrative constructions showing how the measure would read, not measurements of a person. Ratio scale is restored by [Curzi, 2026t] Thm 54.3 and by nothing cheaper.
FVP-3 LIMITING CASES	PASS	`r -> inf` (`P -> 0`): total frame dominance. `r -> 0` (`D -> 0`): no frame; `Delta -> inf` in both, correctly, since neither limb has a finite worst case.
FVP-4 FIXED POINTS	PASS	`r = 1`, `Delta = 0`: veridical perception stated as an equation. Under a correction rule `ln r_{t+1} = (1−lambda) ln r_t` (the F-08 dynamics applied to the frame) this fixed point is attracting for `0 < lambda < 2`.
FVP-5 IDENTIFIABILITY	PASS **for `r`**	`r` is identified from `M/E` without separating `D` and `P` — a strictly better position than F-01, and the reason this entry is often more useful than its parent.

Gate	Verdict	Content
FVP-6 FALSIFICATION	SPECIFIED	Predict `M` from `E` and a frozen `r` estimated on a training block; beat the four baselines. **Killed if `r` estimated on block one does not improve prediction on block two over using `r = 1`.**
FVP-7 REPRODUCIBILITY	**UNTESTED — declared**	Do two investigators recover the same `r` for the same person? Unknown.

PROTOCOL

1. Over `n >= 8` encounters, record a predicted magnitude and a realized magnitude on a fixed modulus (this is F-01's protocol run in prediction mode).
2. Compute `ln r_i` for each; take the mean and standard deviation.
3. `r_hat = exp(mean ln r)`. Report the interval, not the point.
4. Compare `Delta = |mean ln r|` against your deadband from F-08 (`ln(1+c)`); a distortion below the deadband is not resolvable.

WORKED NUMBER

Eight illustrative trials — predicted magnitude against realized magnitude on a fixed modulus:

```
predicted: 70  65  80  75  85  60  90  72
realized : 52  50  58  61  60  49  62  55

mean ln r = 0.2851        sd = 0.0620        SE = 0.0219
r_hat     = 1.3299
95% CI on ln r = [0.2421, 0.3280]  ->  r in [1.274, 1.388]
```

A stable over-frame of about 1.33 with a tight interval that excludes 1 decisively. In the conversion registers: `Delta = 0.2851` nats = 0.4114 bits = 987 cents — a shade under a minor seventh of distortion, and the four-register reading is not decoration; it is a check that the number is in a plausible range for a perceptual quantity.

Reference table:

`r`	`|ln r|`	bits	cents	state
0.50	0.6931	1.0000	2400.0	under-framed
1.00	0.0000	0.0000	0.0	**calibrated**
1.25	0.2231	0.3219	772.6	over-framed
1.50	0.4055	0.5850	1403.9	over-framed
2.00	0.6931	1.0000	2400.0	over-framed

Note the symmetry the log gives you for free: `r = 0.5` and `r = 2` are equally distorted. **Under-framing by half and over-framing by double are the same size of error, and only the log-ratio says so.**

FAULTS

Fault	Signature	Fix
Correcting a distortion below the deadband	Effortful frame-work producing no change	Compare `Delta` to `ln(1+c)`. If below, the instrument cannot resolve it; the work is unmeasurable by construction
Direction confusion	Treating flooding as over-framing	`r < 1` is under-framed — too much intake for the frame. The correction is more frame, not less
Single-encounter diagnosis	`r` estimated from one memorable event	`n >= 8` and report the interval (Protocol 3)
Global `r`	One `r` claimed for a whole person	`r` is domain-specific. A person may be over-framed at work and under-framed at home; a pooled `r` averages them into a fiction

CROSS-REFERENCES. [Curzi, 2026m] (full treatment), the group-scope treatment of the same ratio (doctrine-to-data), F-01, F-08.

23.11.11 F-03 · THE INTERNAL SURPLUS

STATEMENT

```
F_int = ln( 1 + (N−1) u )  =  ln N_eff

N       distinguishable categories held by ONE mind
u       non−parallelism between one's OWN framings, in [0,1]
N_eff   = 1 + (N−1)u, the audited count of genuinely different views
F_int   internal surplus, in nats,  0 <= F_int <= ln N
```

READS. *How many genuinely different views you hold, logged — the many windows of the one tower, counted after the audit for redundancy.*

STATUS. Theorem. The surplus functional [Curzi, 2026], applied within a single observer. Not an analogy: the axioms S1–S4 make no reference to the states belonging to different people.

DERIVATION. `f(u) = ln(1 + (N−1)u)` is uniquely characterized by S1 (geometric dependence), S2 (`f(0) = 0`), S3 (affine effective count), S4 (`f(1) = ln N`). **S3 is the design axiom — it is chosen, not derived, and that must be said wherever the law is leaned on.** The third node of the foundations series HORIZON — three futures cut from three non-parallel glasses — is this theorem applied within one observer, which makes it a derivation rather than an analogy.

FVP

Gate	Verdict	Content
FVP-1 DIMENSIONS	PASS	`N` a count; `u` dimensionless in `[0,1]`; `N_eff` a count; `F_int` in nats.

Gate	Verdict	Content
FVP-2 SCALE TYPE	PASS **for `u`**	`u = 1 − (x.y)^2` is computed from normalized state vectors and is ratio-scale with a true zero (parallel). The **operationalization** of the framings as vectors is where scale trouble enters, and [Curzi, 2026o]'s protocol is the route.
FVP-3 LIMITING CASES	PASS	`u → 0`: `N_eff → 1`, `F_int → 0` — **all your framings are one framing, counted `N` times, at `N` times the cost.** `u → 1`: `N_eff → N`, `F_int → ln N` — orthogonality, the ceiling. `N → 1`: `F_int = 0` for all `u`; one category has nothing to be non-parallel to.
FVP-4 FIXED POINTS	PASS	Extremality [Curzi, 2026]: `F = 0` iff parallel, `F = ln N` iff orthogonal. Both are attained, both are meaningful, and the lower one is the collapse the corpus spends [Curzi, 2026d,h] preventing.
FVP-5 IDENTIFIABILITY	**PARTIAL**	`F_int` is identified given `N` and `u`. `N` and `u` **trade off**: a small `N` at high `u` and a large `N` at low `u` produce identical `F_int`. Separating them requires counting the categories independently of measuring their overlap.
FVP-6 FALSIFICATION	SPECIFIED	The surplus functional [Curzi, 2026] is pure mathematics and makes no empirical claim; what is falsifiable is the **operationalization**. Preregister the framing-elicitation procedure, fit, freeze, and test whether measured `u` predicts held-out performance on a task requiring multiple framings, against the four baselines including shuffled-input.

FVP-7 REPRODUCIBILITY	**UNTESTED — declared**	Do two investigators eliciting one person's framings recover the same `u`? This is exactly the specific-objectivity question of [Curzi, 2026t] and it is open.

PROTOCOL

1. Elicit framings **independently and in writing before any are compared** — the personal-scope form of the silent-write-first rule, which prevents the framings from converging during elicitation.
2. Count them: that is `N`, and it is an upper bound, not a measurement.
3. Estimate pairwise overlap; `u` is one minus the squared cosine, averaged or taken pairwise per [Curzi, 2026o].
4. Compute `N_eff` and `F_int`. **Report `N_eff`, never `N`, when describing how many views you hold.**

WORKED NUMBER

`N = 7` framings, `ln N = 1.9459` nats:

u	N_eff	F_int	% of ceiling	marginal dF/du
0.00	1.000	0.0000	0.0%	6.0000
0.10	1.600	0.4700	24.2%	3.7500
0.30	2.800	1.0296	52.9%	2.1429
0.45	3.700	1.3083	67.2%	1.6216
0.60	4.600	1.5261	78.4%	1.3043
1.00	7.000	1.9459	100.0%	0.8571

The marginal value of the `k`-th genuinely orthogonal framing is `ln k − ln(k−1)`:

```
k=2  0.6931 nats (1.0000 bits)     k=7   0.1542 (0.2224)
k=3  0.4055        (0.5850)        k=8   0.1335 (0.1926)
k=4  0.2877        (0.4150)        k=9   0.1178 (0.1699)
k=5  0.2231        (0.3219)        k=10  0.1054 (0.1520)
k=6  0.1823        (0.2630)        k=12  0.0870 (0.1255)
```

The second genuinely different framing is worth one full bit — the largest single gain you will ever buy. The twelfth is worth 0.126 bits, an eighth as much, and [Curzi, 2026o] calls the fortieth glazing bills. Both facts are the same logarithm, and neither is pessimism: concavity is the lens [Curzi, 2026n].

FAULTS

Fault	Signature	Fix
Counting `N` instead of `N_eff`	"I look at this from six angles"	Measure `u`. Six angles at `u = 0.10` is `N_eff = 1.5`
Pseudo-diversity	Framings differ in vocabulary, agree in prediction	Run the collision test: do the framings ever disagree about an outcome? If not, `u ~ 0`

Fault	Signature	Fix
The N/u trade	Claiming a high F_int without stating which term produced it	FVP-5. Report both, always
Ceiling denial	Effort spent raising u when u is already 0.9	At u = 0.9, F_int is 95.4% of ceiling; the remaining move is to raise N ([Curzi, 2026c])

CROSS-REFERENCES. [Curzi, 2026o] (full treatment), [Curzi, 2026c], [Curzi, 2026c], [Curzi, 2026d], [Curzi, 2026h]; F-01 (ln N bounds M), F-05 (h is eta times the unclaimed part of this).

23.11.12 F-04 · THE SELF-STORAGE LAW

STATEMENT

```
Q_{t+1} = (1 − delta) Q_t + eta ∗ M_t − C_t

Q_t     stored order: character, skill, memory, internalized structure  [Q-units]
M_t     the moment as lived, normalized to [0, ln N]                    [nats]
delta   retention loss per period, in [0,1]                             [1/period]
eta     conversion of experience into durable structure, >= 0           [Q-units/nat]
C_t     cognitive load, effort, maintenance of self, >= 0               [Q-units/period]

Admissibility:      C_t <= (1−delta) Q_t + eta M_t   guarantees Q_{t+1} >= 0
One−step growth:    Q_{t+1} > Q_t  <=>  eta M_t > delta Q_t + C_t
```

READS. *Character is what is left of every moment you have had, after the leak, the conversion loss, and the cost of maintaining yourself.*

STATUS. Theorem. The storage law [Curzi, 2026a], in the internal-scope form the correspondence specifies [Curzi, 2026o]. **The join between the two formulas: the Moment feeds the storage law as its input.**

DERIVATION. Direct substitution of M_t for S_t, licensed by the register convergence's forced consequence that M is bounded by ln N and so shares S_t's range. **The scale-free claim — that a mind and a city run the same equation with different parameters — is a claim about MODEL FORM, badged as such under the corpus's badging convention [Curzi, 2026].**

FVP

Gate	Verdict	Content
FVP-1 DIMENSIONS	PASS	Every term in Q-units per period once eta carries Q-units/nat. delta Q_t is Q-units/period. Both sides agree. **eta's units are the conversion key and stating them is what stops the equation from being a slogan.**

Gate	Verdict	Content
FVP-2 SCALE TYPE	**DEMOTE** (Standing Verdict 1)	`Q` must be at least interval-scale for the difference terms and ratio-scale for `Q_inf` percentages. **Badged: that `Q` is a scalar at all — rather than a vector of incommensurable stores — is a postulate of the corpus (Appendix E), not a finding.** And the input term inherits F-01's demotion: **the `M -> Q` join is structural, not yet quantitative.** The recursion, the two-track ledger, the fixed point and the orderings stand; numbers obtained by feeding a measured `r` through `M` do not. Rasch calibration ([Curzi, 2026t] Thm 54.3, ~123 items per term) is the route to satisfying both.
FVP-3 LIMITING CASES	PASS	`delta -> 0`: no fixed point; `Q_t <= Q_0 + t eta ln N` (Thm 3.3) — the tradition that never forgets and never settles. `delta -> 1`: `Q_{t+1} = eta M_t - C_t`, total amnesia, the state is only the present. `eta -> 0`: `Q` decays to `-C/delta` — **rumination is recursion with `eta ~ 0`.** `C -> 0`: no maintenance cost, `Q_inf = eta M/delta`.
FVP-4 FIXED POINTS	PASS	`Q_inf = (eta M* - c*)/delta` (Thm 3.5). **If `eta M* < c*` the fixed point is negative and the regime is unsustainable or the linear model must be replaced. The theorem does not hide this and neither does this entry.**
FVP-5 IDENTIFIABILITY	**PARTIAL**	From `{Q_t}` alone, `delta` is identified from successive gaps and the composite `eta M* - c*` from `delta Q_inf`. **`eta`, `M*`, `c*` are not separately identified.** Measure two of the three independently (F-01 for `M`, [Curzi, 2026b]'s ledger for `C`) and recover the third.

Gate	Verdict	Content
FVP-6 FALSIFICATION	SPECIFIED	The preregistration protocol [Curzi, 2026i]. Preregister period, `Q` instrument, window. Fit `delta` and `eta` on training, **freeze**, forecast held-out `Q`. Beat persistence, direct-input, matched AR(1), shuffled-input control. **Killed if the frozen model does not beat the shuffled-input control**, since that control destroys exactly the accumulation the law claims.
FVP-7 REPRODUCIBILITY	**UNTESTED — declared**	Do `delta` and `eta` recover across people and across domains within a person? Unknown.

PROTOCOL

1. Declare the **period** and hold it.
2. Instrument `Q` — a calibrated measure of the stored capacity in question, not a mood rating.
3. Log `M_t` per F-01 and `C_t` per [Curzi, 2026b]'s cost ledger, in the same units.
4. Fit `delta` from the decay of `Q` across a deliberate zero-input window (a period with `M ~ 0`), which is the cleanest identification available: with `M = 0`, `Q_{t+1} = (1−delta)Q_t − C_t`.
5. Recover `eta` by residual, and **report it with the identifiability caveat attached**.
6. Check admissibility every period. A violated admissibility condition is a broken model, not a bad week.

WORKED NUMBER

Illustrative: `N = 7`, `u = 0.45` (so `M* = F_int = 1.3083`), `eta = 0.30`, `delta = 0.10`, `C = 0.25`, `Q_0 = 0.80`.

```
Q_inf = (0.30 * 1.3083 − 0.25) / 0.10 = 1.4250 Q−units
one−step growth test at Q = 1.5:  eta*M = 0.3925  vs  delta*Q + C = 0.4000  ->  NO GROWTH
sustainability ceiling at Q = 1.5 (Cor 3.4):  C <= eta lnN − delta Q = 0.4338
```

A ten-period trajectory with a varying moment, including two poor periods:

t	M_t	Q_t	step dQ
0	0.45	0.8000	-0.1950
1	1.10	0.6050	+0.0195
3	0.20	0.7771	-0.2677
4	1.60	0.5093	+0.1791
5	1.60	0.6884	+0.1612
6	1.60	0.8496	+0.1450
7	0.90	0.9946	-0.0795
9	1.60	1.0536	+0.1246
10	—	1.1783	—

One bad period at `t = 3` (`M = 0.20`) cost 0.2677 Q-units, which took the next two good periods to recover. That asymmetry is not psychological; it is `eta M − delta Q − C` evaluated at a low `M`, and it is why cadence beats intensity: the leak runs whether or not the input does.

FAULTS

Fault	Signature	Fix
`eta ~ 0` recursion (rumination)	High `M`, high effort, `Q` flat or falling	Nothing is converting to structure. Change the *form* of the practice (writing, artifact, place), which is what `eta` is
`delta ~ 0` fantasy	A plan in which nothing decays	Name the loss mechanism or the model does not apply (Sections 7–10, CS-3)
Negative fixed point run anyway	`eta M* < c*`, `Q` declining, practice continued	Compute `Q_inf` before starting. Cut `C`, raise `eta` or `u`, or stop
Mood as `Q`	`Q` instrument is a daily feeling rating	Mood is not stored order. `Q` is what remains when the mood has gone
Ignoring admissibility	Model produces `Q < 0` and is still trusted	A violated admissibility condition invalidates the step, not the week

CROSS-REFERENCES. [Curzi, 2026o] (full treatment), [Curzi, 2026a] (the leaky integrator), [Curzi, 2026a] (`delta`), [Curzi, 2026b] (`eta`), [Curzi, 2026b] (`C`); F-01 (the input), F-05, F-09.

23.11.13 F-05 · PERSONAL HEADROOM

STATEMENT

```
h_t = eta * ln N − delta * Q_t − C_t                [Q-units/period]

h_t < 0   unsustainable in this model. No geometry saves it.
h_t = 0   maintenance only. Hold, do not build.
h_t > 0   growth available; any requested increment r_t must satisfy r_t <= h_t.

At any fixed point:   h_inf = eta * ( ln N − F(u*) )     THE ARRIVAL INVARIANT
```

READS. *How much capacity for the new you have this period, if your geometry were perfect.*

STATUS. Theorem. the headroom identity [Curzi, 2026b,h] and Corollary 4.2, at internal scope. The arrival invariant is derived in Sections 7–10, §8.4.

DERIVATION. `h` is the growth condition `eta M_t > delta Q_t + C_t` evaluated at the **maximum possible** moment `M = ln N`. It is therefore the margin at perfect geometry. **Consequence that must travel with the entry: `h > 0` is necessary and not sufficient for growth, because the actual step uses `F(u*)`, not `ln N`.** The shortfall — call it the geometry gap — is `eta(ln N − M_t)`, and it is exactly the quantity the arrival invariant names.

THE CONCAVITY CORRECTION, and it applies to every feasibility check made with this entry. The protocol below asks whether a requested increment `r_t` fits inside `h_t`. That test is run against a surplus figure, and the surplus figure must be the **mean of `F(U_t)`, never `F` of the mean `U`.** What accumulates over periods is `sum of eta F(U_t)`, and because `F` is strictly concave [Curzi, 2026], Jensen's inequality gives

```
mean of F(U_t)  <=  F( mean of U_t )        with equality only if U is constant
```

A system whose geometry varies delivers strictly less surplus than one that sits at its own average every period, and testing feasibility on `F(mean U)` therefore approves increments that cannot be delivered. The gap is the concavity penalty. In the corpus's worked office case it is 0.0761 nats — mean `F` of 1.1501 against `F(mean U)` of 1.2262 — **a loss of 6.2 per cent of the surplus purely to variability**, and it was large enough there to turn a feasible-looking plan into a shortfall. Report `U_req` for legibility if you wish; do not test against it. Regularising a variable geometry recovers the penalty for free, which makes it the cheapest surplus available to most subjects.

FVP

Gate	Verdict	Content
FVP-1 DIMENSIONS	PASS	All three terms in Q-units/period. `eta ln N` is Q-units/nat times nats.
FVP-2 SCALE TYPE	**CONDITIONAL PASS**	Inherits F-04's requirement on `Q` and [Curzi, 2026b]'s requirement that `C` be commensurated into Q-units — **which is itself a postulate of the corpus, badged in Appendix E: that costs of different kinds can be put on one scale.**
FVP-3 LIMITING CASES	PASS	`Q -> 0`: `h -> eta ln N - C`, the maximum headroom a person can have. `Q -> (eta lnN - C)/delta`: `h -> 0`, the ceiling on stored order beyond which maintenance consumes everything. `C -> eta ln N`: `h <= 0` for any `Q > 0`.
FVP-4 FIXED POINTS	PASS	`h = 0` at `Q = (eta ln N - C)/delta` — the **maintenance ceiling**, distinct from and above `Q_inf`. And the arrival invariant: at `Q_inf`, `h = eta(ln N - F(u*))`, independent of `delta` and `C`.
FVP-5 IDENTIFIABILITY	**PARTIAL**	Inherits F-04's non-separation of `eta`, `M*`, `c*`. `h` itself is computable once `eta`, `N`, `delta`, `Q`, `C` are in hand; the burden is on `N` and on the commensuration of `C`.

Gate	Verdict	Content
FVP-6 FALSIFICATION	SPECIFIED	Preregister; predict whether a requested increment `r_t` is achieved, from `h_t` computed in advance. **Killed if achieved increments routinely exceed `h_t`** — that outcome would falsify Corollary 4.2's claim that no policy based on interaction geometry alone can guarantee more.
FVP-7 REPRODUCIBILITY	**UNTESTED — declared**	Cross-individual recovery unrun.

PROTOCOL

1. Obtain `N` (F-03), `eta` and `delta` (F-04), `Q_t` (F-04's instrument), `C_t` ([Curzi, 2026b]).
2. Compute `h_t` each period and plot it. **`h` is the gauge; `Q` is the tank.**
3. Before accepting any new commitment, express its expected increment `r_t` in Q-units and check `r_t <= h_t`.
4. At a settled state, compute `h_inf = eta(ln N − F(u*))` and account for the remainder.

WORKED NUMBER

`eta = 0.30`, `N = 7` (`ln N = 1.9459`), `delta = 0.10`, `C = 0.25`:

Q	h	verdict
0.00	0.3338	growth available
1.00	0.2338	growth available
2.00	0.1338	growth available
3.00	0.0338	growth available, barely
3.34	0.0000	**maintenance ceiling**
4.00	-0.0662	unsustainable

`h = 0` at `Q = (0.30 * 1.9459 − 0.25)/0.10 = 3.3377`. At the fixed point of the F-04 example (`u = 0.45`, `Q_inf = 1.4250`):

```
h_inf = eta ( ln N − F )  = 0.30 * (1.9459 − 1.3083) = 0.1913
check from the gauge      = 0.30*1.9459 − 0.10*1.4250 − 0.25 = 0.191273
```

Identical to six decimal places, and it does not contain `delta` or `C`. The reading: at arrival, this subject has 0.1913 Q-units per period of unclaimed capacity, and it is unclaimed for exactly one reason — their framings claim only 67.2% of the ceiling. **Large headroom at a settled state is not a reserve. It is a report that your framings are parallel.**

FAULTS

Fault	Signature	Fix
Headroom as reserve	`h > 0` read as "I have capacity to spare"	`h_inf = eta(ln N − F)`. Raise `u` or `N`; do not "spend the slack"

Fault	Signature	Fix
`h > 0` read as sufficient	Growth expected because `h > 0`, but `Q` falls	`h` is the margin at `M = ln N`. Actual growth needs `eta M_t > delta Q_t + C_t`
Feasibility tested on `F(mean U)`	A plan that clears the gate on paper and falls short every period	Test on **mean `F(U_t)`**. `F` is strictly concave, so `F` of the mean overstates; the gap was 6.2% in the corpus's worked office case
Uncommensurated `C`	Only monetary or only time costs counted	[Curzi, 2026b]'s five ledgers. An omitted cost inflates `h` and licenses a commitment that cannot be met
Negative `h` treated as motivational	"I need to push harder"	Cor 3.4: **no choice of interaction geometry prevents order from decreasing.** Cut `C`, shed `Q`, or raise `eta`

CROSS-REFERENCES. [Curzi, 2026b] (full treatment at external scope), [Curzi, 2026o], [Curzi, 2026b]; F-03, F-04, F-09.

23.11.14 F-06 · THE LAUNCH BUDGET

STATEMENT

```
L = max( 0, M − C )                    [nats, or Q-units once eta is applied]

L      the surplus available for imagining, planning, or attempting elsewhere
M      the moment as lived, in [0, ln N]
C      the cost of the period, commensurated into the same units

L = 0            no surplus to dream with
L_max = ln N − C the ceiling, when the moment is maximal
```

READS. *Escape is dreamt only out of surplus; when the moment costs everything it produces, there is nothing left to imagine elsewhere with.*

STATUS. Derived formula of the corpus [Curzi, 2026o], formalising the STILLPOINT node of the foundations series [Curzi, 2026] departure-lounge doctrine. Derived, with one badge.

DERIVATION. The storage law's one-step content is `eta M_t − C_t`: what a period contributes before the leak takes its share. `L` is that quantity's positive part, before conversion — the *unallocated* portion of a moment, the part not consumed by the cost of having it.

Postulate L1 (the launch condition). Imaginative and exploratory activity draws on the same budget as maintenance, and draws second. **Badged: an assumption about the ordering of claims on a period's surplus, not a result.** It is what makes `L` a max-with-zero rather than a quantity that can go negative and be carried, and it is consistent with the departure-lounge doctrine — *in those minutes there was no surplus to dream with* is `L = 0` — but the ordering is unmeasured.

FVP

Gate	Verdict	Content
FVP-1 DIMENSIONS	PASS	`M` in nats; `C` must be converted into nats (divide the Q-unit cost by `eta`) or `M` converted into Q-units (multiply by `eta`). **The conversion must be stated; mixing the two is the commonest arithmetic error in this entry.**
FVP-2 SCALE TYPE	**DEMOTE** (Standing Verdict 1)	Subtraction needs interval scale on a common unit; the commensuration of `C` is again a badged postulate (Appendix E). **`M` additionally inherits F-01's demotion, so `L` is reportable as a threshold condition — is the moment above the cost line or not — and not as a magnitude.** The sign of `M - C` is the finding; its size is not, until [Curzi, 2026t] Thm 54.3's instrument exists.
FVP-3 LIMITING CASES	PASS	`M <= C`: `L = 0` — the departure lounge with nothing to depart with. `M -> ln N`: `L -> ln N - C`, the ceiling. `C -> 0`: `L -> M`; the whole moment is available. `C -> ln N`: `L = 0` for every possible moment — **a cost equal to the ceiling makes the person structurally incapable of imagining elsewhere, whatever they experience.**
FVP-4 FIXED POINTS	PASS	The boundary `M = C` is the **no-launch surface**. `L` is continuous but **not differentiable** there — a genuine kink, and the non-smoothness is the phenomenon: the transition from "some budget" to "none" is abrupt, not gradual, which is why people describe it as a wall rather than a slope.
FVP-5 IDENTIFIABILITY	**PARTIAL**	`L` is identified from the difference; `M` and `C` separately are not, if only their difference is observed. Since the intervention differs completely (raise `M` vs cut `C`), **the separation is required before acting, not before measuring.**

Gate	Verdict	Content
FVP-6 FALSIFICATION	SPECIFIED	Preregister `M` and `C` measurement; predict, from a frozen model, which periods produce exploratory output (plans, applications, drafts, attempts). Beat the four baselines. **Killed if exploratory output is uncorrelated with `L` after controlling for `M` alone** — that would say the cost side carries nothing and the doctrine is wrong.
FVP-7 REPRODUCIBILITY	**UNTESTED — declared**	Unrun.

PROTOCOL

1. Measure `M_t` per F-01, normalized to `[0, ln N]`.
2. Measure `C_t` per [Curzi, 2026b]'s ledger and convert to nats by dividing by `eta`.
3. `L_t = max(0, M_t − C_t)`. Log it every period.
4. Report **the count of `L = 0` periods**, not just the mean. The zeros are the finding.

WORKED NUMBER

`M`	`C`	`L`	state
0.20	0.60	0.000	no surplus to dream with
0.45	0.45	0.000	exactly at the surface
0.60	0.45	0.150	launch available
1.90	0.45	1.450	launch available
1.90	1.95	0.000	high moment, higher cost — **the busy trap**

The last row is the entry's most important case. **A person can have an extremely rich moment and zero launch budget, and from the outside they look like someone who has everything and does nothing with it.** The arithmetic says the opposite: they have nothing left, because `C` exceeded `M`.

Over the F-04 example's ten periods with `C = 0.25`:

```
sum L = 9.75      mean L = 0.975      periods with L = 0: 1
L_max = ln N − C  = 1.9459 − 0.25 = 1.6959
```

FAULTS

Fault	Signature	Fix
Order-of-operations reversal	"Get out of your comfort zone" prescribed to someone at `L = 0`	The dream is manufactured *from* surplus. Raise `M` or cut `C` first; the exhortation has no budget to act on ([Curzi, 2026p])
The busy trap	High `M`, high `C`, `L = 0`, and self-blame for lack of ambition	Cut `C`. The moment is fine; the ledger is not

Fault	Signature	Fix
Unit mixing	`M` in nats minus `C` in Q-units	Convert. Divide the Q-unit cost by `eta`
Mean without zeros	Reporting mean `L` across a block containing many zeros	Report the zero count. A mean of 0.5 from alternating 1.0 and 0.0 is a different life from a steady 0.5

CROSS-REFERENCES. [Curzi, 2026p] (full treatment), [Curzi, 2026b], [Curzi, 2026p]; F-01, F-05.

23.11.15 F-07 · THE GRADIENT

STATEMENT

```
g = − grad C                          the desire line, a vector field

C(x)   the local cost of being at / doing configuration x  [Q-units/period]
x      a configuration coordinate: actions-to-begin, distance, latency, friction
g      points in the direction of cheapest motion

Observable proxy, under Postulate G1:
    n(x) ~ exp( −C(x) / theta )   ->   ln n(x) = const − C(x)/theta
    fitted slope b = −(1/theta) dC/dx
```

READS. *Water does not negotiate; read the worn path rather than arguing with it.*

STATUS. Derived formula of the corpus — the GRADIENT node [Curzi, 2026] formalised. Derived, with one badge.

DERIVATION. The storage law's cost term `C_t` is a scalar per period, but the cost of a period depends on what was done in it; treat `C` as a function over a configuration space and the direction of cheapest motion is `−grad C`. That much is definitional. **The empirical content requires a link between cost and behaviour, and that link is a postulate:**

Postulate G1 (the choice rule). The frequency with which a configuration is entered is log-linear in its local cost: `n(x) ~ exp(−C(x)/theta)`, `theta > 0` a choice temperature. **Badged: the standard log-linear choice form, adopted as a modelling assumption — not a result of this corpus and not a claim about any measured population.** It puts behaviour in the same logarithmic register as everything else in the book, at the price of a free `theta` (see FVP-5).

FVP

Gate	Verdict	Content
FVP-1 DIMENSIONS	PASS	`C` in Q-units/period; `x` in whatever the coordinate is (actions, metres, seconds); `grad C` in Q-units per period per unit of `x`. Under G1 the fitted `b` is in `(1/theta)` times those units — **so the fitted slope is a gradient in units of the choice temperature, not in Q-units.**
FVP-2 SCALE TYPE	**CONDITIONAL PASS**	`C` must be ratio-scale ([Curzi, 2026b]). `x` must be at least interval-scale; counts of actions are ratio-scale and are therefore the preferred coordinate. `n` is a count — ratio-scale — which is what makes the log-linear fit legitimate.
FVP-3 LIMITING CASES	PASS	`grad C -> 0`: no desire line; motion is undirected — the flat the foundations series calls the stillpoint [Curzi, 2026]. `|grad C| -> inf`: an infinitely steep wall; the configuration is never entered. `theta -> 0`: choice becomes deterministic, always the cheapest option. `theta -> inf`: choice becomes uniform, cost carries nothing.
FVP-4 FIXED POINTS	PASS	`grad C = 0` at local minima: **the comfort zone, defined without sentiment as a stationary point of the cost field.** The STILLPOINT node of the foundations series [Curzi, 2026] — *you are already there* — is the statement that the present configuration is at or near such a point by construction.

Gate	Verdict	Content
FVP-5 IDENTIFIABILITY	**PARTIAL — and instructively so**	From behaviour alone, only `C/theta` is identified, never `C` and `theta` separately. **But the *gradient* is better identified than the *level*: adding any constant to `C` changes no behaviour and no fitted slope.** So this entry can report reliable differences and cannot report absolute costs. Say so whenever a fitted `b` is quoted.
FVP-6 FALSIFICATION	SPECIFIED	Preregister the coordinate and the count window. Fit `b` on a training block, **freeze**, then **intervene**: remove `k` actions from one configuration and predict the new count as `n * exp(-b k)`. Beat persistence, direct-input, matched AR(1), shuffled-input. **Killed if the predicted response to a manipulated coordinate is not observed** — this is the one entry in the formulary with a cheap, direct, interventional test, and it should be run first.
FVP-7 REPRODUCIBILITY	**UNTESTED — declared**	Does `b` recover across people and across domains? Unknown.

PROTOCOL

1. Choose a coordinate that is a **count**: number of discrete actions required to begin.
2. For `>= 5` activities, record the action count `k_i` and the initiation count `n_i` over a fixed window.
3. Fit `ln n = a + b k` by least squares. Report `b`, `R^2`, and the fitted values.
4. Compute the **halving distance**: `ln(0.5)/b` actions — the number of added actions that halves initiation.
5. **Intervene and re-measure.** Step 5 is not optional; it is FVP-6.

WORKED NUMBER

Illustrative log over one week — six activities, actions-to-begin against initiation count:

actions `k`	observed `n`	fitted `n`
1	26	25.05
2	17	16.62
3	11	11.03
6	3	3.22
9	1	0.94

```
fit:  ln n = 3.6308 - 0.4100 k        R^2 = 0.9982
gradient magnitude |b| = 0.4100 nats of initiation per added action
halving distance = ln(0.5)/(-0.4100) = 1.69 actions
removing 2 actions multiplies initiation by exp(2*0.4100) = 2.271
```

Every 1.69 actions added to the front of a practice halves how often it happens. That is the whole of the GRADIENT node [Curzi, 2026] in one number, and it is the number that makes threshold design an engineering discipline rather than an aesthetic one.

The honest caveat, from FVP-5: **0.4100 is a gradient in units of the choice temperature, and the absolute cost of an action is not recoverable from this fit.** What is recoverable — and what the intervention test checks — is that removing two actions should multiply initiation by about 2.27.

FAULTS

Fault	Signature	Fix
Arguing with the gradient	Exhortation applied to a configuration nobody enters	Regrade. Remove actions. The path is data, not an opinion to be corrected
Level claims from slope data	“This costs me 0.41 Q-units”	FVP-5. Only differences are identified. Report ratios of frequencies, never absolute costs
Ordinal coordinate	x is “difficulty, 1-5”	Use a count. Actions, seconds, metres
No intervention	Fit reported, never tested	FVP-6. The manipulation is cheap and it is the only real test this entry has
Confounded coordinate	High-k activities also happen to be the disliked ones	Manipulate k on **one** activity and hold the activity fixed; that is what makes it an experiment

CROSS-REFERENCES. Curzi [2026p] (full treatment); the corpus’s threshold and intervention material; F-05, F-06.

23.11.16 F-08 · THE RETURN DIFFERENCE

STATEMENT

```
rho_t     = ln( M'_t / M_t )              signed return, in nats

correction:   rho_{t+1} = (1 - lambda) rho_t  lambda = correction gain
stability:    convergent iff 0 < lambda < 2
```

READS. *The world's answer is never the voice you sent, and the difference is the only data in the exchange.*

STATUS. Derived formula of the corpus [Curzi, 2026o], the ECHO node of the foundations series [Curzi, 2026]. Derived, with one badge (Postulate R1, the returnable moment — Sections 3–6, §3.2).

DERIVATION. Sections 3–6 in full. In one line: the corpus works in log-ratios everywhere, so the only difference measure that composes with the rest of the formulary is the log-ratio, and it is forced rather than chosen.

FVP

Gate	Verdict	Content
FVP-1 DIMENSIONS	PASS	`M'/M` dimensionless; `rho` in nats, convertible by the §11.4 keys.
FVP-2 SCALE TYPE	**DEMOTE — binding** (Standing Verdict 1)	Ratio scale with a true zero, or the entry reads as a **sign-only ordering**. `M` and `M'` are moments and inherit F-01's demotion, so **that is where the entry stands today: over-return, null return and under-return are findings; the number of nats is not.** A `rho` computed from Likert data was always void rather than imprecise; a `rho` computed from an uncalibrated magnitude estimate is merely unreportable. [Curzi, 2026t] Thm 54.3 supplies the missing scale, at ~123 items per term for half a logit.
FVP-3 LIMITING CASES	PASS	`M' -> M`: `rho -> 0`, no information (contact or closure). `M' -> 0`: `rho -> -inf`, total non-return — being ignored, and the divergence is correct because there is no finite penalty scale for it. `M -> 0`: undefined, correctly — an echo of nothing is not an echo.
FVP-4 FIXED POINTS	PASS	`rho = 0`, unique and attracting under the correction map for `0 < lambda < 2`. Meaning: agreement between your construction and the world's answer — **which is either contact or closure, and only the scatter test distinguishes them.**

Gate	Verdict	Content
FVP-5 IDENTIFIABILITY	**PARTIAL**	`rho` recoverable from paired estimates. The **decomposition** into frame error and world response is **not identified from `rho` alone**; separating them requires an independent estimate of `M'` or a deliberate manipulation of `D`.
FVP-6 FALSIFICATION	SPECIFIED	Fit `lambda` on training, freeze, predict held-out `rho`. Beat persistence, direct-input, matched AR(1), and the **shuffled-input control** (same `M` series, permuted `M'`). Killed by failure against the shuffled control.
FVP-7 REPRODUCIBILITY	**UNTESTED — declared**	Do `lambda` values recover across people? Unknown; Sections 3–6 §4.11 states the design.

PROTOCOL

1. Fix the modulus; record `M` **before** the return arrives (the single most violated rule).
2. Record `M'` from `>= 2` sources asked **independently**, timestamped to the exchange they answer, not to their arrival.
3. Estimate `sigma_rho` from `>= 8` equivalent exchanges before interpreting anything.
4. Declare the deadband `ln(1+c)` and refuse to read below it.
5. Compute `rho`, `Delta_R`, and per block: `R_net = sum rho`, `R_gross = sum |rho|`, `E_R = |R_net| / R_gross`.
6. After four consecutive returns inside the deadband, run the flattery test.
7. **An echo source may decline; a decline is missing data, never a null return.**

WORKED NUMBER

M	M'	ratio	rho	Delta_R	bits
60	60	1.0000	0.0000	0.0000	0.0000
60	63	1.0500	+0.0488	0.0488	0.0704
60	45	0.7500	-0.2877	0.2877	0.4150
60	90	1.5000	+0.4055	0.4055	0.5850
60	20	0.3333	-1.0986	1.0986	1.5850

Deadband, at three Weber fractions: `c = 0.05 -> 0.0488` nats; `c = 0.10 -> 0.0953`; `c = 0.20 -> 0.1823`. **An subject with `c = 0.20` cannot distinguish the second row of that table from silence.**

Detection cost, `n >= (1.96 sigma/Delta)^2`: at `sigma_rho = 0.30`, resolving a `Delta_R` of 0.05 takes **139 echoes**; resolving 0.20 takes **9**.

FAULTS

Fault	Signature	Fix
Zero read as success	`Delta_R ~ 0` celebrated	Run the scatter test. Converged contact varies; closure does not
The flattering mirror	Four-plus returns inside the deadband, no sign changes, all sources agree	Add a genuinely independent source; compute `n_eff`
The devouring echo	`|rho|` growing, signs alternating with rising amplitude	`lambda >= 2`. Reduce below 1 and hold
Post-hoc `M`	`rho` implausibly near zero across a whole log	Record `M` before the return. Compare a pre-recorded block against a reconstructed one
Worth conversion	Negative `rho` narrated as a statement about the self	FVP-5: the decomposition is not identified. The instrument does not license the claim
Correcting faster than the echo returns	Oscillation appearing only when cadence increased	Correction cadence <= echo cadence

23.11.17 F-09 · THE CONTRACTION AND ARRIVAL

STATEMENT

```
| Q_t − Q_inf | = (1 − delta)^t | Q_0 − Q_inf |          THE ERROR LAW

Q_t = Q_inf + (1 − delta)^t ( Q_0 − Q_inf )             the whole trajectory

Q_inf = ( eta ∗ M∗ − c∗ ) / delta                       the steady−state theorem
tau   = −1 / ln(1 − delta)                             periods per factor of e
t(eps) = ln(eps) / ln(1 − delta)                       periods to close to a fraction eps

a−posteriori distance:  | Q_t − Q_inf | = ((1−delta)/delta) ∗ (last step into Q_t)
```

READS. *Where you are is where you are going, plus what is left of where you started — and what is left of where you started is halving on a fixed schedule.*

STATUS. Theorem. the steady-state theorem [Curzi, 2026a] plus the error law derived from Theorem 3.1; Banach's fixed point theorem supplies existence, uniqueness, and robustness. **The FIXEDPOINT node [Curzi, 2026] FIXEDPOINT is Theorem 3.5, and Sections 7–10 proves the correspondence rather than asserting it.**

DERIVATION. Sections 7–10, §7.2–§7.5. `T(Q) = (1−delta)Q + b` is a contraction on the complete space `(R, |.|)` with constant exactly `1−delta` whenever `delta > 0`; Banach gives the unique fixed point, and subtracting the fixed-point equation from the update gives the error law by induction. **The leak is what makes arrival possible: at `delta = 0` the map is an isometry, there is no fixed point, and `Q_t = Q_0 + tb` grows without bound.**

FVP

Gate	Verdict	Content
FVP-1 DIMENSIONS	PASS	`Q` in Q-units; `(1-delta)^t` dimensionless; `tau` in periods. **The period must be declared or none of it means anything.**
FVP-2 SCALE TYPE	**CONDITIONAL PASS**	Interval scale for the differences, ratio scale for percentage readings. Inherits F-04's badged postulate that `Q` is a scalar.
FVP-3 LIMITING CASES	PASS	`t -> inf`: gap `-> 0`. `delta -> 0+`: no convergence, `Q_inf -> inf` unless `b = 0` — the system that never forgets and never settles. `delta -> 1`: arrival in one step; the state is only the present drive. `Q_0 = Q_inf`: gap zero for all `t` — you were already there.
FVP-4 FIXED POINTS	PASS	`Q_inf = (eta M* - c*)/delta`, unique by Banach, **containing no `Q_0`** — which is why arrival is recognition rather than victory. The error map `e -> (1-delta)e` has the unique fixed point `e = 0`.
FVP-5 IDENTIFIABILITY	**PARTIAL**	`delta` identified from successive gaps; the composite `eta M* - c*` from `delta Q_inf`; the three components **not separately identified** without independent measurement of two of them.
FVP-6 FALSIFICATION	SPECIFIED	Fit `delta` on training, freeze, forecast held-out `Q`. Beat persistence, direct-input, matched AR(1), shuffled-input. **Killed if the frozen geometric-decay model does not beat the shuffled-input control**, since that control destroys the ordering of inputs, which is the entire content of "it accumulates".
FVP-7 REPRODUCIBILITY	**UNTESTED — declared**	Does `delta` recover across people, investigators, domains? Unknown; Sections 7–10 §8.10 states the design.

PROTOCOL

1. Declare the period.
2. Compute `Q_inf` **before** pursuing it, from `eta`, `M*`, `c*`, `delta`.

3. Check the sign. `eta M* < c*` gives a negative fixed point: the loop converges toward destruction, and this must be reported before the practice is run, not discovered during it.
4. Declare the arrival criterion `c` and compute `t_arrive = ln(c)/ln(1−delta)` from a standing start.
5. Track distance from arrival each period as `((1−delta)/delta)` times the last step.
6. At arrival, compute `h_inf = eta(ln N − F(u*))` (F-05) and account for it.

WORKED NUMBER

`delta = 0.10`, `Q_inf = 4.0`, `Q_0 = 0.5`:

t	gap	Q_t
0	3.50000	0.50000
22	0.34467	3.65533
29	0.16485	3.83515
44	0.03394	3.96606
66	0.00334	3.99666

```
to 5%: 29 periods      to 1%: 44 periods      to 0.1%: 66 periods
tau = 9.49 periods     half-life = 6.58 periods
```

Each halving costs 6.58 periods and each factor of ten costs 21.85 periods, and both are constant for the entire trajectory. Closing the gap from 90% to 99% costs 22 periods; closing it from 99% to 99.9% also costs 22 periods; closing the first half costs 7. **That is the arithmetic behind every practice that felt fast at the start and interminable at the end, and nothing slowed down.**

The full convergence table across `delta` is Sections 7–10, §8.1; the four landmarks are `delta = 0.05 -> 59 periods to 5%`, `0.10 -> 29`, `0.20 -> 14`, `0.30 -> 9`.

FAULTS

Fault	Signature	Fix
The unarrived asymptote	“Almost there” for many periods, read as failure	There is no arrival event. Declare `c` in advance
Effort substitution	More effort, no change in `eta`, `u`, `C`, `delta`; same path	Effort acts on the transient. Name which parameter the effort moves; if none, stop
Cadence confusion	Cadence increased, calendar unchanged	`tau` depends on per-period `delta`. Cadence acts through `eta` and `C`
Counterfeit arrival	`Q` rising with no change in your own four parameters	The extra drive is a transfer from someone. Run the audit on every party (Sections 7–10, §8.7.4)
Stall named arrival	Flat `Q`, no `Q_inf` on record, no review date	The arithmetic cannot adjudicate; the documentation can
Low-`delta` noise	Very stable practice, large swings traced to small perturbations months earlier	`1/delta` amplification. Accept it or shed deliberately

CROSS-REFERENCES. Sections 7–10 (full treatment and the proof), [Curzi, 2026a], [Curzi, 2026a], [Curzi, 2026h]; F-04, F-05, Appendix F.

23.12 12 Requirements for formulary use

How to run the formulary. **These are ordering and hygiene requirements; the per-entry protocols sit inside them.**

PF-1 — Run in dependency order. `F–03 -> F–01 -> F–02 -> F–08 -> F–04 -> F–05 -> F–06 -> F–07 -> F–09`. `N` and `u` first because they set the ceiling everything else lives under; the contraction last because it needs every other parameter.

PF-2 — One modulus, one period, one block. All magnitude estimates in a block share a modulus; all rates share a period; both are declared in writing before data collection and are not changed mid-block.

PF-3 — Zero-input window first. Fit `delta` during a deliberate low-input period before fitting anything else. It is the only clean identification of `delta` available at internal scope, and everything downstream depends on it.

PF-4 — Pre-record, never reconstruct. `M` before the return (F-08); `Q_inf` before the pursuit (F-09); the arrival criterion before arrival. **A formulary run on reconstructed inputs produces internally consistent numbers that are jointly wrong, which is the worst available outcome.**

PF-5 — Report intervals, not points. Every estimate carries an `n` and a spread. A point estimate with no `n` is not a measurement.

PF-6 — Compare each quantity to its deadband. `Delta` (F-02) and `Delta_R` (F-08) against `ln(1+c)`; `dQ` (F-04) against the `Q` instrument's resolution. **Below the deadband, report "unresolved", never "zero".**

PF-7 — Carry the identifiability caveats into every conclusion. The non-identifications are: `D` versus `P` (F-01); `N` versus `u` (F-03); `eta`, `M*`, `c*` (F-04, F-05, F-09); frame error versus world response (F-08); `C` level versus `theta` (F-07). **A conclusion requiring one of these separations must name the second measurement that supplied it.**

PF-8 — FVP-7 stays visible. No entry may be reported as validated. The reproducibility gate is open on all nine and the report says so.

PF-9 — Run F-07's intervention test first if you are going to run only one test. It is the cheapest and most direct falsification in the formulary: remove `k` actions and check whether initiation multiplies by `exp(-bk)`.

PF-10 — Other people's ledgers are asked for, never assumed. Where an echo source is a person (F-08) or a cost is carried by a person (F-05, F-09's transfer audit), consent is obtained, a decline path exists, and a decline is recorded as **unknown**, never as satisfied and never as a zero. *(The declination refusal, binding on every entry [Curzi, 2026].)*

PF-11 — Demote in print when a gate fails. A CONDITIONAL PASS whose condition is not met becomes a heuristic ordering in the report, in the same typeface as everything else, with the demotion stated. **A demoted formula is still useful; a formula that hides its demotion is not.**

PF-12 — Freeze before claiming. Any claim that the formulary works follows FVP-6 in full, including the shuffled-input control.

23.13 13 Failure modes of formulary use

Formulary-wide faults — the ones that come from using the collection rather than from any single entry.

Fault	Diagnostic signature	Fix
Consistent-and-wrong	Every number agrees with every other; the picture is coherent and the practice does not behave as predicted	`M` is mismeasured. Six entries are fed by F-01, so a single upstream error propagates coherently. Re-run F-01 with an independent `E` estimate
Gate laundering	The FVP tables are present but every verdict is PASS	Sixty-three gates and no failures is not rigour; it is a copied table. Check FVP-2 and FVP-7 first, since those are the two that genuinely bind
Precision inflation	Four decimal places on a quantity estimated from three observations	PF-5. Report `n` and spread. The formulary's arithmetic is exact; its inputs are not
Formula shopping	Running entries until one produces a flattering number	Run in dependency order (PF-1) and report all nine, including the ones that did not help
Parameter drift	`N`, `delta`, `eta` quietly revised mid-block until the model fits	PF-2 and PF-4. Freeze, then measure. A parameter revised to fit is a parameter that has stopped measuring
Scope leakage	Internal-scope entries applied to a team without re-derivation; the aggregation problem is general, and a single parameter written for a group is not the group's members' parameter [Kirman, 1992, Granovetter, 1978]	the thesis of Series B is that the parameters change between scopes, not that the numbers transfer. [Curzi, 2026s] is the interpersonal formulary; use it
The single-instance conclusion	A whole regime redesigned from one bad week	Every entry's protocol specifies a minimum `n`. One instance is a prompt to measure, not a finding

Fault	Diagnostic signature	Fix
Cross-person comparison	"My `delta` is worse than hers"	FVP-7 is open on all nine. Within-person, within-domain only, until the reproducibility study exists
Ordinal contamination	Ratios and logs computed from ratings scales anywhere in the chain	FVP-2. Trace the chain: an ordinal input at F-01 voids F-02, F-06, F-08 and corrupts F-04, F-05, F-09
Moral arithmetic	The formulary used to argue that someone's `Q` matters less	The declination refusal [Curzi, 2026]. The formulary measures; it does not rank persons, and any use that does has left the corpus

---

23.14 14 Results

Three worked results are reported. Section 14.1 runs the echo instrument end to end on a twelve-week log. Section 14.2 runs the arrival arithmetic on a practice rebuilt after a move, computing the destination before departure and then auditing it. Section 14.3 runs all nine formulary entries over one twelve-week block on a single subject. Section 14.4 collects the validation verdicts.

Every number below is computed from stated parameters under the models developed above, on series that were constructed rather than observed. The source material labels these *illustrative constructions* and that label is retained. No dataset was collected and no person was studied.

23.14.1 14.1 The echo log, read end to end

A twelve-week echo log. The data below are **illustrative, not empirical**: they are a constructed log used to demonstrate the computations, and no claim is made that they describe any real person. Every number derived from them was computed, not estimated by eye.

Setting. An subject produces one unit of work per week in a domain where a return arrives within the same week. Before releasing each week's work, they record `M` — a magnitude estimate of the moment they believe they are sending, on a scale where a fixed reference exchange from the preceding quarter was assigned 50. After the return arrives, they record `M'` on the same scale, from three sources asked independently and before seeing one another (ES-5), averaged. Their declared deadband is `Delta_R_min = 0.05` and their pre-estimated noise from an eight-exchange calibration block is `sigma_rho = 0.09`.

23.14.2 The log

Week	M sent	M' returned	ratio	rho	Delta_R	cumulative mean rho
1	40	22	0.5500	-0.5978	0.5978	-0.5978
2	45	26	0.5778	-0.5486	0.5486	-0.5732
3	50	34	0.6800	-0.3857	0.3857	-0.5107
4	48	35	0.7292	-0.3159	0.3159	-0.4620
5	55	44	0.8000	-0.2231	0.2231	-0.4142
6	52	45	0.8654	-0.1446	0.1446	-0.3693
7	60	55	0.9167	-0.0870	0.0870	-0.3290
8	58	57	0.9828	-0.0174	0.0174	-0.2900
9	55	56	1.0182	+0.0180	0.0180	-0.2558
10	60	63	1.0500	+0.0488	0.0488	-0.2253
11	62	60	0.9677	-0.0328	0.0328	-0.2078
12	60	61	1.0167	+0.0165	0.0165	-0.1891

23.14.3 Block statistics

```
all 12 weeks     mean rho = −0.1891    sd = 0.2257
weeks 1–6        mean rho = −0.3693    sd = 0.1785
weeks 7–12       mean rho = −0.0090    sd = 0.0478

mean Delta_R, weeks 1–6   = 0.3693
mean Delta_R, weeks 7–12  = 0.0368
```

With six observations per half-block, the standard errors and 95% intervals are:

```
weeks 1–6    SE = 0.0729    95% CI on mean rho = [−0.5121, −0.2264]
weeks 7–12   SE = 0.0195    95% CI on mean rho = [−0.0473, +0.0293]
```

The first half-block's interval excludes zero decisively; the second half-block's interval contains zero. The instrument has detected a real, large, consistently signed return difference in weeks 1–6 and cannot detect one in weeks 7–12.

23.14.4 Reading the sign

Every return in weeks 1–6 is negative and none is inside the deadband. This is sustained **under-return**: the world answered systematically smaller than the subject constructed. Per §4.1, the leading candidate is over-framing — `r = D/P > 1`. The size of the implied over-frame is

```
implied over-frame factor = exp( −mean rho over weeks 1–6 )
                          = exp( 0.3693 )
                          = 1.4467
```

The subject was constructing the moment about 1.45 times larger than the world was returning it. That is a specific, checkable, correctable claim, and it is the sort of claim the additive difference measure could not have produced — `M' − M` in weeks 1–6 runs -18, -19, -16, -13, -11, -7, which looks like a shrinking problem, while the ratio shows a shrinking *frame error*, which is a different fact.

23.14.5 Estimating the correction gain from the data

The subject was correcting — not by a written rule, but the log allows the effective gain to be recovered. Per §4.6, if `rho_{t+1} = (1−lambda) rho_t`, then `ln|rho_t|` falls linearly in `t`. Regressing `ln|rho|` on week for weeks 1–8 (the run before the residuals reach the deadband):

```
slope of ln|rho| on t   = −0.4436
per-step factor  g      = exp(−0.4436) = 0.6418
implied gain     lambda = 1 − g        = 0.3582
R^2                     = 0.8587
```

The subject's effective correction gain was 0.36 — comfortably inside the stable, monotone band, which is why the log shows steady shrinkage with no sign reversals until the residuals reach the noise floor. Derived quantities:

```
half-life of the distortion = ln(0.5)/ln(0.6418) = 1.56 weeks
weeks to bring |rho| below the deadband 0.05     = 7
```

The fitted trajectory and the observed one agree to the accuracy the `R^2` implies:

```
fitted |rho| at weeks 1..12:
0.913, 0.586, 0.376, 0.241, 0.155, 0.099, 0.064, 0.041, 0.026, 0.017, 0.011, 0.007
```

Observed week 7 is 0.0870 against a fitted 0.0638; observed week 8 is 0.0174 against 0.0409. From week 9 onward the fitted values are below the deadband and the observed values are indistinguishable from noise, exactly as §4.3 predicts. **After week 8 the model is no longer being tested by the data, because the data cannot resolve it.**

23.14.6 Net, gross, efficiency

```
R_net   = sum rho   = −2.2696
R_gross = sum |rho| =  2.4362
E_R     = 0.9316
```

`E_R = 0.93` is very high. Per §4.9 this is the signature of a **live, consistently directed error** rather than thrash — the world was saying one thing, repeatedly, and the subject moved toward it steadily rather than oscillating around it. Compare the counterfactual: had the same gross activity been produced by a gain above 1, the signs would have alternated and `E_R` would have collapsed toward zero.

23.14.7 The flattery check

Weeks 9–12 give four consecutive returns inside the declared deadband of 0.05 — `+0.0180`, `+0.0488`, `−0.0328`, `+0.0165`. ES-10 fires the alarm. Running the test of §4.5 with `sigma = 0.09` and band `b = 0.05`, the probability of one echo landing inside the band under a live-but-null channel is 0.4215, so four in a row has probability 0.0316 — below 5%.

The alarm fires, and it should, and the alarm is a prompt to test rather than a verdict. Here the test is the scatter criterion: the four residuals are `+, +, −, +` with a standard deviation of 0.0289 against a noise estimate of 0.09. **They vary and they change sign.** That is the signature of converged contact, not of a mirror — a mirror returns the sent moment and produces residuals that do not alternate. The subject records the alarm, records the scatter test that resolves it, and continues. Had the four residuals been `+0.004, +0.006, +0.003, +0.005`, the correct conclusion would have been the opposite one, and the correct action would have been to add a source who had not been asked before.

23.14.8 What the subject does next

Three decisions follow from the block, and each is licensed by a specific number.

1. Stop correcting the frame. Weeks 7–12 have a mean `rho` of -0.0090 with a 95% interval containing zero and a mean `|rho|` of 0.0368, below the declared deadband of 0.05. **There is no resolvable error left to correct at this modulus, and continuing to apply a gain of 0.36 to unresolvable residuals is how a stable subject becomes an oscillating one.** ES-8's instruction is to hold the gain for the block; the block is over, and the next block's gain should be set from the new signal-to-noise, which is now below 1.

2. Increase the sent moment or increase the resolution — but not both blindly. Per §4.4, with `sigma_rho = 0.09` the subject can resolve a `Delta_R` of 0.10 with four echoes and a `Delta_R` of 0.05 with sixteen. If the next question is finer than 0.10, the instrument needs either more echoes per finding or a finer modulus. If it is coarser, the instrument is already adequate and the effort should go elsewhere.

3. Do not conclude anything about the work. ES-12. The block establishes that the subject's construction of the moment moved from about 1.45x the world's return to about 1.0x. It establishes nothing about whether the work is good, and FVP-5 states formally why: the decomposition of `rho` into frame error and world response is not identified from `rho` alone. **The subject has calibrated an instrument. That is the entire finding, and it is worth having.**

23.14.9 The one number to carry out of the section

```
weeks 1–6   mean Delta_R = 0.3693 nats = 0.5328 bits = 1.066 octaves
weeks 7–12  mean Delta_R = 0.0368 nats = 0.0531 bits = 0.106 octaves
```

Twelve weeks of exchange bought about half a bit of correction, and half a bit is a real, respectable, hard-won yield. Anyone expecting more from twelve exchanges has mistaken the register they are working in. The world answers in ratios, the subject hears in logarithms, and the difference between the voice and the answer is the only thing either of them learns.

23.14.10 14.2 Arrival, computed before departure and audited afterwards

A practice rebuilt after a move. As in Sections 3–6, the data are **illustrative** — a constructed case used to demonstrate the computation. No claim is made that these parameters describe any real person.

Setting. An subject restarting a daily practice from zero after a relocation that reset their stored order. Period = one week. They measure, per the protocols of [Curzi, 2026n,o], 40 and 5:

```
N     = 9        distinguishable framings available in the domain
u*    = 0.55     measured non-parallelism among their own framings
eta   = 0.35     conversion of moment into durable structure
delta = 0.12     weekly loss without maintenance
c*    = 0.22     weekly maintenance cost, from the cost ledger
Q_0   = 0        the move reset the store
```

23.14.11 Step 1 — the ceiling and the drive

```
ln N       = ln 9              = 2.1972    the hard ceiling on surplus per interaction
N_eff      = 1 + (9-1)(0.55)   = 5.400     an audited headcount of framings
F(u*)      = ln(5.400)         = 1.6864    the surplus this geometry generates
claimed    = 1.6864 / 2.1972   = 76.8%     of the ceiling
drive b    = 0.35*1.6864 - 0.22 = 0.3702   Q-units per week
```

`b > 0`, so CS-4 passes: the regime is sustainable and the fixed point is positive.

23.14.12 Step 2 — the destination, computed before departure (CS-2)

```
Q_inf = ( 0.35 * 1.6864 - 0.22 ) / 0.12 = 3.0853 Q-units

upper bound check (Thm 3.3, Q_0 = 0):  eta*lnN/delta = 6.4086
3.0853 <= 6.4086.  Consistent.
```

The room is furnished at 3.0853 Q-units, and this was known in week zero.

23.14.13 Step 3 — the schedule

```
tau        = -1/ln(0.88)          =  7.82 weeks
half-life  = ln(0.5)/ln(0.88)     =  5.42 weeks
to 5%      = ln(0.05)/ln(0.88)    = 24 weeks
to 2%                             = 31 weeks
to 1%                             = 37 weeks
```

Declaring `c = 0.05` per CS-5: **arrival is week 24, and this is written down in week zero.**

23.14.14 Step 4 — the trajectory

t (wk)	Q_t	gap	gap / Q_inf	h_t	step dQ
0	0.0000	3.0853	1.0000	0.5490	0.3702
1	0.3702	2.7151	0.8800	0.5046	0.3258
2	0.6961	2.3893	0.7744	0.4655	0.2867
4	1.2351	1.8503	0.5997	0.4008	0.2220
6	1.6525	1.4328	0.4644	0.3507	0.1719
8	1.9757	1.1096	0.3596	0.3119	0.1332
10	2.2261	0.8593	0.2785	0.2819	0.1031
12	2.4199	0.6654	0.2157	0.2586	0.0799
14	2.5700	0.5153	0.1670	0.2406	0.0618
16	2.6863	0.3990	0.1293	0.2267	0.0479
20	2.8460	0.2393	0.0776	0.2075	0.0287
25	2.9590	0.1263	0.0409	0.1939	0.0152
30	3.0187	0.0666	0.0216	0.1868	0.0080

Closed-form check at `t = 30`: `Q_inf + (1-delta)^30 (0 - Q_inf) = 3.018683`. The iteration and the error law agree to six figures, as §7.5 requires.

23.14.15 Step 5 — what the subject experiences, week by week

Weeks 1–5. Steps of 0.37, 0.33, 0.29, 0.25, 0.22, closing 47% of the gap. This is the part everyone calls “fast at the beginning” — it is not fast; it is the same 12% per week as every other week, applied to a large number.

Weeks 6–16. Steps from 0.17 down to 0.048. The gap goes from 46% to 13%. This is the long middle, and per §8.1 it costs what it costs: closing the gap from 50% to 10% takes 12.59 weeks here, against the 5.42 weeks the first halving took. **Nothing has gone wrong. The rate has not changed and cannot change.**

Weeks 17–24. Steps below 0.045. The a posteriori bound (CS-6) at week 20: the step just completed, week 19 to week 20, was 0.0326, giving distance from arrival `<= (0.88/0.12) *`

`0.0326 = 0.2393` — against a true gap of 0.2393. The bound is attained exactly, for the reason §7.6 gives. **The subject can compute their remaining distance from the size of their last week alone, without knowing `Q_inf` at all.**

Week 24. Declared arrival. Gap is under 5% of `Q_inf`. It does not feel like an event, because it is not one — the state at week 24 differs from the state at week 20 by 0.0958 Q-units, about 3.1% of the destination, spread over four weeks, which is at or below most plausible resolutions. **The subject recognises the state because they have been substantially in it since week 16.**

23.14.16 Step 6 — the headroom reading at arrival

```
h_inf = eta ( ln N − F(u*) ) = 0.35 * ( 2.1972 − 1.6864 ) = 0.1788
```

Cross-check from the gauge at `Q_inf`: `0.35*2.1972 − 0.12*3.0853 − 0.22 = 0.178789`. Identical, as §8.4 requires.

The subject arrives with 0.1788 Q-units per week of unclaimed capacity, and §8.4 says exactly what that number is: it is the 23.2% of the ceiling their framings are not generating. It is not free time and it is not energy. **The only way to convert it is to raise `u` toward 1 or to raise `N` above 9,** and [Curzi, 2026c,o] are where those moves live.

23.14.17 Step 7 — the counterfactual, and the levers

Suppose at week 24 the subject wants a higher destination. From §8.5:

Change	New `Q_inf`	Change
baseline	3.0853	—
`eta` 0.35 -> 0.385 (+10%)	3.5772	+15.94%
`delta` 0.12 -> 0.108 (-10%)	3.4281	+11.11%
`u` 0.55 -> 0.605 (+10%)	3.3138	+7.40%
`C` 0.22 -> 0.198 (-10%)	3.2687	+5.94%

The 10% efficiency improvement is worth 2.7 times the 10% cost cut. And the `delta` move carries the §8.6 penalty: at `delta = 0.108` the time constant rises from 7.82 to 8.75 weeks, the time to 5% from 24 to 27 weeks, and the noise gain from 8.33 to 9.26. **Reducing the leak buys a better room, more slowly, with more of every bad week retained.**

23.14.18 Step 8 — the audit that must not be skipped

CS-9. The subject's drive is `eta F(u*) = 0.5902` per week and every component of it is their own: their framings, their conversion, their cost. There is no `x`. The audit passes trivially.

Had there been a transfer — a household absorbing the practice's cost, a colleague covering the work it displaces — the audit would require **that party's** `h`, computed with the transfer as their cost, obtained by asking, with a decline path (CS-10). Per §8.7, an extraction of `x = 0.40` per week against a counterparty whose sustainable ceiling is `x* = 0.3141` would give that party a fixed point of -0.7157 and an exhaustion horizon of **12.04 weeks** — during which the subject's own numbers would look excellent and their fixed point would read 6.4187 instead of 3.0853.

Every measurement the subject could take of themselves would say the practice was working twice as well as it does. That is the whole danger of counterfeit arrival: it is not detectable from inside the system that benefits from it. Only the other ledger shows it, and only if it is asked for.

23.14.19 The one line to carry out of the section

```
Q_t = Q_inf + (1 − delta)^t ( Q_0 − Q_inf )
```

Where you are going does not contain where you started. Where you are is where you are going, plus what is left of where you started, and what is left of where you started is halving every 5.42 weeks. Arrival is not an achievement and not a destination reached by force. It is the moment the second term drops below the resolution of the instrument reading it — and the room, by then, has been furnished for a long time.

23.14.20 14.3 The nine entries over one block

One subject, one twelve-week block, all nine entries. The data are an **illustrative construction** used to demonstrate the full procedure; they describe no real person, and every derived number below was computed.

Setting. An subject running a first full formulary review on a domain of work they have been at for a year. Period = one week. Modulus = 50, assigned to a reference encounter from the preceding quarter and held for the block.

23.14.21 Step 1 — F-03, the ceiling

Framings elicited independently and in writing (Protocol step 1), then compared:

```
N     = 6                     ln N = 1.7918 nats = 2.5850 bits
u     = 0.38 (measured)
N_eff = 1 + 5(0.38) = 2.900   F_int = ln(2.900) = 1.0647 nats
claimed = 1.0647 / 1.7918 = 59.4% of the ceiling
```

Six framings audit to 2.9. That is the first finding of the review and it reframes everything after it: the subject experiences six perspectives and holds slightly under three.

23.14.22 Step 2 — F-01 and F-02, the moment and the calibration

wk	D	P	E	r	|ln r|	M	M_norm
1	62	41	55	1.5122	0.4136	83.171	1.2418
2	58	40	50	1.4500	0.3716	72.500	1.0825
3	66	44	58	1.5000	0.4055	87.000	1.2990
4	60	43	52	1.3953	0.3331	72.558	1.0834
5	64	46	60	1.3913	0.3302	83.478	1.2464
6	59	45	54	1.3111	0.2709	70.800	1.0571
7	55	47	57	1.1702	0.1572	66.702	0.9960
8	52	48	53	1.0833	0.0800	57.417	0.8573
9	50	49	59	1.0204	0.0202	60.204	0.8989
10	49	50	55	0.9800	0.0202	53.900	0.8048
11	51	52	58	0.9808	0.0194	56.885	0.8494
12	50	51	56	0.9804	0.0198	54.902	0.8198

`M_norm` uses a declared range `[0, 120]` scaled to `[0, ln 6]`.

```
mean r,     weeks 1–4  = 1.4644      weeks 9–12 = 0.9904
mean |ln r|, weeks 1–4 = 0.3809      weeks 9–12 = 0.0199
mean M_norm over 12 weeks = 1.0197 nats   (ceiling 1.7918)
```

The subject arrived over-framed by about 46% and left calibrated. Distortion fell from 0.3809 nats — 0.55 bits, 1319 cents — to 0.0199 nats, which is below any plausible deadband. This is the review's success story, and Step 4 is where it turns.

23.14.23 Step 3 — F-08, the echo

Sent moment recorded before the return; returns from two independent sources, timestamped to the exchange:

wk	sent	back	rho	Delta_R
1	55	38	-0.3697	0.3697
2	58	42	-0.3228	0.3228
3	60	47	-0.2442	0.2442
4	57	46	-0.2144	0.2144
5	62	53	-0.1568	0.1568
6	60	54	-0.1054	0.1054
7	58	55	-0.0531	0.0531
8	61	60	-0.0165	0.0165
9	59	57	-0.0345	0.0345
10	60	61	+0.0165	0.0165
11	62	60	-0.0328	0.0328
12	61	62	+0.0163	0.0163

```
mean rho,     weeks 1–4 = −0.2878      weeks 9–12 = −0.0086
mean Delta_R, weeks 1–4 =  0.2878      weeks 9–12 =  0.0250   sd(9–12) = 0.0289
implied over-frame, weeks 1–4 = exp(0.2878) = 1.3335
R_net = −1.5174   R_gross = 1.5830   E_R = 0.9586
```

Fitting the correction gain from the decay of `|rho|` over weeks 1–9:

```
per-week factor g = 0.6911     ->    lambda = 0.3089      R^2 = 0.8808
```

Three independent instruments agree. F-02 says the frame was over-set by 1.46 and came into calibration. F-08 says the returns were under by a factor implying an over-frame of 1.33 and came into calibration. The fitted gain of 0.309 is in the stable monotone band, and `E_R = 0.96` confirms steady directed correction rather than thrash. **The four returns in weeks 9–12 fire the flattery alarm, and the scatter test clears it: the residuals change sign and their sd of 0.0289 is real variation, not a mirror.**

23.14.24 Step 4 — F-04, the storage law, and the turn

Cost from [Curzi, 2026b]'s ledger; `eta` fitted per F-04's protocol.

```
eta = 0.28      delta = 0.09      C = 0.30      Q_0 = 0.40
```

wk	M_norm	Q_t	step dQ	h_t	L_t	admissible?
0	1.2418	0.4000	+0.0117	0.1657	0.9418	yes
1	1.0825	0.4117	-0.0339	0.1646	0.7825	yes
2	1.2990	0.3778	+0.0297	0.1677	0.9990	yes
3	1.0834	0.4075	-0.0333	0.1650	0.7834	yes
4	1.2464	0.3742	+0.0153	0.1680	0.9464	yes
5	1.0571	0.3895	-0.0391	0.1666	0.7571	yes
6	0.9960	0.3504	-0.0527	0.1702	0.6960	yes
7	0.8573	0.2977	-0.0868	0.1749	0.5573	yes
8	0.8989	0.2110	-0.0673	0.1827	0.5989	yes
9	0.8048	0.1437	-0.0876	0.1888	0.5048	yes
10	0.8494	0.0561	-0.0672	0.1966	0.5494	**NO**
11	0.8198	-0.0111	-0.0695	0.2027	0.5198	**NO**
12	—	-0.0806	—	—	—	—

The subject got calibrated and went broke. Stored order fell from 0.40 to below zero over twelve weeks, and the admissibility condition `C <= (1−delta)Q + eta M` failed at week 11 — the week the model itself stops applying, which is a finding and not a rounding artifact.

23.14.25 Step 5 — F-09, the arrival that is a warning

```
mean M_norm = 1.0197
Q_inf = (0.28 * 1.0197 − 0.30) / 0.09 = −0.1609 Q−units       NEGATIVE
tau = 10.603 weeks      half−life = 7.350 weeks
```

Theorem 3.5's failure clause, live: `eta M* < c*`, so the fixed point is negative, and the loop converges anyway — toward the destruction of the thing. F-09's Protocol step 3 exists precisely to catch this **before** a practice is run; the subject ran it after, which is what a first review usually looks like and is why the review was worth doing.

The margin of failure is the number that makes this example worth reading:

```
maximum sustainable cost at u = 0.38:   C <= eta * F_int = 0.28 * 1.0647 = 0.2981
observed cost                        :   C = 0.3000
overshoot                            :   0.0019 Q−units per week  =  0.63%
```

The regime failed by 0.63 percent. Six-tenths of one percent over the sustainability ceiling of Corollary 3.4, sustained for twelve weeks, took the subject from 0.40 Q-units to below zero. There was no crisis, no bad month, no identifiable mistake. **Corollary 3.4 is the single most important sociological statement in the corpus, and this is its personal-scope face: past the ceiling, no choice of interaction geometry prevents order from decreasing, and the arithmetic does not care that the overshoot was small.**

23.14.26 Step 6 — F-05, the headroom paradox

Headroom was **positive and rising** through the entire collapse: 0.1657 at week 0, 0.2027 at week 11. At the fixed point, `h_inf = eta(ln N − F_int) = 0.28 * (1.7918 − 1.0647) = 0.2036`.

Headroom rose because `Q` was falling, and `h` is reduced by `delta Q`. The gauge was correctly reporting that capacity for the new existed *at perfect geometry* while the actual geometry was losing 0.63% per week. This is F-05's central caveat in a live case: **`h > 0` is necessary and not sufficient, and an subject who watched only the headroom gauge would have seen an improving number for twelve weeks.** The geometry gap is the missing piece:

```
geometry gap = eta ( ln N − mean M_norm ) = 0.28 ∗ (1.7918 − 1.0197) = 0.2162
```

That 0.2162 is the part of the ceiling the subject's framings never reached, and it is why `h = 0.20` bought nothing.

23.14.27 Step 7 — F-06 and F-07, the two levers

```
F-06:  sum L over 12 weeks = 8.6365    mean L = 0.7197    L = 0 weeks: 0
       L_max = ln N − C = 1.7918 − 0.30 = 1.4918
```

The launch budget was healthy throughout — never zero, averaging 48% of its ceiling. F-06's "busy trap" in reverse: the subject had budget to imagine with and was losing stored order anyway. `L` and `dQ` are different quantities, and a good `L` does not imply a good `Q`.

F-07, actions-to-begin against weekly initiation count:

actions `k`	observed `n`	fitted `n`
1	22	23.19
2	15	14.86
3	10	9.52
5	4	3.91
8	1	1.03

```
ln n = 3.5888 − 0.4451 k      R^2 = 0.9989
halving distance = 1.557 actions
removing 2 actions from the five-step practice: predicted count 3.91 -> 9.52
```

Removing two actions from the front of the five-step practice is predicted to multiply its frequency by 2.43. This is the review's cheapest intervention and, per PF-9, the one whose prediction should be tested first.

23.14.28 Step 8 — the decision

Four candidate regimes, computed. `M_bar` under a raised `u` is scaled by the ratio of the new `F_int` to the old, which is a modelling choice and is stated as one:

Regime	`u`	`C`	`F_int`	`M_bar`	`Q_inf`	`h_inf`
as-is	0.38	0.30	1.0647	1.0197	**-0.1609**	0.2036
raise `u`	0.55	0.30	1.3218	1.2659	+0.6050	0.1316
cut `C`	0.38	0.24	1.0647	1.0197	+0.5058	0.2036
both	0.55	0.24	1.3218	1.2659	**+1.2716**	0.1316

The minimum requirements, computed exactly:

```
minimum sustained M for Q_inf >= 0:  M >= C/eta = 0.30/0.28 = 1.0714 nats  (59.8% of ln N)
equivalent u, if M is read as F_int: u = (e^1.0714 − 1)/5 = 0.3839
cost that would place Q_inf at 0.5:  C = eta*M_bar − delta*0.5 = 0.2405
```

The subject's measured `u` of 0.38 is 0.0039 below the `u` of 0.3839 that their cost requires. The whole twelve-week decline sits in that fourth decimal place, and both routes out of it are small: cut weekly cost by 0.06 Q-units, or raise `u` from 0.38 to 0.49.

23.14.29 Step 9 — the audit that closes the review

PF-10 and F-09's transfer audit. The subject's drive `eta F_int = 0.2981` per week is entirely their own — no transfer term. But part of their `C` is carried by a household member who absorbs displaced tasks. **That person's headroom is not the subject's to compute.** The review records the question as *asked, answer pending*, with the person free to decline, and the entry stands as **unknown** rather than as satisfied.

This is the only line in the review that cannot be closed by arithmetic, and the declination refusal is why [Curzi, 2026] it is in the report at all.

23.14.30 What the review found, in one paragraph

Six framings that audit to 2.9. A frame over-set by 46% that self-corrected to calibration in eight weeks at a stable gain of 0.31, confirmed independently by the echo log. A healthy launch budget throughout. A rising headroom gauge. And underneath all of it, a weekly cost 0.63% above the sustainability ceiling, converting twelve weeks of genuine improvement into a negative fixed point. No single entry would have found that: F-02 and F-08 said the subject was improving and were right; F-05 said capacity was available and was right. **Only F-04 and F-09, run together against a `Q_inf` computed rather than felt, showed that the room this life was converging on had less in it than the room it started from — by six-tenths of one percent.**

That is what a formulary is for.

23.14.31 14.4 The validation tally

The verdicts the protocol returned on the nine entries are collected here as a count rather than left to be assembled from Section 11.8. **Sixty-three gates were reported across nine entries.**

Entry	Gate 2 (scale type)	Gate 6 (falsification)	Gate 7 (reproducibility)
F-01 The Moment	**DEMOTE** (Standing Verdict 1)	SPECIFIED	UNTESTED — declared
F-02 The Calibration Ratio	**DEMOTE** (Standing Verdict 1)	SPECIFIED	UNTESTED — declared
F-03 The Internal Surplus	CONDITIONAL PASS	SPECIFIED	UNTESTED — declared
F-04 The Self-Storage Law	**DEMOTE** (Standing Verdict 1)	SPECIFIED	UNTESTED — declared
F-05 Personal Headroom	CONDITIONAL PASS	SPECIFIED	UNTESTED — declared
F-06 The Launch Budget	**DEMOTE** (Standing Verdict 1)	SPECIFIED	UNTESTED — declared
F-07 The Gradient	CONDITIONAL PASS	SPECIFIED	UNTESTED — declared
F-08 The Return Difference	**DEMOTE** (Standing Verdict 1)	SPECIFIED	UNTESTED — declared
F-09 The Contraction and Arrival	CONDITIONAL PASS	SPECIFIED	UNTESTED — declared

Five of nine entries are demoted on the scale-type gate. Not one of the nine is marked PASS on the reproducibility gate. The demoted five are exactly the entries whose value passes through the moment `M` or through the calibration ratio `r = D/P`, and the reason is a single external fact about instrumentation: `D` and `P` are not measured on a common ratio scale with

a shared true zero, so their quotient is a number whose value can be set by an admissible relabelling [Curzi, 2026t].

Withdrawn as measured quantities: the magnitude of `D/P`; the distortion $\Delta = |\ln r|$ as a number; and the quantitative form of the moment-to-storage join that supplies `M_t` as the drive in `Q_{t+1} = (1−delta)Q_t + eta M_t − C_t`. Every worked figure above that passes through those quantities is an **illustrative construction demonstrating the arithmetic**, and is labelled as one at its use.

Retained in full force: the limiting cases, the `D = P` fixed point, and the ordering over-framed / calibrated / under-framed. Each requires only ordinal information and each is invariant under every strictly increasing relabelling of the response scale. **What is demoted is magnitude, not structure.**

A separate verdict falls on the audit instrument itself. Standing Verdict 2 records three measured failure modes of the shuffled-input control that every falsification row defers to: against a nominal 0.05 across 500 null trials it false-rejected at **0.108** under independent permutation and **0.120** under circular shift, with only block permutation near nominal at 0.060; a filtered repackaging of the input passed all four baselines at `p = 0.0005` and was caught only by a structural ceiling test, its single-step jump being **38.5 times** the theoretical maximum; and against a confound driving both series the shuffle **passed 98.35 per cent** of 4,000 trials while reporting honestly (48.17 per cent detection) in the clean case [Curzi, 2026u,ac]. **A control measuring 0.108 against a nominal 0.05 is anti-conservative by a factor of 2.2**, and that number belongs beside every result the suite is used to defend rather than in a footnote.

23.15 15 Discussion

23.15.1 15.1 What follows

The four levers are ranked, and the ranking is derived rather than fitted. At the base point `eta = 0.35`, `delta = 0.12`, `N = 9`, `u* = 0.55` and `c* = 0.22`, the elasticities of the fixed point are `eta` **+1.594**, `delta` **−1.000**, `u` **+0.770** and `C` **−0.594**, so that a 10 per cent efficiency gain is worth **2.7 times** a 10 per cent cost cut. Two of these are structural rather than local. The elasticity with respect to `delta` is **exactly −1 at every parameter value**, because `Q_inf` is proportional to `1/delta`: halve the leak, double the destination. And the ratio that ranks efficiency against cost is `eta M*/c*`, which exceeds one whenever the regime is sustainable at all. **Cutting cost is the weakest of the four levers and it is usually the first one attempted.**

Leverage and fragility are the same number. The elasticity with respect to `eta` is `eta M*/(eta M* − c*)`, which diverges as the regime approaches unsustainability. A person operating near the boundary gets very large returns from small improvements in conversion — and equally large losses from small degradations. That is a derived property of the fixed-point formula, not a metaphor, and it is the sharpest practical consequence of the arithmetic.

Convergence certifies nothing, in two distinct ways. First, `eta F(u*) < c*` gives a negative fixed point, and the loop reaches it just as reliably and just as geometrically: a system can arrive, on schedule, at a destination that is a slow depletion [Curzi, 2026a]. Second, a transfer `x` between two systems moves each fixed point by exactly `x/delta` in opposite directions and leaves the sum unchanged. **Transfer relocates a fixed point; it creates none.** At `x = 0.40` against a critical rate `x* = 0.3141`, the donor's steady state is `−0.7157` with an exhaustion horizon of 12.04 periods, while the recipient reads 108 per cent above what its own regime could produce — and every measurement the recipient can take of itself is consistent with a well-run system.

The instrument's resolution is the binding constraint on any personal use of it. A 5 per cent return effect at `sigma_rho = 0.30` needs **139 clean, independent echoes**; at a weekly cycle that is more than two years. Resolving a 20 per cent effect needs nine. **The honest reading is that a personal echo log can detect large distortions and nothing subtle**, and the sample-size law says exactly where the line falls before the log is started rather than after.

Correlated sources attenuate the reading rather than merely widening it. Where a fraction `w` of the apparent independent sources are in fact one source, $\rho_{\text{obs}} = (1 - w)\rho_{\text{true}}$: the estimate is *biased toward zero*, not just noisier, which is the design-effect problem of survey sampling arriving in a personal instrument. The same arithmetic governs the corpus's effective-count work at institutional scope, where a naive count of four jurisdictions collapses to an effective count of one under bloc correlation [Curzi, 2026,?].

23.15.2 15.2 What does not follow

The demotion is not a refutation, and the surviving structure is not a measurement. Five of the nine entries lose their magnitudes and keep their orderings. An ordering is real information — it supports rank correlations, medians, sign tests and monotone regression — and it is not an equation. No demoted quantity may be multiplied, averaged across people, differenced across time as a number, or fed into another formula [Curzi, 2026t].

The reflexive claims in this material are not identified from observation. The internal-scope loop in which a person's construal shapes the world's answer and the answer shapes the construal is a reflexive specification of exactly the kind Manski [1993] analysed, and its endogenous component is not separable from contextual effects or from correlated unobservables in observational data. Shalizi and Thomas [2011] make the same point for network data, and Lyons [2011] show what happens when it is ignored. **This paper adopts no remedy, and every claim resting on the loop is therefore a modelling position rather than an identified empirical result.**

Passing the deadband test would not make the return difference a ratio-scale quantity. Postulate R1 — that the moment enacted and the moment returned lie on one common ratio scale — is the commensurability assumption on which Δ_R rests, and it inherits the whole of the scale-type objection [Curzi, 2026t]. Magnitude estimation is the route by which such a scale could be built [Stevens, 1957, 1946], and it has not been run for moments by anyone.

A high directional efficiency is not evidence of a real effect. The worked log's `E_R = 0.9316` says the returns pointed consistently in one direction; it says nothing about whether the direction was produced by the enacted moments or by a driver common to both series. The shuffle control that is supposed to answer that question passed 98.35 per cent of the time against exactly such a confound [Curzi, 2026u,ac].

The framework does not yet have a differential prediction. Durlauf [2005] asks for a prediction that simpler models do not also make, and Sobkowicz [2020] puts the same question in one line: what observation would distinguish these laws from a neighbouring model that fits equally well? The elasticities of Section 8.5 are the closest this paper comes — they are *point* predictions with numbers rather than directions, which is the right response to Meehl [1967] — but they are predictions of the assumed fixed-point formula and would be made by any model with the same functional form. Watts [2014] is the standing charge that formal social explanation is often commonsense reasoning in dress, and nothing here immunises against it. The external ceiling on how well such things can be predicted at all is low: Salganik et al. [2020] report 160 teams and fifteen years of high-quality longitudinal data with the best machine learning barely beating a four-variable regression, and Hofman et al. [2017] set out the same ceiling generally. Epstein [2008] is the legitimate reply — prediction is one of sixteen reasons to model — and **the corpus is entitled to say which of the other fifteen it claims, but it must say.**

The corpus's own parameters are not exempt from its reflexivity. Lucas [1976] applied to this framework says that `delta`, `eta` and `u` are the decision rules of people who have not read it; Hacking [1995] says the same philosophically, and Ferraro et al. [2005] supplies the warning case in which a theory made people behave worse by assuming the worst of them. Against that, MacKenzie and Millo [2003] documents a reflexive fixed point observed in the field with dates and price data, which is the strongest available existence proof for the mechanism [MacKenzie, 2006, Callon, 1998, Soros, 2013]. **The corpus asserts reflexivity for its subject**

matter and cannot consistently exempt its own parameters; this paper records the inconsistency rather than resolving it.

23.15.3 15.3 Relation to the surrounding literature

The contraction result is Banach's [Banach, 1922] applied to a first-order linear difference equation, and the stability condition and fixed point are textbook [Elaydi, 2005]. The storage law is a leaky integrator and therefore also an exponentially smoothed forecast [Holt, 1957, Brown and Meyer, 1961] and a fixed-gain Kalman filter [Kalman, 1960]; the level-and-rate formalism predates it by forty years [Forrester, 1961], and Sterman [1989] supplies the empirical finding that people systematically misjudge stocks with delays, which is the strongest external support for the practical claims made here about review timing. **This is a shared mathematical form, not a derivation from physics**, and it is labelled as one in Section 3.9.

The ratio register is Weber's and Fechner's [Weber, 1834, Fechner, 1860, 1966], with Stevens' power law as the competing account [Stevens, 1957] and the century-long dispute best summarised by Krueger [1989] rather than adjudicated here. Every failure mode of magnitude estimation that Section 6 lists appears first in Poulton [1968] and Poulton [1979], and the dependence of the exponent on the experimenter's stimulus range is Teghtsoonian [1971]. **A stronger warrant for the logarithm than Fechner's is available and should be used alongside it:** Peters and Gell-Mann [2016] derives a logarithmic form from multiplicative dynamics with no psychological assumption at all, and Peters [2019] supply the reason it matters here — a parameter estimated across individuals does not describe what happens to any one of them over time, which is precisely the direction this paper's quantities are used in.

The design-effect correction is standard survey sampling arriving in an unusual place, and the underlying point — that correlated sources reduce effective independence — is the same one the diversity literature makes about problem-solving groups [Hong and Page, 2004, Thompson, 2014] and that Lorenz et al. [2011] measure directly: social influence collapses the effective count. The "mirror that flatters" is informational cascade [Bikhchandani et al., 1992, Banerjee, 1992] read at personal scope.

Three external results bound what this instrument can claim. Michell [1997] holds that psychology assumes quantitative structure without testing for it, and the conjoint test that would settle it [Luce and Tukey, 1964, Krantz et al., 1971] has not been run for any quantity in this paper. Tversky [1977] shows psychological similarity is asymmetric and violates the triangle inequality, so a `u` built from similarity cannot assume metric behaviour. Schwarz [1999] and Kahneman et al. [2006] show the self-report instrument is exposed to question-wording and focusing-illusion effects, which is a direct threat to a twelve-week personal log.

The enterprise this paper belongs to has a name and a literature, and the corpus is entering it whether or not it intends to. Carrying physical formalism into social and psychological systems was claimed, contested and partially established between 1971 and 2022 [Weidlich, 1971, Galam et al., 1982, Castellano et al., 2009, Jusup et al., 2022], and the standard that programme set is **prediction of observed data, not internal consistency**: Helbing and Molnár [1995] wrote social motivations as literal forces and validated them against measured pedestrian trajectories. Against that standard this paper offers arithmetic on constructed series and nothing else, which is worth stating plainly. Hedström and Ylikoski [2010] names the criterion sociologists will actually apply — an explanation must name a mechanism, not exhibit a fitted curve — and Keuschnigg et al. [2018] is the most constructive position available to a framework in this position. Gallegati et al. [2006] is the field's own indictment by four sympathisers and should be read as a checklist against work of this kind, with McCauley [2006] as the reply.

The decay term has the strongest empirical support of anything in this paper, and it is double-edged. Adaptation to a changed level is well established [Helson, 1948, Brickman et al., 1978]: the hedonic treadmill is the clearest external warrant for a positive `delta` and simultaneously the clearest warning against promising unbounded accumulation. Diener et al. [2006] is the revision that restores room for raising the equilibrium rather than merely returning to it, which is exactly what the four levers of Section 8.5 are for.

Within the corpus, the contraction result appears in three other domains and the parallel is worth stating because it is the same theorem each time. Curzi [2026] reports the contraction as an exact equality with `delta = 0.09` giving `tau = 10.6033`, a half-life of 7.3496, 5 per cent at pass 32, 1 per cent at 48.83 and 0.1 per cent at 73.24. Curzi [2026] states the same two theorems and reports a maximum residual of `2.0624e-15` over a hundred passes, and carries the corpus's register of demotions of which this paper's five are part. Curzi [2026] carries the trichotomy `f > = < f_min` corresponding to `Q_inf > = < 0` with `f_min = k e^(2c/eta)` and `k = 0.483425732988414` — **a defined constant, exact by construction, whose fifteen figures are legitimate for that reason and whose expression as a frequency in hertz is a separate and much stronger claim carrying no external support.** Curzi [2026h] supplies the headroom identity this paper's Section 8.4 depends on: `h_inf = eta(ln N - F(u*))`, verified to six decimals at `eta = 0.35`, `delta = 0.015`, `N = 6`, `u* = 0.55`, giving `Q_inf = 2.840970` and `h_inf = 0.164501`. And Curzi [2026p] is the negative result that keeps momentum out of this formulary: at `beta = 0, 0.5, 0.8, 0.9, 0.95` every trajectory terminates at `x = 1.9972` in basin A, so momentum defeats narrow barriers and is useless against wide shallow ones. Curzi [2026] shows the same concentration arithmetic transferring unchanged to distributed ledgers, with effective counts from 35.0 curated validators (HHI 0.028571) down to 5.94 entities (HHI 0.168400) — **Hill numbers of order 2 on measured shares, which the corpus's own `N_eff = 1 + (N-1)u` is not.**

23.16 16 Verification

The results compound from eight postulates. Each is atomic, each is checkable on its own, and each carries its status.

23.16.1 16.1 Dimensional audit

`[Q]` denotes the dimension of stored order, `[T]` time, `[m]` the magnitude-estimation scale on which moments are placed, and `[1]` a pure number. The period is the unit of `[T]`, so every rate is *per period* and no explicit `[T^-1]` appears once the recursion is written in discrete steps.

Symbol	Dimension	Unit	Status
`M`, `M'`	`[m]`	one common magnitude-estimation modulus, arbitrary but fixed	**not instrumented**; a common ratio scale is *required* and not available
`rho = ln(M'/M)`	`[1]`	nats	**derived**; dimensionless only because `M` and `M'` share `[m]`
$\Delta_R = \lvert\rho\rvert$	`[1]`	nats	**derived**; undefined if either magnitude is non-positive
`c` (Weber fraction)	`[1]`	none	**not measured**; the value 0.10 used below is stipulated
σ_ρ	`[1]`	nats	**estimated** from the log-ratio series, with a standard error
λ (correction gain)	`[1]`	per correction cycle	**estimated** by regression on the log-ratio series

Symbol	Dimension	Unit	Status
`w` (shared-source fraction)	`[1]`	none	**assumed** in the worked case
`Q_t`	`[Q]`	proxy units of stored capability	**measured**, in whatever the declared proxy counts
`F = ln(1+(N−1)u)`	`[1]`	nats	**derived** dimensionless
η	`[Q]` per nat per period	proxy units per nat per period	**measured**; *not* dimensionless
δ	`[1]`	per period	**measured** dimensionless fraction per step
`C`, `c*`	`[Q]` per period	proxy units per period	**measured**
`x` (transfer)	`[Q]` per period	proxy units per period	**assumed** in the worked case
τ, half-life, `t_exhaust`	`[T]`	periods	**derived**
elasticities	`[1]`	none	**derived**, and dimensionless by construction

Does the storage recursion balance? `Q_{t+1} = (1−delta)Q_t + eta M_t − C_t` balances only if every right-hand term carries `[Q]`. The first does because `delta` is dimensionless; the third does by construction; the second does **only if `eta` carries `[Q]` per nat per period**, since `M_t` is used in its normalised form on `[0, ln N]` and is therefore a pure number in nats. `eta` is consequently not dimensionless, and an `eta` reported without a statement of what the proxy counts is half a number [Curzi, 2026a].

Does the return difference balance? `ln(M'/M)` requires a dimensionless argument, which holds if and only if `M` and `M'` are on **one** scale with **one** modulus. Two instruments, however similar, do not license the ratio. That is the whole content of Postulate R1 and it is the reason the entry is demoted.

Where there is no operational unit, it is said. `M` and `M'` have **no operational unit at all** in the corpus as it stands: `[m]` is a placeholder for a scale nobody has built. `Q` is counted in whatever the declared proxy counts, and two people's `Q` values are not comparable unless they declare the same proxy. Comfort itself has no operational unit and is treated as a dimensionless magnitude **by stipulation**, not by measurement.

23.16.2 16.2 The postulates

P1 — The internal store obeys a linear first-order recursion `Q_{t+1} = a Q_t + b_t` with `a` and `b_t` not depending on `Q`. *Status:* **DEFINITION** — the model form, restated from the storage law by setting `a := 1 − delta` and `b_t := eta M_t − C_t` [Curzi, 2026a]. It carries no empirical weight; whether any person is described by it is a postulate recorded in Section 17.

P2 — `0 < delta <= 1` implies `0 <= 1 − delta < 1`. *Status:* **ARITHMETIC.**

P3 — A contraction on a complete metric space has exactly one fixed point, reached from any start. *Status:* **CITED** [Banach, 1922]; the difference-equation form with its stability condition is Elaydi [2005], and the corpus states it exactly, with its *a posteriori* bound, in Curzi [2026].

P4 — The reals with `|x − y|` form a complete metric space. *Status:* **CITED**, elementary [Elaydi, 2005]. It is stated separately from P3 because P3 is useless without it and because a

reader checking the chain should see that the completeness requirement was met rather than assumed.

P5 — The smallest detectable change in a magnitude is a constant fraction of that magnitude. *Status:* **CITED** [Weber, 1834, Fechner, 1860, 1966], with the competing power-law account [Stevens, 1957] and the reconciliation [Krueger, 1989]. **The fraction has not been measured for moment magnitudes**, so the law is cited and its constant is stipulated.

P6 (Postulate R1) — The moment enacted and the moment returned lie on one common ratio scale with one modulus. *Status:* **POSTULATED.** No instrument establishes it. It is the commensurability assumption on which Δ_R depends and it is the postulate whose failure produces the demotion of R6.

P7 — Where a fraction `w` of nominally independent sources are one source, the observed correlation-driven signal is attenuated by `(1 - w)`. *Status:* **ARITHMETIC**, given the independence bookkeeping stated in Section 4.5; the design-effect form `n_eff = n/(1 + (n-1) r_icc)` is the standard survey-sampling statement of the same fact.

P8 — 1.96 is the two-sided 95 per cent quantile of the standard normal distribution. *Status:* **ARITHMETIC**, to the three figures used.

23.16.3 16.3 The compounding chain

```
P1 + P2          -> L1   T(Q) = aQ + b has |T(Q)-T(Q')| = a|Q-Q'| with a = 1-delta < 1,
                         so T is a contraction with modulus 1-delta.          ARITHMETIC

L1 + P3 + P4     -> R2a  T has exactly one fixed point Q_inf = b/delta
                         = (eta M* - c*)/delta, reached from any start.       CITED (banach1922operations)

L1               -> R2b  |Q_t - Q_inf| = (1-delta)^t |Q_0 - Q_inf|, an EQUALITY
                         and not merely a bound, since T is affine.           ARITHMETIC

R2b              -> L2   tau = -1/ln(1-delta); half-life = ln 2 / |ln(1-delta)|;
                         t_p = ln(1-p)/ln(1-delta).                           ARITHMETIC

P6               -> R1   Delta_R = |ln(M'/M)| is a well-formed dimensionless
                         quantity in nats, with sign read first.              POSTULATED (P6)

P5 + P6          -> L3   the smallest detectable return difference is
                         Delta_R,min = ln(1+c).                               CITED + POSTULATED

P8 + L3          -> L4   n >= (1.96 sigma_rho / Delta)^2 echoes are needed to
                         resolve a true return of size Delta.                 ARITHMETIC

P7               -> L5   rho_obs = (1-w) rho_true: correlated sources bias the
                         estimate TOWARD ZERO, not merely widen it.           ARITHMETIC

R2a              -> R4   d ln Q_inf / d ln delta = -1 EXACTLY, at every
                         parameter value, since Q_inf is proportional to
                         1/delta; d ln Q_inf / d ln eta = eta M*/(eta M* - c*);
                         d ln Q_inf / d ln C = -c*/(eta M* - c*);
                         and their ratio is eta M*/c*.                        ARITHMETIC

R2a              -> R5   a transfer x shifts the two fixed points by
                         +x/delta and -x/delta, leaving the sum unchanged;
                         the donor's fixed point crosses zero at
                         x* = eta F_B - C_B.                                  ARITHMETIC
```

```
lambda-loop    -> R3   rho_{t+1} = (1-lambda) rho_t contracts iff
                       |1-lambda| < 1, i.e. 0 < lambda < 2; deadbeat at
                       lambda = 1.                                          ARITHMETIC

R1 + P6 fails  -> R6   the scale-type gate returns DEMOTE on every entry
                       whose value passes through M or r = D/P: F-01, F-02,
                       F-04, F-06, F-08 -- five of nine.                    CITED (ccp:CCP-026) + POSTULAT
```

Every line is checkable from its own inputs. **R2a, R2b, R3, R4 and R5 are arithmetic consequences of one model definition (P1), one arithmetic fact (P2) and one cited theorem (P3) with its completeness condition (P4).** R1 and R6 consume P6, the commensurability postulate, which has no external support — and R6 is precisely the finding that P6 is unmet. **A chain in which the paper's headline result is the failure of one of its own postulates is doing what a validation chain is for.**

What this chain does not establish. It does not establish that any person's stored capability obeys P1. That is a modelling postulate, it is not verified here, and the corpus's one preregistered confirmatory test of the same recursion at institutional scope **failed its second falsification rule**: a 2.8 per cent held-out RMSE advantage over a matched AR(1) against a declared margin of 10 per cent [Curzi, 2026i].

23.16.4 16.4 The verification instance, worked

The elasticities are the result other papers quote, so they are the ones to check by hand. The base point is `eta = 0.35`, `delta = 0.12`, `N = 9`, `u* = 0.55` and `c* = 0.22`.

```
F(u*)  = ln(1 + (9-1) x 0.55) = ln(5.4)          = 1.6863990
eta F  = 0.35 x 1.6863990                        = 0.5902397
Q_inf  = (0.5902397 - 0.22) / 0.12               = 3.0853304
```

The four partial derivatives, then the four elasticities, each being the derivative times the lever divided by `Q_inf`:

```
dQ/d(eta)   =  F/delta            = 1.6863990/0.12   =  14.053325
dQ/d(delta) = -Q_inf/delta        = -3.0853304/0.12  = -25.711087
dQ/d(C)     = -1/delta            = -1/0.12          =  -8.333333
dQ/d(u)     =  eta(N-1)/((1+(N-1)u) delta)
                                  = 2.8/(5.4x0.12)   =   4.320988

E_eta   =  14.053325 x 0.35 / 3.0853304  =  4.9186638/3.0853304  =  +1.594209
E_delta = -25.711087 x 0.12 / 3.0853304  = -3.0853304/3.0853304  =  -1.000000
E_C     =  -8.333333 x 0.22 / 3.0853304  = -1.8333333/3.0853304  =  -0.594208
E_u     =   4.320988 x 0.55 / 3.0853304  =  2.3765432/3.0853304  =  +0.770281
```

The `delta` row is the one to look at. The numerator of `E_delta` is `-Q_inf/delta` times `delta`, which is `-Q_inf`; dividing by `Q_inf` gives `-1` with no parameter left in the expression. **That elasticity is exactly -1 at every parameter value and is not a property of this base point**, so it is `ARITHMETIC` and carries no uncertainty. The other three *are* base-point quantities and would move if the base point moved; they are derived from stipulated parameters and are reported as model output, not as measurements.

The headline ratio checks in one line:

```
E_eta / |E_C|  =  1.594209 / 0.594208  =  2.68291
eta M* / c*    =  0.5902397 / 0.22     =  2.68291
```

The two agree to five decimals because they are the same quantity, which is the content of the claim that a 10 per cent efficiency gain is worth 2.7 times a 10 per cent cost cut, and which shows the ratio favours efficiency whenever `eta M* > c*` — that is, whenever the regime is sustainable at all.

23.16.5 16.5 Three secondary checks

The exhaustion horizon. With `eta = 0.35`, `F_B = ln(1 + 8 x 0.45) = ln 4.6 = 1.5260563` and `C_B = 0.22`, the critical transfer is `x* = 0.35 x 1.5260563 − 0.22 = 0.5341197 − 0.22 = 0.3141197`, the `0.3141` of Section 8.7. At `x = 0.40` the donor's fixed point is `(0.5341197 − 0.40)/0.12 = −0.7156691`, the reported `−0.7157`. Starting from its undisturbed fixed point `0.3141197/0.12 = 2.6176642`, the horizon is

```
t = ln( 0.7156691 / (2.6176642 + 0.7156691) ) / ln(0.88)
  = ln( 0.7156691 / 3.3333333 ) / ln(0.88)
  = (−1.5382458) / (−0.1278334)
  = 12.0353 periods
```

which is the reported `12.04`. **ARITHMETIC.** The trajectory reproduces the source's table exactly: `2.6177, 2.2177, 1.5559, 1.0434, 0.6466, 0.3393, 0.1013, 0.0032, −0.0830` at `t = 0, 1, 3, 5, 7, 9, 11, 12, 13`.

The correction half-life. With a fitted decay factor of `0.6418`, the implied gain is `lambda = 1 − 0.6418 = 0.3582` and the half-life is `ln(0.5)/ln(0.6418) = (−0.693147)/(−0.443481) = 1.5629` cycles, the reported 1.56 weeks. **ARITHMETIC**, given the fit.

The sample-size law. At `sigma_rho = 0.30` and a target of `Delta = 0.05` nats, `n >= (1.96 x 0.30/0.05)^2 = (11.76)^2 = 138.30`, so 139 echoes. At `Delta = 0.20`, `(1.96 x 0.30/0.20)^2 = (2.94)^2 = 8.64`, so 9. **ARITHMETIC.**

23.16.6 16.6 Limits, asymptotics, and the domain of validity

`delta -> 0^+`. `tau -> infinity`, `Q_inf -> infinity`, the map ceases to contract at `delta = 0` exactly, and the error law degenerates to `|Q_t − Q_inf| = |Q_0 − Q_inf|` — no forgetting, no attractor, no arrival [Curzi, 2026a]. **Zero loss is a pathology and not an ideal**, and the elasticity `E_delta = −1` is silent about it because an elasticity is a local statement.

`delta -> 1`. `tau -> 0`, `Q_t = b` for every `t > 0`: the store is a pass-through with no memory. The model remains well defined and stops being a model of storage.

`eta F -> c*` from above. `Q_inf -> 0^+` and `E_eta = eta M*/(eta M* − c*) -> +infinity`. **The domain in which the elasticity ranking is a useful guide is bounded away from the sustainability boundary**, and the divergence is a real constraint on the model's use, not a defect: near the boundary any lever is enormously powerful in both directions.

`u -> 0`. `F -> 0`, `Q_inf -> −c*/delta < 0`: with no non-parallelism there is no drive and the store depletes to a negative fixed point. **`u -> 1`.** `F -> ln N`, `Q_inf` at its ceiling and headroom exactly zero — the state in which the only remaining move is to raise `N`.

`N -> 1`. `F = ln(1) = 0` regardless of `u`, so a single framing generates nothing. **`N -> infinity`.** `F -> infinity` logarithmically, which is why the ceiling `ln N` is the binding constraint and why raising `N` has decreasing returns.

`lambda -> 0`. No correction; `rho` is a fixed point of the correction map and the distortion persists. **`lambda -> 2`.** `|1 − lambda| -> 1` and the loop becomes a sustained oscillation; beyond 2 it diverges. **`lambda = 1`** is deadbeat: one step to zero in the noiseless case, and complete transmission of the noise in every other case.

`M' -> 0` or `M -> 0`. Δ_R diverges and then becomes undefined. The domain is `M > 0`, `M' > 0`; **a null return is recorded as `Delta_R = 0` only when a return of magnitude equal to what was sent came back, and never as a code for "nothing came back"**, which is the zero clause of Section 3.5 and is the single most abused point in the instrument.

23.16.7 16.7 Invariance, and how far each claim has been tested

Scale invariance of the return difference. `Delta_R` is invariant under `M -> aM`, `M' -> aM'` for any `a > 0` — a common change of modulus — and is *not* invariant under `M -> aM + b`. That is exactly the similarity group, and it is why P6 demands a ratio scale rather than an interval one. Tested algebraically; it is an identity.

Start-independence of the fixed point. `Q_inf` does not depend on `Q_0`. Exact, and exhibited in Section 8.1's convergence tables from three starts.

Conservation under transfer. `Q_A,inf(x) + Q_B,inf(x)` is independent of `x`. Exact, and exhibited at five values of `x` in Section 8.7, where the sum column reads `5.7030` in every row. **This is the only conservation law the framework actually has, it holds only for a transfer between two systems sharing one `delta`, and it is worth being precise about that** because Mirowski [1989] shows that borrowing the notation of a conserved quantity without the conservation law is the characteristic failure of this genre. The corpus's `Q` accumulates, leaks and is spent; **nothing about `Q` is conserved in general**, and Cartwright [1999] is the escape route the framework should take — specify the arrangement within which each law holds and stop claiming a universality it does not need.

How many scales the invariances were tested at. Start-independence: three starting values, one parameter set. Transfer conservation: five transfer values, one parameter set, one shared `delta`. The elasticity identities: algebraic, therefore all parameter values, but **verified numerically at exactly one base point.** No invariance in this paper has been tested on data from more than one constructed case.

23.16.8 16.8 Analogy discipline and the precision of the numbers

Every borrowing here is a **shared mathematical form** and is labelled as one where it is used. A leaky integrator is a leaky integrator whether it holds charge or stored capability [Oppenheim et al., 1996, Horowitz and Hill, 2015]; nothing physical transfers with the equation. The "stability boundary" of the correction loop is the unit-circle condition of a first-order discrete system and carries no dynamical-systems result beyond it. The "design effect" is survey sampling. **No result in this paper is a derivation from physics, and none should be read as borrowing a physical result's authority.**

On significant figures: the elasticities, the transfer identities and the deadband formula are **exact by construction** and are quoted to six decimals where that is useful. The fitted correction gain `lambda = 0.3582` and its `R^2 = 0.8587` are **estimates from an illustrative constructed series** and are so labelled at every use; the underlying series was chosen, not observed, so the quantity being estimated is a property of the construction. `sigma_rho = 0.30` and the Weber fraction `c = 0.10` are **stipulated** and every number computed from them inherits that status. The shuffle-calibration figures 0.108, 0.120, 0.060 and 98.35 per cent are **measured from simulation** [Curzi, 2026u,ac] and are quoted to the precision those runs support.

23.17 17 Limitations

Five of the nine formulary entries carry no measured magnitudes, and this is the paper's own finding rather than a concession extracted from it. F-01, F-02, F-04, F-06 and F-08 fail the scale-type gate because `D` and `P` are not instrumented on a common ratio scale with a shared true zero [Curzi, 2026t]. Every worked number in those entries is an **illustrative construction demonstrating the arithmetic**. The route back is constructive and priced — Rasch person measures on one linked scale, at approximately 123 items per term to establish a half-logit distortion — and it has not been walked.

The commensurability postulate is the load-bearing unsupported step. Postulate R1, that `M` and `M'` lie on one ratio scale with one modulus, has no external support and no instrument. If it fails, Δ_R is not a quantity, the deadband is not a threshold, and the sample-size law prices

the resolution of something that has no magnitude. It is badged at every use and it is the first thing a critic should attack.

The Weber fraction for moment magnitudes has never been measured. The value `c = 0.10` used throughout Section 4.3 and carried into every deadband figure is **stipulated by analogy to sensory continua**, where Weber fractions of that order are typical. Nothing licenses the transfer. H1 is therefore reported as **not tested**, not as supported.

Every empirical number in Section 14 comes from an illustrative construction. The twelve-week log, the recovered gain, the `R^2`, the efficiency, the flattery check, the trajectory tables and the nine-entry review are all computed from parameters that were chosen. **No dataset was collected and no person was studied.**

Michell's objection is conceded, not answered. Michell [1997] and Michell [1999] hold that psychology assumes quantitative structure without testing for it. The conjoint conditions [Luce and Tukey, 1964] have not been tested for `M`, for `Q`, for `u` or for any cost ledger in this paper, and `Q` is treated as a ratio-scale scalar **by stipulation**. A Rasch demonstration [Rasch, 1960, Andrich, 1988] would be the alternative route and has not been run either.

The model-comparison standard is not fully met, and the unmet rows are printed rather than omitted. Against the corpus's five requirements:

Requirement	Status in this paper
Out-of-sample performance reported	**NOT MET.** The correction-gain regression of Section 14.1 is an in-sample fit on all twelve weeks of a constructed series; no held-out block was reserved. The out-of-sample protocol exists [Curzi, 2026i] and was not applied here.
Matched null with the same number of free parameters	**NOT MET** for the correction-gain fit. The four-baseline suite is *specified* in every FVP-6 row and *run* in none of them.
Information criterion (AIC or BIC) reported	**NOT MET.** No AIC or BIC is computed here, and — so far as the author can establish — **no information criterion is computed anywhere in the corpus.**
Number of free parameters stated explicitly	**MET.** The correction-gain model has two (intercept and slope of `ln rho_t` on `t`); the storage recursion has four (`eta`, `delta`, `u`, `C`) plus the initial condition.
Effect sizes with intervals, not only p-values	**PARTIALLY MET.** `R^2 = 0.8587` is reported for the gain fit with no confidence interval on λ, which is a defect; the elasticities are exact and need none; no p-value is reported anywhere in this paper.

The falsification instrument this paper's entries defer to is itself mis-calibrated, and every FVP-6 row inherits all three failure modes. Against a nominal 0.05 across 500 null trials, independent permutation false-rejected at **0.108** and circular shift at **0.120**, with only block permutation near nominal at 0.060; a filtered repackaging of the input passed all four baselines at `p = 0.0005` and was caught only by the structural ceiling test, its single-step jump being **38.5 times** the theoretical maximum; and against a shared slow driver the shuffle **passed 98.35 per cent** of 4,000 trials while reporting honestly (48.17 per cent detection) in the clean case [Curzi, 2026u,ac]. **A control measuring 0.108 against a nominal 0.05 is anti-conservative by a factor of 2.2, and that number belongs beside every result the suite is used to defend.**

The reflection problem is unanswered. No remedy — randomisation, an instrument, partial-population variation, or a defended stipulation of the reference group after the man-

ner of Brock and Durlauf [2001] — is adopted [Manski, 1993, Shalizi and Thomas, 2011]. Every claim resting on the reflexive loop is a **modelling position rather than an identified empirical result**.

The functional form of the surplus term is underdetermined. `F(u) = ln(1+(N−1)u)` is used throughout as the drive. Latané [1981] proposes a sub-linear power law and Briscoe et al. [2006] proposes `n log n`; all three are decelerating and all three fit the qualitative facts [Stumpf and Porter, 2012]. **Nothing in this paper discriminates among them**, and the elasticity `E_u = +0.770` is an elasticity *of the assumed form*, not of the phenomenon.

`N_eff = 1 + (N−1)u` is not a Hill number. It is a linear interpolation between 1 and `N` and is the corpus's own construction, with no supporting literature in ecology, economics, political science or information theory. The Hill numbers proper — `1/HHI` at order 2 and `exp(H)` at order 1 [Hill, 1973, Jost, 2006] — are different quantities and are used elsewhere in the corpus on measured shares [Curzi, 2026,?]. Where an effective count appears in this paper it is the affine one.

No scaling or power-law claim is made, and this is stated so that the absence is deliberate rather than accidental. No exponent in this paper is estimated from a distribution; the procedure of Clauset et al. [2009] is binding on any such claim elsewhere in the corpus and this paper does not substitute for it.

One presentational defect in the source is recorded rather than silently repaired. The source reports the elasticity of `u` as `+0.770` and, in the same table row, that a 10 per cent increase in `u` raises `Q_inf` by **7.40** per cent. Those differ because an elasticity is a first-order local quantity while `F(u) = ln(1+(N−1)u)` is concave in `u`, so a finite 10 per cent step returns less than the elasticity predicts; the corresponding rows for `eta` and `C` agree exactly (+15.94 against +1.594 and +5.94 against −0.594) precisely because `Q_inf` is *linear* in those two. **Both numbers are correct and the source prints them side by side without saying they are different things**; they are separated explicitly in Section 8.5 above, and a reader who reads `+0.770` as predicting a 7.70 per cent response to a 10 per cent move will find 7.40 and think one of them wrong. Everything else checked reproduced exactly: the four elasticities to six decimals, the identity `E_eta/|E_C| = eta M*/c* = 2.68291`, the transfer table's conserved sum of `5.7030` at five transfer rates, the exhaustion trajectory at nine values of `t`, the horizon of 12.04 periods, the correction half-life of 1.5630 cycles, and the sample-size entries 139 and 9.

The parameters of every worked case were chosen, not measured. `eta = 0.35`, `delta = 0.12`, `N = 9`, `u* = 0.55`, `c* = 0.22`, `sigma_rho = 0.30`, `c = 0.10`, `w`, and every transfer rate. The results are exact arithmetic on stipulated inputs and are labelled as such throughout.

23.18 18 Conclusion

The return difference. The quantity a person can read from the world's answer is $\Delta_R = |\ln(M'/M)|$, the absolute log-ratio between the moment enacted and the moment returned, **with the sign read first and the magnitude second**, and it rests on badged Postulate R1 that the two lie on one common ratio scale. `Delta_R = 0` records a **null exchange, not a success**: zero means no information came back, and treating it as a confirmation is the instrument's most common misuse. The smallest audible echo is the Weber deadband $\Delta_{R,\min} = \ln(1+c)$. Resolving a true return of size Δ takes `n >= (1.96 sigma_rho/Delta)^2` clean independent echoes — **139 of them for a 5 per cent return at `sigma_rho = 0.30`, and 9 for a 20 per cent return** — and where a fraction `w` of the sources are in fact one source, `rho_obs = (1−w) rho_true`, so correlation biases the reading **toward zero** rather than merely widening it.

Correction. Correcting a distortion by a fraction λ of the observed error gives `rho_{t+1} = (1−lambda) rho_t`, which contracts for $0 < \lambda < 2$, diverges at $\lambda \geq 2$, and at $\lambda = 1$ is deadbeat — one step to zero in the noiseless case and **completely noise-transparent in every other**. On the worked twelve-week log the sign read over-framing at an implied factor of **1.4467**, the recovered gain was $\lambda = 0.3582$ with `R^2 = 0.8587` and a **distortion half-life of 1.56 weeks**, and directional efficiency was `E_R = 0.9316`.

Arrival, proved rather than asserted. `T(Q) = (1−delta)Q + b` is a contraction with constant `1 − delta`, so Banach supplies the unique start-independent fixed point `Q_inf = (eta M* − c*)/delta`, and the error law is an **equality and not a bound**: `|Q_t − Q_inf| = (1−delta)^t |Q_0 − Q_inf|`, which coincides with the closed-form solution. These are the statements downstream papers should quote rather than paraphrase.

The elasticities, stated for citation. At the base point `eta = 0.35`, `delta = 0.12`, `N = 9`, `u* = 0.55`, `c* = 0.22`, giving `F = 1.6863990` and `Q_inf = 3.0853304`, the elasticities of the fixed point are

$$\texttt{eta}\ +1.594 \cdot \texttt{delta}\ -1.000 \cdot \texttt{u}\ +0.770 \cdot \texttt{C}\ -0.594,$$

so that **a 10 per cent efficiency gain is worth 2.7 times a 10 per cent cost cut**. All four are **derived, not fitted, and carry no uncertainty**: they are exact partial derivatives of a closed-form expression evaluated at stipulated parameters. **The `delta` elasticity is exactly −1 at every parameter value**, because `Q_inf` is proportional to `1/delta` — halve the leak, double the destination — and is therefore a structural fact rather than a property of this base point. The other three are base-point quantities and would move if the base point moved. The ratio that ranks efficiency against cost is `eta M*/c* = 0.5902397/0.22 = 2.68291`, identical to `E_eta/|E_C| = 1.594209/0.594208`, and it exceeds one whenever the regime is sustainable at all. **Leverage and fragility are the same number**: `E_eta = eta M*/(eta M* − c*)` diverges as the regime approaches unsustainability.

Convergence certifies nothing. `eta F < c*` yields a negative fixed point that the loop reaches just as reliably. And a transfer `x` between two systems shifts their fixed points by $\pm x/\delta$ and leaves the sum unchanged, so **transfer relocates a fixed point and creates none**: at `x = 0.40` against a critical rate `x* = 0.3141`, the donor's steady state is **−0.7157** with exhaustion at **12.04 periods**, while the recipient reads **108 per cent** above what its own regime could produce.

And the formulary demotes five of its own nine entries. Under the corpus's Formula Validation Protocol [Curzi, 2026t], Standing Verdict 1 returns **DEMOTE on the scale-type gate for F-01, F-02, F-04, F-06 and F-08** — every entry whose value passes through the moment `M` or the calibration ratio `r = D/P` — because `D` and `P` are not instrumented on a common ratio scale with a shared true zero. **Withdrawn as measured quantities: the magnitude of `D/P`; the distortion $\Delta = |\ln r|$ as a number; and the quantitative form of the moment-to-storage join.** Every worked figure derived from them in this paper is an **illustrative construction demonstrating the arithmetic**, labelled as such at its use. **Retained in full force: the limiting cases, the `D = P` fixed point, and the ordering over-framed / calibrated / under-framed**, all of which require only ordinal information and none of which the demotion touches. What is demoted is magnitude, not structure. Standing Verdict 2 records that the shuffled-input control on which every falsification row depends is **anti-conservative at 0.108 against a nominal 0.05**, **blind to repackaging**, and **passed 98.35 per cent of trials against a shared slow driver**. **A formulary that demotes five of its own nine entries, names exactly what survives, prices the study that would restore the rest, and prints the miscalibration of its own audit instrument is the protocol working. It is not a caveat and it is not an apology.**

23.18.1 Declarations

Data and code availability

No external dataset was collected for this paper and no human subjects were studied. Every number in Section 14 — the twelve-week echo log, the recovered correction gain and its `R^2`, the efficiency, the flattery check, the trajectory tables, and the nine-entry formulary review — is computed from stated parameters under the models developed in the text, and every table can be re-derived from the equations and parameter values printed beside it. The source manuscript labels these worked series **illustrative constructions** and that label is retained on every one of them. The shuffle-calibration figures quoted in Sections 11.6, 15 and 17 are

simulation results reported in Curzi [2026u] and Curzi [2026ac] and are theirs, not this paper's. The figures are generated by the scripts named in each caption; those scripts contain no data beyond the numbers printed in this paper and the model equations of Sections 4, 8 and 11.

Funding

This research received no external funding.

Conflicts of interest

The author declares no conflicts of interest. The validation verdicts reported here were reached by applying the author's own protocol to the author's own formulary, which is a structural conflict that no declaration removes; it is the reason the demotion count is reported as a headline number rather than as an appendix entry.

Author contributions

Single author. Michael Laurence Curzi derived the results, produced the worked constructions and the figures, ran the formulary audit, and wrote the paper.

Ethics

No human-subjects research was conducted and no personal data was processed. The worked logs are constructed. Two constraints in the source material are design constraints on prospective work and are not reports of any study performed: **an echo source may decline and is then recorded as missing data, never as a null return**, and **a cost carried by another person is counted in that person's ledger, by asking, with a decline path**. Section 8.7's transfer analysis is arithmetic about two coupled recursions and is not a recommendation; its ethical reading is left to the reader.

Preregistration

This paper reports no preregistered test. Every FVP-6 row in the formulary of Sections 11 to 13 records the falsification gate as **SPECIFIED** — the procedure that would run it is given and it has not been run — and every FVP-7 row records **UNTESTED, declared**: no cross-individual study of any of these quantities has been conducted. The preregistered protocol for testing the same recursion at institutional scope, together with the confirmatory application that **failed** its second falsification rule — a 2.8 per cent held-out RMSE advantage over a matched AR(1) against a declared margin of 10 per cent — is reported in Curzi [2026i]. The measured behaviour of the four-baseline suite itself, including a demand-characteristic confound with a true coefficient of zero that passed the whole suite 52.7 per cent of the time, is reported in Curzi [2026u]. Any applied claim resting on this paper inherits both results.

Chapter 24

The Dyad and the Group Moment: Opposition Is Parallel, Calibration Costs All the Headroom, and Distortion Does Not Average

Abstract. At pair scale the surplus law reduces to u = sin^2(theta) with the affine effective count N_eff = 1 + (N-1)u, and the extremality condition yields a result that surprises practitioners: because u depends only on the magnitude of the alignment, a pair in perfect opposition has u = 0, N_eff = 1 and surplus exactly zero, the same as a pair in perfect agreement. Complementarity is orthogonality, not opposition, and a pair at 45 degrees in an N = 12 domain already captures three-quarters of the available ceiling. Sustainability sets a minimum viable angle u_min = (exp(C/eta) - 1)/(N-1), computed at 0.0778 or 16.2 degrees for the worked partnership, below which no joint store exists at all. Non-parallelism decays geometrically with u = 0 globally attracting, so difference is a maintained condition; restoring it every twelve quarters recovers 58 per cent of the total available gain. Reciprocity is asymmetric where u is symmetric: the joint books read identically at imbalance a = 0 and a = 2.20 while one partner's private store carries a negative fixed point. At group scope ln r = ln D - ln p_bar - F makes surplus an exact subtractive correction to distortion, capped at ln N, with an infeasibility floor when D/p_bar > N. Perfect calibration r = 1 is shown to force headroom exactly to zero. Aggregation is refused: an aggregate reading Delta = 0.2324 concealed units at 1.12 and 1.92 and overstated bankable input 4.2553 times. No pair and no organisation was measured: every reproducibility gate reads untested, and the group-scope magnitudes are demoted to illustrative constructions at the scale-type gate.

Keywords: pair surplus; minimum viable angle; reciprocity asymmetry; group moment; calibration ratio; zero headroom; aggregation fallacy

Series: B. Engineering the Surplus **Paper:** CCP-024

24.1 1 Introduction

Two questions sit under most of what is written about collaboration. The first is what a pair of people produces that neither produces alone. The second is what happens to that quantity when the unit of analysis stops being two people and becomes an organisation. This paper answers both inside one formalism and reports three results that run against the usual advice.

The framework's interaction surplus is `F(u) = ln(1 + (N−1)u)`, where `u` measures the non-parallelism of two states in an `N`-category domain and `N_eff = 1 + (N−1)u` is the resulting effective count [Curzi, 2026]. At pair scale the geometry reduces to `u = sin^2(theta)` for `theta` the angle between the two states, and the extremality condition of the surplus functional is stated on the *squared* alignment. That single detail produces the paper's first result. **A pair in perfect opposition and a pair in perfect agreement both read `u = 0`, `N_eff = 1` and surplus exactly zero.** Systematic mutual contradiction is not a source of difference; it is a copy with a sign flip, and it pays a coordination cost for nothing. Complementarity is orthogonality, not opposition, and it is a middle condition with a failure mode at each end.

At group scale the same arithmetic joins the framework's other equation. Writing the organisation's collective perception as a mean intake per channel times an audited effective count of channels, `P = p_bar . N_eff`, and taking logarithms of the doctrine-to-data ratio `r = D/P` gives

```
ln r = ln D − ln p_bar − F
```

an identity in which the group's interaction surplus subtracts from its log-distortion one nat for one nat. The correction is therefore capped at `ln N`, and an organisation whose doctrine load exceeds its domain size — `D/p_bar > N` — cannot be calibrated by any arrangement of its people whatsoever, leaving a residual floor `Delta_min = ln(D/p_bar) − ln N` that only doctrine reduction can move. At the fixed point `r = 1` the input sits at its ceiling, the store reaches its maximum, and headroom is identically zero. Perfect calibration is therefore not an unqualified target, which is not a result anyone would guess from the equation's rhetoric.

The third result is negative and it is about measurement practice. **Distortion does not average.** A headquarters at `Delta = 1.1239` and a field unit at `Delta = 1.9169` aggregate to `Delta = 0.2324`, a figure that reads as near-calibrated while both halves are severely distorted in opposite directions. The aggregate ratio is a weighted mediant of the unit ratios, so it always lies between them, and when they straddle the fixed point it can sit arbitrarily close to it. Computing bankable input from the aggregate overstates it by a factor of 4.26 in the worked case. This is the error Quetelet [1835] committed at the founding of social physics — reading the mean of a distribution as a type rather than as a statistic — and it is the error Kirman [1992] names as the standing problem of aggregation in economics. Granovetter [1978] makes the same point constructively: it is the *distribution* of thresholds, not their mean, that determines what a population does.

Five contributions are new here relative to the surrounding literature rather than relative to the framework. First, the opposition identity and its consequence that a diagnostic built to catch epistemic uniformity by listening for agreement will not catch its mirror image. Second, the minimum viable angle `u_min = (e^{C/eta} − 1)/(N−1)`, a survival line computable from three measurable parameters, below which a pair sustains no joint store at all. Third, the reciprocity asymmetry `a = |ln(eta_AB/eta_BA)|`, which is invisible in a pair's joint account and total in its private ones. Fourth, the exact join between the surplus law and the calibration ratio, with its `ln N` correction ceiling and its infeasibility floor. Fifth, the zero-headroom identity at perfect calibration.

What this paper does not have is a measured organisation. Every reproducibility gate reported below reads untested, the group-scope magnitudes are demoted to illustrative constructions at the scale-type gate, and the paper says so in its Results rather than in a footnote. The framework's own audit of the moment equation returns the same verdict at both scopes and prices the instrument that would restore the magnitudes at approximately 123 items per term [Curzi, 2026]. That is the honest state of the work, and it is stated here so that no reader mistakes a specification for a report.

Sections 2 and 3 state the hypotheses and the framework, including the identification problem that governs every applied reading of the group-scope results. Section 4 develops the pair. Section 5 collects the pair-scope design requirements and failure modes. Section 6 develops the group moment and the join. Section 7 develops the two calibration pathologies and their

opposite corrections. Section 8 works three systems end to end. Sections 9 to 12 discuss what follows, verify the chain from minimal postulates, state the limitations, and conclude.

24.2 2 Hypotheses

The algebraic results below — the opposition identity, the join, the zero-headroom identity — are theorems about equations and cannot be falsified by observation. They are labelled as derivations where they appear. What can be falsified is the claim that the equations describe real pairs and real organisations. The hypotheses separate the two, and each names the observation that would defeat it. The protocol that operationalises them, a preregistered fit against four declared baselines with a frozen model and a held-out window, is specified and applied in Curzi [2026i], whose own confirmatory application failed its second falsification rule with a 2.8 per cent held-out RMSE advantage over a matched AR(1) against a declared 10 per cent margin.

H1 — The opposition identity holds behaviourally. A pair whose positions are reliably recoverable from each other by *inversion* produces the same joint output as a pair whose positions are recoverable by *copying*, and less than an oblique pair matched on ability. **Predicted:** measured `u` near zero in both cases, and held-out joint output tracking `ln N_eff` rather than the presence or absence of overt disagreement. **Falsified by:** systematically contradicting pairs outperforming matched agreeing pairs on held-out joint output, at equal measured `u`.

H2 — The minimum viable angle binds. A pair whose measured non-parallelism is below `u_min = (e^{C/eta} − 1)/(N−1)` accumulates no durable joint store, whatever its effort. **Predicted:** for the worked partnership, `u_min = 0.0778`, or `theta = 16.2` degrees; pairs below their own line show a store that declines geometrically at rate `delta` irrespective of activity level. **Falsified by:** a pair sustaining a growing, externally verified store while measured `eta F(u) < C` over several multiples of `1/delta`.

H3 — Non-parallelism decays and difference is a maintained condition. In a working pair, `u` falls geometrically at a per-period rate `lambda > 0`, and `u = 0` is globally attracting. **Predicted:** `u_t = u_0 (1−lambda)^t`, with a measurable half-life `ln 2 / (−ln(1−lambda))`; for the worked practice, `lambda = 0.0600` per quarter and a half-life of 11.2 quarters. **Falsified by:** a constant-`u` baseline predicting held-out `u` as well as the decay model across pairs with no restoration events.

H4 — Reciprocity failure is invisible in the joint account. Where the two directional conversion rates differ, the joint store is unchanged and the private stores diverge. **Predicted:** at fixed mean conversion, the sum of the two private steady states is constant in the imbalance `a = |ln(eta_AB/eta_BA)|` while the individual values separate linearly; at `a = 2.20` one partner's private steady state is negative. **Falsified by:** measured private stores that do not diverge with measured directional imbalance, or a joint store that moves with `a` at fixed mean conversion.

H5 — Surplus enters the calibration ratio as an exact subtractive term. For an organisation whose collective perception is a mean intake times an audited effective count, `ln r` falls by exactly one nat for each nat of interaction surplus gained. **Predicted:** `ln r = ln D − ln p_bar − F` computed via the join agrees with `ln D − ln P` computed directly, to measurement error, and the two disagree only when one of the three measurements is wrong. **Falsified by:** measured `P` failing to track `p_bar . N_eff` across organisations with independently measured `u`.

H6 — Pseudo-diversity manufactures over-framing on a computable schedule. An organisation that adds no doctrine, cuts no collection and changes no policy

crosses from calibrated to over-framed at `t* = ln(u*/u_0)/ln(1−lambda)` with `u* = (D/p_bar − 1)/(N−1)`. **Predicted:** a dated, parameter-free crossing; at `D/p_bar = 4.0`, `u_0 = 0.55`, `lambda = 0.08` and `N = 12`, `t* = 8.41` periods. **Falsified by:** `r` failing to cross 1 within a preregistered tolerance of `t*`, or a constant-`u` model predicting the observed `r` series as well as the decay model.

Four further claims are **not** hypotheses and are labelled accordingly rather than dressed as testable propositions.

The **moment equation** `M = (D/P).E` is a **postulate** of this framework. Nothing in the framework's mathematical papers derives it, and this paper does not upgrade it. The **commensurate-units convention**, which expresses `D`, `P` and `E` in effective independent evidence-channels per decision period, is a **modelling choice** made so that the ratio is dimensionless; without it the formula is dimensionally void. The **aggregation postulate** `P = p_bar . N_eff` is a **modelling choice** adopted because it is the simplest assumption that makes an aggregate behave like a count. The **contact postulate** `S = ln N . e^{−Delta}` is a **postulate**, and its symmetry — over-framing and under-framing attenuating equally at equal `|ln r|` — is its most doubtful commitment and is separately falsifiable by fitting distinct exponents on the two branches.

The identification of a person, or of an intelligence channel, with a unit vector in an `N`-category space is a **postulate** about encoding, testable in principle and untested in fact. It is badged wherever it is used, and Section 11 records that no reproducibility gate in this paper has been run by anyone.

24.3 3 Framework and method

24.3.1 3.1 What is presupposed

Two results are used throughout and are established elsewhere in this corpus. Neither is an empirical claim.

The surplus functional. For two unit state vectors `x` and `y` drawn from a domain that can express `N` distinguishable categories,

```
F(x,y) = f( u(x,y) ),     u(x,y) = 1 − (x . y)^2 = || x ^ y ||^2   in [0,1]

f(u) = ln( 1 + (N−1) u ),     N_eff = e^{F} = 1 + (N−1) u
```

and `f` is uniquely characterised by four axioms — angle-only dependence, zero at parallel, an affine effective count, and normalisation at orthogonality [Curzi, 2026]. The third axiom is a **design axiom**: the effective count is affine in `u` because the framework chose it to be, and every linear-looking result downstream is a consequence of that choice. The same construction, with `u = 1 − rho^2` recovered from error decorrelation and the affine form badged as design axiom S3 rather than as a theorem, is developed for the single-observer case in Curzi [2026o].

The effective-count idiom is standard practice in ecology and political science, where `1/HHI` and `exp(H)` are the two canonical members of the family [Hill, 1973, Jost, 2006, Laakso and Taagepera, 1979]. It must be said plainly here, and it is said again in Section 11, that **`1 + (N−1)u` is not a member of that family.** It is a linear interpolation between 1 and `N`, it is this framework's own construction, and no literature in ecology, economics, political science or information theory contains it. The concentration instrument that *is* a Hill number of order two — `1/HHI`, with the worked jurisdictional case returning a naive HHI of 0.345000 and 2.898551 effective jurisdictions against a bloc-HHI of 1.000000, an effective count of 1.00 and a surplus term of exactly zero — is a separate quantity [Curzi, 2026]. Wherever this paper writes "effective count" it means `N_eff = 1 + (N−1)u` and nothing else.

Two independent warrants exist for the logarithm and the argument needs only the weaker one. The Fechnerian warrant makes sensation proportional to the logarithm of a

dimensionless stimulus ratio measured from a floor [Fechner, 1966]; it requires a contested perceptual story to be true. The stronger warrant assumes nothing psychological: the time-average growth rate of a multiplicatively evolving quantity is the expectation of its logarithm [Peters and Gell-Mann, 2016], so where a stock compounds rather than adds, the logarithm is the ergodic-average object. The ceiling `ln N` also has an information-theoretic reading as the most an ensemble of `N` equiprobable categories can carry [Shannon, 1948], though this framework does not identify surplus with Shannon entropy and the reading is licensed to bound and nothing more.

The functional form is nevertheless underdetermined by the evidence, and this paper says so rather than waiting to be told. Social impact rises as a *power* of the number of sources with an exponent below one [Latané, 1981], and network value has been argued to grow as `n log n` [Briscoe et al., 2006]. Both are decelerating in count, both reproduce the qualitative facts the framework's logarithm reproduces, and **nothing assembled in this corpus discriminates between them.** What the framework's form has that the alternatives do not is an axiomatic characterisation with the design axiom declared at the point where the choice is made; what it does not have is a discriminating measurement. The general form of this problem — many mechanisms producing indistinguishable curves — is stated compactly by Stumpf and Porter [2012], and the demand for a *differential* prediction, one that simpler models do not also make, by Durlauf [2005].

The storage law. The framework's dynamical core is

```
Q_{t+1} = (1 − delta) Q_t + eta S_t − C_t,     S_t = F(U_t) = ln(1 + (N−1) U_t)
```

a first-order linear difference equation whose update map is a contraction with modulus `1 − delta`, giving the unique start-independent steady state `Q_inf = (eta S − C)/delta` and, at `delta = 0`, no fixed point at all and a bound degrading to `Q_0 + t eta ln N` [Curzi, 2026a]. The associated headroom gauge is `h_t = eta ln N − delta Q_t − C_t`. The quartet of a level, an inflow, an outflow and a delay is the standard vocabulary of system dynamics, formalised four decades before this framework [Forrester, 1961, Sterman, 1989]; headroom is the framework's name for organisational slack [Cyert and March, 1963], and its behaviour near exhaustion has the same shape as utilisation approaching one in a queue [Kingman, 1962].

24.3.2 3.2 Why the pair is the exact scale

The surplus functional is a statement about a *pair* of states. Every application to a group of forty is a modelling extension of a two-body result, badged as such in the framework's roster-reduction result [Curzi, 2026c]. In the dyad there is no extension and no badge to apply, and the triangle inequality is known to fail for geometric triples, so surplus cannot be chained across three states. **The pair is therefore the only scale at which the law is exact**, which is an argument for measuring pairs directly rather than inferring them from a group figure. It is also the reason the group-scope material in Sections 6 and 7 runs under postulates that the pair-scope material does not need.

24.3.3 3.3 The group-scope postulates

Three postulates carry the material from pair scope to group scope. Each is stated with its badge, because none is derived.

> **The commensurate-units convention [modelling choice].** Express `D`, `P` and `E` in one currency: **effective independent evidence-channels per decision period.** `P` is what the organisation takes in — channels consulted, audited for redundancy, times mean intake per channel. `D` is what its standing model asserts about the same decision space without looking: the decision-relevant propositions doctrine fixes in advance, each weighted by the fraction of decisions it constrains, summed. `E` is

the decision-relevant structure actually present in the environment, in the same currency.

The aggregation postulate [modelling choice]. Collective perception is the mean per-channel intake times the effective count of channels, `P = p_bar . N_eff` with `N_eff = 1 + (N−1)u`, where `N` is the number of distinct domains the organisation's intelligence can express and `u` the mean non-parallelism between its channels.

The contact postulate [postulate]. The surplus a group can bank in a period is the ceiling `ln N` attenuated by its distortion, `S_t = ln N . e^{−Delta_t}` with `Delta_t = |ln r_t|`.

The convention is the weakest joint in the construction and is doing real work: without it the moment equation is dimensionally void, and Section 6.12 shows exactly where it fails. The aggregation postulate is the point at which a hundred analysts reading one wire service become one channel, which is the reason a surplus law belongs in an account of institutional perception at all.

24.3.4 3.4 Identification: the reflection problem

This is the most serious methodological objection to the group-scope half of this paper and it is stated here, in the method, rather than in a footnote.

The framework's reflexive structure is that an aggregate influences its members and the members constitute the aggregate. The aggregation postulate is exactly that structure: `P` is built from the mean non-parallelism `u` of channels that are themselves shaped by the organisation whose perception `P` is. **That is a linear-in-means reflexive specification, and Manski [1993] proves that its endogenous social effect is not identified from observational data.** It cannot be separated from contextual effects or from correlated unobservables, and no quantity of data recovers it. Shalizi and Thomas [2011] reinforce the point for network data specifically: influence and selection are generically confounded, and Lyons [2011] documents what happens when that is ignored.

Four remedies are known and none is free: randomise the treatment, find an instrument, exploit partial-population variation, or stipulate the reference group and defend the stipulation. Brock and Durlauf [2001] shows what a defensible version of the last looks like, deriving a mean-field structure from standard discrete choice with the identification conditions stated.

This paper adopts none of them. The reference group is stipulated — the channels are whatever the organisation's channel audit enumerates — but the stipulation is not defended against the alternatives that would produce the same observations. Consequently **every applied reading of `u`, of `P`, and of the join `ln r = ln D − ln p_bar − F` in this paper is a modelling position rather than an identified empirical result.** The algebra of the join is untouched by this: it is an identity between defined quantities. What is touched is any claim that observing an organisation could confirm the mechanism, and no such claim is made below.

The same objection turned on the framework itself is the Lucas critique [Lucas, 1976]. The framework asserts that systems change when they are modelled and measured; it then treats `delta`, `eta`, `u` and `lambda` as constants over an estimation window. Both cannot be true without qualification. The position taken here is the narrow one: the parameters are treated as stable only over a declared window and only while the order proxy is not itself a reported target — which is why the requirements in Sections 5 and 6 insist on an order proxy with an external referent, and why a measure that becomes a target ceases to be a measure [Goodhart, 1975, Campbell, 1979]. Classifications of people interact with the people classified [Hacking, 1995], and a framework that gives people laws to manage their own arrangements by is building an engine rather than describing a machine [MacKenzie, 2006]. The one documented case in which a theory became true by being used — Black–Scholes prices coming to fit a market that had adopted the model — is MacKenzie and Millo [2003], and it is the existence proof this

framework's reflexivity needs; Jussim and Harber [2005] is the counterweight, finding that self-fulfilling effects in classrooms are real but small and often dissipate.

24.3.5 3.5 Aggregation, and the mean read as a type

Section 7.7's result that distortion does not average is a special case of an old and general problem. Quetelet [1835] founded social physics on *l'homme moyen* and made the error the phrase encodes: a mean of a distribution treated as a type rather than as a statistic. Kirman [1992] states the modern form — a representative agent's behaviour need not correspond to any member's, and aggregation is not benign. Granovetter [1978] shows constructively that it is the distribution of thresholds and not their mean that fixes the collective outcome, and Schelling [1971] is the canonical demonstration that an aggregate pattern need not reflect any individual's preference. Wherever this paper writes a single `Q`, `delta`, `u` or `r` for a group, that objection applies, and Section 7.7 computes its price.

24.3.6 3.6 Standing honesty clauses

1. **The framework's mathematical papers are pure mathematics and make no empirical claim.** The extremality result is about vectors. That partnerships and institutions behave this way is this framework's proposal.
2. **As deployed, the surplus functional is a lower bound** on a pair's or an ensemble's information, not the information itself. An `N_eff` of 3.09 does not mean the pair contains 3.09 perspectives; it means the geometry that was measured guarantees at least that much.
3. **Surplus is not Shannon entropy or mutual information.** The logarithm is not a Shannon logarithm and channel-capacity intuitions do not import.
4. **The triangle inequality fails for geometric triples**, which is why the pair is the exact scale.
5. **The affine effective count is a design axiom**, chosen, not derived.
6. **No thermodynamic claim is made anywhere in this paper.**
7. **The predictive-processing correspondence** sometimes noted for the moment equation — precision-weighted priors against sensory evidence — is a structural correspondence between formalisms, not an identity, and is offered as a parallel and nothing more.

24.3.7 3.7 Analogy discipline

The licence to carry physics formalism into social systems is not one this framework can grant itself: it was claimed, contested and partially bounded by others over the preceding half-century [Galam et al., 1982, Castellano et al., 2009]. Every physical form used here is therefore labelled at first use as one of three things — a derivation, a shared mathematical form, or an analogy — and the discipline is one this corpus already imposes on itself, requiring that a user be able to distinguish a borrowed theorem, an ordinary observed effect, and this framework's own conjecture in three separate sentences on demand [Curzi, 2026]. The storage law's identification with a first-order discrete section is a **shared mathematical form**: the same difference equation governs both, and nothing about charge or capacitance is claimed to hold of an institution [Oppenheim et al., 1996, Elaydi, 2005]. The contraction argument is a **derivation**, because the premises of the fixed-point theorem are literally satisfied by the map [Banach, 1922]. The reading of the contact postulate as a law of the minimum — a group banks at the rate of the scarcer of frame and intake — is an **analogy**, offered as motivation and never as evidence; the framework has no citation for it and none is manufactured here.

The standard this borrowing must meet is the one set by social-force models that were validated against measured pedestrian and vehicle trajectories [Helbing and Molnár, 1995]: **prediction of observed data, not internal consistency.** This paper does not meet that standard and says so. The general critique of importing physical formalism into social science, including the specific hazard of borrowing the grammar of a conserved quantity without the conservation law that gave it content, is Mirowski [1989]; the escape route, which this paper

takes, is to specify the arrangement within which each law is claimed to hold rather than to claim universality it does not need [Cartwright, 1999]. Laws written at the social level should be derived at that level rather than imported from a lower one [Anderson, 1972], and an explanation is owed a mechanism rather than a fitted curve [Hedström and Ylikoski, 2010]. Where the charge is that such models forecast nothing, the answer is that prediction is one of sixteen reasons to model and this paper is claiming several of the others [Epstein, 2008].

No scaling, power-law or heavy-tail claim is made anywhere in this paper, so the maximum-likelihood, Kolmogorov–Smirnov and likelihood-ratio procedure that any such claim would require [Clauset et al., 2009] does not apply. The distributional statements that *are* made — that non-parallelism decays geometrically, and that the store approaches its fixed point geometrically — are exponents **defined by the model, not estimated from data**, and Section 11 records that they have not been tested against a constant-`u` baseline on any real series.

24.4 4 The pair

Sociology begins at two. One person is psychology. Three is already a network with three channels, a majority and a possible coalition. Two is the irreducible case: one relation, no majority, no topology. This section develops the surplus law where it is exact, states the result that surprises practitioners, and computes the price of ignoring it.

24.4.1 4.1 The pair surplus, stated exactly

For two unit states `x` and `y` in a domain that can express `N` distinct categories, `x . y = cos(theta)`, and therefore the identity that runs this section:

```
u = 1 − cos^2(theta) = sin^2(theta)
```

Non-parallelism is the squared sine of the angle between two people's states. It is zero when they point the same way, zero when they point exactly opposite ways, and one when they are at right angles. The middle clause is not rhetorical and Section 4.6 is the reason it matters.

The extremality result of the surplus functional states that `F(x,y) = 0` if and only if `x` and `y` are parallel, that is `(x . y)^2 = 1`, equivalently `u = 0` [Curzi, 2026]. The "only if" direction does the work. It is not merely that parallel states produce little; **zero surplus occurs in exactly one circumstance and no other.** If a pair is producing nothing, the formalism names the cause uniquely: either the states are parallel, or the surplus is strictly positive. The mathematical content is immediate, `f(0) = ln(1 + (N−1).0) = ln 1 = 0`, and strict monotonicity leaves nothing else at zero.

The sociological reading is a separate matter and is badged:

> **The dyadic identification [postulate].** The state `x` of a person, with respect to a given decision domain, is taken to be a unit vector in an `N`-category space whose components are that person's weighting across the domain's `N` distinguishable categories. Two people's non-parallelism `u` is then estimable from disagreement, error decorrelation and prediction diversity.

The framework's mathematics does not say human beings are unit vectors. It says that *if* a system's interaction surplus depends on pair geometry through the four axioms, *then* it takes exactly one form. The identification of a person with a state is this framework's, it is testable, and it is badged so that no reader mistakes the theorem's certainty for the identification's. The single most dangerous objection to that identification is Michell [1997]'s: psychology routinely fails to test whether its attributes are quantitative at all before measuring them. Section 11 concedes it and names the remedy that was not run.

24.4.2 4.2 The domain size is not the headcount

This is the most common error made with the pair formula and it is closed first.

`N` is not the headcount. The headcount in a pair is two, always; if `N` were the headcount, the ceiling on pair surplus would be `ln 2 = 0.6931` nats for every pair in the world. `N` is the **number of distinguishable categories the ambient domain can express** — the dimension of the space the two states live in — entering through the normalisation axiom `f(1) = ln N`.

A couple deciding how to spend a Saturday works in perhaps `N = 6`: rest, repair, obligation, pleasure, money, others. A two-person engineering partnership deciding a structural approach may work in `N = 12` or more. **Two people can carry a large `N` between them, and that is what makes a good pair valuable.**

```
ln N is the hard ceiling on the surplus of ONE interaction

N =  2  ->  ln N = 0.6931          N = 12  ->  ln N = 2.4849
N =  4  ->  ln N = 1.3863          N = 16  ->  ln N = 2.7726
N =  6  ->  ln N = 1.7918          N = 24  ->  ln N = 3.1781
N =  8  ->  ln N = 2.0794
```

A pair working an `N = 12` domain at right angles produces 2.4849 nats; the same two people, parallel, produce 0.0000 in the same domain. **The domain sets the ceiling; the angle decides how much of it is obtained.**

24.4.3 4.3 Angle is the control variable

Because `u = sin^2(theta)`, every statement about a pair can be made in degrees. This is the most useful translation in the section, because people can estimate an angle and cannot estimate a squared wedge norm.

theta (deg)	cos theta	u = sin^2 theta
0	+1.0000	0.0000
5	+0.9962	0.0076
10	+0.9848	0.0302
15	+0.9659	0.0670
20	+0.9397	0.1170
25	+0.9063	0.1786
30	+0.8660	0.2500
40	+0.7660	0.4132
45	+0.7071	0.5000
50	+0.6428	0.5868
60	+0.5000	0.7500
70	+0.3420	0.8830
80	+0.1736	0.9698
90	+0.0000	1.0000

A pair fifteen degrees apart has `u = 0.067` — seven per cent of the way to orthogonal, not seventeen. The squared sine punishes small angles severely: two colleagues who see things a little differently are, in this accounting, almost the same instrument. The other end is equally instructive — between 60 and 90 degrees `u` moves only from 0.75 to 1.00. **Most of the available non-parallelism is bought in the first sixty degrees.** A partner need not be an opposite in everything, only genuinely oblique.

24.4.4 4.4 The pair-surplus and effective-count tables

`F(u) = ln(1 + (N−1)u)`, computed across the domain sizes a working pair might occupy.

u	N=2	N=3	N=4	N=6	N=8	N=12	N=16	N=24
0.00	0.0000	0.0000	0.0000	0.0000	0.0000	0.0000	0.0000	0.0000
0.01	0.0100	0.0198	0.0296	0.0488	0.0677	0.1044	0.1398	0.2070

0.70	0.5306	0.8755	1.1314	1.5041	1.7750	2.1633	2.4423	2.8391
0.90	0.6419	1.0296	1.3083	1.7047	1.9879	2.3888	2.6741	3.0773
1.00	0.6931	1.0986	1.3863	1.7918	2.0794	2.4849	2.7726	3.1781

The effective count is the same information in the units practitioners can argue about.

u	N=4	N=8	N=12	N=24
0.00	1.000	1.000	1.000	1.000
0.05	1.150	1.350	1.550	2.150
0.10	1.300	1.700	2.100	3.300
0.20	1.600	2.400	3.200	5.600
0.30	1.900	3.100	4.300	7.900
0.50	2.500	4.500	6.500	12.500
0.70	3.100	5.900	8.700	17.100
0.90	3.700	7.300	10.900	21.700
1.00	4.000	8.000	12.000	24.000

In an `N = 12` domain a pair at `u = 0.50` has an effective count of **6.5** — two people, six and a half. The same pair at `u = 0.05` has an effective count of **1.55**. **The same two human beings register 6.5 or 1.55 depending only on the angle between their states.** Ability does not move that number; ability lives in `N` and in the conversion rate `eta`. The angle is its own parameter and it is the one usually left unmanaged.

24.4.5 4.5 The marginal structure

Differentiating, `dF/du = (N−1)/(1 + (N−1)u)`. At `N = 12`:

u	F(u)	dF/du
0.00	0.0000	11.0000
0.05	0.4383	7.0968
0.10	0.7419	5.2381
0.20	1.1632	3.4375
0.30	1.4586	2.5581
0.50	1.8718	1.6923
0.70	2.1633	1.2644
0.90	2.3888	1.0092
1.00	2.4849	0.9167

The marginal return on non-parallelism at `u = 0` is **twelve times** the marginal return at `u = 1`, which is strict concavity restated. The engineering consequence is asymmetric. **The first**

small increment of difference in a pair is the most valuable thing that can be added to it, and the first small increment of convergence is the most expensive thing that can be lost. A pair drifting from `u = 0.10` to `u = 0.05` loses 0.3036 nats over an interval of 0.05, a rate of 6.07 nats per unit of `u`. A pair drifting from `u = 0.90` to `u = 0.50` loses 0.5170 nats over an interval of 0.40, a rate of 1.29 nats per unit. **Difference lost near the parallel wall is worth nearly five times what the same difference is worth near orthogonality.**

As a fraction of the ceiling at `N = 12`, `F/ln N` runs 0.1764 at `u = 0.05`, 0.2986 at 0.10, 0.4681 at 0.20, 0.5870 at 0.30, 0.7533 at 0.50, 0.8706 at 0.70 and 0.9613 at 0.90. **A pair at 45 degrees already captures three-quarters of what a perfectly orthogonal pair could.** Perfection is not the target; obliqueness is.

The monotonicity of surplus in `u` is, however, the framework's most exposed claim and the literature runs both ways. Supporting it: the bridging value of weak ties and structural holes, with measured effect sizes [Granovetter, 1973, Burt, 2004]; the ecological result that a portfolio of distinct components buys stability [Schindler et al., 2010]; and the finding that diverse problem-solver collections can outperform higher-ability ones [Hong and Page, 2004]. Against it, and cited here rather than left for a reviewer: the formal objection that the last result is a property of its modelling assumptions rather than a theorem about groups [Thompson, 2014]; the measured inverted U in creative collaboration, where success rises with cohesion and then falls [Uzzi and Spiro, 2005]; the short-run costs of surface-level diversity [Mannix and Neale, 2005, van Knippenberg and Schippers, 2007]; the finding that diversity in the short run reduces trust and civic participation, from a scholar who did not want the result [Putnam, 2007], with its rebuttal [Abascal and Baldassarri, 2015]; and the ecological results that increasing diversity and connectance destabilises randomly assembled systems [May, 1972]. **A monotone claim cannot survive that list unqualified**, and this paper restricts it to the regime the arithmetic covers: `u` in `[0,1]` with `C` held fixed. Where cohesion and coordination cost respond to `u`, the curve may turn over and this framework does not say where. Contact across difference produces value only under conditions [Allport, 1954], and `u` needs the same qualification. Finally, three incompatible constructs travel under the word "diversity" — separation, variety and disparity [Harrison and Klein, 2007] — and **`u` is a disparity measure**: it registers how far apart two states are, not how many types are present.

24.4.6 4.6 Opposition is also parallel

Write the alignment between the two states as `rho = x . y`, a correlation in `[−1, +1]`. Then `u = 1 − rho^2`, and `u` depends only on the *magnitude* of `rho`. At `N = 12`:

rho	u	N_eff	F
+1.00	0.0000	1.0000	0.0000
+0.95	0.0975	2.0725	0.7288
+0.90	0.1900	3.0900	1.1282
+0.70	0.5100	6.6100	1.8886
+0.50	0.7500	9.2500	2.2246
0.00	1.0000	12.0000	2.4849
−0.50	0.7500	9.2500	2.2246
−0.90	0.1900	3.0900	1.1282
−1.00	0.0000	1.0000	0.0000

A pair in perfect opposition has `u = 0`, `N_eff = 1` and surplus exactly zero — the same as a pair in perfect agreement. The extremality result covers both cases, because it is stated on `(x . y)^2 = 1`, which is satisfied by `rho = +1` and by `rho = −1` alike. This is not a quirk of notation but a sociological statement following from the geometry with no interpretive help:

> **The mirror and the mirror-image are the same instrument.** A partner who agrees about everything and one who disagrees about everything carry identical infor-

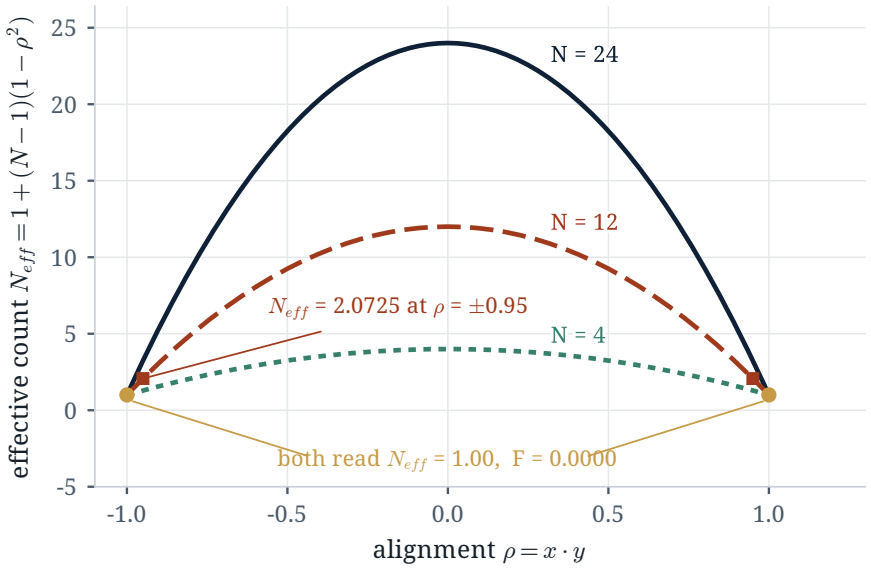

Figure 24.1: **A pair in perfect opposition and a pair in perfect agreement both read an effective count of exactly 1.00 and surplus exactly 0.0000 nats**, because non-parallelism `u = 1 - rho^2` sees only the magnitude of the alignment. At `N = 12` the effective count peaks at 12.00 where the states are orthogonal and falls symmetrically to 1.00 at both `rho = +1` and `rho = −1`; the culture-fit hire at `rho = +0.95` and the sparring partner at `rho = −0.95` both read 2.0725. Computed from the model at the parameter values tabulated in Section 4.6; generated by `figs/src/CCP-024_fig01.py`.

mation, because either position is fully recoverable from the other's. Reflexive contradiction is a copy with a sign flip.

Much of what is called creative tension in partnerships is `rho` near `−1` and generates no surplus at all. It generates heat, which enters the model as cost `C`, not as input `S`. **An opposition pair is a parallel pair with a cost overhead**: it pays `C` and returns zero surplus, a worse position than working alone, since a lone operator at least pays nothing for the redundancy.

The result is not local to the pair. It is the same arithmetic as the framework's roster reduction, where `u` enters `N_eff = 1 + (N−1)u` and `u` sees only `|rho|`, so a systematic contrarian is audited out of the effective count exactly as a systematic agreer is [Curzi, 2026c]. It is also a failure mode **distinct from** the parallel-wall pathology while sharing its arithmetic: the parallel wall is a room that sounds like consensus, the opposition pair is a room that sounds like debate, and both read `N_eff = 1`. **A diagnostic built to catch the parallel wall by listening for agreement will not catch this one**, which is why the obliqueness test below is stated on predictability rather than on assent. The identity recurs across the corpus in domains with no social content at all: in the frequency register, `rho = +1` and `rho = −1` both give `u = 0`, `F = 0` and the same folded note [Curzi, 2026]; in the concentration register, three nominally distinct jurisdictions with a naive effective count of 2.898551 collapse to a bloc count of 1.00 and a surplus term of exactly zero [Curzi, 2026]. The harmonic register carries an exact pairwise identity of the same family, the doubling theorem `HD_ess(i,j) = 2log2(pq)` with `G_ess = 2G(pq) − 1` for the essence ratio `p^2/q^2`, **verified exactly over all sixty-six pairs at `N = 12`** [Curzi, 2026] — which is the closest thing in this corpus to an exhaustively checked pair-scale result, and the standard against which the present section's single-instance checks should be read.

24.4.7 4.7 Complementarity is orthogonality, not opposition

Reading the alignment table by name: `rho = +1.00` is identity, a copy; `rho = +0.95` is the culture-fit hire, `N_eff` 2.07; `rho = +0.50` is complementarity, `N_eff` 9.25; `rho = 0` is maximal complementarity, `N_eff` 12.00; `rho = −0.95` is the sparring partner, `N_eff` 2.07 again; `rho = −1.00` is identity inverted, also a copy.

Complementarity is a middle condition and both extremes of agreement are its failure modes. Advice to find someone who completes you is, read through the law, correct; advice to find someone who challenges everything you say prescribes the right-hand collapse of the same curve.

The operational test is neither "do we agree?" nor "do we argue?":

> **The obliqueness test.** Given the partner's position on a question in the domain, can it be predicted from one's own — by copying it, or by inverting it? If either rule works reliably, `u` is near zero and the pair is producing nothing. **A useful partner is one whose position cannot be computed from one's own by any simple rule.**

Two cautions attach. If `u` is read as a similarity measure over people it cannot be assumed to behave metrically, because psychological similarity is asymmetric and violates the triangle inequality [Tversky, 1977] — the empirical counterpart of the framework's own clause that the triangle inequality fails for geometric triples. And the measured alignment between two people is not a fixed property: social influence measurably collapses the effective count of an ensemble [Lorenz et al., 2011], which is Section 4.12's subject.

24.4.8 4.8 Crossing and divergence within a pair

Non-parallelism decomposes into two sources, and the decomposition applies to a pair as cleanly as to a roster [Curzi, 2026]. For a pure block vector,

```
u = u_cross + u_div        u_cross = beta^2            (between-category difference)
                           u_div   = alpha^2 sin^2 gamma   (within-category difference)
                           alpha^2 + beta^2 = 1

max( f(u_cross), f(u_div) )  <=  f(u)  <=  f(u_cross) + f(u_div)
```

At `N = 12`, worked:

beta^2	gamma	u_cross	u_div	u	f(u_c)	f(u_d)	f(u)	max	sum
0.00	30deg	0.0000	0.2500	0.2500	0.0000	1.3218	1.3218	1.3218	1.3218
0.25	30deg	0.2500	0.1875	0.4375	1.3218	1.1192	1.7600	1.3218	2.4410
0.25	60deg	0.2500	0.5625	0.8125	1.3218	1.9723	2.2963	1.9723	3.2941
0.50	45deg	0.5000	0.2500	0.7500	1.8718	1.3218	2.2246	1.8718	3.1936
0.60	20deg	0.6000	0.0468	0.6468	2.0281	0.4152	2.0937	2.0281	2.4434
0.00	80deg	0.0000	0.9698	0.9698	0.0000	2.4569	2.4569	2.4569	2.4569

Every row satisfies `max <= f(u) <= sum`, and the bound is never tight in the middle rows. That is the honest content of subadditivity: **the pair never gets more than the sum of the two sources, and usually noticeably less.** No synergy beyond additivity is promised, and a design assuming it is unfunded.

At pair scope the two sources have plain names. **`u_cross` is a pair that spans two trades** — an engineer and a clinician, a composer and a statistician: different vocabularies, different training lineages, different failure intuitions. **`u_div` is a pair that shares a trade and disagrees inside it** — two structural engineers who differ on the same question. They are not substitutes. The `beta^2 = 0.60, gamma = 20` degree row is the cross-disciplinary pair that never argues; the

`beta^2 = 0`, `gamma = 30` degree row is the same-trade pair that argues constantly. Both have real surplus. Neither has both kinds. **Diagnose both, and do not accept one as evidence of the other.** The decomposition has been carried through in a group case at `N = 6`, returning `u_cross = 0.72`, `u_div = 0.03`, `u = 0.75`, a balance index of 0.0206, ceiling utilisation of 0.8696 and zero within-block dissents across forty decisions [Curzi, 2026d], which is the extreme instance of one source starved.

24.4.9 4.9 The pair's cost floor

Coordination channels count as `n(n−1)/2` [Brooks, 1975, Conway, 1968]:

```
n     channels    channels per person
---   --------    -------------------
 2        1              0.50
 3        3              1.00
 4        6              1.50
 5       10              2.00
 6       15              2.50
 8       28              3.50
```

The pair is the only human structure with fewer channels than people. Everything else costs more in coordination than it has heads to pay with. That is the structural reason pair-based practices — the two-person cockpit, the two-person research collaboration, the marriage — recur across every domain that works under load. It also means the pair has the highest headroom per person available to any social form, because `C` is at its floor.

The corollary is uncomfortable. **A pair that produces nothing has no excuse available.** It cannot blame coordination overhead, because it has the minimum, and under the extremality result exactly one cause remains. A parallel argument in the frequency register reaches the same place from the cost side: the net octave gain of a group of `m` runs `NET(m) = 2log2(m) − 1.442695(kappa/eta)m(m−1)`, so a pair is viable in the best case if and only if `kappa/eta <= ln 2 = 0.693147` [Curzi, 2026].

24.4.10 4.10 Reciprocity: non-parallelism is symmetric, conversion is not

`u(x,y) = u(y,x)` identically, since it is built from `(x . y)^2`. Therefore:

> **The surplus of a pair is a joint property. Neither person owns it, neither person produced it, and it cannot be divided between them.**

No accounting scheme can attribute a pair's surplus to one member, and any incentive structure that tries is measuring something the law says does not exist. **Conversion is a different matter, and conversion is where reciprocity lives.**

> **The directional conversion postulate [postulate].** A pair has two conversion parameters, one per direction. The joint store converts at the mean `(eta_AB + eta_BA)/2`; each partner's private store converts at the rate directed toward them. Reciprocity is the condition `eta_AB = eta_BA`, and its violation is measured on a log-ratio, `a = |ln(eta_AB / eta_BA)|`.

```
a = 0        symmetric
a = 0.4055   a 3:2 imbalance
a = 0.6931   a 2:1 imbalance
a = 1.3863   a 4:1 imbalance
a = 2.1972   a 9:1 imbalance
```

Running each partner's private store at `delta = 0.15`, `C_A = C_B = 0.25`, `u = 0.45`, `N = 12`, so `S = 1.7834`, and holding the **mean conversion fixed at 0.50** in every row:

eta_AB	eta_BA	mean	a	Q_A(inf)	Q_B(inf)	sum
0.50	0.50	0.50	0.0000	+4.2780	+4.2780	+8.5559
0.60	0.40	0.50	0.4055	+3.0890	+5.4669	+8.5559
0.70	0.30	0.50	0.8473	+1.9001	+6.6558	+8.5559
0.80	0.20	0.50	1.3863	+0.7112	+7.8448	+8.5559
0.90	0.10	0.50	2.1972	−0.4777	+9.0337	+8.5559

The sum is constant down the whole column and the individual outcomes are not, which is exactly what an aggregate measurement misses:

> **Reciprocity failure is invisible in the joint account and total in the private one.** The partnership's books read identically at `a = 0` and at `a = 2.20`. At `a = 2.20` one partner's private store has a *negative* steady state — the storage law's declared failure mode, reached not by any deficiency of the pair's geometry but purely by the direction of its conversion [Curzi, 2026a].

A partnership described as productive but one-sided is describing exactly this. The productivity is real and sits in the sum; the one-sidedness is real and sits in the split. Both are true at once. The wider literature on reciprocity supplies the normative half of this — the dyad-to-group move has its formal core in repeated interaction and indirect reciprocity [Axelrod, 1984, Nowak and Sigmund, 2005], and the governance of shared stores under monitored reciprocity is the subject of a large empirical programme [Ostrom, 1990] — but **none of that literature contains this quantity**, and `a` is offered here as this framework's construction.

24.4.11 4.11 The return difference

For a pair, let `M` be what one partner sends into the relation and `M'` what comes back. The return difference is `Delta_R = |ln(M'/M)|`.

M'/M	Delta_R	
3.00	1.0986	
2.00	0.6931	
1.50	0.4055	
1.25	0.2231	
1.10	0.0953	
1.00	0.0000	<– no information returned
0.90	0.1054	
0.75	0.2877	
0.50	0.6931	
0.33	1.1087	

`Delta_R = 0` means the pair returned the sender's own signal unchanged. **An echo is not a reply.** In the pair this is the behavioural face of `u = 0`: the partner whose response is always the sender's own position restated is not a partner but a surface. The magnitude says how much came back; the sign of `ln(M'/M)` says which direction the world moved the sender.

24.4.12 4.12 Every working pair destroys its own non-parallelism

Here is the structural problem that makes this a maintenance question rather than a selection question. A pair that works together converges: shared vocabulary, shared references, shared

priors, shared blind spots. Every one of those is `Q` going up and `u` going down. **The pair's stored order and its input geometry are in direct conflict, and the conflict is not a design error. It is what success looks like from the inside.**

The same mechanism is documented outside this framework and with a simulation attached: an organisation whose members learn fast homogenises and destroys the variance that produced its advantage [March, 1991]. Formal models of belief updating reach the same fixed point — a row-stochastic influence matrix drives a population to consensus [DeGroot, 1974] — and the device that prevents collapse in those models, a stubbornness term anchoring each agent to its initial position [Friedkin and Johnsen, 1990], is formally the same object as this framework's leak. Bounded-confidence models predict the *number* of surviving clusters from a coupling parameter [Deffuant et al., 2000, Hegselmann and Krause, 2002], which is an effective count derived from an interaction constant and is prior art for this genre of result.

Model the drift as geometric decay, `u_t = u_0 (1 - lambda)^t`:

```
lambda   half-life of u (periods)
------   -------------------------
0.02              34.31
0.05              13.51
0.08               8.31
0.10               6.58
0.20               3.11
0.30               1.94
```

At `u_0 = 0.60`, `lambda = 0.10`, `N = 12`, twenty periods run as follows:

```
t      u        N_eff     F
---    ------   -------   ------
 0     0.6000    7.6000   2.0281
 5     0.3543    4.8972   1.5887
10     0.2092    3.3013   1.1943
15     0.1235    2.3589   0.8582
20     0.0729    1.8024   0.5891
```

Twenty periods of successful collaboration take a pair from an effective count of 7.6 to an effective count of 1.8. Nobody did anything wrong. They agreed with each other, repeatedly, because they were learning from each other, which is what they were supposed to do. **A pair has no internal source of `u`. It must import.** The geometric form is a modelling choice and is badged as one: pairs may converge in bursts around shared projects rather than smoothly, and the exponent here is defined by the model rather than estimated from data.

24.4.13 4.13 The minimum viable angle

Setting the steady state to zero and solving for the non-parallelism below which the pair holds no store at all: `Q_inf >= 0` requires `eta F(u) >= C`, so

```
S_min = C / eta
u_min = ( e^{C/eta} - 1 ) / (N - 1)
```

For a pair with `eta = 0.55`, `C = 0.34`, `N = 12`:

```
S_min = 0.34 / 0.55 = 0.6182
u_min = (e^0.6182 - 1) / 11 = 0.0778
N_eff at u_min = 1.8556
```

Below `u = 0.078` this pair sustains no joint store whatsoever. The relationship does not merely become less productive; its equilibrium goes negative and everything it built erodes at rate `delta`. In degrees, `u = 0.0778` is `theta = 16.2`. **Sixteen degrees is this partnership's survival line**, and every pair has such a line, computable from three numbers it can measure. The line is a threshold in the modelling sense and nothing more: it is where a linear model reports that it has left its own domain, not a cliff observed in any pair.

24.4.14 4.14 Maintenance beats selection, computed

If `u` decays and there is no internal source, the only lever left is periodic re-injection: importing difference on a schedule. Take the same pair — `eta = 0.55`, `delta = 0.12`, `C = 0.34`, `N = 12` — starting at `u_0 = 0.62` with drift `lambda = 0.06` per quarter, and compare restoring `u` to 0.62 every `k` quarters against no restoration, measured by the store after 24 quarters:

```
restoration interval    Q at t = 24
--------------------    -----------
never                      2.7064
every 12 quarters          4.7070
every  8 quarters          5.3283
every  6 quarters          5.6209
every  4 quarters          5.8991
every  2 quarters          6.1615
```

Restoring once every twelve quarters — one deliberate importation of difference every three years — recovers **58 per cent** of the gap between doing nothing and doing it every six months: 4.7070 against 2.7064, with a maximum of 6.1615. Moving from twelve-quarterly to six-quarterly buys 0.9139 further units of store; moving from six-quarterly to two-quarterly buys 0.5406 more.

The returns on restoration frequency are themselves concave, and the first restoration is worth more than all subsequent increases in frequency combined. A pair that never restores loses roughly two-thirds of its potential store and experiences the loss as fatigue. What counts as a restoration is specified in requirement S-12: not a holiday, but the deliberate introduction of a state the pair cannot predict from its own. The general finding that a leaky integrator responds to cadence rather than to intensity is developed with its step, impulse and frequency responses in Curzi [2026a].

24.4.15 4.15 Validation gates at pair scope

Each formula is carried through a seven-gate protocol: dimensions, scale type, limiting cases, fixed points, identifiability, falsification, and reproducibility. The tables below are the findings. **Every reproducibility row reads untested**, and that is the honest state of the work rather than an omission.

Table V-P1 — Non-parallelism `u = 1 - (x.y)^2`

Gate	Finding
1 Dimensions	`x`, `y` unit vectors; `x.y` dimensionless; `u` dimensionless in `[0,1]`. Both sides agree. **PASS.**

Gate	Finding
2 Scale type	`u` is ratio-scaled with a true zero (exact parallelism) and a true maximum. The *components* of `x` need at least interval scale to normalise; with ordinal rankings only, `u` must come from a rank-correlation surrogate and **demotes to an ordering, not a magnitude**. **CONDITIONAL PASS — the encoder must be declared.**
3 Limiting cases	`u -> 0`: identical or exactly opposite states (Section 4.6). `u -> 1`: orthogonal, no mutual predictability. Both nameable; `u` is bounded, so no divergence. **PASS.**
4 Fixed points	`u = 0`, the invariant of the copy relation and the unique zero of `F`; `u = 1`, the invariant of independence. Both attained. **PASS.**
5 Identifiability	`u` is recoverable from disagreement rates and error decorrelation without observing `x` and `y`. It does **not** distinguish `rho = +0.9` from `rho = -0.9`; sign information is lost and must be recovered separately. **PASS WITH DECLARED AMBIGUITY.**
6 Falsification	Preregister `u` from pre-discussion disagreement; predict held-out joint output; beat persistence, direct-input, matched autoregressive and shuffled-input baselines. **Kill condition: `u` at `t` fails to improve prediction of `t+1` output over the shuffled control.**
7 Reproducibility	The cross-pair test: same operationalisation, different observer, different pair, same domain — does `u` recover? **UNTESTED. This is the gate that decides whether the dyadic identification is science, and it has not been run.**

Table V-P2 — Pair surplus `F = ln(1 + (N-1)u)` and `N_eff = 1 + (N-1)u`

Gate	Finding
1 Dimensions	`(N-1)u` dimensionless, so the logarithm's argument is dimensionless as required. `F` in nats; `N_eff` a pure count. **PASS.**
2 Scale type	`N` a count (ratio scale, true zero); `u` ratio-scaled per Table V-P1; `F` in nats inherits ratio scale. **PASS, conditional on V-P1's encoder.**
3 Limiting cases	`u -> 0`: `F -> 0`, `N_eff -> 1`, the non-event. `u -> 1`: `F -> ln N`, the ceiling. `N -> infinity` at fixed `u > 0`: `F` diverges logarithmically — real divergence, so slow as to be useless. `N -> 1`: `F -> 0` for all `u`, correct, since a one-category domain admits no difference. **PASS.**

Gate	Finding
4 Fixed points	`F = 0` if and only if `u = 0`; `F = ln N` if and only if `u = 1`. Unique both ways. **PASS — the strongest fixed-point result in the paper.**
5 Identifiability	`N` from enumerating declared categories, `u` from the decorrelation protocol — separately recoverable. But `F` alone does **not** identify `(N, u)`: `F = 0.6931` arises from `(N=2, u=1)` and from `(N=12, u=0.0909)`. **Report `N` and `u`, never `F` alone. PASS ONLY IF BOTH ARE REPORTED.**
6 Falsification	As V-P1, plus the preregistered prediction that output scales with `ln N_eff` rather than with headcount or mean ability. **Kill condition: headcount or mean ability predicts held-out joint output better than `ln N_eff`.**
7 Reproducibility	**UNTESTED at pair scope.** The nearest published evidence that group output tracks something other than member ability is a collective-intelligence factor measured in short laboratory tasks, with a turn-taking equality term [Woolley et al., 2010]. That is supporting context and not confirmation: it is a group-scale, laboratory, short-task result and not a pair-scale field result.

Table V-P3 — Pair storage `Q_{t+1} = (1−delta)Q_t + eta S_t − C_t`

Gate	Finding
1 Dimensions	`Q` in declared order-units; `S` in nats; **`eta` therefore carries order-units per nat per period** and must be reported with them; `delta` dimensionless per period; `C` in order-units per period. **PASS, provided `eta`'s units are declared.**
2 Scale type	Requires `Q` ratio-scaled with a true zero. For a pair the order proxy — shared method, joint artefacts, documented decisions — must be countable. **PASS where the proxy is a count; FAILS and demotes where it is a satisfaction rating.**
3 Limiting cases	`delta -> 0`: no fixed point, `Q_t <= Q_0 + t.eta.ln N` — the pair that never forgets and never revises [Curzi, 2026a]. `delta -> 1`: total amnesia each period. `eta -> 0`: the pleasant partnership that builds nothing. `C` large: negative `Q_inf`. **PASS — every divergence names a real condition.**
4 Fixed points	`Q_inf = (eta F(u*) − c*)/delta` for `delta > 0`, unique, reached geometrically since the map is a contraction with modulus `1−delta` [Banach, 1922]. **PASS.**

Gate	Finding
5 Identifiability	`delta` from decay under zero input; `eta` from attributable change in `Q` per unit `S`; `C` from tally. **Known hazard: if the order proxy repackages the input, `eta` and the surplus term are not separately identifiable.** Acute for pairs — "we have a great shorthand" is both. **CONDITIONAL PASS; the proxy must be independently justified.**
6 Falsification	Fit the frozen model, report held-out performance against four baselines. **Kill condition: the shuffled-input control matches the fitted model held-out** [Curzi, 2026i].
7 Reproducibility	**UNTESTED.** Whether `(delta, eta)` from one pair transfer to another pair in the same trade has not been run.

Table V-P4 — Reciprocity asymmetry `a = |ln(eta_AB / eta_BA)|`

Gate	Finding
1 Dimensions	Ratio of two identically-united quantities; argument dimensionless; `a` in nats. **PASS.**
2 Scale type	Requires both conversions ratio-scaled with a true zero, that is a direction that converts nothing. Attainable where `eta` is attributable durable output per unit input. **PASS.**
3 Limiting cases	`a -> 0`: perfect reciprocity. `a -> infinity`: one direction converts nothing — the audience relation, the extractive partnership. Both nameable. **PASS.**
4 Fixed points	`a = 0`, which is exactly the reciprocity condition. It is **not** an attractor: nothing in the model drives `a` down, which is why reciprocity needs a protocol. **PASS, fixed point unstable in practice.**
5 Identifiability	The two directional conversion rates are identifiable only if each private store is measured separately. **From the joint store alone they are NOT identifiable** — every row of Section 4.10's table sums to the same total. **PASS ONLY UNDER SEPARATE MEASUREMENT; this is why "the partnership is doing well" is not evidence of reciprocity.**
6 Falsification	Preregister `a` from directional attribution; predict divergence of the two private stores. **Kill condition: `a` fails to predict store divergence beyond chance.**
7 Reproducibility	**UNTESTED.**

Table V-P5 — Return difference `Delta_R = |ln(M'/M)|`

Gate	Finding
1 Dimensions	`M` and `M'` share units by construction, so the ratio is dimensionless and `Delta_R` is in nats. **PASS.**
2 Scale type	**The binding gate.** `M'/M` requires `M` ratio-scaled with a true zero. With only ordinal reports, `Delta_R` demotes to "the reply differed / did not differ" — an ordering, not a magnitude. **CONDITIONAL, and in most pair settings the condition is not met without a magnitude-estimation procedure** [Stevens, 1946].
3 Limiting cases	`M' -> M`: `Delta_R -> 0`, the echo. `M' -> 0`: `Delta_R` diverges, total absorption. `M -> 0`: undefined, correctly, since nothing was sent. **PASS.**
4 Fixed points	`M' = M`: the relation returns what entered it. **This is a null, not an ideal.** The design target is `Delta_R` bounded away from zero, not minimised. **PASS.**
5 Identifiability	Only the ratio is recoverable, never `M` and `M'` separately. Report the ratio with its direction. **PASS WITH DECLARED LIMITATION.**
6 Falsification	Preregister that pairs with persistently low `Delta_R` show lower held-out joint output. **Kill condition: no relation beyond the shuffled control.**
7 Reproducibility	**UNTESTED, and blocked upstream by gate 2.** Until magnitude estimation of `M` is established this gate cannot be attempted. Stated rather than skipped.

Table V-P6 — Non-parallelism decay `u_t = u_0 (1−lambda)^t`

Gate	Finding
1 Dimensions	`lambda` dimensionless per period; `u` dimensionless; `t` a count. **PASS.**
2 Scale type	Ratio scale in `u` per Table V-P1, count scale in `t`. **PASS.**
3 Limiting cases	`lambda -> 0`: `u` constant — a pair that works together and never influences the other, which is the mark of a pair not actually collaborating. `lambda -> 1`: collapse to `u = 0` in one period, total capture of one partner by the other. Both real. **PASS.**
4 Fixed points	`u = 0`, unique and **globally attracting for any `lambda > 0`.** The central engineering fact: convergence is the default and difference is the maintained condition. **PASS.**
5 Identifiability	`lambda = 1 − (u_1/u_0)^{1/dt}` from two clean `u` measurements with no restoration between. **PASS.**

Gate	Finding
6 Falsification	Preregister `lambda` from periods 1–8, predict `u` at period 16, compare to a constant-`u` baseline. **Kill condition: constant-`u` predicts held-out `u` as well as the decay model.**
7 Reproducibility	**UNTESTED.** Geometric decay is the simplest assumption, not a measured law. **The functional form is a modelling choice, badged as one, and its exponent is defined by the model rather than estimated.**

24.4.16 4.16 Scope constraint on use

Interventions at pair scope act on people who did not attend the design meeting. **Nothing here licenses arranging a person's partnerships for them, selecting their associates by measured obliqueness, or scoring a relationship they did not agree to have measured.** These instruments are for a pair to point at itself, or for an institution to point at partnerships it is itself constituting — a review pairing, a co-authorship, a two-person watch. The moment a protocol removes a person's ability to decline the measurement or the pairing, it is outside the framework's scope and stays outside. The corpus's own treatment of this seam is stricter than a permission rule and bounds what may be claimed here: category innocence is refused as a defence of acquisition, moving a harm through a discovered gap in a scheme is forbidden, and the case in which the feedback loop runs through another person's will is conceded to be an unsettled seam the corpus does not close [Curzi, 2026]. The open-design principle applies to the instruments themselves: a protocol should remain defensible when everything about it except the participants' data is public [Kerckhoffs, 1883].

24.5 5 Design requirements and failure modes at pair scope

24.5.1 5.1 Requirements

Each requirement names the parameter it moves.

S-1 Declare the domain and count it. Write down the domain's `N` — the distinguishable categories the pair's work must span — and justify each, before any pairing is assessed. `[N]` *Test: an independent reader lists the same categories from the written definition.*

S-2 Never report `F` without `N` and `u`. Per gate 5 of Table V-P2, `F` alone does not identify the pair. `[reporting]`

S-3 Estimate `u` before the pairing is fixed. Independent pre-discussion estimates on at least eight domain questions; disagreement and error decorrelation. `[u]` *Test: estimates recorded before the two people spoke about the questions.*

S-4 Apply the obliqueness test. If either position is reliably recoverable from the other by copying or by inversion, record `u` near zero and do not assume surplus. `[u]` *Test: predictive accuracy of the copy rule and of the inversion rule, both measured.*

S-5 Reject opposition as a substitute for complementarity. A pair whose disagreement is systematic and total is `rho` near `−1` and `u` near zero. Record it as a similarity failure, not as productive tension. `[u, C]`

S-6 Measure `u_cross` and `u_div` separately and report both; a pair rich in one and starved of the other is a diagnosable condition with a specific fix. `[u]`

S-7 Compute the minimum viable angle. `u_min = (e^{C/eta} − 1)/(N−1)`; every standing pair should know its own. `[Q]` *Test: the number is written down and dated.*

S-8 Measure `delta` and `eta` before promising anything: `delta` from decay under zero input, `eta` from attributable durable output per unit input. `[delta, eta]`

S-9 Justify the order proxy independently of the input. The `Q` proxy must not restate interaction volume. "We talk constantly" is an input measure; "a documented method a third party executed successfully" is an order measure. `[Q]`

S-10 Require an artefact per period. Periods producing no durable object are running at `eta` near zero regardless of how they felt. `[eta]` *Test: name the artefact for each of the last six.*

S-11 Measure `lambda`, the convergence rate. Two clean `u` measurements, six or more periods apart, with no restoration in between: `lambda = 1 - (u_1/u_0)^{1/dt}`. `[u maintenance]`

S-12 Schedule restoration. Interval no longer than the measured half-life of `u`. A restoration is a deliberate importation of a state the pair cannot predict from its own: a third party from another lineage in a working session, a rotation into an unfamiliar problem class, an adversarial review by someone differently trained. **A holiday is not a restoration; it changes `C`, not `u`.** `[u]` *Test: restorations are on the calendar, each naming its source of difference.*

S-13 Measure both private stores, not only the joint one. Per gate 5 of Table V-P4, reciprocity is unidentifiable from the joint account. `[eta, reciprocity]`

S-14 Set a reciprocity threshold and act on it. Recommended trigger: `a > 0.6931`, a two to one directional imbalance, prompts a review of what flows each way. Below that, note and monitor. **The threshold is a design choice and not an empirical finding; no distribution of measured `a` exists.** `[reciprocity]`

S-15 Keep `Delta_R` bounded away from zero. Replies that restate the sender return no information. Where `M` cannot be ratio-scaled, demote to the ordinal test — did the reply contain a position the sender could not have generated? — and record it as ordinal. `[information]`

S-16 Do not add a third person to fix a pair problem. One head triples the channels, from one to three, and raises `C` at once; it raises `u` only if the third is oblique to both. Compute headroom first. `[C, u]`

S-17 Compute headroom before requesting an increment. `h = eta ln N - delta Q - C`; no increment may exceed `h`. `[h]`

S-18 Recognise that headroom falls as the pair succeeds. `delta Q` grows with `Q`, so a long partnership spends more of its budget maintaining what it built. Plan the transition to maintenance rather than being surprised by it. `[h]`

S-19 Shed `Q` deliberately when headroom goes negative. Retiring a shared method or dropping an accumulated obligation are legitimate and underused moves. `[Q, h]`

S-20 Every measurement here is opt-in for both parties. `[ethics]`

24.5.2 5.2 Failure modes

Each names its damaged parameter, its signature, its measurement and its fix.

FM-P1 The mirror pair. Two people selected for similarity — same training, lineage, incentives — whose agreement is read as corroboration. *Damages:* `u -> 0`, therefore `S -> 0`. *Signature:* pre-discussion estimates agree within noise; neither can name a question on which they expect to differ; meetings are short, pleasant and produce no revisions. *Measurement:* copy-rule predictive accuracy above 0.9 on held-out domain questions. *Fix:* import. The pair has no internal source of `u`. A practitioner from an unrelated trade in a working session, on a schedule, not as a one-off.

FM-P2 The opposition pair. Systematic mutual contradiction mistaken for rigour, `rho` near `-1`. *Damages:* `u -> 0`, `C` up. *Signature:* each position is predictable by inverting the other's; conflict constant, positions stable, nothing moved in a year. *Measurement:* inversion-rule predictive accuracy above 0.9. *Fix:* as FM-P1 — the same fault with a sign flip — plus cut `C`: the heat is dissipation and buys nothing.

FM-P3 The converged pair. A pair that began oblique and became parallel through successful collaboration. The commonest failure in long partnerships and the least likely to be

diagnosed, because every step that produced it was correct. *Damages:* `u`, via `lambda`. *Signature:* `Q` peaks then declines while headroom stays positive; fatigue reported; the decline attributed to market conditions or workload. *Measurement:* two `u` measurements six or more periods apart; a halving is decisive. *Fix:* restoration at or below the measured half-life. The first restoration recovers most of what is available.

FM-P4 The one-way channel. Conversion flows overwhelmingly one way; one private store grows, the other reaches a negative equilibrium. *Damages:* `eta` directionally; `Q` for one member. *Signature:* the joint account looks healthy; one partner reports growth, the other depletion, and both reports are accurate. *Measurement:* separate private stores; `a = |ln(eta_AB/eta_BA)|`. **Not detectable from the joint account.** *Fix:* reallocate what flows each way. Where the asymmetry is structural — a genuine mentorship — say so and set an end date rather than running it as a partnership.

FM-P5 The pleasant void. High `u`, high `S`, `eta` near zero. Genuinely different people who enjoy each other and build nothing. *Damages:* `eta`. *Signature:* "we had a great conversation"; no artefact for six periods; `Q` flat or declining despite strong measured `u`. *Measurement:* artefact count; `eta` as attributable change in `Q` per unit input. *Fix:* capture mechanisms at pair scale — decision log, written summary, changed default, built object. **Nearly always the cheapest intervention available, and it should be tried before anything is done to `u`.**

FM-P6 The echo partner. One member returns the other's own signal, `Delta_R` near zero. *Damages:* information return; downstream, `u`. *Signature:* every reply is a restatement, elaboration or endorsement; nothing comes back that the sender could not have generated. *Measurement:* `Delta_R` where `M` is ratio-scaled; the ordinal demotion of S-15 otherwise. *Fix:* structural, not personal — independent estimate before discussion at pair scale, both write first and then compare. Defeats the echo mechanically, with no confrontation.

FM-P7 The sub-angle pair. A pair below its own `u_min`: the steady state is negative and the store erodes at rate `delta` whatever anyone does. *Damages:* `Q`, terminally. *Signature:* everything built two years ago is degrading; effort produces maintenance, never gain. *Measurement:* `u_min` against measured `u`. *Fix:* raise `u` by import, raise `eta` by capture, or cut `C`. Raising `N` is logarithmic and the worst buy. **If none is available, no arrangement of these two people prevents decline.**

FM-P8 The third-person reflex. Adding a third member to fix a pair deficit. Channels go from one to three, `C` rises at once, `u` rises only if the newcomer is oblique to both. *Damages:* `C`, and often `u`, if the third is a lineage-mate of either. *Signature:* headroom falls after the addition; output does not rise. *Measurement:* `h` before and after. *Fix:* prevention — measure the newcomer's `u` against **both** members first. A third oblique to one and parallel to the other buys less than the channel count costs.

FM-P9 The unjustified proxy. The order measure repackages the input measure — "we have great shorthand" counted as `Q`, when shorthand is downstream of interaction volume. *Damages:* measurement validity; `eta` unidentifiable. *Signature:* `eta` near 1 with little residual; excellent training fit, held-out failure. *Measurement:* is the order proxy derivable from the input without anything outside the pair? *Fix:* an order proxy with an external referent — work a third party can execute, a decision whose outcome is later observable, a physical artefact.

FM-P10 The unbadged identification. Treating the dyadic identification as though it were the extremality theorem. *Damages:* the argument's warrant. *Signature:* "the mathematics proves this partnership cannot work." *Measurement:* read the sentence — does it assert something about vectors or about people? *Fix:* restate with the badge on. The theorem is exact about states; the identification of people with states is this framework's, is testable, and has not passed the reproducibility gate.

24.6 6 The group moment

The framework's second equation is the moment equation, given at the scale of one person as `M = (D/P).E`, with `D` the frame a mind brings, `P` the intake it achieves, `E` the environment, and `M`

the moment as lived. This section takes the same equation, keeps every symbol, changes only the referent of each, and asks whether it still says anything.

It does, and the reason is not rhetorical: **the group version acquires a term the personal version does not have, and that term is the interaction surplus.** `D` becomes shared doctrine — the standing model an organisation carries about the world it operates in. `P` becomes collective perception: the intelligence the organisation actually gathers, audited for redundancy. `E` is the environment. `M` is the situation as the group constructs it, which is never the environment itself.

24.6.1 6.1 The equation at group scope

```
M = ( D / P ) . E

D  shared doctrine        the standing model: what the organisation already asserts
P  collective perception  intelligence gathered, audited for redundancy
E  environment            the world the organisation is in
M  constructed situation  the situation the organisation acts on

r     = D / P             the doctrine-to-data ratio (dimensionless)
Delta = | ln r |           distortion, in nats

ln M = ln D - ln P + ln E     the log form
```

Status. `M = (D/P).E` is a **postulate**, this framework's own, stated in the open. It is not a theorem of the framework's mathematical papers and nothing here derives it. It is a proposed structure whose consequences are computable and, by the protocol of Section 6.12, falsifiable. Everything downstream that is proven comes from the surplus functional or the storage law and is labelled as such; everything else inherits the postulate's status. The framework's own audit reaches the same verdict independently and at both scopes [Curzi, 2026].

24.6.2 6.2 The commensurate-units convention

Dimensional balance requires `D` and `P` to share units so that `r` is dimensionless. At personal scope this is handled by magnitude estimation. At group scope there is a cleaner route, because organisations already count the thing: the convention of Section 3.3 expresses `D`, `P` and `E` in effective independent evidence-channels per decision period. All three are then counts with a true zero, hence ratio-scaled, and `M` inherits `E`'s units.

This convention is doing real work and it is the weakest joint in the construction. It is badged, and Section 6.12 shows exactly where it fails.

24.6.3 6.3 The aggregation postulate and the exact join

`P` is not headcount. A hundred analysts reading the same wire service are one channel. That is the framework's effective count [Curzi, 2026c], and it is the entire reason a surplus law belongs in an account of perception. Under the aggregation postulate, `P = p_bar . N_eff` with `N_eff = 1 + (N-1)u`. Taking logarithms and substituting:

```
ln P = ln p_bar + ln N_eff = ln p_bar + F        since F = ln N_eff exactly

ln r = ln D - ln p_bar - F                       THE JOIN
```

The surplus of the group appears in the doctrine-to-data ratio as a subtractive term, one nat for one nat. Every nat of interaction surplus the organisation's channels generate reduces

its log-distortion by exactly one nat. That is not an analogy between the two equations; it is an identity, and it holds because `F` is defined as `ln N_eff` and the logarithm is the register both formulas live in.

Two consequences follow immediately and both are hard.

Consequence 1 — the correction ceiling. Since `0 <= F <= ln N`, the total reduction in `ln r` available from interaction geometry alone is at most `ln N`:

```
N =  4  ->  max reduction 1.3863 nats   ->  r divided by at most  4
N =  8  ->  max reduction 2.0794 nats   ->  r divided by at most  8
N = 12  ->  max reduction 2.4849 nats   ->  r divided by at most 12
N = 24  ->  max reduction 3.1781 nats   ->  r divided by at most 24
N = 40  ->  max reduction 3.6889 nats   ->  r divided by at most 40
```

Consequence 2 — the infeasibility condition. Setting `r = 1` requires `N_eff = D/p_bar`, and `N_eff <= N`. Therefore:

> **If `D/p_bar > N`, the organisation cannot be calibrated by any arrangement of its people.** The residual distortion is at least `Delta_min = ln(D/p_bar) − ln N`, and no recruitment, rotation, red team or restructuring closes it. The only remaining move is to reduce `D`.

This is the exact analogue, in the perceptual register, of the storage law's statement that if the cost exceeds `eta ln N − delta Q_t` no interaction geometry prevents decline [Curzi, 2026a]. **Both are `ln N` ceilings, and both say the same thing: geometry is bounded, and past the bound what is carried must change, not who is carrying it.** The general form of the objection is the requisite-variety bound: a regulator cannot correct more variety than it can itself express [Ashby, 1958].

24.6.4 6.4 The contact postulate

The moment must serve as the storage law's input, `Q_{t+1} = (1−delta)Q_t + eta M_t − C_t`, with `M` normalised to `[0, ln N]`. The normalisation is stated rather than assumed: the contact postulate of Section 3.3 sets `S_t = ln N . e^{−Delta_t}`.

That exponential has an exact and more legible form. Since `e^{−|ln r|} = min(r, 1/r)` identically — an algebraic identity, verifiable at `r = 0.1, 0.25, 0.5, 0.8, 1.0, 1.25, 2.0, 4.0, 10.0` to machine precision:

```
S_t / ln N  =  min(D, P) / max(D, P)
```

A group banks at the rate of the scarcer of frame and intake. Doctrine that cannot be fed with evidence and evidence that cannot be framed are equally useless, and the binding one is whichever is smaller. This is a limiting-factor reading of the ratio and it is offered as an **analogy**: the framework has no citation for it and none is manufactured here. The attenuation is symmetric, which is the postulate's substantive commitment and the first thing Section 6.12's falsification test attacks.

The band table, distortion to attenuation:

Delta	r (either side)	S / ln N
0.00	1.000	1.0000
0.05	1.051 or 0.951	0.9512
0.10	1.105 or 0.905	0.9048
0.20	1.221 or 0.819	0.8187
0.35	1.419 or 0.705	0.7047

```
0.50    1.649 or 0.607      0.6065
0.69    1.994 or 0.502      0.5016
1.00    2.718 or 0.368      0.3679
1.39    4.015 or 0.249      0.2491
2.00    7.389 or 0.135      0.1353
```

A two-to-one doctrine-to-data ratio halves what the organisation can bank.

24.6.5 6.5 The four limiting cases

Every limit corresponds to a real, nameable phenomenon, and at group scope they are more recognisable than at personal scope because organisations fail publicly.

Case 1 — `P -> 0`: doctrine with no intelligence, `M` diverges. At `D = 1.0`, `E = 1.0`:

```
P        r          M        Delta
-----    -------    ------   ------
1.000      1.00      1.00    0.0000
0.500      2.00      2.00    0.6931
0.200      5.00      5.00    1.6094
0.100     10.00     10.00    2.3026
0.050     20.00     20.00    2.9957
0.020     50.00     50.00    3.9120
0.010    100.00    100.00    4.6052
0.001   1000.00   1000.00    6.9078
```

The divergence is real and the phenomenon has a name in every language: **an organisation with a model and no collection is not blind, it is certain.** The constructed situation grows without bound while the environment stays where it is. Note what the arithmetic says about the *feel* of the condition. `M` is large. The organisation experiences a rich, detailed, confident picture. **Nothing in the subjective quality of `M` distinguishes a well-informed organisation from a hallucinating one; only the ratio does.** That is the single most important reason the ratio has to be measured rather than sensed, and it is the same structural point that makes an over-framed body's self-assessment improve as its condition worsens [Vaughan, 1996].

Note also that `P -> 0` does not require anyone to stop collecting. Under the aggregation postulate `N_eff -> 1` as `u -> 0`, so **an organisation whose channels become parallel has `P` collapse to a single channel's worth while its collection budget stays flat.** That is Section 7's mechanism, and it belongs here because it belongs to the limit.

Case 2 — `D -> 0`: intelligence with no frame, `M -> 0`. At `P = 1.0`, `E = 1.0`:

```
D        r          M        Delta
-----    ------     ------   ------
1.000    1.0000     1.0000   0.0000
0.500    0.5000     0.5000   0.6931
0.200    0.2000     0.2000   1.6094
0.100    0.1000     0.1000   2.3026
0.050    0.0500     0.0500   2.9957
0.010    0.0100     0.0100   4.6052
0.001    0.0010     0.0010   6.9078
```

The organisation constructs no situation at all: **sensation is not experience.** At group scope, an organisation holding an enormous quantity of data and no model of what it is for produces no decision. The data lake with no question. The dashboard nobody can act on. The limit is genuinely `0` and not merely small, and that is worth stating: a group with no doctrine does not act badly, **it does not act**. The paralysis of the perfectly open-minded institution is a prediction of the formula, not a moral observation.

Case 3 — `E -> 0`: no environment, `M -> 0` for any `r`. The organisation's environment has gone: its market has vanished, its constituency has dissolved, its problem has been solved or has migrated. **`M = 0` regardless of how good its doctrine and intelligence are**, because a ratio multiplied by nothing is nothing. This limit is often mistaken for the others and the distinction is diagnostic. An organisation at `E -> 0` has excellent internal metrics and produces nothing that lands. Its doctrine may be perfectly calibrated to its intake, with distortion zero, and it will still generate no moment. **Calibration is not sufficiency. A perfectly calibrated instrument pointed at nothing reads nothing.**

Case 4 — `D = P`: `M = E`, the fixed point.

```
r = 1  ->  Delta = 0  ->  M = E  ->  S = ln N
```

When doctrine matches intelligence, the situation the organisation constructs equals the environment it is in. That is undistorted contact, stated as an equation.

24.6.6 6.6 The zero-headroom identity

There is a structural result at that fixed point which does not appear at personal scope, and it is the most surprising thing in this section. Put `r = 1` into the contact postulate: `S = ln N`, the maximum. The storage law's steady state is then `Q_inf = (eta ln N − C)/delta`, and headroom at that steady state is

```
h = eta ln N − delta Q_inf − C
  = eta ln N − delta (eta ln N − C)/delta − C
  = eta ln N − eta ln N + C − C
  = 0        exactly
```

> **A perfectly calibrated organisation converges to exactly zero headroom.** Not by coincidence and not by mismanagement: by arithmetic. Perfect contact drives the input to the ceiling, the ceiling drives the store to its maximum, and the maximum store consumes the entire budget in maintenance.

This is the framework's success-consumes-its-own-headroom thesis arriving from the perceptual side, and it is the organisational-slack result stated as an identity [Cyert and March, 1963]. It warns against a naive reading of `r = 1` as an unqualified goal. Calibration maximises what is banked; it does not leave room to build something new with it. **An organisation that wants headroom at equilibrium must run below its maximum store, which means either shedding `Q` deliberately or accepting `r` not equal to 1.** The trade is stated rather than pretended away, and it is the same shape as the queueing result that reserve, not prudence, is what keeps a response time finite [Kingman, 1962]. A structurally identical bind is recorded elsewhere in this corpus and bounds how far the identity may be read as bad news: the property that makes an insurance reserve resistant to third-party claims — real liabilities owed to unrelated parties — is the same property that makes it unavailable to its owner, leaving only 7.58 per cent realisable within a year [Curzi, 2026]. **A store that is maximal is not thereby a store that is available**, and that is a general feature of reserves rather than a peculiarity of calibrated organisations.

24.6.7 6.7 The calibration requirement, computed

Solving `r = 1` for the non-parallelism required: `N_eff = D/p_bar`, so

```
u* = ( D/p_bar − 1 ) / ( N − 1 )        feasible only if D/p_bar <= N
```

The full table, across domain sizes and doctrine loads:

D/p_bar	N=4	N=8	N=12	N=16	N=24	N=40
1.5	0.1667	0.0714	0.0455	0.0333	0.0217	0.0128
2.0	0.3333	0.1429	0.0909	0.0667	0.0435	0.0256
3.0	0.6667	0.2857	0.1818	0.1333	0.0870	0.0513
4.0	1.0000	0.4286	0.2727	0.2000	0.1304	0.0769
6.0	--	0.7143	0.4545	0.3333	0.2174	0.1282
8.0	--	1.0000	0.6364	0.4667	0.3043	0.1795
12.0	--	--	1.0000	0.7333	0.4783	0.2821
16.0	--	--	--	1.0000	0.6522	0.3846
24.0	--	--	--	--	1.0000	0.5897
40.0	--	--	--	--	--	1.0000

"--" = INFEASIBLE: D/p_bar exceeds N; no geometry calibrates this organisation.

Three readings, each an engineering rule.

Doctrine is expensive in `u`. An organisation whose standing model supplies six channels' worth of constraint, working an `N = 12` domain, needs `u = 0.4545` — mean pairwise non-parallelism of 0.45 across its intelligence channels, `theta = 42.4` degrees. That is a high bar, and organisations measured by channel-audit protocols typically come in an order of magnitude below it. **That comparison is this framework's own impression and not a measured distribution; no empirical distribution of institutional `u` exists.**

A large `N` is a doctrine subsidy. The same `D/p_bar = 6.0` needs `u = 0.4545` at `N = 12` and only `u = 0.1282` at `N = 40`. Breadth of domain buys tolerance for doctrine. But `N` moves the ceiling only logarithmically and is the most expensive lever there is. **Raising `N` from 12 to 40 to relieve a doctrine problem is a real move and a bad buy.**

The infeasible region is large and it is where heavy institutions live. A long-established body carrying `D/p_bar = 16` in an `N = 12` domain is in the infeasible zone. Its residual distortion floor is:

```
Delta_min = ln(D/p_bar) - ln N

N=12, D/p_bar=18  ->  Delta_min = 0.4055        S <= 0.6667 ln N
N=12, D/p_bar=24  ->  Delta_min = 0.6931        S <= 0.5000 ln N
N=12, D/p_bar=48  ->  Delta_min = 1.3863        S <= 0.2500 ln N
N=24, D/p_bar=48  ->  Delta_min = 0.6931        S <= 0.5000 ln N
N=24, D/p_bar=96  ->  Delta_min = 1.3863        S <= 0.2500 ln N
```

An institution carrying four times its domain size in doctrine cannot bank more than a quarter of its ceiling, no matter who it hires. The only lever left is `D`.

24.6.8 6.8 Worked mechanics of the join

Fix `D = 6.0`, `p_bar = 1.0`, `N = 12`, and let the group's own geometry vary. This is the join running end to end: `u` sets `F`, `F` sets `ln r`, `ln r` sets `Delta`, `Delta` sets `S`.

u	F	ln r	r	Delta	M/E
0.0000	0.0000	+1.7918	6.0000	1.7918	6.0000
0.0200	0.1989	+1.5929	4.9180	1.5929	4.9180
0.0500	0.4383	+1.3535	3.8710	1.3535	3.8710
0.1000	0.7419	+1.0498	2.8571	1.0498	2.8571
0.2000	1.1632	+0.6286	1.8750	0.6286	1.8750
0.3000	1.4586	+0.3331	1.3953	0.3331	1.3953

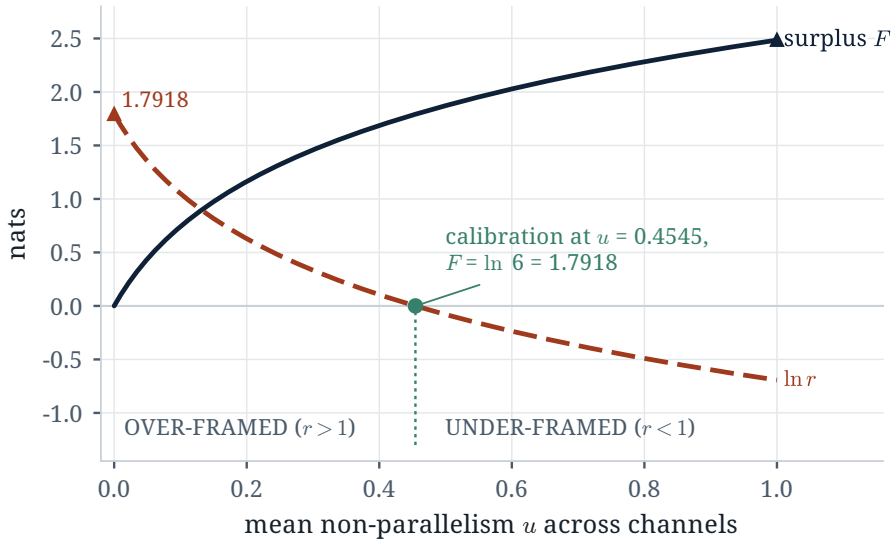

Figure 24.2: **The group's interaction surplus subtracts from its log-distortion one nat for one nat**: at `D = 6.0`, `p_bar = 1.0` and `N = 12` the two curves are mirror images about the crossing at `u = 0.4545`, where `F = 1.7918 = ln 6` and `ln r = 0.0000`. Past the crossing the organisation over-corrects into under-framing, reaching `ln r = −0.6931` at perfectly orthogonal channels. Computed from the identity `ln r = ln D − ln p_bar − F` at the parameters tabulated in Section 6.8; generated by `figs/src/CCP-024_fig02.py`.

0.4167	1.7198	+0.0720	1.0746	0.0720	1.0746
0.4545	1.7918	0.0000	1.0000	0.0000	1.0000
0.5000	1.8718	−0.0800	0.9231	0.0800	0.9231
0.7000	2.1633	−0.3716	0.6897	0.3716	0.6897
0.9000	2.3888	−0.5970	0.5505	0.5970	0.5505
1.0000	2.4849	−0.6931	0.5000	0.6931	0.5000

Read the `ln r` column against the `F` column. **They move one for one, in opposite directions, exactly:** `ln r = ln 6 − F = 1.7918 − F` on every row. The surplus of the group *is* the de-framing of the group, in the same units, with no conversion constant.

Read the last four rows for the other half of the story. **Past `u = 0.4545` the organisation over-corrects into under-framing.** At `u = 1.0` — perfectly orthogonal channels — the same doctrine load produces `r = 0.5` and `M/E = 0.5`: the organisation now under-constructs the situation. **Diversity is not monotonically good in this model.** It reduces `ln r`, and reducing `ln r` is good only while `r > 1`. An organisation already under-framed and adding channels is making its condition worse, and the formula says so plainly. This is the sense in which the two pathologies of Section 7 require *opposite* corrections.

24.6.9 6.9 The moment as storage input, and the operating envelope

Take a group with `eta = 0.42` order-units per nat, `delta = 0.14` per period, `C = 0.55` order-units per period, `N = 12` so `ln N = 2.4849`. The minimum input for a non-negative equilibrium is `S_min = C/eta = 1.3095` nats.

S	eta.S	Q_inf
0.0000	0.0000	−3.9286
0.3000	0.1260	−3.0286
0.6000	0.2520	−2.1286

```
0.9000   0.3780   −1.2286
1.2000   0.5040   −0.3286
1.5000   0.6300   +0.5714
1.8000   0.7560   +1.4714
2.1000   0.8820   +2.3714
2.4849   1.0437   +3.5261
```

Converting distortion to input by the contact postulate and reading off the distortion at which this group stops being able to hold anything at all:

```
S_min / ln N = 1.3095 / 2.4849 = 0.5270
min(r, 1/r) >= 0.5270   ->   0.527 <= r <= 1.898   ->   Delta <= 0.6406
```

> **This organisation must keep its doctrine-to-data ratio between 0.53 and 1.90. Outside that band its steady-state store is negative and its institution erodes at rate `delta` regardless of effort.**

That is a concrete, computable operating envelope derived from three stipulated parameters and a badged postulate. **It is demoted to an illustrative construction at the scale-type gate in Section 6.12, and it must not be quoted as a measurement.**

24.6.10 6.10 The two-track ledger

The envelope above is stated on `Q`, and `Q` is the wrong ledger to optimise. The framework's established result is that **over-framing increases stored order**, and the result transfers to group scope without modification, because the storage law does not know what scale it is running at:

```
ALL STORED ORDER   Q_{t+1}   = (1−delta) Q_t   + eta M_t − C_t     M_t = min(r_t E_t, ln N)
VERIDICAL ORDER    Q^V_{t+1} = (1−delta) Q^V_t + eta V_t − C_t     V_t = E_t . min(r_t, 1)

STORED ERROR       Z_{t+1}   = (1−delta) Z_t + eta (M_t − V_t)     [the cost term cancels]
CORRECTION LOAD    C_t       = c_0 + kappa Z_t
```

An over-framed institution accumulates more stored order than a calibrated one. It is simply not true stored order. The doctrine, the procedure manual, the settled interpretation, the confident forecast — all of it banks at rate `eta` whether or not the environment supplied it, because there is no term in the recursion that asks. **Dogma banks faster than knowledge, and the bill arrives on a lag, as correction load rising with accumulated error.** That lag is why an over-framed body looks excellent on its own metrics for years, and it is why organisational learning that homogenises looks like improvement throughout [March, 1991].

This sharpens the zero-headroom result into something less comfortable. Section 6.6 showed that `r = 1` is not an unqualified goal because it converges to zero headroom. The two-track ledger shows that a body optimising raw `Q` is not merely failing to aim at `r = 1` — **it is being actively driven away from it.** Above the fixed point the veridical track is flat at `E` while the raw track keeps climbing. Differentiating the steady state for `r > 1`:

```
Q_inf = (eta M − c_0 − kappa eta (M − V)/delta) / delta
dQ_inf/dM = eta (1 − kappa/delta) / delta
```

The knife edge is exactly `kappa = delta`. Where correction load accrues more slowly than stored order decays, raw `Q_inf` rises without bound in `r`, and every incentive attached to raw `Q` — headcount, published procedure, doctrinal coverage, confident forecasts issued — is an incentive to over-frame. That is not a claim about anyone's character. It is the arithmetic of what the organisation is being paid in, and it is the standard failure of a measure that has become a target [Goodhart, 1975, Campbell, 1979].

Requirement. Report `Z` alongside `Q`, or report `Q^V` instead of `Q`. A body that reports only its total store is reporting a number that rises fastest when it is most wrong.

24.6.11 6.11 Requirements at group scope

G-1 Declare the decision space and count `N`. Enumerate the distinct domains the organisation's intelligence must span, and justify each as genuinely distinct rather than relabelled. `[N]` *Test: an independent reader reproduces the list from the written definition.*

G-2 Adopt the commensurate-units convention explicitly. Write down, before measuring, what one effective evidence-channel per period means in this organisation. `[dimensions]`

G-3 Audit the channels for redundancy before counting them. Headcount and subscription count are not `P`. Compute `N_eff = 1 + (N−1)u` with `u` from error decorrelation on questions with later-observable answers. `[P, u]`

G-4 Measure `p_bar` separately from `N_eff`. `P` alone does not identify them, and the two have entirely different fixes. `[P]`

G-5 Enumerate the doctrine. List the decision-relevant propositions the standing model fixes in advance; weight each by the fraction of decisions it constrains; sum. That is `D`. `[D]` *Test: the list is written, dated, and each entry names the decisions it governs.*

G-6 Run the over-determination check. Compute `ln r` twice — once as `ln D − ln P`, once as `ln D − ln p_bar − F` — and require agreement. A mismatch means one of the three measurements is wrong; find out which before proceeding. `[identification]`

G-7 Never report `Delta` without the sign of `ln r`. The two pathologies map to the same magnitude and require opposite corrections. `[reporting]`

G-8 Never report `D` without an independent measurement of `P`. `D` is unidentifiable without the anchor. `[reporting]`

G-9 Compute the infeasibility check first. If `D/p_bar > N`, stop: no arrangement of people calibrates this organisation. Record the residual floor `Delta_min = ln(D/p_bar) − ln N` and proceed to doctrine reduction. `[D, N]`

G-10 Compute the operating envelope. From `eta`, `C` and `N`, derive `S_min = C/eta` and the band `min(r, 1/r) >= S_min/ln N`. `[operating limits]` *Test: the two band edges are written down and dated.*

G-11 Treat `E` as measurable and measure it. An organisation that never estimates the decision-relevant structure in its environment cannot distinguish Case 3 from Cases 1 and 2. `[E]`

G-12 Do not treat `r = 1` as an unqualified target. Exact calibration drives equilibrium headroom to zero. Decide deliberately whether the organisation is optimising banked order or preserving capacity for the new. `[h]`

G-13 Justify the order proxy independently of the input. The organisation's `Q` measure must not be a repackaging of its intelligence volume. `[Q]`

G-14 Preregister before intervening. Encoder, fit window, freeze date, held-out window, four baselines including the shuffled-input control, and the kill conditions [Nosek et al., 2018, Curzi, 2026i]. `[falsifiability]`

G-15 Re-measure `u` on a schedule. `u` decays. A calibrated organisation drifts into over-framing with no change in doctrine. Interval no longer than the measured half-life of `u`. `[u]`

G-16 No protocol here may remove a person's ability to decline — to decline the measurement, to decline the channel role, or to decline the dissent it asks of them. `[ethics]`

24.6.12 6.12 Validation gates, and the demotion of the magnitudes

One verdict governs three of the five tables below and is stated before them rather than buried inside them. Running the framework's formula-validation protocol on the moment equation returns **DEMOTE at gate 2**, and the verdict carries to group scope [Curzi, 2026]. Section 6.2

argued that channel-counting gives `D` and `P` a true zero; that argument is here **corrected**. A count supplies a zero and a unit *within one declared encoder*, but nothing links two encoders, and without linkage the magnitude of `r` moves when the encoder moves. An organisation's channel count is more auditable than a person's frame, which is a real advantage at the identifiability gate; it is not the same thing as a scale.

> **NOT REPORTABLE AS MEASURED QUANTITIES, at group scope as at personal scope:** the magnitude of `D/P`; the distortion `Delta = |ln r|` as a number; and the quantitative form of the join from the moment into the storage law. Every figure in Sections 6.7, 6.8 and 6.9 — the `u*` table, the `Delta_min` floors, the 0.53 to 1.90 envelope — is an **illustrative construction demonstrating the structure of the model**, and is to be read as such.
>
> **STILL IN FORCE:** the four limiting cases; the `D = P` fixed point and its zero-headroom consequence; the ordering over-framed / calibrated / under-framed; the *sign* of `ln r`; and the algebraic identity `ln r = ln D − ln p_bar − F`, which is an identity and does not depend on any scale claim. **What is demoted is magnitude, not structure.**

The route out is a Rasch measurement on one common linked scale, under which `Delta = |ln(D/P)| = |theta_D − theta_P|` becomes genuinely ratio-scaled, because Rasch separation supplies the true zero that division requires [Rasch, 1960]. The framework prices that instrument at **approximately 123 items per term for a half-logit distortion at 95 per cent confidence** [Curzi, 2026]. At institutional scope the items are decisions with later-observable answers, which is the one respect in which the group version is genuinely cheaper: **an organisation with a decision log is already accumulating the item bank.**

Table V-G1 — The group moment `M = (D/P).E`

Gate	Finding
1 Dimensions	Under the commensurate-units convention, `D`, `P`, `E` are all in effective evidence-channels per period. `D/P` dimensionless; `M` inherits `E`'s units. **PASS, and it passes ONLY because the convention was declared. Without it the formula is dimensionally void.**
2 Scale type	Division requires ratio scale with a true zero on a **common** scale. Channel-counts supply a zero and a unit within one declared encoder but supply no linkage between encoders, so the magnitude of `r` is encoder-dependent. **DEMOTE: the magnitude of `D/P` and of `Delta` is withdrawn as a measured quantity; the ordering, the limits, the fixed point and the sign of `ln r` stand.** Where an implementation substitutes rating scales for counts the position is worse: division is impermissible outright. **Route out: Rasch logit difference, about 123 items per term** [Curzi, 2026].
3 Limiting cases	All four worked in Section 6.5. `P –> 0`: the certain organisation. `D –> 0`: the paralysed one. `E –> 0`: the obsolete one. `D = P`: `M = E`. Every divergence names a real, observable institutional condition. **PASS.**

Gate	Finding
4 Fixed points	`r = 1` implies `M = E`, undistorted contact, unique. Plus the derived result of Section 6.6: at that fixed point `h = 0` exactly. **PASS, with the trade stated.**
5 Identifiability	**THIS GATE FAILS AS THE FORMULA IS NAIVELY WRITTEN, and the failure must be printed.** From observations of `M` and `E` alone, only the ratio `r` is recoverable, never `D` and `P` separately. Demonstration: `(D,P) = (6.0, 3.0)`, `(2.0, 1.0)`, `(0.5, 0.25)` and `(120.0, 60.0)` all give `r = 2.0000` and, at `E = 1`, identical `M = 2.0000`. **Four distinct parameter sets, one observation.** *The repair:* an independent anchor on `P` — a direct count of audited channels and their intake — makes `D` recoverable as `D = r.P`. **CONDITIONAL PASS, and only with the anchor.**
6 Falsification	Preregister the encoder for `D`, `P`, `E`; fit on training periods; freeze; report held-out. Four baselines: persistence, direct-input (`E` alone), matched autoregressive, and the shuffled-input control. **Kill conditions: (a) `E` alone predicts held-out decision quality as well as `(D/P).E`; (b) the shuffled-`r` control matches the fitted model; (c) the sign of the residual is independent of the sign of `ln r`.**
7 Reproducibility	The cross-institution test: same operationalisation, different organisations, different analysts. **UNTESTED. Nobody has run it. This gate decides whether this section is science, and stating that plainly is a requirement of the protocol.**

Table V-G2 — Distortion `Delta = |ln r|, r = D/P`

Gate	Finding
1 Dimensions	`r` dimensionless by V-G1; `Delta` in nats, commensurate with `F`. **PASS.**
2 Scale type	`Delta` *would be* a magnitude on a ratio scale — **and this is corrected here: that property is inherited from `r`, whose magnitude V-G1 demotes.** Pending instrumentation `Delta` is **ORDINAL**: it ranks bodies and periods by distance from contact and does not license the statement that one distortion is twice another. **DEMOTE.** Becomes ratio-scaled exactly when read as a Rasch logit difference and by nothing cheaper.

Gate	Finding
3 Limiting cases	`r -> 0`: `Delta` diverges, total under-framing. `r -> infinity`: `Delta` diverges, total over-framing. `r = 1`: `Delta = 0`. The two divergences are **distinct pathologies mapped to the same magnitude**, which is the measure's one real weakness. **PASS ONLY IF THE SIGN OF `ln r` IS REPORTED ALONGSIDE. Never report `Delta` bare.**
4 Fixed points	`Delta = 0` if and only if `r = 1` if and only if `D = P`. Unique. **PASS.**
5 Identifiability	`Delta` is recoverable wherever `r` is, and is more robustly recoverable, since it survives any rescaling that multiplies `D` and `P` by a common factor. **PASS — and this robustness is why `Delta` is the reportable quantity and `D` and `P` are not.**
6 Falsification	Preregister that decision quality declines monotonically in `Delta` on both sides of 1. **Kill condition: no monotone relation, or a relation present on one side and absent on the other** — the latter falsifies the symmetry of the contact postulate specifically, which is a useful and separable result.
7 Reproducibility	**UNTESTED.**

Table V-G3 — Aggregation `P = p_bar . N_eff`, `N_eff = 1 + (N−1)u`

Gate	Finding
1 Dimensions	`p_bar` in intake-units per channel per period; `N_eff` a pure count; `P` in intake-units per period. Matches `D`'s units by the convention. **PASS.**
2 Scale type	`N` a count; `u` ratio-scaled per Table V-P1, conditional on the channel encoder; `p_bar` a mean of ratio-scaled intakes. **PASS, conditional on the encoder being declared.**
3 Limiting cases	`u -> 0`: `N_eff -> 1`, `P -> p_bar` — **a hundred parallel channels are one channel.** `u -> 1`: `P -> p_bar . N`, the maximum. `p_bar -> 0`: `P -> 0`, Case 1. `N -> 1`: `P = p_bar` for all `u`, correct. **PASS; each limit is a real institutional condition.**
4 Fixed points	`u = 0` is the invariant of the parallel organisation and is **globally attracting under the decay of Table V-P6** — `u` is maintained, not owned. `u = 1` is the invariant of full independence and is not attracting at all. **PASS, with the asymmetry noted: the bad fixed point is the stable one.**

Gate	Finding
5 Identifiability	`N` by enumerating declared intelligence domains; `u` by error decorrelation across channels on questions with later-observable answers; `p_bar` by direct intake tally. All three separately obtainable. **But `P` alone does not identify `(p_bar, N_eff)`** — a well-read single channel and a barely-read diverse set give the same `P`. **PASS IF ALL THREE ARE REPORTED.** The reflection problem of Section 3.4 bites here and is not answered by reporting all three.
6 Falsification	Preregister that held-out forecast accuracy tracks `N_eff` rather than channel headcount or channel budget. **Kill condition: headcount or budget predicts held-out accuracy better than `N_eff`.** This is a clean, cheap test and it is the one an organisation with a forecasting record can run first.
7 Reproducibility	**UNTESTED at institutional scale.** The nearest published evidence that group performance tracks something other than member ability is laboratory, short-task and small-group [Woolley et al., 2010]. Supporting context; not confirmation. The closest empirical analogue of an effective count at scale measures adoption against the number of *distinct connected components* among a person's contacts [Ugander et al., 2012], and it is a different quantity.

Table V-G4 — Contact `S = ln N . e^{-Delta} = ln N . min(r, 1/r)`

Gate	Finding
1 Dimensions	`Delta` in nats, `e^{-Delta}` dimensionless in `(0,1]`, `ln N` in nats, `S` in nats. Matches the storage law's input requirement exactly. **PASS.**
2 Scale type	Requires `r` ratio-scaled, which V-G1 demotes. `S` is in nats and would be ratio-scaled with a true zero, but it is computed from `r` and can be no better than its input. **DEMOTE: the postulate's ORDERING — contact banks more than distortion, in either direction, monotonically — stands on ordinal information alone. The banked-nats figures of Section 6.9 do not.**

Gate	Finding
3 Limiting cases	`Delta -> 0`: `S -> ln N`, the ceiling, achieved only at exact calibration. `Delta -> infinity`: `S -> 0`, the organisation banks nothing — true in both directions, the certain institution and the flooded one alike. Bounded above by `ln N`, so the postulate is **consistent with the proven range and does not smuggle in surplus above the ceiling. PASS.**
4 Fixed points	`S = ln N` at `r = 1`, and the derived consequence `h = 0` at the resulting `Q_inf`. **PASS.**
5 Identifiability	`S` is a deterministic function of `r` and `N`, both independently obtainable. **No free parameters — which is a strength: the postulate has nothing to tune and therefore nothing to overfit. PASS.**
6 Falsification	Two separable kill conditions. **(a) Functional form: fit `S = ln N . e^{-k.Delta}` and test `k = 1`; a fitted `k` significantly different from 1 falsifies this postulate while leaving the framework standing. (b) Symmetry: fit separate exponents for `r > 1` and `r < 1`; if they differ, the symmetric form is wrong and the correction protocols must be reweighted.**
7 Reproducibility	**UNTESTED.** Both (a) and (b) are cheap and could be run by any organisation with a decision log and a forecast record; this is the most tractable open test in the paper.

Table V-G5 — The join `ln r = ln D - ln p_bar - F`

Gate	Finding
1 Dimensions	Every term in nats after taking logarithms of dimensionless or commensurate quantities. **PASS.**
2 Scale type	Log-ratios are interval-scaled differences; the identity is an equation between such differences. **PASS.**
3 Limiting cases	`F -> 0`: `ln r -> ln(D/p_bar)`, maximum distortion for the given doctrine load. `F -> ln N`: `ln r -> ln(D/(p_bar.N))`, minimum achievable. `D -> 0`: `ln r` diverges downward, Case 2. **PASS.**
4 Fixed points	`F* = ln(D/p_bar)` gives `r = 1`, feasible if and only if `D/p_bar <= N`. **The infeasibility condition is the fixed point's domain of existence, and it is the hardest result in this section. PASS.**

Gate	Finding
5 Identifiability	Given independent measurements of `D`, `p_bar` and `u`, the identity is over-determined — `ln r` can be computed two ways and the two must agree. **This over-determination is a consistency check and it is the most useful diagnostic available: a mismatch means one of the three measurements is wrong. PASS.**
6 Falsification	The identity itself is algebraic and cannot be falsified; what is falsifiable is the aggregation postulate it rests on. **Kill condition: measured `P` fails to track `p_bar . N_eff` across organisations with known `u`.**
7 Reproducibility	**UNTESTED, and it inherits V-G3's status.**

24.6.13 6.13 Failure modes at group scope

FM-G1 The void denominator. `P` computed as headcount or subscription count, without the redundancy audit. *Damages:* `P` overstated, therefore `r` understated; the organisation believes it is calibrated. *Signature:* large, well-funded intelligence function; confident briefings; recurring surprises. *Measurement:* error decorrelation across channels on questions with observable answers. *Fix:* recompute `P` as `p_bar . N_eff`. Expect the number to fall by a large factor: at `u = 0.05` in an `N = 12` domain, `N_eff = 1.55` against a headcount that may be forty. The formal statement that an unaudited count is worthless, because one party can present as many, is the Sybil result [Douceur, 2002].

FM-G2 The unidentified ratio. `D` reported without an independent `P`. Four distinct parameter sets produce the same observation. *Damages:* measurement validity. *Signature:* doctrine described in absolute terms — "our model is very strong" — with no channel count behind it. *Measurement:* ask for `P`; if it is not measured, `D` is not measured. *Fix:* the anchor — count the audited channels, then `D = r.P`.

FM-G3 The bare magnitude. `Delta` reported without the sign of `ln r`. *Damages:* diagnosis; the correction is applied in the wrong direction. *Signature:* a distortion score with no direction, followed by an intervention that makes things worse. Adding channels to an already under-framed organisation is the common instance. *Measurement:* read the report; is `ln r` signed? *Fix:* always report the signed log-ratio.

FM-G4 The calibrated irrelevance. `r = 1`, `Delta = 0`, and `E -> 0`. Perfect contact with a vanished environment. *Damages:* `M`, totally, while every internal metric reads well. *Signature:* excellent internal process metrics; outputs that land nowhere; a constituency that has migrated. *Measurement:* estimate `E` directly. *Fix:* outside the scope of this equation — the organisation must change what environment it is in. The formula's contribution is the diagnosis, not the remedy.

FM-G5 The zero-headroom success. The organisation calibrates, banks to its maximum, and finds `h = 0` exactly. Every period is maintenance. *Damages:* `h`. *Signature:* a well-run institution that cannot start anything, with no identifiable culprit. *Measurement:* `h = eta ln N − delta Q − C` at the current `Q`, against `Q_inf = (eta ln N − C)/delta`. *Fix:* shed `Q` deliberately, or raise `eta`, or cut `C`. **Do not attempt to fix it by degrading calibration; that reduces `S` faster than it releases budget.**

FM-G6 The proxy that was the input. The order proxy is a repackaging of intelligence volume — "we produced 400 assessments" counted as stored order. *Damages:* identifiability of `eta`; the whole model becomes untestable. *Signature:* excellent training fit, held-out failure; `eta` near 1 with negligible residual. *Fix:* an order proxy with an external referent: decisions whose outcomes are later observable, standing capability a third party can verify, infrastruc-

ture that survives staff turnover.

FM-G7 The unbadged equation. `M = (D/P).E` presented as though it were a theorem. *Damages:* the argument's warrant. *Signature:* "the mathematics shows this organisation is over-framed." *Measurement:* read the sentence. *Fix:* restate with the badge on: the moment equation is a postulate, its consequences are computable, and the reproducibility gate has not been run.

24.7 7 Doctrine-to-data: two pathologies, opposite corrections

Section 6 established the group moment and its calibration ratio. This section is about the two ways an organisation gets that ratio wrong. Both failures are common, both are measurable with instruments an organisation can build from records it already keeps, and both are correctable.

They are not, however, correctable by the same means. **The two pathologies map to the same distortion magnitude and require opposite interventions, which is why an unsigned diagnosis is worse than no diagnosis at all.** An organisation told it is distorted and not told in which direction will reach for the nearest available remedy — usually more collection — and half the time that remedy is the disease.

This section also closes a loop. The framework's pseudo-diversity result describes an institution whose members are epistemically parallel, whose agreement is read as convergence, and whose effective count is one [Curzi, 2026c]. That result prices the condition in surplus. Here it is priced in perception, and the result is stronger than the analogy suggests: **pseudo-diversity is not merely correlated with over-framing. It is a mechanism that manufactures over-framing, from constant doctrine, with no one adding a single new belief.**

24.7.1 7.1 The two directions and the lever asymmetry

```
r = D / P          Delta = | ln r |          M = r.E          S = ln N . min(r, 1/r)

r > 1   OVER-FRAMED     M > E    doctrine outruns intelligence
r = 1   CALIBRATED      M = E    undistorted contact
r < 1   UNDER-FRAMED    M < E    intelligence outruns doctrine
```

`Delta` is a magnitude and discards the sign. That is adequate for comparing severity and fatal for choosing a treatment, because the two conditions sit on opposite sides of a fixed point and every lever moves `ln r` in one direction only.

LEVER	effect on ln r	helps OVER-framed	helps UNDER-framed
raise u (more independence)	decreases	YES	NO – makes it worse
raise N (broader domain)	decreases	YES (weakly, log)	NO – makes it worse
raise p_bar (deeper intake)	decreases	YES	NO – makes it worse
cut D (shed doctrine)	decreases	YES	NO – makes it worse
raise D (build a frame)	increases	NO – makes it worse	YES
triage P (cut channels)	increases	NO – makes it worse	YES

Every standard organisational virtue in the left column — more diversity, more breadth, more collection, less dogma — is a poison to an under-framed institution. Section 6.8 computed this: an organisation carrying `D/p_bar = 6.0` at `N = 12` reaches `r = 0.5` at `u = 1.0`, and its bankable input falls from the ceiling of 2.4849 nats back to 1.2425. Diversity past the calibration point is a cost, and the model says so without hedging. This is the governing rule of the section and it is stated as a requirement, not a suggestion:

> **Never report a distortion without its sign.** Report `ln r`, signed. `Delta` exists for comparing severity across units, never for prescribing.

24.7.2 7.2 The manufacturing result

The framework's finding is that `u` is not a property an institution acquires but a quantity that decays and must be maintained; Section 4.12 showed the same decay in the two-person case and gave it a half-life. Putting that decay into the join produces something specific.

```
ln r_t = ln D − ln p_bar − F_t          F_t = ln( 1 + (N−1) u_t )
with   u_t = u_0 (1 − lambda)^t
```

Hold `D` fixed. Hold `p_bar` fixed. Hold `N` fixed. Hold headcount, budget and collection volume fixed. **`ln r` still rises, monotonically, because `F_t` falls.**

> **The manufacturing result.** An organisation that adds no doctrine, cuts no collection and changes no policy will drift from calibration into over-framing at a rate set entirely by the decay of `u`. The crossing occurs at
>
> ```
> u* = ( D/p_bar − 1 ) / ( N − 1 )        t* = ln( u* / u_0 ) / ln( 1 − lambda )
> ```
>
> and after `t*` the organisation is over-framed, with an unchanged model, by arithmetic alone.

Worked, at `N = 12`:

D/p_bar	u_0	lambda	u*	t* (periods)
4.0	0.55	0.08	0.2727	8.41
4.0	0.55	0.04	0.2727	17.18
3.0	0.30	0.06	0.1818	8.09

Roughly two years, at quarterly periods and an eight-per-cent-per-quarter convergence rate, from calibrated to over-framed with nobody doing anything. Halving the decay rate roughly doubles the time, as the logarithmic form requires; it does not prevent the crossing.

This is why the connection to pseudo-diversity is a mechanism and not an analogy. Its signature — `u -> 0`, `N_eff -> 1`, surplus `ln 1 = 0` — enters `r = D/(p_bar . N_eff)` as a *collapsing denominator*. **The institution's doctrine did not grow. Its denominator vanished.** The same erosion of local variety by a legibility-seeking centre is documented historically [Scott, 1998], and the homogenising effect of fast mutual learning is documented with a simulation [March, 1991].

24.7.3 7.3 The honesty clauses of this section

1. Every instrument below estimates `r` **through a proxy**, and each proxy carries its own badged postulate linking the observable to the ratio. None of them measures `D` or `P` directly.
2. Only `r` is identifiable from `M` and `E`; `D` requires an independent anchor on `P`.
3. The contact postulate's symmetry — over- and under-framing attenuating equally at equal `Delta` — is **untested** and is the first thing a real study should attack.
4. `Delta` values here are model quantities. **No empirical distribution of institutional `Delta` exists**, because nobody has measured one. Where a threshold is recommended, it is derived from the organisation's own `S_min = C/eta`, not from a literature.
5. The reproducibility gate is unrun for every formula here.

24.7.4 7.4 The over-framed institution and its instruments

Clinical description. `r > 1`. The organisation's standing model supplies more constraint on its decisions than its audited intelligence does. It therefore constructs a situation larger and more determinate than its environment. It sees what its model predicts. The condition is not stupidity and it is not usually arrogance: it is the ordinary end-state of a successful institution, because doctrine accumulates while `u` decays.

The behavioural signature, in the order it usually appears: assessments become faster and more confident; new evidence arrives and is *absorbed* — explained within the model — rather than escalated; conclusions stop moving and the revision rate falls; surprises arrive from outside the model's categories, are treated as one-offs, and are absorbed; internal metrics improve while external outcomes do not.

The last point is the diagnostic crux. **An over-framed organisation's self-assessment improves as its condition worsens**, because self-assessment is conducted through `M`, and `M` is exactly what is inflated. That is why every instrument below is built on records with an *external* referent. Four instruments follow, each with its postulate, its data requirement, its scale type, and what it can and cannot conclude.

I-1 The revision rate.

> **The revision postulate [postulate].** A calibrated organisation revises standing conclusions at some baseline rate `sigma*` determined by the volatility of its environment. The observed revision rate `sigma` — the fraction of intelligence products that alter a standing conclusion — estimates the ratio by `r_hat = sigma* / sigma`.

Data: a decision or assessment log with, per product, a recorded before-state and after-state of the standing conclusion. Scale: `sigma` is a proportion, ratio-scaled with a true zero.

```
sigma   r_hat    ln r_hat   reading
-----   ------   --------   ------------------
0.40    0.500    -0.6931    under-framed
0.30    0.667    -0.4055    under-framed
0.20    1.000    +0.0000    calibrated (sigma* = 0.20 here)
0.15    1.333    +0.2877    over-framed
0.10    2.000    +0.6931    over-framed
0.05    4.000    +1.3863    over-framed, severe
0.02   10.000    +2.3026    over-framed, severe
```

Limits, stated plainly. `sigma*` is not known a priori and must be estimated from the environment's own volatility, which requires an external referent. **Without a defensible `sigma*` this instrument produces an ordering, not a magnitude**, and must be reported as such. It remains useful in that demoted form: `sigma` falling over time in a stable environment is evidence of drift toward over-framing.

I-2 The anomaly disposal audit. Take every observation over a period that was inconsistent with the standing model. Classify each as **escalated** (it changed something), **absorbed** (it was explained within the model), or **discarded** (it was set aside as noise, error or an outlier).

```
A = (absorbed + discarded) / total anomalies       escalation rate = 1 - A

A       escalation   odds absorb:escalate   ln odds
----    ----------   --------------------   -------
0.30       0.70            0.43 : 1         -0.8473
0.50       0.50            1.00 : 1         +0.0000
0.70       0.30            2.33 : 1         +0.8473
0.80       0.20            4.00 : 1         +1.3863
0.90       0.10            9.00 : 1         +2.1972
```

```
0.95       0.05          19.00 : 1         +2.9444
0.98       0.02          49.00 : 1         +3.8918
```

The log-odds is the right register: it is a log-ratio, commensurate with `ln r` and with `F`. **This instrument is the most robust of the four**, because it requires no baseline — the raw classification counts are meaningful on their own, and the audit runs on records the organisation already generates whenever it writes down why something was not acted on.

Its weakness is that anomaly identification is itself performed through the model. **An organisation severely over-framed does not record anomalies as anomalies; it does not see them.** The audit therefore *understates* severe cases, which makes a high `A` conclusive and a low `A` inconclusive. That must be said in the report.

I-3 The calibration curve. Plot stated confidence against realised frequency across a forecast record. Over-framed institutions are overconfident: the 90 per cent band contains the outcome less than 90 per cent of the time. Under-framed institutions are the reverse or, much more commonly, make no quantified forecasts at all, which is itself the diagnosis.

Data requirement: a forecast register with resolution dates and recorded outcomes. Scale: proportions on both axes, ratio-scaled. **This instrument does not estimate `r` numerically without a further postulate mapping overconfidence to the ratio, and no such postulate is invented here. It is reported as corroborating evidence with a direction, not as a magnitude.** Its value is that it is entirely external: nothing about it passes through `M`.

I-4 The channel audit — the structural instrument. The other three are behavioural. This one measures the mechanism directly, and the manufacturing result makes it indispensable.

```
Step 1.  Enumerate the intelligence channels and the N declared domains.
Step 2.  For questions whose answers later become observable, record each
         channel's assessment BEFORE any cross-channel discussion.
Step 3.  Compute pairwise error decorrelation; take the mean as u.
Step 4.  N_eff = 1 + (N-1)u.   F = ln N_eff.   P = p_bar . N_eff.
Step 5.  ln r = ln D - ln p_bar - F, with D from the doctrine enumeration.
Step 6.  Cross-check against ln D - ln P.  They must agree.
```

Worked at `N = 12`, showing what headcount hides:

```
u       N_eff     F        P/headcount at 40 staff
-----   ------   ------    -----------------------
0.00     1.000   0.0000            0.0250
0.02     1.220   0.1989            0.0305
0.05     1.550   0.4383            0.0387
0.10     2.100   0.7419            0.0525
0.15     2.650   0.9746            0.0663
0.25     3.750   1.3218            0.0938
0.40     5.400   1.6864            0.1350
0.60     7.600   2.0281            0.1900
```

A forty-person intelligence function at `u = 0.05` has an audited intake of 1.55 channels — under four per cent of its headcount. That is the number that goes in the denominator, and it is the number nobody computes. The channel audit is the only instrument of the four that says *why*: the other three say that `r` is high; this one says whether `D` grew or `P` collapsed, and those have different fixes.

24.7.5 7.5 The under-framed institution and its instruments

Clinical description. `r < 1`. Audited intelligence exceeds the constraint the standing model supplies. The organisation constructs a situation smaller and less determinate than its environment. It cannot make its inputs mean anything. This is the less-discussed pathology and it

is at least as common: it is the natural state of a new organisation, a merged one, a rapidly expanded one, and any organisation that responded to a past over-framing episode by collecting more.

The behavioural signature: intake grows and dashboards multiply; decision latency grows and items are deferred pending further information; the standing request is always for more data; nothing is retired, because no conclusion is ever firm enough to close a line of enquiry; and staff describe the work as overwhelming and the organisation as lacking direction. **Both reports are accurate and they are the same report.**

Under-framing is **not** ignorance. It is the opposite: a surfeit of intake with insufficient frame to convert intake into a situation. Case 2 of Section 6.5 gives the limit exactly — `D -> 0` implies `M -> 0`, not `M` small but `M` zero. A perfectly open-minded institution does not decide badly; it does not decide.

I-5 The intake-to-decision ratio.

> **The conversion postulate [postulate].** Let `kappa` be intake-units consumed per decision closed. A calibrated organisation runs at some `kappa*` set by its decision complexity. Then `r_hat = kappa* / kappa`.

```
kappa / kappa*     r_hat     ln r_hat
--------------    ------    --------
      0.25        4.0000    +1.3863     over-framed: decides on almost nothing
      0.50        2.0000    +0.6931
      1.00        1.0000    +0.0000     calibrated
      2.00        0.5000    -0.6931
      4.00        0.2500    -1.3863     under-framed
      8.00        0.1250    -2.0794     under-framed, severe
```

Data: an intake tally and a decision log, both of which most organisations keep. Scale: both are counts, so `kappa` is ratio-scaled. Same limitation as I-1: `kappa*` requires justification, and without one the instrument produces an ordering rather than a magnitude. **Trend in `kappa` under stable decision complexity is the usable form.**

I-6 The unread ratio and the backlog slope. Two counts: intelligence products produced, and intelligence products demonstrably consulted in a decision within their useful life. The ratio is a direct, external, ratio-scaled measure of intake the organisation cannot frame. A rising backlog with a stable production rate is a queueing statement read backwards: with `L = lambda W`, a growing queue at constant arrival rate means growing residence time [Little, 1961]. **Under-framing shows up in the queue before it shows up in anyone's account of the problem**, which makes this the earliest available indicator, and the same delay-and-stock misjudgement is measured experimentally in the beer distribution game [Sterman, 1989].

I-7 The instrument proliferation count. Count distinct standing reports, dashboards and metrics; count how many are cited in decisions. Proliferation with flat citation is diagnostic: the organisation is answering an inability to frame by adding intake, which moves `r` in exactly the wrong direction. **This instrument detects the characteristic self-inflicted worsening of under-framing.**

I-8 The forecast-absence test. Ask for the organisation's quantified forecasts with resolution dates. An over-framed organisation has them and they are overconfident. An under-framed organisation **does not have them at all** — not because it is careless, but because a forecast is an act of doctrine and it has insufficient doctrine to make one. Binary, external and cheap. Its absence is not proof, but combined with I-5 and I-6 it is close to conclusive on direction. The general case for putting a risky prediction on the record rather than a directional one is Meehl [1967].

24.7.6 7.6 Reading the instruments together, and the manufacturing result computed

No single instrument is sufficient. The direction table:

		OVER-FRAMED	UNDER-FRAMED
I-1	revision rate sigma	LOW	HIGH
I-2	anomaly absorption A	HIGH	LOW (or unclassifiable)
I-3	calibration curve	overconfident	underconfident / absent
I-4	channel audit u, N_eff	LOW u, LOW N_eff	HIGH N_eff relative to D
I-5	intake per decision kappa	LOW	HIGH
I-6	unread ratio, backlog	LOW	HIGH, rising
I-7	instrument proliferation	LOW	HIGH with flat citation
I-8	quantified forecasts	present, wrong	absent

Rules for reading. **Direction requires at least two instruments agreeing, one behavioural and one structural**, and I-4 should be one of them wherever the data allow, because it is the only one that identifies the cause. **A mixed reading is not noise; it is usually a mixed organisation. I-2 is conclusive when high and inconclusive when low. Where `sigma*` and `kappa*` cannot be defended, report I-1 and I-5 as orderings, not magnitudes**, and print the demotion.

Now take an organisation calibrated on the under-framed side and let nothing happen except `u` decay: `N = 12`, `D = 4.0`, `p_bar = 1.0`, `u_0 = 0.55`, `lambda = 0.08` per period, and for the storage side `eta = 0.42`, `delta = 0.14`, `C = 0.55`.

t	u	N_eff	F	P	r	ln r	Delta	S	Q_inf
0	0.5500	7.050	1.9530	7.050	0.567	−0.5667	0.5667	1.4099	+0.3011
3	0.4283	5.711	1.7424	5.711	0.700	−0.3561	0.3561	1.7404	+1.2927
6	0.3335	4.668	1.5408	4.668	0.857	−0.1545	0.1545	2.1291	+2.4588
9	0.2597	3.857	1.3498	3.857	1.037	+0.0365	0.0365	2.3958	+3.2589
12	0.2022	3.224	1.1707	3.224	1.241	+0.2156	0.2156	2.0031	+2.0806
15	0.1575	2.732	1.0051	2.732	1.464	+0.3812	0.3812	1.6973	+1.1632
18	0.1226	2.349	0.8539	2.349	1.703	+0.5324	0.5324	1.4591	+0.4488
21	0.0955	2.050	0.7180	2.050	1.951	+0.6683	0.6683	1.2737	−0.1075
24	0.0743	1.818	0.5976	1.818	2.200	+0.7887	0.7887	1.1293	−0.5407

The crossing is at `u* = (4.0 − 1)/11 = 0.2727`, reached at `t* = ln(0.2727/0.55)/ln(0.92) = 8.41` periods.

Read the trajectory as a story, because it is a common institutional history. **Periods 0 to 6:** the organisation is under-framed and improving; its distortion falls, its bankable input rises, its equilibrium store rises. Everything anyone measures is getting better. **Period 9:** calibration, `Delta = 0.037`, `S = 2.3958` against a ceiling of 2.4849. Peak performance, and it is genuinely peak: `Q_inf = 3.26`. **Periods 12 to 18:** the same process continues and now runs the other way. `u` keeps falling, `F` keeps falling, `ln r` keeps rising, and every quantity that improved now degrades — **driven by the identical underlying trend, with no change of behaviour, no change of doctrine, and no decision by anyone. Period 21:** `Q_inf` goes negative and the institution's standing capability erodes.

> **The mechanism that produced the golden period is the mechanism that produced the decline. They are the same mechanism at different points on one monotone curve.**

This is why organisations are reliably unable to diagnose themselves at period 18. The behaviour that was rewarded at period 6 — building shared understanding, converging on a common view, reducing internal friction — is the behaviour that is killing them at period

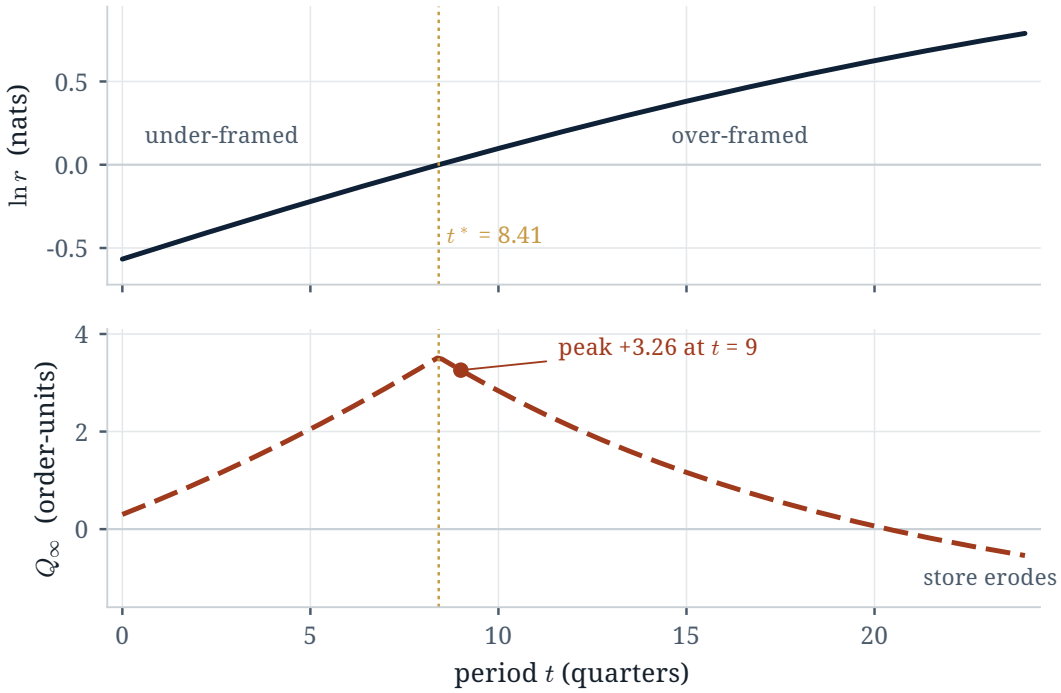

Figure 24.3: **An organisation that changes nothing crosses from under-framed to over-framed on a computable date.** With doctrine, collection budget, headcount and domain all held fixed, non-parallelism decaying at 8 per cent per period drives `ln r` monotonically upward through zero at `t* = 8.41` periods, and the equilibrium store rises to a genuine peak of `+3.26` at period 9 before falling through zero at period 21. Modelled at `N = 12`, `D = 4.0`, `p_bar = 1.0`, `u_0 = 0.55`, `lambda = 0.08`, `eta = 0.42`, `delta = 0.14`, `C = 0.55`, tabulated in Section 7.6; generated by `figs/src/CCP-024_fig03.py`.

18, and it never changed. **Pseudo-diversity manufactures over-framing, and it does so most effectively in organisations that are proud of their cohesion.** Cohesion is often the enemy of the measured collective-intelligence factor [Woolley et al., 2010] because cohesion drives `u` toward zero; in this section's terms, it drives the denominator of `r` toward `p_bar`. The same interaction that raises local agreement can freeze global diversity into non-interacting blocs, with a sharp transition between the monocultural and fragmented phases [Axelrod, 1997].

24.7.7 7.7 Distortion does not average

Organisations are not uniform. A headquarters and a field operation can sit on opposite sides of the fixed point, and the aggregate figure will report neither. Take two units, `N = 12`, `p_bar = 1.0` throughout:

```
unit          u       N_eff = P     D       r        ln r       Delta     S
----------   -----   ----------   -----   ------   --------   ------   ------
HQ           0.11       2.210      6.80   3.0769   +1.1239    1.1239   0.8076
Field        0.62       7.820      1.15   0.1471   −1.9169    1.9169   0.3654

AGGREGATE (D and P summed):          7.95 / 10.030 = 0.7926    ln r = −0.2324
```

The aggregate reads `Delta = 0.2324` — nearly calibrated — while both halves are severely distorted, at 1.12 and 1.92. The aggregate is not an average of the units' distortions and it is not a summary of them; it is a different quantity, and here it is actively misleading.

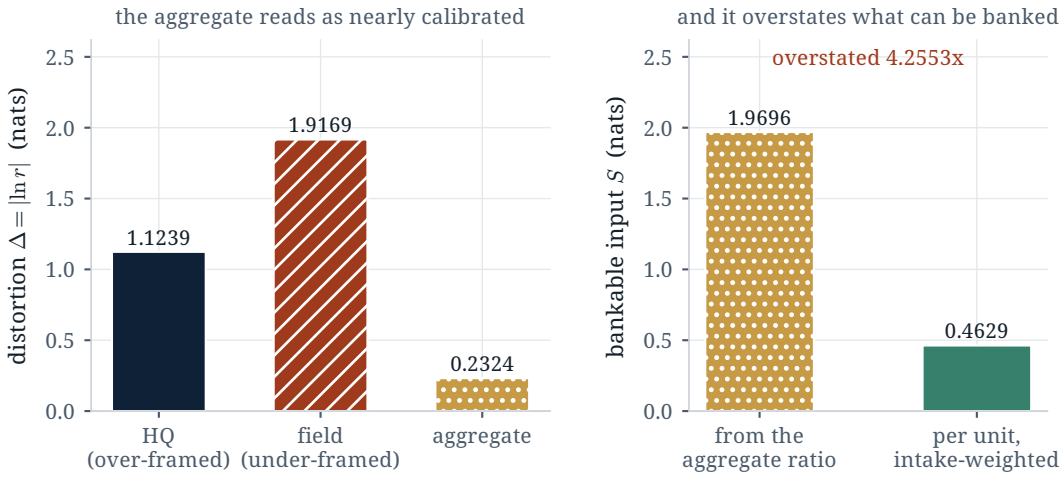

Figure 24.4: **An aggregate that reads as nearly calibrated conceals two units in opposite ditches**: the headquarters at `Delta = 1.1239` over-framed and the field at `Delta = 1.9169` under-framed combine to an aggregate `Delta = 0.2324`, and bankable input computed from that aggregate reads 1.9696 nats against a true intake-weighted 0.4629 — an overstatement of 4.2553 times. Computed from the two-unit case tabulated in Section 7.7 at `N = 12` and `p_bar = 1.0`; generated by `figs/src/CCP-024_fig04.py`.

The arithmetic of why: `r_agg = (D_1+D_2)/(P_1+P_2)` is a weighted mediant, so it always lies between `r_1` and `r_2`. When both units are distorted in the **same** direction the aggregate lies between them and understates the worse one, which is tolerable. When they are distorted in **opposite** directions the aggregate lies between two values straddling 1, and can sit arbitrarily close to 1 while both units are arbitrarily far from it. **Cancellation in the books, no cancellation in the world.** This is the general aggregation objection made concrete [Kirman, 1992, Quetelet, 1835], and the reason a distribution rather than its mean is what determines an outcome [Granovetter, 1978].

The consequence for banking is severe:

```
S computed from the aggregate ratio:          2.4849 x 0.7926 = 1.9696
S computed per unit and intake-weighted:      0.4629
OVERSTATEMENT FACTOR:                         4.2553
```

Computing an organisation's bankable input from its aggregate ratio overstates it by a factor of 4.26 in this case. The aggregate is not conservative and not approximately right; it is wrong in the dangerous direction. *(The exact ratio recomputed at full precision is 4.2553. The source manuscript prints this quantity twice, once as 4.26 and once, for the same numbers, as 4.25; the value is stated here to four decimals so that the discrepancy is a rounding convention rather than a disagreement.)*

> **Rule. Compute `r` per decision-making unit. Aggregate the units' `S`, weighted by intake, never the units' `D` and `P`.**

One further consequence, which is where the correction protocols start: a mixed organisation has an obvious-looking remedy — move doctrine from the over-framed unit to the under-framed one — and it does not fully work. Doctrine total is 7.95 and intake total is 10.030. **Even perfect redistribution leaves the organisation doctrine-poor overall by 2.080 units, or 26.2 per cent of its standing doctrine.** Redistribution alone can equalise the distortion; it cannot remove it.

24.7.8 7.8 Correction protocols

Over-framed. The correction runs in one direction only: `ln r` must come down. There are exactly four levers and they have very different prices.

O-1 Raise `u`. Recruit across training lineages, rotate, stand up genuinely independent channels, commission from unaligned sources, install adversarial review, import a practitioner from an unrelated trade. *Price and ceiling:* `ln r` falls by exactly the gain in `F`, one nat for one nat, and the total available is `ln N`. Concavity means the early gains are the large ones: at `N = 12`, moving `u` from 0.14 to 0.30 buys 0.5264 nats; moving from 0.60 to 0.90 buys 0.3607. **Raise `u` first, and expect the second independent channel to be worth more than the twentieth.** *The trap:* `u` gained is `u` that will decay again at rate `lambda`. This lever must be operated as a maintenance schedule, not a project. **A one-off diversity intervention buys a decaying quantity and is the commonest wasted correction.**

O-2 Raise `p_bar`. Deepen the intake of existing channels: longer collection, better instrumentation, more careful reading. *Price:* directly proportional and unbounded in principle. In practice it is bounded by budget and by the fact that deepening a channel does not make it independent. **`p_bar` and `u` are not substitutes: a hundred times more of one wire service is still one channel.**

O-3 Raise `N`. Broaden the declared domain. *Price:* logarithmic and expensive. It raises the ceiling on what `u` can buy but buys nothing by itself. **Worst of the four, and the one most often reached for, because expanding scope is easier to authorise than admitting error.**

O-4 Cut `D`. Retire standing assumptions. Sunset guidance. Shed doctrine. *Price:* unbounded, since `D` can go to zero, but it costs `Q`, and shedding `Q` is legitimate, underused and hard. **This is the only lever that works in the infeasible region `D/p_bar > N`.**

The comparison, at `N = 12`, `D = 5.2`, `p_bar = 1.0`, `u = 0.14`:

```
target r     via u                      via D
--------     ----------------------     ------------------------
1.898        u = 0.1582  (x 1.13)       D = 4.821  (-7.3 %)
1.500        u = 0.2242  (x 1.60)       D = 3.810  (-26.7 %)
1.200        u = 0.3030  (x 2.16)       D = 3.048  (-41.4 %)
1.000        u = 0.3818  (x 2.73)       D = 2.540  (-51.2 %)
```

Getting merely inside the operating envelope costs a 13 per cent increase in `u` or a 7 per cent cut in doctrine. Full calibration costs nearly a tripling of `u` or halving the standing model. Stabilise before optimising, and take the cheap fraction of the distance first.

```
O-STEP 1.  Confirm direction with two instruments, one of them I-4.
O-STEP 2.  Compute the infeasibility check: is D/p_bar > N?
           If YES -> only O-4 works. Go to step 5.
O-STEP 3.  Compute the operating envelope from S_min = C/eta.
           Target the envelope edge, not r = 1.
O-STEP 4.  Price O-1 and O-2 against O-4 at that target. Take the cheapest.
O-STEP 5.  If O-4: enumerate the doctrine, rank by (decisions constrained) /
           (evidence supporting), retire from the top.
O-STEP 6.  Install the maintenance schedule for u BEFORE declaring the
           correction complete. Without it, t* restarts.
O-STEP 7.  Preregister the held-out test before intervening.
```

Step 5's ranking deserves a note. The doctrine to retire first is not the doctrine most likely to be wrong; it is the doctrine that constrains the most decisions on the least evidence. **A weakly supported proposition that governs one decision a year is a curiosity. A weakly supported proposition that governs every decision is the whole problem.**

Under-framed. The correction runs the other way and it is **not** the mirror image, for a reason that matters: building a frame is a slower, more skilled and more contestable act than adding a channel.

U-1 Raise `D` — build the frame. Adopt an explicit model. Write the standing assumptions down. Commit to a hypothesis before collecting. Publish quantified forecasts with resolution dates. Close lines of enquiry. *Price:* this is the only lever that addresses the cause, and it is expensive in the one currency institutions guard most closely: **someone must be willing to be wrong in writing.** Under-framing persists not because frames are hard to obtain but because an unstated frame cannot be falsified and a stated one can. At `N = 12`, `u = 0.55` so `P = 7.05`, `eta = 0.42`, `delta = 0.14`, `C = 0.55`:

D	r	Delta	S	Q_inf
0.50	0.0709	2.6462	0.1762	−3.3999
1.00	0.1418	1.9530	0.3525	−2.8712
2.00	0.2837	1.2599	0.7049	−1.8138
3.00	0.4255	0.8544	1.0574	−0.7564
4.00	0.5674	0.5667	1.4099	+0.3011
5.00	0.7092	0.3436	1.7623	+1.3585
6.00	0.8511	0.1613	2.1148	+2.4159
7.05	1.0000	0.0000	2.4849	+3.5261

This organisation's equilibrium store crosses zero between `D = 3` and `D = 4`. Below that it cannot hold anything, no matter how good its intelligence is. The remedy is not better collection. It has excellent collection. **It needs a model, and until it has one its collection is unbankable.**

U-2 Triage `P` — cut channels deliberately. The uncomfortable lever, and it is real. Reducing the number of independent channels raises `r` toward 1. Worked at `D = 1.6`, `N = 12`:

u	P	r	Delta	S
0.5500	7.050	0.2270	1.4830	0.5640
0.4500	5.950	0.2689	1.3134	0.6682
0.3500	4.850	0.3299	1.1090	0.8198
0.2500	3.750	0.4267	0.8518	1.0602
0.1500	2.650	0.6038	0.5046	1.5003
0.0545	1.599	1.0003	0.0003	2.4841

Reaching calibration by triage alone would require destroying almost all of this organisation's independence — `u` from 0.55 to 0.055 — and it would work, in the sense that `S` returns to the ceiling. **The lever is stated and then the reason it is nearly always wrong is stated.** First, it is irreversible on the timescale that matters: `u` destroyed must be rebuilt from recruitment, and rebuilding difference has no internal source. Second, it caps the organisation's future, because `N_eff` is the ceiling on every later correction. Third, it is the same move as pseudo-diversity, chosen deliberately, so the whole trajectory of Section 7.6 applies immediately. **Use triage only for genuinely redundant channels — channels whose measured pairwise `u` against existing ones is near zero.** Those cost budget and contribute nothing to `N_eff`, so cutting them raises `r` almost not at all and frees resources for U-1. That is the honest, narrow, defensible version of this lever.

```
U-STEP 1.  Confirm direction with two instruments; I-8 and I-6 are the cheapest pair.
U-STEP 2.  Compute the operating envelope from S_min = C/eta and locate the
           D at which Q_inf crosses zero. That is the minimum viable frame.
U-STEP 3.  Build the frame: write the standing assumptions, commit to
           hypotheses, publish forecasts with resolution dates.
U-STEP 4.  Close lines of enquiry explicitly. An unclosed enquiry is
           continuing intake against a frame that does not yet exist.
U-STEP 5.  Triage ONLY channels with measured near-zero pairwise u.
```

```
U-STEP 6.  Re-measure. Under-framed organisations correct FAST once the
           frame lands, because D is the numerator and moves directly.
U-STEP 7.  Set the over-framing alarm now: record t* from the current u,
           lambda and D, and diarise the re-measurement before it.
```

Step 7 closes the loop. An organisation that corrects under-framing by building doctrine has raised `D` — and `D` does not decay, while `u` does. It has therefore shortened its own `t*` and set itself on the trajectory of Section 7.6. **The correction for one pathology is the seed of the other, and the only defence is to have computed the crossing date in advance.**

24.7.9 7.9 Validation gates for the instruments

Table V-C1 — Revision-rate estimator `r_hat = sigma*/sigma` (I-1)

Gate	Finding
1 Dimensions	`sigma`, `sigma*` are proportions, dimensionless; `r_hat` dimensionless. **PASS.**
2 Scale type	Proportions are ratio-scaled with a true zero. **PASS for `sigma`. The gate binds on `sigma*`:** if the baseline cannot be estimated from an external referent, `r_hat` has no magnitude and **the instrument must be demoted in print to an ordering.**
3 Limiting cases	`sigma -> 0`: `r_hat` diverges, an organisation that never revises — real, nameable, the severe end of over-framing. `sigma -> 1`: every product overturns a conclusion, `r_hat -> sigma*`, the maximally unstable frame. **PASS.**
4 Fixed points	`sigma = sigma*` gives `r_hat = 1`. Not an attractor; nothing drives `sigma` toward `sigma*`. **PASS, with instability noted.**
5 Identifiability	`sigma` is recoverable from a decision log with before/after states. `sigma*` is **not recoverable from the organisation's own records** and requires environmental volatility measured externally. **CONDITIONAL PASS.**
6 Falsification	Preregister `sigma` over a fit window; predict held-out surprise rate. **Kill condition: `sigma` fails to predict held-out surprise rate beyond the shuffled-input control.**
7 Reproducibility	**UNTESTED.** Cross-institution recovery of `sigma*` for comparable environments is the specific open question.

Table V-C2 — Anomaly absorption `A`, reported as `ln(A/(1-A))` (I-2)

Gate	Finding
1 Dimensions	`A` a proportion; the log-odds in nats, commensurate with `ln r` and `F`. **PASS.**

Gate	Finding
2 Scale type	Counts of anomalies by disposal class: ratio-scaled with a true zero. **PASS, and this is the strongest scale-type position of any instrument here, because it needs no baseline.**
3 Limiting cases	`A -> 1`: nothing is ever escalated, log-odds diverge upward; the sealed model. `A -> 0`: everything is escalated, log-odds diverge downward; a frame so weak that no observation can be placed. Both real. **PASS.**
4 Fixed points	`A = 0.5`, log-odds 0. This is **not** claimed to correspond to `r = 1`; the mapping from `A` to `r` is not established and none is invented. **PASS as a fixed point of the instrument, NOT of the ratio.**
5 Identifiability	`A` recoverable from disposal records. **The known bias, printed: anomaly identification is performed through the model, so severe over-framing suppresses the denominator. High `A` is conclusive; low `A` is not. CONDITIONAL PASS with declared bias.**
6 Falsification	Preregister `A`; predict the rate of later-observable events the organisation had classified as noise. **Kill condition: no relation between `A` and the missed-event rate beyond the shuffled control.**
7 Reproducibility	**UNTESTED.** Inter-rater agreement on the three disposal classes is a prerequisite and has not been established.

Table V-C3 — Intake-to-decision estimator `r_hat = kappa*/kappa` (I-5)

Gate	Finding
1 Dimensions	`kappa` in intake-units per decision; `kappa*` the same; `r_hat` dimensionless. **PASS, provided intake-units are the convention's units.**
2 Scale type	Both are ratios of counts, ratio-scaled. **PASS for `kappa`; binds on `kappa*` exactly as V-C1 binds on `sigma*`. Demote to an ordering where `kappa*` is undefended.**
3 Limiting cases	`kappa -> 0`: decisions taken on no intake, `r_hat` diverges, over-framing. `kappa -> infinity`: unbounded intake per decision, `r_hat -> 0`, the paralysed institution. **PASS.**
4 Fixed points	`kappa = kappa*`. **PASS.**
5 Identifiability	`kappa` from intake tally and decision log, both routinely kept. `kappa*` requires an external standard of decision complexity. **CONDITIONAL PASS.**

Gate	Finding
6 Falsification	Preregister `kappa`; predict held-out decision latency and reversal rate. **Kill condition: no relation beyond the shuffled control.**
7 Reproducibility	**UNTESTED.**

Table V-C4 — The manufacturing model `ln r_t = ln D − ln p_bar − ln(1 + (N−1)u_0(1−lambda)^t)`

Gate	Finding
1 Dimensions	All terms in nats; `lambda` dimensionless per period; `t` a count. **PASS.**
2 Scale type	Inherits Tables V-G1 and V-G3's conditions plus Table V-P6's on `u` decay. **CONDITIONAL, and the conditions are declared upstream.**
3 Limiting cases	`t -> infinity`: `u -> 0`, `N_eff -> 1`, `ln r -> ln(D/p_bar)` — the parallel wall, and `r` **converges** rather than diverging, which is correct: over-framing has a ceiling set by the doctrine load, not an unbounded runaway. `lambda -> 0`: `r` constant, no drift. **PASS.**
4 Fixed points	`u = 0` is globally attracting for `lambda > 0`. The crossing `t*` is not a fixed point but a threshold, and it exists if and only if `u_0 > u*`. **PASS.**
5 Identifiability	`lambda` from two clean `u` measurements; `u_0` from the channel audit; `D`, `p_bar`, `N` from the enumeration protocols. All separately obtainable. **`t*` is then a prediction with no free parameters, which makes it directly testable. PASS**, subject to the reflection problem of Section 3.4, which is not answered by parameter-counting.
6 Falsification	**The strongest test available here: preregister `t*` from measurements at `t = 0`, then measure `r` at `t*` and at `2t*`.** Kill condition: `r` fails to cross 1 within a preregistered tolerance of `t*`, or the constant-`u` baseline predicts the observed `r` series as well as the decay model.
7 Reproducibility	**UNTESTED.** Whether `lambda` recovered in one organisation transfers to another of comparable structure is unknown.

24.7.10 7.10 Requirements and failure modes at calibration scope

DD-1 Diagnose direction before magnitude. Two instruments minimum, one behavioural and one structural, with I-4 preferred as the structural one. `[direction]`

DD-2 Report `ln r` signed. Never report `Delta` bare. `[reporting]`

DD-3 Compute `r` per decision-making unit, never for the whole organisation. `[measurement]`
Test: the report contains one `ln r` per unit and no organisation-wide `D/P`.

DD-4 Aggregate `S`, intake-weighted — never aggregate `D` and `P`. The aggregate ratio overstated bankable input by a factor of 4.2553 in Section 7.7's case. `[measurement]`

DD-5 Run the infeasibility check before designing any correction. If `D/p_bar > N`, only doctrine reduction works; record `Delta_min = ln(D/p_bar) − ln N` and say so in the report. `[feasibility]`

DD-6 Derive thresholds from the organisation's own `S_min = C/eta`, not from a literature. No empirical distribution of institutional `Delta` exists. `[thresholds]`

DD-7 Demote `sigma*`- and `kappa*`-dependent instruments to orderings where the baseline is undefended, in print. `[honesty]`

DD-8 Treat high anomaly absorption as conclusive and low absorption as inconclusive. The instrument's bias runs one way. `[I–2]`

DD-9 Compute `t*` and diarise it. `t* = ln(u*/u_0)/ln(1−lambda)`, with `u* = (D/p_bar − 1)/(N−1)`. Re-measure before it, not after. `[drift]` *Test: `t*` is written down with its date of expiry.*

DD-10 Install the `u` maintenance schedule before declaring an over-framing correction complete. Otherwise `t*` simply restarts. `[u, maintenance]`

DD-11 Rank doctrine for retirement by decisions-constrained per unit of supporting evidence, not by likelihood of being wrong. `[O–4]`

DD-12 Correct under-framing by building the frame, not by cutting channels. Triage only channels with measured near-zero pairwise `u`. `[U–1, U–2]`

DD-13 Require quantified forecasts with resolution dates from any unit claiming calibration. Their absence is diagnostic. `[I–3, I–8]`

DD-14 Set the over-framing alarm at the moment an under-framing correction lands. Raising `D` shortens `t*`. `[loop closure]`

DD-15 Preregister every correction — encoder, fit window, freeze, held-out window, four baselines including the shuffled-input control, and the kill conditions [Nosek et al., 2018]. `[falsifiability]`

DD-16 No instrument or correction here may remove a person's ability to decline — to decline being measured, to decline a channel role, or to decline the dissent the protocol asks of them. `[ethics]`

FM-C1 The unsigned diagnosis. `Delta` reported without the sign of `ln r`; the correction is chosen by reflex. *Signature:* an under-framed unit receiving a diversity, breadth or collection intervention, and performing worse afterwards. *Fix:* re-diagnose; reverse the lever.

FM-C2 The cancelling aggregate. Organisation-wide `D/P` computed from summed numerators and denominators, with units distorted in opposite directions. *Damages:* measurement, in the dangerous direction — bankable input overstated 4.2553 times in Section 7.7. *Signature:* a near-calibrated headline figure and universally poor unit-level performance. *Fix:* aggregate `S`, intake-weighted, never `D` and `P`.

FM-C3 The one-off diversity project. `u` raised once, as a project, with no maintenance schedule. *Damages:* `u`, on a delay; `t*` restarts from the new `u_0`. *Signature:* a correction that works, is declared complete, and is followed by the same diagnosis two to four years later. *Fix:* the lever is a schedule, not a project.

FM-C4 The collection reflex. An under-framed organisation responding to its own confusion by collecting more. *Damages:* `r` falls further; the loop is self-reinforcing. *Signature:* instrument proliferation with flat citation; a rising backlog; a standing request for more data that is never satisfied. *Fix:* build the frame. Stop collecting against a frame that does not exist.

FM-C5 The triage overshoot. Under-framing corrected by cutting independent channels rather than by building doctrine. *Damages:* `u`, `N_eff`, and every future correction's ceiling. *Signature:* calibration achieved, followed by rapid drift into over-framing — Section 7.6's trajectory, entered deliberately. *Fix:* restrict triage to channels with measured near-zero pairwise `u`; rebuild `N_eff` before it is needed.

FM-C6 The invisible anomaly. Severe over-framing suppresses anomaly recognition, so

the anomaly audit returns a low absorption rate and reads as healthy. *Signature:* low `A`, low `sigma`, and a high surprise rate from outside the model's categories. *Measurement:* cross-check I-2 against I-1 and I-4; a low `A` with a low `sigma` is the signature, a low `A` with a healthy `sigma` is genuine. *Fix:* never read a low `A` alone as calibration.

FM-C7 The scope expansion. Over-framing addressed by raising `N` because it is the politically easiest lever. *Damages:* `C` rises, `ln r` barely moves, the underlying `u` problem is untouched. *Signature:* a remit that grows while distortion holds steady. *Fix:* O-1 or O-4. `N` is the most expensive lever and the least rewarding.

FM-C8 Corrected into the other ditch. An under-framing correction lands, `D` rises, and no one recomputes `t*`. *Damages:* the loop is not closed; over-framing arrives on schedule and is treated as a new problem. *Signature:* an organisation with a documented history of alternating between "we have no direction" and "we are not listening", every few years. *Fix:* the alarm is set at the moment of correction, not after the next failure.

24.8 8 Results: three systems worked end to end

Three constructed cases are carried end to end. **Every number below is the example's own. None is drawn from a real partnership or a real organisation and none should be cited as empirical.** The arithmetic is reproducible from the stated parameters, and that is the entire claim being made for it.

24.8.1 8.1 A two-person design practice

Two people found a small design practice — one trained as a structural engineer, one as an industrial designer — in a domain they define as `N = 12` categories: structure, material, cost, fabrication, use, maintenance, regulation, client, schedule, aesthetics, environment, disposal. They review quarterly.

Encoding. The state encoder is each partner's weighting across the twelve domain categories on a project brief, elicited independently before discussion. The interaction observable is pre-discussion disagreement across the twelve categories, per project. The order observable `Q` is durable practice assets: documented details a third party can execute, standing supplier relations, reusable specifications, precedents that survive to the next project. One quarter is one period. The cost observable `C` is coordination time, rework, the overhead of joint decision-making, and maintenance of the asset library. **`Q` is measured by third-party executability, external to the pair's own interaction volume**, which satisfies requirement S-9.

Baseline, quarter 0.

```
N     = 12       ln N = 2.4849
u     = 0.62     measured by pre-discussion disagreement over 14 briefs
eta   = 0.55     order-units per nat
delta = 0.12     per quarter
C     = 0.34     order-units per quarter
Q_0   = 0.00     new practice

N_eff = 1 + 11(0.62) = 7.8200
S_0   = ln(7.8200)   = 2.0567 nats
```

Two people with an effective count of 7.82. In degrees, `u = 0.62` is `theta = 51.9`, well inside the productive band. Decomposing per S-6: roughly `u_cross = 0.50` (two trades) and `u_div = 0.12` (each defers to the other inside the other's specialism). Checking the decomposition bound at `N = 12`:

```
f(0.50) = 1.8718     f(0.12) = 0.8416     f(0.62) = 2.0567
max = 1.8718  <=  2.0567  <=  2.7134 = sum      [bound satisfied]
```

The pair is rich in `u_cross` and thin in `u_div`. That is flagged now and it becomes the story.

The minimum viable angle.

```
S_min = C / eta = 0.34 / 0.55 = 0.6182
u_min = (e^0.6182 - 1) / 11   = 0.0778        theta_min = 16.2 degrees
N_eff at u_min = 1.8556
```

The practice's survival line is 16.2 degrees; at quarter 0 they are at 51.9 degrees.

Convergence measured. Two clean `u` measurements, quarters 0 and 8, no restoration between:

```
u_0 = 0.62      u_8 = 0.378      lambda = 1 - (0.378/0.62)^{1/8} = 0.0600 per quarter
half-life of u  = ln 2 / (-ln(1-0.06)) = 11.2 quarters
```

Their difference has a half-life of under three years. They did nothing wrong; they learned each other's trades, which is what a good cross-disciplinary pair does.

The trajectory with no restoration. Running `Q_{t+1} = (1-0.12)Q_t + 0.55 S_t - 0.34` with `u_t = 0.62(0.94)^t`:

t	u	N_eff	S	Q	h	step
0	0.6200	7.820	2.0567	0.0000	+1.0267	+0.7912
2	0.5478	7.026	1.9496	1.4579	+0.8518	+0.5574
4	0.4841	6.325	1.8445	2.4766	+0.7295	+0.3773
8	0.3779	5.157	1.6404	3.5785	+0.5973	+0.1328
10	0.3339	4.673	1.5419	3.8009	+0.5706	+0.0519
12	0.2951	4.246	1.4459	3.8719	+0.5621	−0.0094
16	0.2304	3.534	1.2625	3.6993	+0.5828	−0.0896
20	0.1799	2.979	1.0914	3.2684	+0.6345	−0.1319
24	0.1404	2.545	0.9340	2.7064	+0.7019	−0.1511

The practice peaks at quarter 12 with `Q = 3.87` and declines thereafter, holding `Q = 2.71` by quarter 24 — roughly its quarter-5 position, six years in. Now read the headroom column, which is the diagnostic point of the whole example.

> **Headroom is positive at every single step, and it is HIGHER at quarter 24 (+0.70) than at quarter 10 (+0.57).** The framework's master gauge never once signalled a problem. It could not: `h = eta ln N - delta Q - C` contains no term for `u`. Headroom measures the *budget*, not the *input*. A pair can have ample budget and nothing to spend it on.

Headroom says what could be banked; `u` says what there is to bank. A partnership dies with a healthy balance sheet. Headroom *improves* as the practice declines, because `delta Q` shrinks with `Q`: the gauge gets more encouraging exactly as the situation gets worse. That is not a defect in the gauge but a demonstration that one gauge is not a dashboard.

What the partners will say at quarter 20. They will report that the work has become repetitive, that clients are less interesting, that the market has changed, and that they are tired. All four reports will be sincere. None will mention that their effective count has fallen from 7.82 to 2.98. **Non-parallelism is the parameter that decays without any experience of decaying**, because from the inside convergence feels like competence.

The intervention. Restoring `u` to 0.62 on a schedule at or below the measured 11.2-quarter half-life, `Q` at quarter 24 reads:

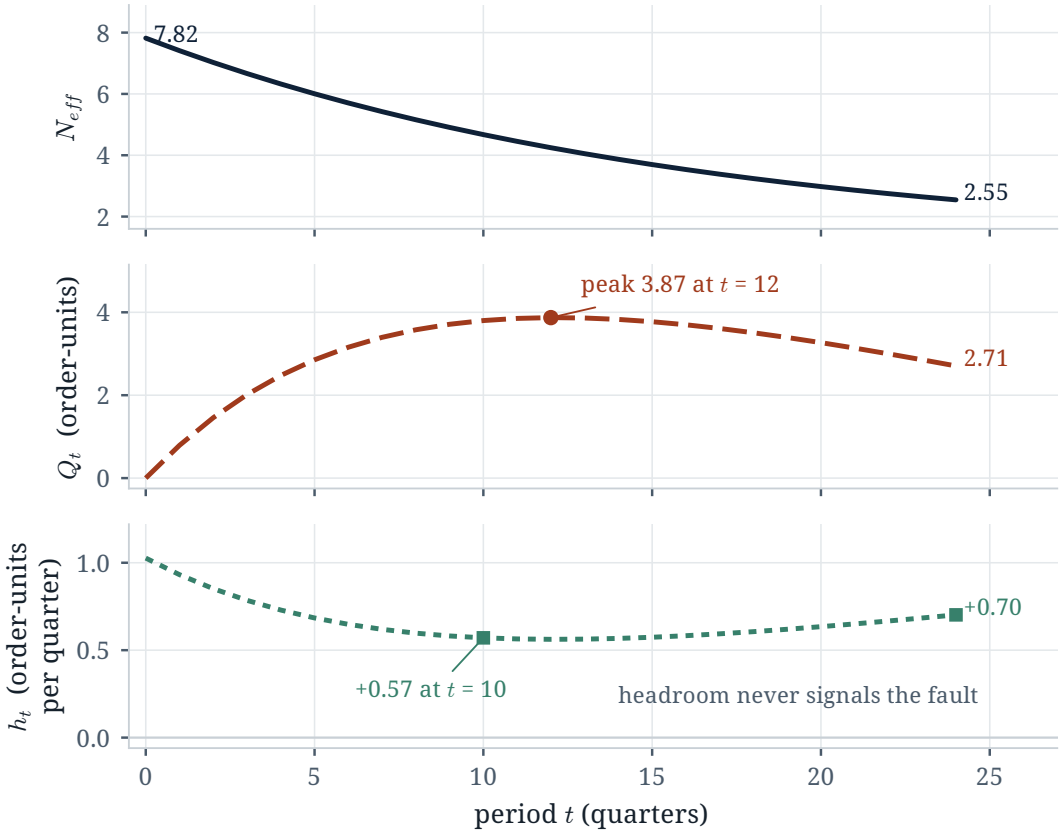

Figure 24.5: **A partnership can decline for twelve quarters while its master gauge improves.** As non-parallelism decays at 6 per cent per quarter, the pair's effective count falls from 7.82 to 2.55 and its store peaks at 3.87 in quarter 12 before falling back to 2.71 by quarter 24 — while headroom stays positive throughout and reads higher at quarter 24 (+0.70) than at quarter 10 (+0.57), because the headroom gauge contains no term for `u`. Modelled at `N = 12`, `u_0 = 0.62`, `lambda = 0.06`, `eta = 0.55`, `delta = 0.12`, `C = 0.34`, tabulated in Section 8.1; generated by `figs/src/CCP-024_fig05.py`.

```
restoration interval    Q at t=24    gain vs never
--------------------    ---------    -------------
never                     2.7064          --
every 12 quarters         4.7070       +2.0006
every  8 quarters         5.3283       +2.6219
every  6 quarters         5.6209       +2.9145
every  4 quarters         5.8991       +3.1927
every  2 quarters         6.1615       +3.4551
```

Restoring once every twelve quarters captures 58 per cent of the total available gain; a six-fold increase in effort, to two-quarterly, captures the remaining 42 per cent. Concavity again: do it at all before arguing about how often. Concretely, a restoration here is a fabricator, a regulator, a maintenance contractor or a practitioner from an unrelated trade, brought into a live working session with standing to disagree, for one project. Not a lecture. Not a conference. Someone whose position on the twelve categories neither partner can predict, inside the actual work. This addresses the deficit flagged at baseline: their `u_cross` was strong and is eroding as they learn each other's trades, while `u_div` was thin from the start. **A third trade rebuilds `u_cross`; a dissenting practitioner from one of their own trades rebuilds `u_div`. They need both, and the diagnosis says which is more urgent.**

What would falsify this. The prediction is specific and preregisterable. First, `u` measured at quarter 8 and quarter 16, with restoration events at quarters 4 and 12, will be higher than the no-restoration decay curve predicts for those quarters, 0.378 and 0.230. Second, `Q` measured by third-party executability at quarter 24 will exceed the quarter-12 peak of 3.87 under a restoration schedule of 12 quarters or shorter. Third, the fitted storage model, frozen after quarter 12, will beat all four baselines on quarters 13 to 24 held out. **The framework is falsified for this practice if the shuffled-input control — the same surplus series with its time order randomised — predicts held-out `Q` as well as the fitted model.** That would mean the timing of the pair's non-parallelism carried no information about the timing of what it built, which is precisely the claim the storage law makes.

The arithmetic is exact; the parameters are constructed. The reproducibility gate has not been run on any of it, at pair scope, by anyone, and until it has, this is a specification for how to find out rather than a report of what is known.

24.8.2 8.2 A regional authority

A regional authority of about forty staff, responsible for infrastructure decisions across a defined territory, reviewing quarterly. It commissions surveys, maintains a monitoring programme, takes submissions, and reads the technical literature.

Encoding. The state encoder is each intelligence channel's assessment vector across the twelve decision domains. The interaction observable is cross-channel error decorrelation on questions whose answers become observable within 24 months. The order observable `Q` is standing capability that survives staff turnover: verified asset records, executable procedures, precedent decisions upheld on review. One quarter is one period. The cost observable `C` is coordination, committee time, compliance, and maintenance of the standing record. **`Q` is measured by survival across turnover**, which is external to intelligence volume and satisfies requirement G-13.

Baseline.

```
N       = 12        ln N = 2.4849       twelve declared decision domains
u       = 0.14      measured by cross-channel error decorrelation
p_bar   = 1.00      one intake-unit per genuinely independent channel per quarter
D       = 5.20      doctrine load, in the same currency
E       = 1.00      environment, normalised to one unit for legibility
eta     = 0.42      order-units per nat
```

```
delta   = 0.14      per quarter
C       = 0.55      order-units per quarter

N_eff = 1 + 11(0.14) = 2.5400
F     = ln(2.5400)   = 0.9322 nats
P     = p_bar . N_eff = 2.5400
```

Forty staff, an intelligence function with twelve declared domains, and an effective count of 2.54. The ratio of audited channels to headcount is `2.54 / 40 = 0.0635`: the authority's audited intake is worth about six per cent of its headcount.

The ratio, computed two ways.

```
direct:       ln r = ln D - ln P             = 1.6487 - 0.9322 = 0.7165
via the join: ln r = ln D - ln p_bar - F     = 1.6487 - 0.0000 - 0.9322 = 0.7165   AGREE
```

The over-determination check passes, so the three measurements are mutually consistent.

```
r     = e^{0.7165} = 2.0472
Delta = 0.7165 nats,  sign POSITIVE  ->  OVER-FRAMED
M     = r . E = 2.0472
```

The authority constructs a situation about twice as large as its environment. It sees two units of structure where one exists. Behaviourally: it is confident, it is fast, and it is wrong in a direction its own model predicts.

The infeasibility check.

```
D / p_bar = 5.20 / 1.00 = 5.20        N = 12        5.20 <= 12  ->  FEASIBLE
u* = (5.20 - 1) / 11 = 0.3818         N_eff* = 5.20      F* = 1.6487
```

The authority *can* be calibrated by geometry alone. It needs `u = 0.3818`, which is `theta = 38.2` degrees of mean non-parallelism across its channels, against a measured 0.14 at `theta = 22.0` degrees. That is a large but not impossible move.

The operating envelope.

```
S_min = C / eta = 0.55 / 0.42 = 1.3095 nats
S_min / ln N    = 1.3095 / 2.4849 = 0.5270
band: 0.5270 <= min(r, 1/r)   ->   0.527 <= r <= 1.898       Delta <= 0.6406
```

The authority's `r = 2.0472` is outside its own operating envelope — not marginally, `Delta = 0.7165` against a limit of 0.6406. Confirming with the contact postulate and the storage law:

```
S       = ln N . min(r, 1/r) = 2.4849 x (1/2.0472) = 1.2138 nats
eta.S   = 0.42 x 1.2138 = 0.5098
Q_inf   = (0.5098 - 0.55) / 0.14 = -0.2872
```

A negative equilibrium. The storage law does not hide this failure mode: as modelled, the authority's standing capability erodes to nothing with a time constant of `1/delta = 7.1` quarters, and the erosion will be attributed to turnover, budget and the declining quality of submissions.

Lever A — raise `u` (recruit across lineages, rotate, commission from unaligned sources, stand up a genuinely independent channel):

u	N_eff	P	r	Delta	S	eta.S	Q_inf
0.1400	2.540	2.540	2.0472	0.7165	1.2138	0.5098	−0.2872
0.2000	3.200	3.200	1.6250	0.4855	1.5292	0.6423	+0.6589
0.2400	3.640	3.640	1.4286	0.3567	1.7394	0.7306	+1.2897
0.3000	4.300	4.300	1.2093	0.1900	2.0548	0.8630	+2.2359
0.3818	5.200	5.200	1.0000	0.0000	2.4848	1.0436	+3.5259
0.4500	5.950	5.950	0.8739	0.1347	2.1717	0.9121	+2.5865

Two things to read. **The authority crosses back into its operating envelope at `u = 0.158`** — the value at which `N_eff = 5.20/1.898 = 2.7397` — well short of full calibration. It does not need to be perfect; it needs to be inside the band. And **the last row over-corrects.** At `u = 0.45` the authority passes calibration and begins under-framing, and `Q_inf` falls from 3.53 to 2.59. Diversity past the calibration point is a cost, exactly as Section 6.8 predicted.

Lever B — cut `D` (retire standing assumptions, sunset guidance, shed doctrine):

D	r	Delta	S	Q_inf
5.20	2.0472	0.7165	1.2138	−0.2872
4.50	1.7717	0.5719	1.4026	+0.2792
4.00	1.5748	0.4541	1.5779	+0.8052
3.50	1.3780	0.3206	1.8033	+1.4814
3.00	1.1811	0.1664	2.1039	+2.3831
2.54	1.0000	0.0000	2.4849	+3.5261

The authority re-enters its envelope at `D = 4.82`, since `2.5400 x 1.898 = 4.8209` — a reduction of about seven per cent in standing doctrine. **Both levers reach the same destination and the arithmetic is symmetric, because the contact postulate is symmetric in `ln r`.** Which to pull is not a question the formula answers; it is a question of cost.

Headroom, and the trap at the end.

Q	h = eta.lnN − delta.Q − C
0.0	+0.4937
1.0	+0.3537
2.0	+0.2137
3.0	+0.0737
4.0	−0.0663
5.0	−0.2063

`h = 0 exactly at Q = 3.5261`

Compare that to Section 6.6's derived result: `Q_inf` at perfect calibration is `(eta ln N − C)/delta = 3.5261`, and `h = 0` at `Q = 3.5261`. **They are the same number, as the algebra requires.** If the authority calibrates fully and holds there, it arrives at exactly zero headroom and can thereafter maintain but never build.

The recommendation the model supports is therefore not "calibrate fully". It is: get inside the envelope, stop short of the fixed point, and hold `Q` below `Q_inf` deliberately. Target `u` near 0.24, which gives `Delta = 0.36`, `Q_inf = 1.29`, and residual headroom at that store of `0.4937 − 0.14(1.29) = +0.31`. **Slightly distorted and solvent beats perfectly calibrated and saturated**, which is a direct consequence of the arithmetic rather than of the equation's rhetoric.

What would falsify this. `r` measured quarterly for eight quarters; held-out prediction of decision quality, assessed at 24-month outcome observation, for quarters 9 to 16; four baselines — persistence, `E` alone, matched autoregressive, and the shuffled-`r` control; and four preregistered kill conditions, of which the cheapest is a fitted exponent `k` in `S = ln N . e^{−k.Delta}`

significantly different from 1, or significantly different between the `r > 1` and `r < 1` branches. **That last condition can falsify one postulate while leaving the framework intact, and it costs a decision log and a forecast record.**

24.8.3 8.3 A two-site agency

An agency with two decision-making units: a headquarters that sets policy and a field operation that executes and observes. Both work the same `N = 12` decision domains. Quarterly periods. Storage parameters shared: `eta = 0.42`, `delta = 0.14`, `C = 0.55` per unit, so `S_min = C/eta = 1.3095` nats and the operating envelope is `min(r, 1/r) >= 1.3095/2.4849 = 0.5270`, that is `0.527 <= r <= 1.898`.

Baseline, per unit. Channel audit and doctrine enumeration, `p_bar = 1.0` in both units:

```
unit     u       N_eff = P    D       ln r       r        Delta    S = lnN.min(r,1/r)
-----   -----   -----------   -----   --------   ------   ------   ------------------
HQ      0.11       2.210      6.80   +1.1239   3.0769   1.1239         0.8076
Field   0.62       7.820      1.15   −1.9169   0.1471   1.9169         0.3654
```

The headquarters is over-framed at `Delta = 1.12`. The field is under-framed at `Delta = 1.92`. Both are outside the envelope and both would have equilibrium stores well below zero. The aggregate, for contrast only:

```
D_total = 7.95    P_total = 10.030    r_agg = 0.7926    Delta_agg = 0.2324
```

The agency's headline figure says it is nearly calibrated. It is not: it has one unit at 3.08 and one at 0.147. Computing bankable input from the aggregate gives 1.9696 nats against a true intake-weighted 0.4629, an overstatement of 4.2553 times.

Corroboration. Reading the instruments per unit:

```
                              HQ                      FIELD
I−1  revision rate            low                     high
I−2  anomaly absorption A     high, conclusive        low, inconclusive
I−3  calibration              overconfident           no quantified forecasts
I−5  intake per decision      low                     high
I−6  backlog                  flat                    rising
I−8  forecasts present        yes                     no
```

Two instruments agree in each unit, one behavioural and one structural. The field's low `A` is read as inconclusive per DD-8, and the cross-check clears it: the field's `sigma` is high, so its low absorption is genuine and not suppression.

Infeasibility check.

```
HQ:     D/p_bar = 6.80   vs   N = 12    ->  FEASIBLE.  u* = (6.80−1)/11 = 0.5273
Field:  D/p_bar = 1.15   vs   N = 12    ->  FEASIBLE, but the fix runs the other way.
```

The headquarters can be calibrated by geometry, but it needs `u = 0.5273` from a measured 0.11 — a factor of 4.8. That is a very large move and prices doctrine reduction into the conversation immediately.

The obvious move, and why it is insufficient. The agency's instinct will be redistribution: move doctrine from HQ to the field. Under strict conservation of `D` and `P`:

```
D_total = 7.95        P_total = 10.030

Best achievable by redistributing D alone (P fixed):
```

```
    D_HQ = 2.210, D_field = 5.740
    ->  r_HQ = 1.0000,  r_field = 0.7340,  mean Delta = 0.1546

Best achievable by redistributing both (any split):
    both units at r = D_total/P_total = 0.7926,  Delta = 0.2324 each
```

Redistribution gets both units inside the envelope. It cannot calibrate both, because the totals do not match: the agency is doctrine-poor overall by `10.030 - 7.95 = 2.080` units, 26.2 per cent of its standing doctrine. That is a finding invisible without per-unit measurement. The agency does not have a distribution problem alone. It has a distribution problem *and* a shortfall, and the shortfall is in doctrine, which is the opposite of what the headquarters diagnosis on its own would suggest.

The intervention. *Stage 1 — redistribute.* Move 4.59 units of doctrine from HQ to the field: HQ to `D = 2.21`, field to `D = 5.74`.

```
HQ:     r = 2.210/2.210 = 1.0000   Delta = 0.0000   S = 2.4849
Field:  r = 5.740/7.820 = 0.7340   Delta = 0.3092   S = 1.8239
```

Both are inside `0.527 <= r <= 1.898`. Intake-weighted `S` rises from 0.4629 to `(2.210 x 2.4849 + 7.820 x 1.8239)/10.030 = 1.9695` — a factor of 4.25. What "moving doctrine" means concretely: HQ retires standing guidance and the field adopts explicit standing assumptions and publishes forecasts. **It is not a transfer of documents. It is HQ ceasing to determine what the field will find, and the field starting to commit to what it expects.**

Stage 2 — the shortfall. The agency still needs 2.080 units of net new doctrine to bring both units to calibration. This is built, not moved: explicit models, committed hypotheses, published forecasts with resolution dates, and closed lines of enquiry.

Stage 3 — the headquarters' `u`. HQ sits at `u = 0.11`, `N_eff = 2.21`. Even after Stage 1 it is calibrated at a very low effective count, which means it has almost no margin: any future growth in `D` puts it straight back over the line. Raise `u` toward 0.30 (`N_eff = 4.30`) as insurance, on a maintenance schedule.

The alarm. The field has just received doctrine. Compute its crossing date now. Post-Stage-1 field: `D = 5.74`, `p_bar = 1.0`, `u_0 = 0.62`, and suppose `lambda = 0.06` per quarter measured per S-11.

```
u* = (5.74 - 1)/11 = 0.4309
t* = ln(0.4309/0.62) / ln(0.94) = 5.88 quarters
```

The field crosses from under-framed to over-framed in under six quarters, and the agency should diarise re-measurement at quarter 4, not quarter 8. Without the alarm, the field's correction becomes the field's next pathology.

What would falsify this. `ln r` measured per unit quarterly for eight quarters after the intervention; held-out prediction of unit-level decision quality, assessed at 24-month outcome observation, for quarters 9 to 16; four baselines including the shuffled-`ln r` control; and **the specific, cheap, decisive test: the field's predicted crossing at `t* = 5.88` quarters.** `t*` is computed from three independently measured quantities with **no free parameters**. Kill condition: the field's `r` fails to cross 1 within a preregistered tolerance around quarter 6, or a constant-`u` model predicts the observed `r` series as well as the decay model.

That last test is the one to run first. It is a dated, parameter-free prediction about an observable quantity, checkable with a channel audit and a decision log — which is the form of risky prediction the social sciences most often avoid [Meehl, 1967]. It does not, however, escape the identification problem of Section 3.4: a crossing observed on schedule is consistent with the mechanism and is also consistent with any correlated unobservable that moves on the same timetable.

24.9 9 Discussion

24.9.1 9.1 What follows

The angle is a managed parameter and it is usually unmanaged. The same two people are worth an effective count of 6.5 or 1.55 in the same domain depending only on the angle between their states, and ability moves neither number. Where a pair or an organisation has a selection process and no maintenance process, it is managing the wrong variable.

A diagnostic built on assent will miss half the failures it is meant to catch. The opposition identity means an organisation can sound like a debating society and read `N_eff = 1`. Every instrument here that bears on non-parallelism is therefore stated on predictability, not on agreement or disagreement.

Two ceilings coincide, and the coincidence is informative. The perceptual correction available from interaction geometry is `ln N`, and the sustainable growth available to the storage law is bounded by `eta ln N`. Both say that geometry is bounded and that past the bound what is carried must change, not who carries it. That is a statement about the shape of the model rather than a discovery about institutions, and it is labelled as such.

Calibration has a price and the price is capacity. At `r = 1` the input is at the ceiling, the store is at its maximum, and the entire budget goes to maintenance. An organisation that wants to start something must either shed store deliberately or accept distortion. This is the framework's success-consumes-its-own-headroom thesis reached from a second direction, and it is the same object as organisational slack [Cyert and March, 1963].

The unit of measurement is the decision-making unit and never the organisation. Distortion does not average; the aggregate is a mediant, not a mean, and it can read as calibrated while every unit is in a ditch.

The correction for one pathology seeds the other. Doctrine does not decay; non-parallelism does. Every successful under-framing correction shortens the crossing date, and an organisation that does not compute the date acquires an alternating history it will describe as bad luck.

24.9.2 9.2 What does not follow

Nothing here shows that any pair or any organisation behaves this way. Every reproducibility gate reads untested. The three worked systems are constructed.

The group-scope magnitudes are not measurements. They are demoted at the scale-type gate and reported as illustrative constructions. The 0.53 to 1.90 envelope, the `u*` requirements and the `Delta_min` floors are structure exhibited, not quantity measured.

No claim is made that observing an organisation could identify the mechanism. Section 3.4 gives the reason: the specification is reflexive and the endogenous effect is not identified from observational data [Manski, 1993].

Monotonicity of surplus in `u` is not established outside the model. The literature contains an inverted U [Uzzi and Spiro, 2005], short-run costs of diversity [Mannix and Neale, 2005, Putnam, 2007], and destabilisation of randomly assembled systems by connectance [May, 1972]. The model's monotone claim holds inside the model and its domain of application is not known.

The logarithm is not established against its rivals. A sub-linear power law [Latané, 1981] and an `n log n` law [Briscoe et al., 2006] fit the same qualitative facts, and nothing here discriminates.

`Delta_R`, the return difference, is not a magnitude in most settings. Its scale-type gate binds and it demotes to an ordering unless a magnitude-estimation procedure is in place.

The framework does not license arranging anyone's relationships. The scope constraint of Section 4.16 is a constraint on use and not a caveat.

24.9.3 9.3 Relation to the surrounding literature

The pair-scope material sits alongside three literatures. The **diversity-and-performance** literature supplies both the supporting result [Hong and Page, 2004, Woolley et al., 2010] and the objections that make citing it responsible [Thompson, 2014, Harrison and Klein, 2007, Uzzi and Spiro, 2005]. **Portfolio theory** stated this framework's central point in 1952 with the mathematics attached: diversification benefit depends on covariance, not count, so N uncorrelated holdings and N perfectly correlated holdings are not the same N [Markowitz, 1952]. That is the opposition identity in a different register, and the framework's own bloc-collapse arithmetic reaches it a third time [Curzi, 2026,?]. The measured collapse of correlation structure under stress [Longin and Solnik, 2001] is the same warning as the decay of u: the effective count falls exactly when it is needed. **Ecology** supplies both the demonstration that effective count buys stability [Schindler et al., 2010] and the objection that diversity–stability correlations can arise from statistical averaging alone with no mechanism [Doak et al., 1998], which the framework must answer and has not.

The group-scope material sits alongside **opinion dynamics** and **organisational learning**. The reflexive map has an older form in which beliefs are updated by a row-stochastic influence matrix and consensus is the dominant left eigenvector [DeGroot, 1974]; the convergence conditions that model states explicitly are conditions this framework's fixed point assumes silently, and the stubbornness term that prevents collapse [Friedkin and Johnsen, 1990] is formally this framework's leak. The manufacturing result is the organisational-learning result [March, 1991] with a crossing date attached. The literature also supplies a hard limit on what a reflexive fixed point can be asked to predict: social influence raised both inequality and *unpredictability* in a controlled experiment, with the same inputs producing different winners in parallel worlds [Salganik et al., 2006].

Two negative results bound the whole enterprise and are cited here rather than left for a reviewer. The predictability ceiling on social outcomes is low: with fifteen years of high-quality longitudinal data and 160 teams, life outcomes were barely predictable, and the best machine learning barely beat a four-variable regression [Salganik et al., 2020, Hofman et al., 2017]. And the standing charge against opinion-dynamics modelling — many models, negligible empirical discrimination between them — has been made twice, eleven years apart, with the situation unchanged [Sobkowicz, 2020]. **The question that literature asks is what observation would distinguish this framework's laws from a neighbouring model that fits equally well, and the honest answer for the group-scope material in this paper is: the parameter-free crossing prediction t∗, and nothing else.** The field's own indictment of importing physics without the accompanying statistical care is Gallegati et al. [2006], with the reply [McCauley, 2006]; both should be read as a checklist against this paper rather than as background.

24.10 10 Verification

The results of this paper compound from ten postulates. Each is atomic, each is checkable on its own, and each carries its status. **Where a postulate could be dropped and a result still follow, it has been dropped**; what remains is what the chain actually consumes. **The chain below ends in results whose steps are largely DEFINITION and POSTULATED, and that is stated here rather than left for the reader to notice.** A result honestly labelled as following from two postulates is worth more than the same result implied to be measured.

24.10.1 10.1 Dimensional audit

`[Q]` denotes the dimension of stored order, `[I]` the dimension of intake, and `[T]` the dimension of time. The period is the unit of `[T]`, and every rate below is *per period*, which is why no explicit `[T^-1]` appears once the equations are written in discrete steps.

Symbol	Dimension	Unit	Status
`x`, `y`	`[1]`	none	**defined** unit vectors in an `N`-category space
`u`	`[1]`	none	**defined** dimensionless: `u = 1 - (x.y)^2`, in `[0,1]`
`theta`	`[1]`	degrees or radians	**derived** from `u = sin^2(theta)`
`N`	`[1]`	a count of categories	**defined** by enumeration of the declared domain
`N_eff`	`[1]`	a count of effective channels	**derived** `1 + (N−1)u`; **not a Hill number**
`F`, `S`	`[1]`	nats	**derived** dimensionless: a logarithm of a count
`Q`	`[Q]`	proxy units (documented details, executable procedures, precedents)	**measured**, in whatever unit the declared order proxy counts
`eta`	`[Q]` per nat per step	proxy units per nat per period	**measured**; *not* dimensionless
`delta`	`[1]`	per period	**measured** dimensionless fraction per step
`C`	`[Q]` per step	proxy units per period	**measured**
`h`	`[Q]` per step	proxy units per period	**derived**
`Q_inf`	`[Q]`	proxy units	**derived**: `[Q]/step` divided by `[1]/step` returns `[Q]`
`lambda`	`[1]`	per period	**measured** dimensionless fraction per step
`a`	`[1]`	nats	**derived** log of a ratio of two identically-united quantities
`M`, `M'`	undeclared	undeclared	**the source is silent.** The return difference `Delta_R = |ln(M'/M)|` requires only that `M` and `M'` share units; the paper never says what they are
`p_bar`	`[I]` per channel per step	intake-units per channel per period	**measured** by tally
`P`	`[I]` per step	intake-units per period	**derived** `p_bar . N_eff`

Symbol	Dimension	Unit	Status
`D`	`[I]` per step	intake-units per period, by the commensurate-units convention	**measured** by doctrine enumeration, in the convention's units
`E`	`[I]` per step	intake-units per period	**measured**, and in practice rarely measured at all
`r`	`[1]`	none	**derived** `D/P`, dimensionless **only because the convention says so**
`Delta`	`[1]`	nats	**derived** `|ln r|`
`kappa`	`[Q]` per step per `[Q]`	per period	**measured**, correction load per unit stored error
`sigma`, `A`	`[1]`	proportions	**measured** counts over counts

Does the storage law balance? `Q_{t+1} = (1−delta)Q_t + eta S_t − C_t` balances if and only if every term on the right carries `[Q]`. The first does, since `delta` is dimensionless. The third does by construction. The second does only if `eta S_t` carries `[Q]`, and since `S_t` is a dimensionless count in nats, **`eta` must carry `[Q]` per nat per step**. It is therefore not dimensionless, and it must be reported with its units. Consequently `eta ln N` carries `[Q]` per step and is commensurable with `delta Q_t` and with `C_t`, which is what makes the headroom gauge a well-formed subtraction. A headroom calculation in which `C` is denominated in hours or currency while `Q` is denominated in documented procedures is dimensionally malformed however tidy it looks.

Does the moment equation balance? Only under the commensurate-units convention. `D/P` is dimensionless if and only if `D` and `P` are expressed in the same currency, and `M` then inherits `E`'s units. **Without the convention the formula is dimensionally void**, and that is stated in Table V-G1 rather than assumed away. The convention is a **modelling choice**, not a measurement, and Section 6.12 records that a count supplies a unit within one encoder and no linkage between encoders.

Where the framework has no operational unit, it is said here. `Q` is stored order and stored order has no natural unit: it is counted in whatever the declared proxy counts, and two systems' `Q` values are not comparable unless they declare the same proxy. `M` and `M'` in the return difference are **never given a dimension by the source at all**; only their ratio is used, so the formula is well posed, but any claim that `Delta_R` is commensurable with `F` or with `Delta` rests on a unit the paper does not supply. That silence is recorded rather than quietly filled.

24.10.2 10.2 The postulates

P1 — Non-parallelism is `u = 1 − (x.y)^2` for unit vectors `x, y`. *Status:* **DEFINITION.** It carries no empirical weight on its own; the claim that a person or a channel *is* such a vector is the dyadic identification, badged separately at Section 4.1.

P2 — The surplus functional is `f(u) = ln(1 + (N−1)u)`, with `N_eff = e^f = 1 + (N−1)u` and `0 <= f <= ln N`. *Status:* **CITED** — established from four axioms, one of which is an explicit design axiom, in Curzi [2026]. The functional form is not established against its rivals [Latané, 1981, Briscoe et al., 2006].

P3 — For unit vectors, `x.y = cos(theta)`. *Status:* **ARITHMETIC.** Hence `u = 1 − cos^2(theta) = sin^2(theta)`.

P4 — The storage law is `Q_{t+1} = (1−delta)Q_t + eta S_t − C_t`, with `delta`, `eta`, `C` not depending on `Q`. *Status:* **DEFINITION** — the model form adopted by the framework.

P5 — A map `T(Q) = aQ + x` with `0 <= a < 1` on a complete space has exactly one fixed point, reached from any start. *Status:* **CITED** [Banach, 1922], with the elementary difference-equation route reaching the same condition [Elaydi, 2005].

P6 — Headroom is `h = eta ln N − delta Q − C`. *Status:* **DEFINITION.**

P7 — Collective perception is `P = p_bar . N_eff`. *Status:* **POSTULATED** — a modelling choice with no external support. It is the point at which a hundred parallel channels become one, and it is not identified from observational data (Section 3.4).

P8 — The moment is `M = (D/P).E`, so `r = D/P` and `Delta = |ln r|`. *Status:* **POSTULATED** — this framework's own, with no external literature for either the relation or the reading of `r` as a calibration ratio.

P9 — Bankable input is `S = ln N . e^{−Delta}`. *Status:* **POSTULATED.** Its symmetry in the sign of `ln r` is its substantive and separately falsifiable commitment.

P10 — Non-parallelism decays geometrically, `u_t = u_0 (1−lambda)^t`. *Status:* **POSTULATED** — a modelling choice; the exponent is defined by the model, not estimated from data.

24.10.3 10.3 The compounding chain

P1 + P3	-> L1	u = sin^2(theta), and u is a function of |x.y| alone.	ARITHMETIC
L1 + P2	-> R1	rho = x.y = +1 and rho = −1 both give u = 0, hence N_eff = 1 and F = 0. Opposition and agreement are the same reading.	ARITHMETIC
P2	-> L2	0 <= F <= ln N, with F = 0 iff u = 0 and F = ln N iff u = 1.	CITED (ccp:CCP−A02)
P4 + P5	-> L3	for delta > 0 the fixed point is unique and equals Q_inf = (eta F(u) − C)/delta.	CITED (banach1922operations)
L3	-> R2	Q_inf >= 0 iff F(u) >= C/eta, that is u >= u_min = (e^{C/eta} − 1)/(N−1).	ARITHMETIC
P7 + P8	-> R3	ln r = ln D − ln P = ln D − ln p_bar − F.	ARITHMETIC
R3 + L2	-> R3a	the reduction in ln r available from geometry is at most ln N; r = 1 is feasible iff D/p_bar <= N, and otherwise Delta_min = ln(D/p_bar) − ln N.	ARITHMETIC
P9 at Delta=0	-> L4	S = ln N, the ceiling.	ARITHMETIC
L4 + L3	-> L5	Q_inf = (eta ln N − C)/delta.	ARITHMETIC
L5 + P6	-> R4	h = eta ln N − delta(eta ln N − C)/delta − C = 0 exactly.	ARITHMETIC
P8 on two units	-> R5	r_agg = (D1+D2)/(P1+P2) is a mediant of r1 and r2, so it lies strictly between them; where r1 > 1 > r2 it can lie arbitrarily close to 1 while both units are arbitrarily far from it.	ARITHMETIC
P4 with two directional eta	-> R6	holding the mean conversion fixed, the sum of the two	

```
                    private steady states is constant in
                    a = |ln(eta_AB/eta_BA)| while the two values separate.  ARITHMETIC

P10 + R3      -> R7 ln r rises monotonically in t; the crossing of r = 1
                    occurs at t* = ln(u*/u_0)/ln(1-lambda) with
                    u* = (D/p_bar - 1)/(N-1).                              ARITHMETIC
```

Every line is checkable from its own stated inputs. **R1 and R2 consume one definition, one arithmetic fact and one cited functional form, and nothing else.** They are the paper's strongest results in the epistemic sense, and both are about pairs.

R3, R3a, R4, R5 and R7 all consume P7, P8 or P9, each of which is POSTULATED with no external support. The algebra is exact and the postulates are not established. In particular: **R4, the zero-headroom identity, is an arithmetic consequence of two postulates and a definition. It is not a finding about organisations and must not be quoted as one.** R5 is the least exposed of the group-scope results, because a mediant is a mediant whatever `D` and `P` mean; it survives even if P8's interpretation is wrong, provided only that `r` is computed as a ratio of two additively aggregable quantities.

What the chain does not establish. It does not establish that any pair obeys P1 or P4, or that any organisation obeys P7, P8 or P9. Those are the framework's postulates, they are not verified here, and the one preregistered confirmatory test of the storage law reported in this corpus did not meet its own declared margin [Curzi, 2026i]. A chain whose steps are ARITHMETIC, DEFINITION and CITED delivers the mathematics with certainty and delivers nothing whatever about institutions.

24.10.4 10.4 A worked numerical instance

The smallest set of checks that exercises the whole chain. Each can be redone by hand or in a line of arithmetic.

Check 1 (R1). `rho = −1` gives `u = 1 − (−1)^2 = 1 − 1 = 0`. At `N = 12`, `N_eff = 1 + 11(0) = 1` and `F = ln 1 = 0`. `rho = +1` gives the same three numbers. For contrast, `rho = −0.95` gives `u = 1 − 0.9025 = 0.0975`, `N_eff = 1 + 11(0.0975) = 2.0725` and `F = ln 2.0725 = 0.7288`, identical to `rho = +0.95`. **ARITHMETIC.**

Check 2 (R2). With `eta = 0.55`, `C = 0.34`, `N = 12`: `C/eta = 0.34/0.55 = 0.618182`; `e^0.618182 = 1.855555`; `(1.855555 − 1)/11 = 0.077778`; `N_eff = 1 + 11(0.077778) = 1.855555`, which is `e^{C/eta}` as it must be. In degrees, `theta = arcsin(sqrt(0.077778)) = arcsin(0.278886) = 16.20`. **ARITHMETIC.**

Check 3 (R3, the over-determination check). With `D = 5.20`, `p_bar = 1.00`, `u = 0.14`, `N = 12`: `N_eff = 1 + 11(0.14) = 2.5400`; `F = ln 2.5400 = 0.932164`; `P = 2.5400`. Computing `ln r` directly, `ln 5.20 − ln 2.5400 = 1.648659 − 0.932164 = 0.716495`. Computing it via the join, `1.648659 − ln 1.00 − 0.932164 = 1.648659 − 0 − 0.932164 = 0.716495`. **The two agree to every digit printed, which is the diagnostic the requirement G-6 asks for.** `r = e^{0.716495} = 2.047244`, which is `5.20/2.5400` exactly. **ARITHMETIC.**

Check 4 (R4). With `eta = 0.42`, `delta = 0.14`, `C = 0.55`, `N = 12` so `ln N = 2.484907`: `eta ln N = 1.043661`; `Q_inf = (1.043661 − 0.55)/0.14 = 3.526150`; `h = 1.043661 − 0.14(3.526150) − 0.55 = 1.043661 − 0.493661 − 0.55 = 0.000000`. **The identity is exact and the cancellation is visible in one line. ARITHMETIC.**

Check 5 (R5). Two units at `N = 12`, `p_bar = 1.0`. HQ: `u = 0.11`, `P_1 = 1 + 11(0.11) = 2.21`, `D_1 = 6.80`, `r_1 = 3.076923`, `ln r_1 = +1.123930`. Field: `u = 0.62`, `P_2 = 7.82`, `D_2 = 1.15`, `r_2 = 0.147059`, `ln r_2 = −1.916923`. Aggregate: `(6.80 + 1.15)/(2.21 + 7.82) = 7.95/10.03 = 0.792622`, `ln r_agg = −0.232434`. Bankable input from the aggregate: `2.484907 x 0.792622 = 1.969608`. Per unit and intake-weighted: `(2.21 x 0.807633 + 7.82 x 0.365427)/10.03 = (1.784869 + 2.857639)/10.03 = 0.462863`. Ratio: `1.969608/0.462863 = 4.2553`. **ARITHMETIC.**

Check 6 (R6). With `delta = 0.15`, `C = 0.25`, `u = 0.45`, `N = 12`: `S = ln(1 + 11(0.45)) = ln 5.95 = 1.783391`. At `eta_AB = 0.90`, `eta_BA = 0.10`: `Q_A = (0.10 x 1.783391 − 0.25)/0.15 = (0.178339`

– 0.25)/0.15 = −0.477740 and Q_B = (0.90 x 1.783391 – 0.25)/0.15 = (1.605052 – 0.25)/0.15 = +9.033680; the sum is 8.555940. At eta_AB = eta_BA = 0.50, each partner is at (0.891696 – 0.25)/0.15 = 4.277970 and the sum is 8.555940. **The same sum, and one negative private store.** a = |ln(0.90/0.10)| = ln 9 = 2.197225. **ARITHMETIC.**

Check 7 (R7). With D/p_bar = 4.0, N = 12, u_0 = 0.55, lambda = 0.08: u* = (4.0 – 1)/11 = 0.272727; u*/u_0 = 0.495868; ln 0.495868 = −0.701290; ln 0.92 = −0.083382; t* = 8.4125 periods. At t = 8, u = 0.55(0.92)^8 = 0.283281 and N_eff = 4.116 so r = 0.9718 < 1; at t = 9, u = 0.260618, N_eff = 3.867, r = 1.0344 > 1. **The crossing sits between periods 8 and 9, as t* = 8.41 requires. ARITHMETIC.**

24.10.5 10.5 Limits, asymptotics and the model's valid domain

u –> 0. N_eff –> 1, F –> 0, Q_inf –> –C/delta < 0, and at group scope P –> p_bar and ln r –> ln(D/p_bar), its maximum for the given doctrine load. **r converges rather than diverging**, which is correct: over-framing has a ceiling set by the doctrine load, not an unbounded runaway.

u –> 1. N_eff –> N, F –> ln N, the ceiling is attained and no further gain is available from geometry. At group scope, if D/p_bar < N the organisation over-corrects past calibration into under-framing.

N –> 1. ln N = 0 and F = 0 for every u. **A single-category domain has zero available surplus, not a small amount**, so Q_inf = –C/delta <= 0 and headroom is negative at any positive stock. This is why a bloc-collapse operation that reduces an entity map to one effective perimeter yields a surplus term of exactly zero [Curzi, 2026].

N –> infinity. ln N grows without bound but only logarithmically, and the marginal gain ln N – ln(N–1) behaves as 1/N. Against this, coordination cost grows with the number of pairs [Brooks, 1975, Conway, 1968], which is quadratic. **The two curves cross, and beyond the crossing additional categories cost more than the ceiling they buy.**

delta –> 0. No fixed point exists at all: the map is an isometry, the geometric series does not converge, and the bound degrades to Q_0 + t.eta.ln N [Curzi, 2026a]. **The limit is singular**: at exactly delta = 0 the fixed point does not exist rather than being infinite. This value is outside the model's valid domain.

delta –> 1. The system has no memory and Q_{t+1} –> eta S_t – C_t, an instantaneous transducer. At delta = 1 the storage law is not a storage law and any claim about accumulation is vacuous.

eta –> 0. Q_inf = –C/delta <= 0: the pleasant partnership that builds nothing, and no interaction geometry of any quality changes the outcome.

lambda –> 0. u is constant — a pair or an organisation that works together and never influences itself, which is the mark of a collaboration that is not happening. **lambda –> 1:** collapse to u = 0 in one period, total capture.

r –> 0 and r –> infinity. Delta diverges in both directions and S –> 0 in both. The two divergences are distinct pathologies mapped to the same magnitude, which is the measure's one real weakness and the reason the sign must always be reported.

P –> 0, D –> 0, E –> 0. Worked in Section 6.5. Each names a real institutional condition; E –> 0 sends M –> 0 for any r at all, and is the only limit that is not diagnosable from r.

Stated domain. The results are claimed for u in [0,1]; N >= 2; delta in (0,1); eta > 0; lambda in (0,1); p_bar > 0; D > 0; and D/p_bar <= N where calibration is claimed to be reachable. Outside that domain the equations still have solutions and those solutions should not be interpreted as statements about a pair or an institution.

24.10.6 10.6 Invariance

The scale-invariance of r is real and is worth stating as such. Delta = |ln r| survives any rescaling that multiplies D and P by a common positive factor, and this is why Delta is the

reportable quantity while D and P are not. What breaks it is a rescaling that touches only one of the two, which is exactly what happens when the encoder for doctrine differs from the encoder for intake — the failure Section 6.12 records at the scale-type gate.

The storage law is invariant in form under a change of order unit provided eta and C rescale with Q while delta, N and u are unchanged. **delta, u, N and lambda are therefore the unit-free quantities and Q, eta and C are the unit-carrying ones.** Two systems can be compared on the first group directly; they cannot be compared on the second unless they share a proxy.

How far the invariance has been exercised. Within this paper: three constructed systems at two scopes, all stipulated rather than observed. **That is three systems, one author, and no independent replication.** The invariance is a claim about form that has been exercised, not an invariance that has been established.

24.10.7 10.7 Scale type, model comparison, and the precision of the numbers

Scale type. u, Q, D, P and r are treated as ratio-scale quantities throughout — differences, ratios and logarithms are all taken. **The conjoint-measurement conditions that would license that treatment have not been tested** [Luce and Tukey, 1964, Krantz et al., 1971], and Michell [1997] argues that psychology systematically fails to test whether its attributes are quantitative at all before measuring them. **That is the strongest single objection to this framework and it is conceded rather than answered here.** The treatment of u and of Q as quantities is a stipulation. At group scope the framework has already run its own audit and demoted the magnitude of r and of Delta to ordinal pending a Rasch demonstration [Curzi, 2026, Rasch, 1960], which is the right instinct applied consistently rather than once. Delta_R demotes for the same reason wherever M is not ratio-scaled.

Model comparison — NOT MET, and the row is reported rather than omitted. The rigour standard for this corpus requires, wherever a fit is reported: out-of-sample performance, a matched null with the same number of free parameters, an information criterion so that the parameter count is paid for, an explicit count of free parameters, and effect sizes with intervals. **This paper fits nothing, so no information criterion applies to it directly.** But the corpus's one applied fit reports held-out error against four baselines and **no AIC or BIC anywhere**, so the parameter count has never been paid for in this corpus, and a 2.8 per cent margin over a two-parameter autoregressive baseline may not be a margin at all [Curzi, 2026i]. **The status of that row across this corpus is NOT MET.** The free parameters this paper's models would carry, counted explicitly: the pair storage model has four (delta, eta, C, and u_0) plus lambda if decay is fitted, giving five; the group-scope model adds D, p_bar and N, giving eight, of which N is enumerated rather than fitted. The contact postulate has **zero** free parameters as written, which is its one genuine strength: it has nothing to tune and therefore nothing to overfit, and its falsifying test is whether a fitted exponent k differs from 1.

Effect sizes and intervals. Nothing in Section 8 carries an interval, because nothing in Section 8 was measured. That is honest for a constructed example and it is not a substitute for the intervals a real application owes.

Precision. The numbers in this paper are of two kinds and are quoted accordingly. *Defined or derived-from-defined* quantities — ln 12 = 2.4849, ln 9 = 2.197225, u_min = 0.077778, t* = 8.4125, the overstatement factor 4.2553 — are exact to the precision printed and may be recomputed to any further precision. *Illustrative model output* — every entry in every trajectory table, every Q_inf, the 0.53 to 1.90 envelope — is the output of stipulated parameters and **carries no measurement uncertainty because there was no measurement**; four decimal places there record the arithmetic, not the confidence. **Measured or fitted quantities do not appear in this paper at all**, because nothing in it was measured. One constant used elsewhere in this corpus and referred to at Section 4.6 — k = (9/8)^2/phi^2 = 0.483425732988414 — is a **defined** constant, exact because it is a ratio of exact quantities; attaching hertz to it is a **separate and much stronger claim**, badged POSTULATED in its own paper [Curzi, 2026], and this paper makes no use of the frequency reading. Golden-ratio claims are the classic site of numerology in quantitative work, and the sceptical literature is cited here precisely so that the distinction

between *choosing* a constant and *finding* one in nature is on the record [Markowsky, 1992].

24.11 11 Limitations

The three worked systems are constructed, not observed. No dataset was collected for this paper. Every number in Section 8 is the output of stated parameters under the stated model, carried through so a reader can re-derive it. They demonstrate that the procedure runs and that it reports its own failures; they are not evidence that any pair or organisation behaves this way and they must never be cited as such.

Every reproducibility gate in this paper reads untested. Tables V-P1 to V-P6, V-G1 to V-G5 and V-C1 to V-C4 all return UNTESTED at gate 7. Nobody has run the cross-pair test, the cross-institution test, or the inter-rater agreement study that the anomaly audit presupposes. **Until one is run, this paper is a specification for how to find out rather than a report of what is known.**

The group-scope magnitudes are demoted and the demotion is the paper's own. The 0.53 to 1.90 operating envelope, the `u*` calibration requirements and the `Delta_min` floors are illustrative constructions demonstrating the model's structure. They are not measurements, and the framework's independent audit reaches the same verdict at both scopes [Curzi, 2026]. What survives is structure: the four limits, the `D = P` fixed point, the zero-headroom identity, the ordering, the sign of `ln r`, and the algebraic join.

The reflection problem, which outranks every other objection here. Section 3.4 states it in full. The aggregation postulate is a linear-in-means reflexive specification whose endogenous effect is not identified from observational data [Manski, 1993], reinforced for network data by Shalizi and Thomas [2011]. **No fit, however well designed and however honestly held out, recovers the parameter.** This paper adopts no remedy — not randomisation, not an instrument, not partial-population variation, and not a defended stipulation of the reference group [Brock and Durlauf, 2001] — so **every applied reading of `u`, `P` and the join is a modelling position rather than an identified empirical result.** Even the parameter-free crossing prediction `t*` is only a consistency test: a crossing on schedule is equally consistent with any correlated unobservable moving on the same timetable.

The Lucas critique applied to this framework's own parameters. The framework asserts that systems change when modelled and measured, then treats `delta`, `eta`, `u` and `lambda` as constants over an estimation window. **Both cannot be true without qualification** [Lucas, 1976, Hacking, 1995]. The position taken is the narrow one: the parameters are stable only over a declared window and only while the order proxy is not itself a reported target, which is why requirements S-9 and G-13 exist and why the two-track ledger of Section 6.10 is a requirement rather than a suggestion. A framework that tells people their arrangements obey a decay law should also ask what that assumption will make true [Ferraro et al., 2005].

`N_eff = 1 + (N−1)u` is not a Hill number and no external literature contains it. `1/HHI` is the Hill number of order two and `exp(H)` is the Hill number of order one, and both are fully grounded [Hill, 1973, Jost, 2006, Laakso and Taagepera, 1979]. `1 + (N−1)u` is a linear interpolation between 1 and `N`, adopted by design axiom. **A reviewer who reaches for the Hill-number literature as support will find that it does not apply.** The two quantities travel under one effective-count heading across this corpus, which is a real exposure.

The functional form is underdetermined. A sub-linear power law in the number of sources [Latané, 1981] and an `n log n` law [Briscoe et al., 2006] fit the same qualitative facts as `ln(1 + (N−1)u)`. **The logarithm is chosen for its axiomatic characterisation, not established by measurement**, and nothing assembled here discriminates.

Surplus monotone increasing in `u` is contested and the contrary evidence is real. The inverted U in creative collaboration [Uzzi and Spiro, 2005], the short-run costs of surface-level diversity [Mannix and Neale, 2005, van Knippenberg and Schippers, 2007], the reduction of trust and civic participation [Putnam, 2007], the destabilisation of randomly assembled systems by connectance [May, 1972], and the finding that redundancy can reduce safety [Sagan,

1993] all bear against a monotone claim. **This paper does not know where the curve turns and does not claim to.**

Comfort, stored order, doctrine and intake have not been shown to be quantities. Michell [1997] is the objection; conjoint measurement [Luce and Tukey, 1964] or a Rasch demonstration [Rasch, 1960] is the remedy; **neither has been run for any quantity in this paper.**

Which parameters were chosen rather than measured. All of them. In the three worked systems, `(N, u, eta, delta, C, lambda, D, p_bar, E)` are stipulated. The reciprocity threshold `a > 0.6931` in requirement S-14 is a design choice, not an empirical finding: **no distribution of measured reciprocity asymmetry exists.** The claim in Section 6.7 that organisations typically come in an order of magnitude below the required `u` is **this framework's impression and not a measured distribution**; no empirical distribution of institutional `u` or of institutional `Delta` exists.

Two roundings in the source manuscript are recorded rather than silently corrected. First, the overstatement factor of Section 7.7 is printed in the source once as 4.26 and once, for the same two-unit case, as 4.25; the exact value is 4.2553, and both printed figures are correct roundings under different conventions. Second, the source describes the step from a six-quarterly to a two-quarterly restoration schedule as "halving again", which is a reduction by two thirds; the tabulated values are used here directly and the description is not repeated. Neither affects a result.

Constant parameters over an estimation window is an assumption organisations violate. Turnover, reorganisation and a change of leadership all move `delta`, `eta`, `N` and `lambda`. A fit spanning a regime change is fitting an average of two systems, neither of which exists.

The limiting-factor reading of the contact postulate has no citation. The reading that a group banks at the rate of the scarcer of frame and intake is offered as an analogy in Section 6.4. No supporting entry exists in this corpus's bibliography, none was manufactured, and the reading carries no evidential weight.

`M` and `M'` in the return difference have no declared dimension. Section 10.1 records the silence. Only their ratio is used, so the formula is well posed, but any claim that `Delta_R` is commensurable with `F` rests on a unit the framework does not supply.

Nothing in this paper is a human-subjects finding. No interventions were run, no participants were recruited, and the declination constraint of Section 4.16 is a design constraint on prospective work rather than a report of past practice.

Unmet rigour checks, printed rather than left to a reviewer. (i) *Model comparison:* **NOT MET.** No information criterion is computed anywhere in this paper, and none is computed anywhere in this corpus's one applied fit [Curzi, 2026i]; the parameter count has never been paid for. (ii) *Effect sizes with intervals:* not applicable here because nothing was measured, and outstanding for any application. (iii) *Scale type:* the conjoint conditions were not tested [Luce and Tukey, 1964]. (iv) *Independent replication:* none, for any parameter, anywhere in this corpus [Open Science Collaboration, 2015, Ioannidis, 2005]. (v) *Differential prediction:* the demand for a prediction that simpler models do not also make [Durlauf, 2005, Sobkowicz, 2020] is met by exactly one item in this paper — the parameter-free crossing date `t*` — and by nothing else. (vi) *Directional versus point prediction:* directional predictions are nearly costless in the social sciences [Meehl, 1967]; this paper does make point predictions with constants, which is the right answer to that objection, but none of them has been put at risk. (vii) *Predictability ceiling:* the best available evidence says social outcomes are barely predictable even with excellent data and many teams [Salganik et al., 2020, Hofman et al., 2017], and nothing here should be read as promising otherwise.

24.12 12 Conclusion

R1 — Opposition is parallel. Because the surplus functional's extremality condition is stated on the squared alignment, `u = 1 - rho^2` sees only the magnitude of `rho`. A pair in perfect opposition and a pair in perfect agreement therefore both read `u = 0`, `N_eff = 1` and surplus exactly

0.0000 nats. **The mirror and the mirror-image are the same instrument**, and a systematic contrarian is audited out of the effective count exactly as a systematic agreer is. Complementarity is a middle condition — at `N = 12`, `rho = +0.95` and `rho = −0.95` both give `N_eff = 2.0725`, while `rho = 0` gives 12.00 — and both extremes of agreement are its failure modes. A pair at 45 degrees already captures three-quarters of the ceiling.

R2 — The minimum viable angle. Setting the steady state to zero gives `u_min = (e^{C/eta} − 1)/(N−1)`, computed at **0.0778, or 16.2 degrees**, for a pair with `eta = 0.55`, `C = 0.34`, `N = 12`. Below its own line a pair sustains no joint store whatsoever: the equilibrium is negative and everything built erodes at rate `delta`. Every pair has such a line and it is computable from three numbers it can measure.

R3 — The exact join. `ln r = ln D − ln p_bar − F`. **The group's interaction surplus subtracts from its log-distortion one nat for one nat, with no conversion constant.** Because `0 <= F <= ln N`, the correction available from interaction geometry is capped at `ln N`, and **if `D/p_bar > N` no arrangement of people calibrates the organisation**, leaving a residual floor `Delta_min = ln(D/p_bar) − ln N` that only doctrine reduction can move.

R4 — Calibration costs all the headroom. At `r = 1` the input sits at its ceiling `ln N`, the store reaches `Q_inf = (eta ln N − C)/delta`, and headroom is `h = eta ln N − (eta ln N − C) − C = 0` exactly. **A perfectly calibrated organisation converges to exactly zero headroom, by arithmetic rather than by mismanagement**, so calibration is not an unqualified target: an organisation that wants room to build must either shed store deliberately or accept `r` not equal to 1.

R5 — Distortion does not average. A headquarters at `Delta = 1.1239` and a field unit at `Delta = 1.9169` aggregate to `Delta = 0.2324` — a near-calibrated headline figure concealing two units in opposite ditches. The aggregate ratio is a weighted mediant of the unit ratios and can sit arbitrarily close to 1 while both units are arbitrarily far from it. Computing bankable input from the aggregate gives 1.9696 nats against a true intake-weighted 0.4629, an **overstatement of 4.2553 times**. Compute the ratio per decision-making unit and aggregate the units' bankable input, weighted by intake, never their doctrine and intake separately.

R6 — Reciprocity is asymmetric where non-parallelism is symmetric. With `a = |ln(eta_AB/eta_BA)|` and the mean conversion held fixed, the sum of the two private steady states is constant while the individual outcomes separate: **the joint books read identically at `a = 0` and at `a = 2.20`, and at `a = 2.20` one partner's private store has a negative steady state.** Reciprocity failure is invisible in the joint account and total in the private one, and it is unidentifiable from the joint store alone.

The counter-result, stated in the same plain language. This paper has not shown that any pair or any organisation behaves this way. Every reproducibility gate reads untested. The group-scope headline envelope of 0.53 to 1.90 is demoted to an illustrative construction at the scale-type gate, along with the calibration requirements and the distortion floors; what survives the demotion is the four limits, the `D = P` fixed point, the zero-headroom identity, the three-way ordering, the sign of the log-ratio, and the algebraic join, all of which stand on ordinal information or on algebra alone. The specification is nonetheless precise enough that the test can be built: named quantities, declared units, a stated normalisation, an over-determination check, and a dated parameter-free prediction — `t* = ln(u*/u_0)/ln(1−lambda)` — that costs a channel audit and a decision log to check.

24.12.1 Declarations

Data and code availability

No external dataset was collected for this paper. All numerical results are computed from the stated parameters under the models developed in the text, and every table can be re-derived from the equations and parameter values printed beside it. The three systems worked in Section 8 are constructed examples with declared parameters, not field observations. The

figures are generated by the scripts named in each caption; those scripts contain no data beyond the numbers printed in this paper and the model equations of Sections 3 to 7.

Funding

This research received no external funding.

Conflicts of interest

The author declares no conflicts of interest.

Author contributions

Single author. Michael Laurence Curzi conceived the work, derived the results, produced the worked examples and figures, and wrote the paper.

Ethics

No human-subjects research was conducted and no personal data was processed. The three worked systems are constructed. The declination constraint stated in Section 4.16 and repeated in requirements S-20, G-16 and DD-16 — that no protocol removing a person's ability to decline measurement, a channel role, or the dissent it asks of them is within the framework's scope — is a design constraint on prospective work and is not a report of any study performed.

Preregistration

This paper reports no preregistered test of its own; its results are derivations. The preregistration templates it specifies — Sections 8.1, 8.2 and 8.3, and gate 6 of every validation table — are proposals for prospective work. The preregistered protocol for testing the storage law against a real system, together with the confirmatory application that **failed** its second falsification rule with a 2.8 per cent held-out RMSE advantage over a matched autoregressive baseline against a declared margin of 10 per cent, is reported in Curzi [2026i]. That is the current evidential status of every applied claim in this paper, and it is weaker than the mathematics.

Chapter 25

Trust, Reciprocity and Obligation as Quantities: Where Trust Enters the Storage Law, and Nine Ways the Internal/External Correspondence Breaks

Abstract. This paper gives trust an operational location in the storage law: it reduces retention loss, $\delta_{\text{eff}} = \delta_0 + (1-a)(1-v)$, where a is the measured reliance rate — the probability that an unverified commitment is honoured — and v the verified fraction. The steady-state dividend is superlinear: at $a = 0.50$ the stock is 0.4679 and at $a = 0.99$ it is 5.0529. Its point elasticity is $a/(\delta_0 + 1 - a)$, which is 10.56 at $a = 0.95$, and not the $a/(1-a)$ the source material quotes, a form valid only at $\delta_0 = 0$; that correction is one of four defects found in the source and reported here. Verification is shown to be all-or-nothing under a linear verification cost, with threshold $a^* = 1 - c_v\delta_0/(K - c_v)$, computed at 0.8479 for a unit cost of 0.20. Reciprocity enters conversion, $\eta = \eta_{\max}\rho$ with $\rho = 2\min(x_{ij}, x_{ji})/(x_{ij} + x_{ji})$, and obligation is the antisymmetric part of the same matrix; the node-level imbalance index is proved to satisfy $1 - B \geq \rho$ and flatters one worked network by 15.4 per cent. An eight-firm consortium at $u = 0.52$ was collecting 73.8 per cent of its surplus ceiling and still had steady state -0.0836 and headroom -0.4582; the binding fault was $\rho = 0.3824$, not difference, and raising ρ to 0.8947 and a to 0.88 moved the fixed point to $+1.8701$, while trust alone moved it to -0.2114. Graduated sanction gains 1.0 per cent of input against expulsion's -7.7. The correspondence between one head and one group is then audited and breaks in nine named ways, three severe and one absolute: the recursion and the geometry transfer; the licence to apply them does not.

Keywords: trust as retention; verification threshold; reciprocity index; obligation asymmetry; graduated sanction; scope correspondence; mean-field error

Series: B. Engineering the Surplus **Paper:** CCP-025

25.1 1 Introduction

Three words carry more rhetorical weight in the literature of institutions than almost any others, and all three are ordinarily left as adjectives. A team is described as *high-trust*. A community is said to have *strong reciprocal norms*. A network is *dense with obligation*. None of those descriptions tells an engineer what to build, what to measure, or what observation would defeat the claim.

This paper converts all three into quantities that enter the storage law

```
Q_{t+1} = (1 − delta) Q_t + eta S_t − C_t,     S_t = F(U_t) = ln(1 + (N−1) U_t)
```

at a named position, with a stated dimension, an obtainable measurement, and a computed price. The conversion is not decorative. **Each of the three attaches to a different parameter**, which is why they behave differently, fail differently, and why the intervention that repairs one will not repair another. Trust is located in the retention loss `delta`; reciprocity is located in the conversion efficiency `eta`; obligation is the antisymmetric part of the same interaction matrix from which reciprocity is read.

The location matters because the storage law's steady state, `Q_inf = (eta F(u*) − c*)/delta`, is a ratio. A parameter in the denominator and a parameter in the numerator are not substitutes and are not even commensurable in their effects: when the numerator is negative, improving the denominator makes the equilibrium worse. Section 6.5 exhibits a case in which a trust intervention — the intervention every member of a failing consortium would have nominated — moves the fixed point from `−0.0836` to `−0.2114`, while a reciprocity intervention on the same system moves it to `+0.7394`. That inversion is the paper's most immediately usable result, and it is arithmetic rather than sentiment.

The second half of the paper audits a claim the corpus has been relying on throughout: that the internal scope (one mind: framings, character, cognitive load) and the external scope (one group: members, institution, coordination overhead) are the same relational system measured twice. The proven part of that claim is narrow and secure — the recursion contains no term naming a substrate, so every theorem about it holds wherever the recursion holds. The rest is a thesis, and Section 8 states **nine specific places where it fails**, three of them severe and one absolute. Every one of the nine is downstream of a single fact: the parts of a society can leave and the parts of a mind cannot.

Four contributions are new relative to the surrounding literature rather than relative to the framework. First, an operational definition of trust — the measured rate at which *unverified* commitments are honoured — that has a true zero, a true ceiling, and an estimator, together with the demonstration that it occupies exactly the position in the storage law that verification spending occupies and is free at the margin. Second, the result that the verification budget's optimum is always at an endpoint, with an explicit switching threshold `a*` and an explicit statement of the linearity assumption that produces the bang-bang structure. Third, the identity `rho = 2 min(x_ij,x_ji)/(x_ij+x_ji) = 1 − |Skew_ij|/Sym_ij`, which makes reciprocity and obligation two readings of one measurement, together with the bound `1 − B >= rho` showing that the node-level index is an upper bound on reciprocity and is biased toward good news. Fourth, a computed audit of the internal/external correspondence that reports its own breakdowns rather than its own scope.

The framework's static half — the surplus functional `F(u) = ln(1 + (N−1)u)`, its uniqueness under four axioms, and the affine effective count `N_eff = 1 + (N−1)u` badged there as design axiom S3 rather than as a theorem — is presupposed and not re-derived; it is established in that form, with `u = 1 − rho^2` from error decorrelation, in Curzi [2026o]. The contraction that supplies the fixed point is stated exactly — `T(Q) = (1−delta)Q + b` is a contraction with constant `1−delta`, giving `Q_inf = (eta M* − c*)/delta` and the exact error law `|Q_t − Q_inf| = (1−delta)^t |Q_0 − Q_inf|` — in Curzi [2026q]. The founding reframing on which the whole apparatus rests, that comfort is the felt total of present costs so the present state is a local minimum of the comfort landscape by definition rather than by luck, is presupposed from Curzi [2026].

Sections 2 and 3 state the hypotheses and the framework, including the identification problem that bounds every applied claim in the paper. Sections 4 to 6 develop trust, reciprocity and obligation and price the institutional design principles against them. Sections 7 and 8 develop the correspondence and then audit it. Section 9 works three systems end to end and reports four defects found in the source material. Sections 10 to 13 discuss what follows, verify the chain, state the limitations, and conclude.

25.2 2 Hypotheses

The formal results in Sections 3 to 5 are theorems and definitions about an equation and cannot be falsified by observation; they are labelled where they appear. What can be falsified is the claim that these quantities, measured as specified, occupy the positions claimed for them. Each hypothesis below names the observation that would defeat it. The protocol that operationalises testing of this kind — a preregistered fit, a frozen model, and held-out comparison against four declared baselines — is specified in Curzi [2026i], whose own confirmatory application of it failed its second falsification rule: a 2.8 per cent held-out RMSE advantage over a matched AR(1) against a declared 10 per cent margin, despite +40.3 per cent over persistence, +97.7 per cent over direct input, and `p = 0.0005` against the shuffled-input control.

H1 — Trust is a retention parameter. The reliance rate `a`, defined as the measured probability that an unverified commitment is honoured within one period, enters the storage law only through the loss term, as `delta_eff = delta_0 + (1 − a)(1 − v)`. **Predicted:** agreements in high-`a` relations survive unmaintained longer than agreements in low-`a` relations, with half-life `ln 2 / −ln(1 − delta_eff)`; and raising `a` at fixed interaction volume raises `Q` without raising `eta S`. **Falsified by:** a system in which `a` rises while `rho` and `S` stay flat and the measured conversion `eta = dQ_attributable / S_input` also rises — which would place trust on the input side, where the model says it does not sit.

H2 — The verification optimum is an endpoint. With verification cost linear in coverage, `C_v = c_v v`, the steady state is linear-fractional in `v`, so its derivative has constant sign and the optimum is `v = 0` or `v = 1`, switching at `a* = 1 − c_v delta_0 / (K − c_v)` with `K = eta S − C_0`. **Predicted:** bodies verifying on the wrong side of `a*` show a measurable `Q` penalty relative to matched bodies verifying on the correct side. **Falsified by:** an interior optimum observed under a verification cost measured to be linear in coverage. **Note:** an interior optimum under a *convex* cost is predicted by the model and does not falsify it; the falsifier requires the linearity to be measured first.

H3 — Only the matched fraction of interaction converts. `eta = eta_max rho` with `rho = 2 min(x_ij, x_ji)/(x_ij + x_ji)`. **Predicted:** the count of shared structures surviving a full year is monotone in `rho` and is *not* monotone in total directed volume `Sym`. **Falsified by:** durable structure accumulating in proportion to total volume with `rho` uncorrelated — which is the observation the worked consortium of Section 9.1 was designed to be vulnerable to.

H4 — The order of operations is numerator before denominator. Where `eta S − C < 0`, lowering `delta` lowers `Q_inf` further. **Predicted:** in a system with a negative numerator, a trust intervention alone moves the fixed point *away* from zero, and the joint intervention's interaction term exceeds either main effect. **Falsified by:** a measured system with `eta S < C` in which a `delta` reduction alone raises the observed long-run stock. This hypothesis is the sharpest in the paper because its prediction is counter-intuitive and its falsifier is cheap.

H5 — The node-level imbalance index is an upper bound, never an estimate. `1 − B >= rho`, where `B = sum_i |b_i| / (2 * total volume)`. **Predicted:** in any directed interaction matrix, `1 − B` is at least `rho`, with equality only when no member is simultaneously a creditor to one partner and a debtor to another. **Falsified by:** a single counterexample matrix. This is a theorem, so a falsifier would be an arithmetic error rather than an empirical finding; it is stated as a hypothesis only because the *bias direction* — that the gap is systematically toward good news — is an empirical claim and is not proved here.

H6 — The correspondence is of dynamics and geometry, not of agency. The recursion and the redundancy audit transfer between scopes; exit, heterogeneity of interests, preference aggregation, reciprocity, sanction and rivalry do not. **Predicted:** normalised trajectories at the two scopes are the same curve to within a few per cent (Section 7.5 computes 2 per cent on a constructed pair), while a heterogeneous group's fitted `delta` drifts downward over an unmaintained interval and an individual's does not. **Falsified by:** internal trajectories systematically non-exponential in normalised time while external ones are exponential, or the reverse; or fitted `delta` drifting in individuals as it does in heterogeneous groups, which would make the correspondence *stronger* than this paper claims.

Three claims in this paper are not hypotheses and are labelled accordingly. The mapping of trust onto `delta`, of reciprocity onto `eta`, and of obligation onto the antisymmetric part are **modelling postulates** (Section 3.2): they are choices about how a measured social quantity enters a proven equation, and none is derived. The thesis that the internal and external scopes are one relational system is **the author's thesis**, not a theorem, and Section 8.11 states what would kill it. The declination constraint — that no intervention within the framework's scope may remove a person's ability to decline — is a **normative stipulation**; it is not derived from the mathematics and no external citation in this corpus's bibliography establishes it, which is recorded here and again in Section 12.

25.3 3 Framework

25.3.1 3.1 What is presupposed

Two results are used throughout and are established elsewhere in this corpus. Neither is an empirical claim.

The surplus functional. For two unit state vectors `x` and `y` drawn from an ensemble of `N` categories,

```
F(x,y) = f(u(x,y)),    u(x,y) = 1 − (x . y)^2   in [0,1],    f(u) = ln(1 + (N−1) u)
```

with `N_eff = 1 + (N−1)u` the effective count and `0 <= F(u) <= ln N` the hard ceiling [Curzi, 2026o]. The affine effective count follows from a design axiom that is chosen rather than derived, and every use of `N_eff` in this paper inherits that status.

`1 + (N−1)u` is not a Hill number and no external literature contains it. The effective-number idiom is standard in ecology and political science, where `1/HHI` and `exp(H)` are the canonical members of the family — the Hill numbers of order two and one respectively [Hill, 1973, Jost, 2006, Laakso and Taagepera, 1979]. `1 + (N−1)u` is a linear interpolation between 1 and `N`, is this framework's own construction, and a reviewer reaching for the Hill-number literature as support will find that it does not apply. Where an effective count appears anywhere below, it is this one, and it is identified as such. The genuinely Hill-numbered concentration instrument used elsewhere in the corpus is a different quantity: Curzi [2026] reports Jersey 40.0, Guernsey 35.0 and Isle of Man 25.0 giving a naive HHI of 0.345000 and 2.898551 effective jurisdictions

against a bloc-HHI of 1.000000, `N = 1.00` and a surplus term of exactly zero, and the two must not be conflated.

Two warrants exist for the logarithm and the argument needs only the weaker one. The Fechnerian warrant makes sensation proportional to the logarithm of a dimensionless stimulus ratio [Fechner, 1966], and requires a contested perceptual story to be true. The stronger warrant assumes nothing psychological: Peters and Gell-Mann [2016] shows that the time-average growth rate of a multiplicatively evolving quantity is the expectation of its logarithm, so a logarithmic evaluation follows from the dynamics alone. Where a stock compounds rather than adds, the logarithm is the ergodic-average object. The ceiling `ln N` also has an information-theoretic reading as the maximum an ensemble of `N` equiprobable categories can carry [Shannon, 1948], but the framework does not identify surplus with Shannon entropy and the reading is licensed to do no more than bound.

The functional form is underdetermined by the evidence, and this paper says so rather than waiting to be told. At least two published alternatives reproduce the same qualitative facts: social impact rising as a power of the number of sources with an exponent below one [Latané, 1981], and network value growing as `n log n` rather than as `n^2` [Briscoe et al., 2006]. Both give diminishing returns to count, no threshold, and monotonicity. **Nothing assembled in this paper discriminates between them.** What the corpus's form has is an axiomatic characterisation with a declared design axiom at the point where the choice is made; what it does not have is a discriminating measurement.

The storage law. The engine of the paper is the first-order recursion above, with the results this paper consumes stated exactly in Curzi [2026q]: the map `T(Q) = (1−delta)Q + b` is a contraction with constant `1−delta`, the fixed point is `Q_inf = (eta F(u*) − c*)/delta`, and the error law `|Q_t − Q_inf| = (1−delta)^t |Q_0 − Q_inf|` is an equality rather than a bound. The admissibility condition `C_t <= (1−delta)Q_t + eta S_t` guarantees `Q_{t+1} >= 0`; the one-step growth condition is `eta S_t > delta Q_t + C_t`; the headroom gauge is `h_t = eta ln N − delta Q_t − C_t`. Curzi [2026h] supplies the identity that headroom at equilibrium is unused variety, `h_inf = eta(ln N − F(u*))`, verified to six decimals at `eta = 0.35`, `delta = 0.015`, `N = 6`, `u* = 0.55`, giving `Q_inf = 2.840970` and `h_inf = 0.164501`; that identity is what makes a positive headroom at a settled state a statement about unrealised geometry rather than about spare effort.

The steady-state result carries a clause this paper leans on twice. If `eta F(u*) < c*` the equilibrium is negative, and the theorem does not conceal it: the regime is unsustainable in this model, or the linear model must be replaced. A negative `Q_inf` is not a small stock. It is the model reporting that it has left its domain. Sections 6.5 and 9.1 turn on that clause.

25.3.2 3.2 The three mapping postulates, badged

Three mappings are introduced. **Each is a postulate — a modelling choice about how a measured social quantity enters a proven equation — and none is derived from the results of Section 3.1.** They are stated here with their badges attached so that the badge does not have to be re-attached at every use. They are labelled `PT`, `PR` and `P0` rather than by their initials alone, to keep them distinct from the results `R1`–`R6` this paper contributes.

Postulate PT — trust enters as retention. For a relation whose stored order consists of standing commitments, the per-period retention loss decomposes as

```
delta_eff = delta_0 + (1 − a)(1 − v)
```

where `a` in `[0,1]` is the **reliance rate**, the measured probability that an unverified commitment is honoured within the period; `v` in `[0,1]` is the fraction of commitments actually re-verified; and `delta_0 >= 0` is the verification-irreducible loss — death, departure, genuine forgetting, external shock. **The postulate is that verification is effective**: a verified commitment does not lapse for want of confirmation.

Postulate PR — reciprocity enters as conversion. For a relation carrying directed interaction volumes `x_ij` and `x_ji` over an accounting window, only the *matched* portion of the volume converts into durable structure:

```
eta = eta_max * rho,     rho = 2 min(x_ij, x_ji) / (x_ij + x_ji)
```

where `eta_max` is the conversion efficiency the relation would have at perfect balance. **The postulate is the word *only*.** The arithmetic of `rho` is a definition and carries no claim.

Postulate PO — obligation is the antisymmetric part. Writing the interaction matrix `X` as its symmetric and antisymmetric parts,

```
X = Sym + Skew,    Sym_ij = (x_ij + x_ji)/2,    Skew_ij = (x_ij − x_ji)/2
```

`Sym` measures the relation and `Skew` measures the obligation. The decomposition is exact and unique for any square matrix; **the postulate is the interpretation of the two parts**, not the algebra.

25.3.3 3.3 Identification: the objection that no amount of fitting can answer

This is the most serious methodological problem in the paper and it belongs here, where the loop is introduced, rather than in a caveat at the end.

The framework's central applied specification is reflexive. The group's interaction geometry `U_t` is a property of the group; the group's stored order shapes what its members do next; and the members are what the group is made of. Written as `T(x) = W(x, M(x))`, that is exactly a linear-in-means reflexive specification, and Manski [1993] proves that **the endogenous social effect in such a specification is not identified from observational data**. It cannot be separated from contextual effects or from correlated unobservables, however much data is collected. Shalizi and Thomas [2011] reinforce the point for network data, where influence and selection are generically confounded. Kirman [1992] makes the companion aggregation objection: the behaviour of an aggregate is not in general the behaviour of a representative member, so a scalar model of a heterogeneous body is a modelling decision and not a summary — a point this paper computes rather than asserts in Section 8.2.

The consequence for this paper is exact. The derivations of Sections 4, 5 and 7 are statements about an equation and are untouched. But the interpretation of a measured `rho` as *causing* a conversion efficiency, rather than as a contextual effect, a common shock, or selection, is **not identified by observation alone**, and no held-out comparison recovers it. This limitation is deeper than any the falsification protocol of Curzi [2026i] tests for, and it would remain if every rule in that protocol passed.

No remedy is adopted in this paper, so the honest label is a modelling position. The known routes are randomisation, an instrument, partial-population variation, or stipulating the reference group and defending the stipulation; the last is the most realistic here and Brock and Durlauf [2001] is its template. The measurement protocols of Section 6.6 point toward it — Protocol A randomises non-verification within a pre-declared consequence tier, which is a genuine partial-population design at the level of the *commitment*, not of the person — but no protocol in this paper randomises at the level at which the reflexive parameter lives. **Until one of them is executed, `eta` and `rho` as applied quantities are coefficients in a declared specification and not identified social effects**, and every applied statement in this paper inherits that status.

One existence proof is worth naming because it is the strongest thing available on the other side. MacKenzie and Millo [2003] documents a reflexive fixed point observed in the field, with dates and price data: a model that, once adopted, moved the world toward its own predictions. That establishes that reflexive fixed points occur. It does not identify this one.

25.3.4 3.4 Scale type, and the seven gates

Every formula in this paper is audited against a seven-gate protocol, and the gate names are used in short form throughout: **G1** dimensions, **G2** scale type, **G3** limiting cases, **G4**

fixed points, **G5** identifiability, **G6** falsification, **G7** reproducibility. Verdicts are `PASS`, `PASS (conditional)` with the condition stated, `FAIL` with the consequence stated, `DEMOTE` where a quantity survives as an ordering but not as a magnitude, or `OPEN` where the gate has not been run. **`OPEN` is not a failure and it is not a pass; it is a debt, and it is recorded as one.**

G7 is `OPEN` for twenty-four of the twenty-five formulary entries of Appendix A and `PARTIAL` for the twenty-fifth, because nothing in this material has been through a cross-lab reproducibility trial. The reproducibility literature is unambiguous about what that is worth [Open Science Collaboration, 2015, Ioannidis, 2005].

G2 is where this paper is most exposed and the exposure is stated rather than managed. Michell [1997] argues that psychology routinely assumes its attributes have quantitative structure without testing whether they do, and that the assumption is usually false or at least unexamined. **That is the strongest objection to this framework and it bites hardest on a paper that treats trust, obligation and reciprocity as quantities.** The formal remedy exists: conjoint measurement supplies the test for whether an attribute has additive quantitative structure at all [Luce and Tukey, 1964, Krantz et al., 1971], and a Rasch demonstration is the psychometric alternative [Rasch, 1960]. **Neither has been run for any quantity in this paper, and until one is, every ratio-scale treatment below is a stipulation.**

The stipulation is not equally exposed everywhere, and the difference is worth stating. `a`, `v`, `rho`, `B` and `tau` are **proportions of counted events** — honoured commitments out of unverified commitments, matched flow out of total flow, departures out of roster. A proportion of a count has a true zero and a defensible ratio scale provided the count is a count, which is why trust was defined as a rate rather than as a belief: the ordinal self-report that the usual definition produces cannot be divided, and averaging it is not licensed [Stevens, 1946, Likert, 1932]. `Q`, `eta` and `C` carry the framework's declared order proxy and inherit its scale, which the substitution test supplies and a five-point culture survey does not. `D` and `P` — and therefore `M`, `r` and every band table computed from them — are **demoted**: the division requires a common ratio scale with a shared true zero across two separately instrumented terms, and no such instrument exists. Curzi [2026] records the same demotion in the corpus's register, where the moment equation was demoted on scale. **What survives the demotion is the ordering — over-framed, calibrated, under-framed — the `D = P` fixed point, and the sign of `ln r`, which is the operationally decisive part because the two faults take opposite corrections. What is withdrawn is the magnitude.**

25.3.5 3.5 Standing honesty clauses

Repeated wherever the law is used, and stated once here.

- **As deployed, the surplus functional is a lower bound** on the ensemble's information, not the information itself. Every price quoted in this paper is a floor.
- **The triangle inequality fails for geometric triples.** Subadditivity holds on the parameter `u` only. Three-party obligation chains do not compose metrically, and no bound in this paper may be chained through an intermediate party. The point is not exotic: psychological similarity is known to be asymmetric and to violate the triangle inequality [Tversky, 1977].
- **The static half of the framework is pure mathematics** and makes no empirical or metaphysical claim. Surplus is not identified with Shannon entropy or mutual information, and no thermodynamic negentropy law is proved.
- **Applying the storage law to a relation, a team or an institution is a modelling decision**, badged as such every time it is made, and answerable through the protocol of Curzi [2026i].
- **The external results cited below are cited for what their authors actually reported.** The transfer of any of them into this parameterisation is a modelling assumption, badged at each use.
- **The declination constraint governs absolutely: no intervention in this paper may remove a person's ability to decline.** Section 5.5 shows this is load-bearing rather than

decorative, because the highest-reliance obligation networks on record are precisely the ones that violate it. The constraint is a normative stipulation of the framework and is labelled as one; Curzi [2026] states the corpus's boundary in its strongest form, refusing category innocence as a defence of acquisition, forbidding the movement of any harm through a discovered gap in a scheme, and conceding that the case where the feedback loop runs through another person's will is an unsettled seam the corpus does not close. This paper does not close it either.

- **The classification of every claim as established mathematics, established psychology, or declared postulate follows the corpus's three-drawer honesty ledger**, which classifies four items of established mathematics, seven of established psychology, and exactly three declared postulates, with every protocol stated to run on the first two and steer by the third [Curzi, 2026]. The three postulates of Section 3.2 are declared in that third drawer.

25.4 4 Trust as a retention parameter

25.4.1 4.1 An operational definition

The usual definition is refused first. Trust is commonly defined as a belief or a feeling — an expectation held by one party about another. That definition is unmeasurable except by asking, and asking produces a self-report on an ordinal scale, which cannot be divided, multiplied, or entered into a ratio (Section 3.4). The operational definition used here is:

> **Trust on a relation is the measured rate at which unverified commitments are honoured.**

Call it `a`, the **reliance rate**. It is a probability; it is dimensionless; it has a true zero — no unverified commitment ever holds — and a true ceiling; and it is estimable from records most organisations already keep. **It is a property of a relation in a domain, not of a person**: a supplier's `a` on delivery dates and their `a` on cost estimates are different numbers and must be measured separately.

The definition's whole content is the word "unverified." A commitment that was checked says nothing about trust; it says something about the checking. Trust is visible only in the commitments that were *not* checked, which is why measuring it requires deliberately not checking some of them, and why that in turn requires an ethics protocol (Section 6.6, Protocol A). The framing is compatible with the standard treatment of trust as a bet on another's future action under incomplete information [Gambetta, 1988], and with the repeated-game result that reciprocation under a long shadow of the future is a self-enforcing equilibrium rather than a disposition [Axelrod, 1984, Axelrod and Hamilton, 1981]; **what is new here is not the concept but the location of the measured rate inside a stock equation.**

25.4.2 4.2 Why trust reduces `delta` and nothing else

Consider a relation whose stored order `Q` is a set of standing commitments: agreements about who does what, who may draw on what, what a given signal means. That is the ordinary content of institutional `Q`.

Each period a commitment either carries forward or lapses, and lapse has two causes.

1. **Irreducible causes.** The person leaves, the memory genuinely goes, the world changes under the agreement. No confirmation prevents these. Rate: `delta_0`.
2. **Confirmation-addressable causes.** The commitment is nominally still in force but nobody has confirmed it, and in the absence of confirmation the parties diverge on what it says or whether it binds. Rate, per unconfirmed commitment: `1 - a`.

If a fraction `v` of commitments is re-verified each period, the confirmation-addressable loss applies only to the remaining `1 − v`, which is Postulate PT. Its content is immediate: **there are two ways to hold `delta` down, and trust is the one that does not cost anything per period.** Raising `a` and raising `v` reduce the same term. Raising `v` costs `C_v = c_v v` in the dissipation budget. Raising `a` costs nothing recurrent.

That is the precise sense in which trust is a retention device: it occupies the exact position in the storage law that verification spending occupies, and it is free at the margin. **The claim is a shared position in one equation, not a physical derivation** — the analogy discipline of Section 11.8 applies.

25.4.3 4.3 The verification frontier and the half-life of an agreement

Fix `a`. Varying `v` from 0 to 1 traces a straight line in the `(delta, C_v)` plane:

```
delta = delta_0 + (1 − a)(1 − C_v / c_v)
```

Endpoints, computed with `delta_0 = 0.04` and `c_v = 0.25`:

a	`v = 0` (verify nothing)	`v = 1` (verify everything)
0.50	`delta` = 0.5400, `C_v` = 0.0000	`delta` = 0.0400, `C_v` = 0.2500
0.70	`delta` = 0.3400, `C_v` = 0.0000	`delta` = 0.0400, `C_v` = 0.2500
0.85	`delta` = 0.1900, `C_v` = 0.0000	`delta` = 0.0400, `C_v` = 0.2500
0.95	`delta` = 0.0900, `C_v` = 0.0000	`delta` = 0.0400, `C_v` = 0.2500

Read the table by its intercepts. **Trust moves the `delta`-intercept toward the origin and leaves the cost intercept exactly where it was.** Every point on a high-`a` frontier weakly dominates the corresponding point on a low-`a` frontier: same verification spend, lower loss. That is the geometric statement of the dividend, and it is why trust is not a substitute for verification but a rotation of the whole trade-off.

The half-life consequence, with `v = 0`, computed as `t_half = ln 2 / −ln(1 − delta)`:

a	`delta_eff`	half-life of an unmaintained agreement (periods)
0.50	0.5400	0.893
0.70	0.3400	1.668
0.80	0.2400	2.526
0.90	0.1400	4.596
0.95	0.0900	7.350
0.99	0.0500	13.513

An agreement in a relation at `a = 0.50` is half-forgotten before the next period ends. The same agreement at `a = 0.99` survives thirteen and a half periods. **The agreement is identical and the document is identical; what differs is the rate at which the document stops describing what people do.**

25.4.4 4.4 The steady-state dividend, and a correction to its elasticity

Take the steady state with `N = 8`, `u = 0.55`, so `S = ln(1 + 7(0.55)) = 1.5790`; `eta = 0.35`; `C_0 = 0.30`; hence the net input `K = eta S − C_0 = 0.2526`:

```
Q_inf = K / delta_eff = 0.2526 / (0.04 + (1 − a))
```

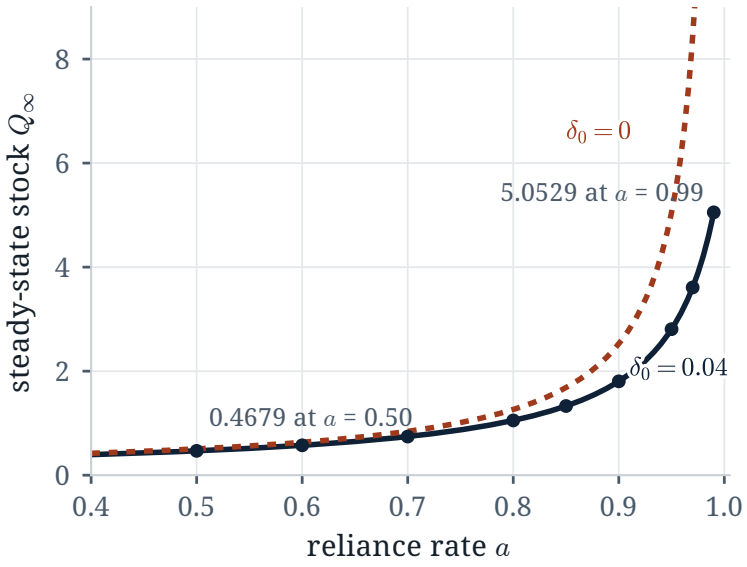

Figure 25.1: **The stock dividend from reliance is superlinear but it is bounded by the irreducible loss, and the corpus's own elasticity formula omits that bound.** Steady state `Q_inf = K/(delta_0 + 1 − a)` with `K = 0.2526`, plotted against the reliance rate; the marked points are the nine entries of the Section 4.4 table, from 0.4679 at `a = 0.50` to 5.0529 at `a = 0.99`. The dotted curve is the same law with `delta_0 = 0`, which reaches 25.26 at `a = 0.99` and is the curve whose elasticity is the frequently quoted `a/(1−a)`. Modelled from the parameters stated in Section 4.4; generated by `figs/src/CCP-025_fig01.py`.

a	delta_eff	Q_inf	share of the a = 0.99 ceiling
0.50	0.5400	0.4679	9.3%
0.60	0.4400	0.5742	11.4%
0.70	0.3400	0.7431	14.7%
0.80	0.2400	1.0527	20.8%
0.85	0.1900	1.3297	26.3%
0.90	0.1400	1.8046	35.7%
0.95	0.0900	2.8071	55.6%
0.97	0.0700	3.6092	71.4%
0.99	0.0500	5.0529	100.0%

Because `Q_inf` varies as `1/delta`, the point elasticity of stored order with respect to the reliance rate is

```
E(a) = (dQ_inf/da)(a/Q_inf) = a / delta_eff = a / (delta_0 + 1 − a)
```

The source material for this paper quotes that elasticity as `a/(1−a)`, giving 1.00, 2.33, 4.00, 9.00, 19.00 and 99.00 at `a` = 0.50, 0.70, 0.80, 0.90, 0.95 and 0.99. That form holds only in the limit `delta_0 -> 0`, and it is inconsistent with the table printed immediately above it, which carries `delta_0 = 0.04`. The two columns are given side by side here rather than one being quietly replaced:

`a`	0.50	0.70	0.80	0.90	0.95	0.99
elasticity as `a/(1−a)`, i.e. at `delta_0 = 0`	1.00	2.33	4.00	9.00	19.00	99.00
elasticity at this table's `delta_0 = 0.04`	**0.93**	**2.06**	**3.33**	**6.43**	**10.56**	**19.80**

A one per cent improvement in the reliance rate at `a = 0.95` buys 10.6 per cent more stored order at `delta_0 = 0.04`, not nineteen; the same one per cent at `a = 0.50` buys 0.93 per cent, which does round to one. The qualitative claim survives the correction and is the useful part: the last increments of reliability are worth far more than the first, and organisations that are nearly reliable are qualitatively different from organisations that are mostly reliable. It also explains the reverse — why a single prominent breach in a high-`a` institution is so destructive. That is not sentiment; it is `1/delta_eff`.

The honest caveat, which the source states correctly and which the corrected elasticity now matches. The superlinearity is an artefact of the model's `1/delta` steady state, which assumes the linear law holds as `delta -> 0`. It does not. As `delta` approaches `delta_0` the irreducible term dominates and the curve flattens; the table already includes `delta_0 = 0.04`, which is why the `a = 0.99` entry is 5.05 and not 25.26. **Anyone quoting the elasticity must quote `delta_0` with it, and must use the form that contains it.**

25.4.5 4.5 The verification threshold, and why the optimum is at an endpoint

Take `Q_inf(v) = (K − c_v v)/(delta_0 + (1−a)(1−v))` and differentiate. Writing `A = 1 − a`:

```
sign( dQ_inf/dv ) = sign[ A (K − c_v) − c_v ∗ delta_0 ]
```

The sign does not depend on `v`. **The objective is a linear-fractional function of the verification rate, so its optimum is always at an endpoint: verify everything, or verify nothing.** The switch happens at

```
a∗ = 1 − c_v ∗ delta_0 / (K − c_v),      valid when K > c_v
```

With `K = 0.2526` and `delta_0 = 0.04`:

unit verification cost `c_v`	`a∗`	reading
0.02	0.9966	verify unless the relation is essentially perfect
0.06	0.9875	verify unless `a` exceeds 98.75%
0.12	0.9638	verify below 96.4%
0.20	0.8479	verify below 84.8%
0.24	0.2381	verify only in near-total distrust
>= 0.2526	never	verification consumes the entire net input

Check the two ends against intuition, because a formula that surprises at the ends is usually wrong. **Cheap verification means one should verify almost always** — which is why retail commerce, where verification is a barcode scan, does not run on trust and does not need to. **Expensive verification means one should verify almost never** — which is why relations whose

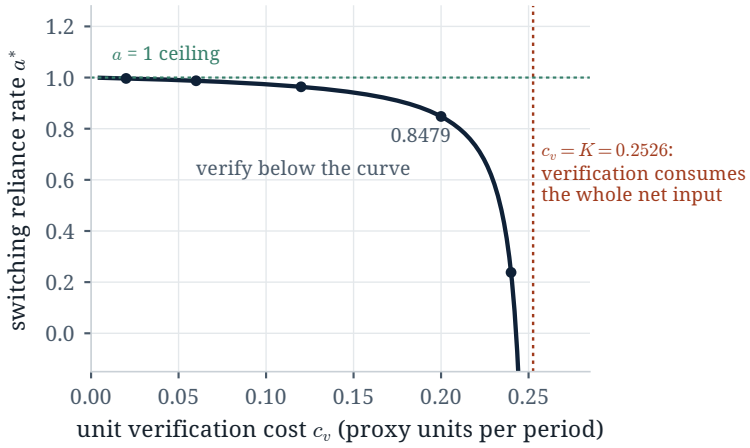

Figure 25.2: **Verification is worth buying only below a threshold reliance rate, and the threshold collapses as the verification cost approaches the net input.** The switching reliance rate `a* = 1 − c_v delta_0/(K − c_v)` at `K = 0.2526` and `delta_0 = 0.04`; the marked points are the five finite entries of the Section 4.5 table (0.9966, 0.9875, 0.9638, 0.8479, 0.2381) and the vertical asymptote is `c_v = K = 0.2526`, beyond which verification consumes the whole net input and is never worth buying. Modelled from the parameters stated in Section 4.5; generated by `figs/src/CCP-025_fig02.py`.

content is judgement, taste, discretion or intent run on trust and have no alternative, since auditing a judgement costs more than the judgement is worth.

This is the practical content of the trust parameter: trust is valuable exactly in proportion to the cost of the verification it displaces. Where verification is cheap, trust is a luxury. Where verification is expensive or impossible, trust is the only available control on `delta`, and its absence is not a cultural deficiency but a hard ceiling on stored order.

Model artefact, flagged. The endpoint result follows from the *linearity* of `C_v = c_v v`. Real verification costs are convex — the first ten per cent of checks are cheap and the last ten per cent are punishing — and with a convex cost the optimum is interior. Use the endpoint result as a signpost about direction, never as an instruction to audit everything or nothing. **What survives convexification is the threshold structure: there is an `a` above which additional verification destroys more order than it saves.** A caution on how `c_v` is priced in practice. Curzi [2026] computes a structurally parallel trade in a disclosure setting: concealment costing USD 210,000 against a compliant USD 561,000 breaks even at an examination probability `p* = (561,000 − 210,000)/41,500,000 = 0.008458`, and **the visible 62.6 per cent saving counts the invoice and not the exposure.** The same error is available here. `c_v` is the invoice for verification; the quantity that belongs opposite it is not the invoice for trust, which is zero, but the exposure carried when an unverified commitment fails. **A verification budget priced on invoices alone will sit on the wrong side of `a*` in exactly the direction that looks cheapest.**

There is a second reason not to read the `v = 1` corner as safe. Redundancy added to a system does not monotonically improve it: Sagan [1993] documents cases in which added redundancy reduced safety by increasing complexity, opacity and the opportunity for common-mode failure. A verification regime is redundancy, and the same caution applies.

25.4.6 4.6 Four things trust is not

Four negations, each a common and expensive error.

Trust is not scalar. There is no such thing as an organisation's trust level. There is a matrix `a_ij^(d)` indexed by pair and by domain, and averaging it discards the only information it carries. A supplier at `a = 0.98` on delivery and `a = 0.55` on cost forecasts is not an `a = 0.77`

supplier; they are a supplier to rely on for one thing and audit for another, and the average would prescribe exactly the wrong action in both domains.

Trust is not a feeling. The feeling is a predictor of `a`, sometimes good and sometimes catastrophically bad, and it is available before the data. It is a prior, not the measurement, and where prior and measurement disagree the measurement is the datum. Self-report about the causes of one's own judgements is precisely the measurement known to be unreliable [Nisbett and Wilson, 1977].

Trust is not an input. It appears nowhere in `eta S_t`. A high-trust group with no interaction surplus accumulates nothing; it merely loses nothing slowly. The extremality result holds: `S = 0` exactly when the parties' framings are parallel, and it stays zero however much the parties rely on one another. **Trust protects the store; it does not fill it.**

Trust is not always desirable. `delta` is not a fault to be minimised. A system with no forgetting cannot revise, because revision is the replacement of an old weighting by a new one and replacement requires that the old weighting fall; the organisational-learning literature reaches the same place from the other side, where too-fast convergence on a shared code destroys the variance that made the body capable [March, 1991, Levinthal and March, 1993]. High `a` on a commitment that ought to lapse is exactly the mechanism by which obsolete procedure outlives its purpose — the commitment is honoured, unverified, forever, because nobody reopens what is trusted. **The engineering target is not maximum `a`; it is `a` high on the commitments that should persist and deliberately low on the ones that should not.** That is what a sunset clause is: a scheduled reduction in `a` on a specific agreement.

25.5 5 Reciprocity and obligation

25.5.1 5.1 The reciprocity index

Reciprocity is usually described as a norm — the expectation that a favour will be returned. As a norm it is unmeasurable; as a *flow balance* it is trivially measurable, provided the flows can be counted.

Let `x_ij` be the volume of transfers from `i` to `j` over an accounting window `w`, in some common unit. The **matched volume** of the dyad is the part both parties supplied:

```
matched_ij = 2 min(x_ij, x_ji)
total_ij   = x_ij + x_ji
rho_ij     = matched_ij / total_ij = 2 min(x_ij, x_ji) / (x_ij + x_ji)
```

Equivalently, and this identity is the bridge to obligation,

```
rho_ij = 1 − |x_ij − x_ji| / (x_ij + x_ji)
```

The two expressions are the same number, since `a + b − |a − b| = 2 min(a,b)`. **The reciprocity index is simultaneously the matched fraction of the volume and one minus the normalised imbalance.** It is dimensionless, has a true zero (all flow one way) and a true one (perfect balance), and is invariant to the unit in which flows are counted — all three properties are required before it may multiply anything.

x_ij	x_ji	matched	total	rho	eta = 0.45 rho
10	10	20	20	1.0000	0.4500
10	8	16	18	0.8889	0.4000
10	6	12	16	0.7500	0.3375
10	5	10	15	0.6667	0.3000
10	4	8	14	0.5714	0.2571

x_ij	x_ji	matched	total	rho	eta = 0.45 rho
10	2	4	12	0.3333	0.1500
10	1	2	11	0.1818	0.0818
10	0	0	10	0.0000	0.0000

25.5.2 5.2 Why the matched fraction is the converting fraction

`eta` is the fraction of interaction surplus that becomes durable structure. Postulate PR asserts that the durable fraction is the matched fraction, and the reasoning is this.

An unreturned transfer creates a claim held by one party. A claim held by one party persists at the *debtor's* convenience; it is an entry in one ledger and the other ledger has no matching row. There is no mechanism by which both parties are separately motivated to maintain it, and no independent copy against which drift can be detected. A returned transfer creates a claim held by both. Both maintain it, both can check it, and it survives the departure of either one's memory of the original transaction.

Structure that only one party holds is not structure; it is a debt. That sentence is the postulate, and it is the reason `eta = eta_max rho` rather than `eta = eta_max`. It is consonant with, but not derived from, the finding that reputation extends reciprocity beyond the dyad by giving third parties a copy of the record [Nowak and Sigmund, 2005] — a mechanism that works precisely by manufacturing the second ledger the unmatched transfer lacks.

The consequence at steady state is severe, because `eta` sits in the numerator while `delta` sits in the denominator. With `S = 1.5790`, `C = 0.30`, `delta = 0.10`, `eta_max = 0.45`:

x	y	rho	eta	eta S	Q_inf = (eta S − C)/delta
10	10	1.0000	0.4500	0.7106	+4.1055
9	6	0.8000	0.3600	0.5684	+2.6844
8	3	0.5455	0.2455	0.3876	+0.8757
12	2	0.2857	0.1286	0.2030	-0.9699
5	0	0.0000	0.0000	0.0000	-3.0000

The negative entries are not small numbers; they are the steady-state theorem's own statement that the regime is unsustainable and that the linear model must be replaced. **A relation running at `rho = 0.29` does not accumulate slowly. It fails to accumulate at all, and it does so while the interaction volume — fourteen transfers a period — looks perfectly healthy on a dashboard.**

The same sign trichotomy appears in the corpus in frequency form. Curzi [2026] establishes a minimum sustainable frequency `f_min = k e^(2c/eta)` with the trichotomy `f > = < f_min` corresponding exactly to `Q_inf > = < 0`, which is the same three-way verdict this table reports through `rho` rather than through contact rate. **That paper's constant `k = 0.483425732988414` is a *defined* constant — the exact ratio `(9/8)^2 / phi^2`, computable to arbitrary precision, which is why fifteen figures are legitimate there — and the attachment of the unit `Hz` to it is a separate and much stronger claim, badged in this paper's verification chain as `POSTULATED` rather than derived.** Because the definition passes through the golden ratio, the standing scepticism about golden-ratio claims applies wherever it appears [Markowsky, 1992]. **Nothing in the present paper depends on `k`.**

25.5.3 5.3 The accounting window

`rho` is not a property of a relation. It is a property of a relation *and an accounting window*. A favour returned in month nine counts as reciprocated if the window is a year and unrecipro-

cated if the window is a quarter. For fifteen favours with mixed return lags, five of them long and two never returned:

window `w` (months)	1	2	3	6	12	24
estimated `rho`	0.1333	0.2667	0.4000	0.6000	0.8000	0.8667

The same relation measures at `rho = 0.13` and `rho = 0.87` depending on a choice the analyst makes. That is an identifiability failure on gate G5 and a researcher degree of freedom of exactly the kind that inflates false-positive rates when it is exercised after the data are seen [Simmons et al., 2011, Gelman and Loken, 2013]. There are three honest responses.

1. **Preregister the window** before looking at the data, and justify it from the domain's natural cycle — the length of a project, a season, a budget year [Nosek et al., 2018].
2. **Report the whole curve**, not a single number. The *shape* is informative: a curve rising steeply and plateauing early describes a fast-settling relation; one still rising at 24 months describes a relation carrying long debt.
3. **Set the window from the decay rate.** The principled choice is `w = 1/delta`, the time constant: beyond that horizon the structure the return was supposed to build has already leaked away, so a return arriving later is arriving into an emptier store. This is the option this paper recommends, and it is the one used in Section 9.3.

25.5.4 5.4 Obligation as the antisymmetric part

Take the interaction matrix `X` and split it as in Postulate PO. Every square matrix has exactly one such decomposition. `Sym` is the dyad's traffic; `Skew` is the standing debt. Note immediately that `rho_ij = 1 - |Skew_ij|/Sym_ij`, **so reciprocity and obligation are two readings of one measurement, not two measurements.**

At the node level, define each member's **net obligation balance** as the row sum of `Skew`:

```
b_i = sum_j (x_ij - x_ji) = (total given) - (total received)
```

`b_i > 0` means `i` is a net creditor, and necessarily `sum_i b_i = 0`. Define the **network imbalance index**

```
B = sum_i |b_i| / (2 * total volume)
```

with `B = 0` perfect balance at every node and `B` approaching 1 a pure one-directional flow.

A small theorem, stated because it prevents a common error. Node-level balance can hide dyad-level imbalance, since a member who is a creditor to one partner and a debtor to another shows `b_i = 0`. Formally `|sum_j (x_ij - x_ji)| <= sum_j |x_ij - x_ji|` by the triangle inequality on the reals, so the node-level imbalance never exceeds the dyad-level imbalance, and therefore

```
1 - B  >=  rho
```

`1 - B` is an upper bound on reciprocity, never an estimate of it. In the worked consortium of Section 9.1 the two numbers are `1 - B = 0.4412` and `rho = 0.3824`: the node-level index overstates the health of the network by 15.4 per cent, and it does so systematically, in the direction of comfort. **Report both, or report `rho`.**

25.5.5 5.5 Two literatures read through the parameters

Two of the most cited empirical bodies on this subject describe the same structural object from opposite ends, and the parameterisation separates them cleanly. **Both are cited for what their authors reported; the transfer into this parameterisation is a modelling assumption, badged here once for both.**

Protection markets and the price of a guarantee. Where central enforcement has failed, an order can be maintained through networked obligation, and a market arises in guarantees. In these terms the finding is that such a market arises precisely where `a` is low and `c_v` is high — where commitments are not honoured unverified and verifying them independently is prohibitively expensive. **What is sold in such a market is not a good but a reduction in `delta`**: a third party guarantees that the commitment holds, so the parties need not verify. That is an economically coherent product, and its existence is what the frontier of Section 4.3 predicts when `a` is low and `c_v` is unaffordable. The standing treatment of trust as the object being traded in such arrangements is Gambetta [1988]. **A caution on attribution:** the source material for this paper attributes the specific Sicilian protection-market study to Gambetta (1993), which is a separate monograph and is **not present in this corpus's bibliography**; the reading above is therefore this paper's own and is cited only to the 1988 volume for the concept of trust it develops.

And here the boundary must be stated rather than the mechanism admired. The guarantee is enforced by removing the ability to decline. Under the declination constraint that is not a permitted intervention, and under the framework's own accounting it is not even a good one: coerced compliance raises *measured* `a` while leaving the underlying relation at `rho` near zero, because the flows are one-directional by construction. The system therefore shows a low `delta` and an `eta` near zero simultaneously — which is a negative equilibrium propped up by continuous coercive input. **An obligation network that removes exit is not a trust system. It is a capture system, and the two are distinguishable by measuring `rho`, which the first has and the second does not.** That is a testable difference and it is the reason the ethical rule and the engineering rule point the same way here.

Social capital and the persistence of civic tradition. Putnam et al. [1993] studied the divergence in institutional performance between northern and southern Italian regions after identical formal structures were devolved in 1970, and attributed the difference to accumulated civic tradition. The mapping is direct:

reported construct	parameter
social capital	`Q`, stored order held on relations rather than in a centre
civic association	the input term `eta S`: interaction that leaves structure
horizontal networks	high `rho`: mutual, balanced, both parties hold the claim
vertical patron-client ties	low `rho`: one-directional, only the patron holds the claim
the persistence of tradition	low `delta`: `Q` with a very long time constant

The most striking claim — that the divergence traces to civic patterns centuries old — is, in this notation, a claim that `delta` is very small: a store with a half-life measured in generations. **That is exactly the regime in which `Q_inf = (eta S − C)/delta` becomes enormous for even modest input, and it is also the regime in which recovery from a low `Q` is hopelessly slow, because the same small `delta` that preserves a good store preserves a bad one. Low `delta` is symmetric. It is not a virtue; it is a memory.** Fukuyama [2001] argues in the development context that social capital is far easier to erode than to create by policy, which is the same asymmetry read from the other side.

The honest note, required. The causal argument has been contested by historians and political scientists on the historical evidence and on the direction of causation. This paper takes no position on that dispute. What the framework offers is not a verdict but a decomposition: the competing hypotheses make **different predictions about which parameter moves first**, and that is a measurable difference rather than an interpretive one.

The contrary evidence, printed here rather than left for a reviewer. The corpus's founding claim is that surplus rises with unlikeness. The largest piece of contrary evidence in the social sciences bears directly on it, and it comes from the same author as the social-capital result above: Putnam [2007] reports that ethnic diversity in the short run **reduces** trust and civic participation, including trust in one's own group, with the benefits appearing only over longer horizons. In this parameterisation that is a claim that raising `u` raises `C` and lowers `a` faster than it raises `eta S` — which the storage law can express perfectly well and which the corpus's own headroom gauge would report as `h < 0`. It is not a refutation of the arithmetic; it is a warning that the sign of the net effect is an empirical question the arithmetic does not settle. Abascal and Baldassarri [2015] is the principal rebuttal, finding that the effect largely disappears under better controls for confounded neighbourhood characteristics, and the pair should be cited together. Two further constraints belong beside them. Contact across difference produces value **only under conditions** — equal status, common goals, cooperation, institutional support [Allport, 1954] — and the meta-analytic test finds contact does reduce prejudice with those conditions facilitating rather than gating the effect [Pettigrew and Tropp, 2006]. And the returns to difference are not monotone: Uzzi and Spiro [2005] finds an inverted U, with team performance rising and then falling as the mix of novel and repeat collaborators increases. **The surplus curve turns over, and `F(u) = ln(1 + (N−1)u)` as written does not.** That is a genuine mismatch between the functional form and the best available evidence, and it is recorded again in Section 12.

25.6 6 Institutional design, priced against the parameters

25.6.1 6.1 The eight design principles mapped to parameters

Ostrom [1990] derived eight design principles common to long-enduring common-pool resource institutions, against the standing prediction that a commons without private property or central authority must degrade [Hardin, 1968]. **The pair must be cited together**: the design principles are the empirical refutation of the prediction, and the prediction is what makes the principles interesting. The polycentric generalisation — many formally independent centres of decision — is stated in Ostrom [2010], and the meta-analytic audit that tests the principles against a large body of case material, finding most supported and several in need of splitting, is Cox et al. [2010]. **This paper's use of the principles presupposes that decentralised resource governance with graduated sanctions, monitoring and nesting is empirically viable; that presupposition rests on those sources and is not established here.**

The corpus has previously treated the principles collectively as `eta`-raising devices. Mapping each to the parameter it actually improves is more discriminating, and **they do not all improve the same thing — three of them improve something other than `eta`.**

#	Design principle	Parameter improved	Mechanism, in this parameterisation
1	Clearly defined boundaries	`N`, and `C`	Makes `N` a countable set rather than a rhetorical one; excludes uncounted draws that appear in the model as unexplained `C`

#	Design principle	Parameter improved	Mechanism, in this parameterisation
2	Congruence: rules match local conditions; benefits proportional to costs	`rho`, hence `eta`	"Proportional" is literally `rho -> 1`. A rule allocating benefit in proportion to contribution *is* a balance condition on the flow matrix
3	Collective-choice arrangements	`u`, hence `S`	Brings members' non-parallel framings into rule-making. Rules written by one framing have `u = 0` at the point where variety was needed
4	Monitoring, by monitors accountable to the appropriators	`c_v`, **not `a`**	Section 6.2. This is the principle most often misread
5	Graduated sanctions	preserves `rho` and `N`	A maximal first sanction deletes the edge; a graduated one preserves it. Section 6.3
6	Conflict-resolution mechanisms, rapid and low-cost	`C`, directly	Unresolved conflict is a standing dissipation term. "Rapid and low-cost" is a specification on `C`, not on justice
7	Minimal recognition of the right to organise	protects `Q` from external shock	Guarantees `Q` is not zeroed by an outside authority; in the model it bounds a catastrophic `delta` event away from 1
8	Nested enterprises	`C`, by orders of magnitude	The only principle that changes the *scaling exponent* rather than a coefficient. Section 6.4

25.6.2 6.2 Monitoring lowers the verification cost; it does not raise reliance

The fourth principle deserves its own treatment because the usual reading is wrong. Monitoring is routinely described as "building trust." In this parameterisation it does no such thing. Monitoring by the appropriators themselves — the specific condition, that the monitors are the users or are accountable to them — reduces `c_v`, the unit cost of verification, because observation is a by-product of use rather than a separate expedition. Lowering `c_v` moves `a*`:

`c_v`	`a*`	policy
0.20	0.8479	verify only below 85% reliance

c_v	a*	policy
0.12	0.9638	verify below 96%
0.06	0.9875	verify below 98.75%
0.02	0.9966	verify below 99.7%

Cheap monitoring raises the threshold above which one should stop verifying; it does not raise the reliance rate. The confusion produces the wrong intervention: a body that believes monitoring builds trust responds to a breach by monitoring more, which lowers `delta` through `v` at a cost in `C`, and leaves `a` exactly where it was. The condition that the monitors be accountable to the appropriators is what keeps the monitoring off the `C` line as pure overhead, and it is the part usually dropped in transfer [Cox et al., 2010].

25.6.3 6.3 Graduated sanction against expulsion, computed

Take the eight-firm consortium of Section 9.1 in its post-intervention state, in which firm 3 is the largest net creditor and a hypothetical rule-breaker. Two responses:

response	`rho` after	`N` after	`S` after	`eta S`	change
intact	0.8947	8	1.5347	0.6179	—
expulsion (maximal sanction)	0.8947	7	1.4159	0.5701	**-7.7%**
30% flow reduction, edge kept (graduated)	0.9038	8	1.5347	0.6242	**+1.0%**

Expulsion is priced entirely in `N`, and it is charged even when the expelled member was reciprocating perfectly. The consortium loses 7.7 per cent of its input by removing one of eight distinct participants, and it recovers none of that by having been right. The graduated response costs volume for two periods and returns a slightly *higher* `eta S`, because the reduction fell on the most imbalanced flows. **The fifth principle is not leniency. It is the observation that the sanction which destroys the relation charges the sanctioner the whole of `ln N − ln(N−1)`.**

Two qualifications, both disclosed rather than absorbed. First, the expulsion row holds `u` fixed at 0.52 across the removal, so the surplus after expulsion is `ln(1 + 6(0.52)) = 1.4159`. **That assumes departure-invariance in `u`, which Section 8.2 and Appendix A.1 (IF-05) show is the exception rather than the rule**: in a heterogeneous body the loss from removing the most divergent member is more than twice the loss from removing a random one, so the `−7.7%` figure is a *floor* on the cost of expulsion and not an estimate of it. Second, the post-sanction `rho = 0.9038` is stated in the source material without the modified flow matrix that would produce it, so **it cannot be independently recomputed from anything printed here**; the sign of the change is the defensible content and the magnitude is not.

25.6.4 6.4 Nesting changes the exponent

Communication paths in a group of `n` number `n(n−1)/2` [Brooks, 1975], and the structure of a body's communication tends to reproduce itself in what the body builds [Conway, 1968]. **Cost grows quadratically while surplus grows logarithmically**, so for any positive per-path cost there is an `n` beyond which no arrangement helps. With `eta = 0.40` and per-path cost `c_1 = 0.0009`:

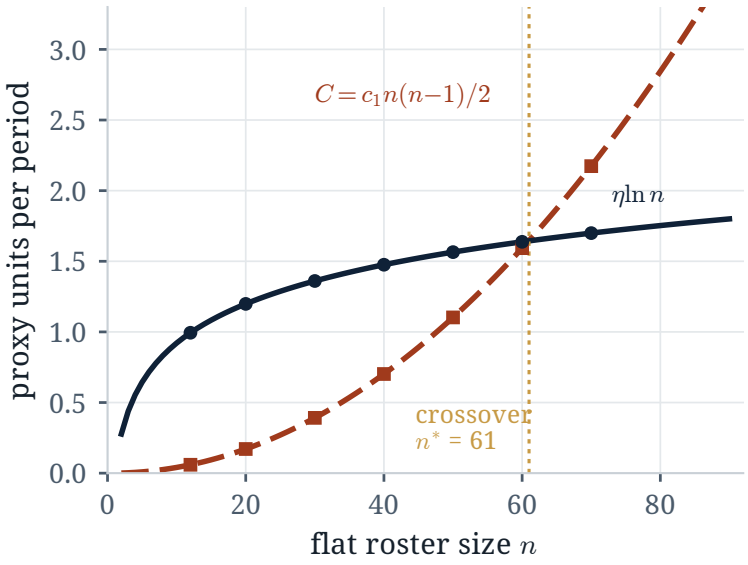

Figure 25.3: **Coordination cost overtakes the surplus ceiling at a computable roster size, and the crossover moves by a factor of five for a factor of twenty in the per-path cost.** Quadratic cost `C = c_1 n(n−1)/2` against the logarithmic ceiling `eta ln n` at `eta = 0.40` and `c_1 = 0.0009`; markers are the seven rows of the Section 6.4 table and the crossover is at `n = 61`. Both exponents are **defined by the model, not estimated from data**, so no power-law fitting procedure applies. Modelled from the parameters stated in Section 6.4; generated by `figs/src/CCP-025_fig03.py`.

n	paths	C = c_1 * paths	eta ln n	h at delta Q = 0
12	66	0.0594	0.9940	+0.9346
20	190	0.1710	1.1983	+1.0273
30	435	0.3915	1.3605	+0.9690
40	780	0.7020	1.4756	+0.7736
50	1225	1.1025	1.5648	+0.4623
60	1770	1.5930	1.6377	+0.0447
70	2415	2.1735	1.6994	**-0.4741**

Crossover at `n = 61`, and the crossover is exquisitely sensitive to the per-path cost:

c_1	0.0005	0.0010	0.0020	0.0050	0.0100
crossover n	85	58	39	23	16

A note on the exponents, required. The `n^2` in the cost and the `ln n` in the ceiling are **exact combinatorics and an exact logarithm within the model; neither is an estimated scaling exponent.** No distribution was fitted and no heavy tail is claimed, so the procedure that any estimated power-law claim would require [Clauset et al., 2009] does not apply here — and would apply immediately to any attempt to read `c_1` off observed organisational cost data, which is the step at which a real exponent would have to be estimated and reported with its uncertainty.

Now nest. The eighth principle records that large enduring systems in the sample were organised as *nested enterprises*: small units whose delegates form the next unit, and so on. Model it as span `g` and depth `d`, giving `N = g^d` members and `(g^d − 1)/(g − 1)` groups, each carrying `g(g−1)/2` internal paths:

span `g`	depth `d`	`N`	groups	nested paths	flat paths	ratio
3	3	27	13	39	351	1 : 9
3	4	81	40	120	3,240	1 : 27
4	3	64	21	126	2,016	1 : 16
5	3	125	31	310	7,750	1 : 25
6	3	216	43	645	23,220	1 : 36
8	3	512	73	2,044	130,816	1 : 64
10	4	10,000	1,111	49,995	49,995,000	1 : 1,000

Flat coordination cost is `O(N^2)`. Nested coordination cost is `O(N)`. That is not a coefficient improvement, it is a change of exponent, and it is the only structural move in the entire parameter set with that property. The surplus ceiling `eta ln N` is untouched by nesting — `N` is still `N` — so nesting is a pure reduction of `C` at constant ceiling.

Paths per member, holding `N` at 1000 and varying the span:

span `g`	3	4	5	6	8	10	12
paths per member	1.50	2.00	2.50	3.00	4.00	5.00	6.00

Coordination cost per member converges to `g/2` and therefore falls monotonically as the span narrows. **This does not mean spans of three are optimal**, and the model says why: narrowing the span increases depth, and depth is a delay and a distortion term that appears in the doctrine-to-data ratio, not in `C`. Each tier is an opportunity for doctrine to be reasserted and data to be summarised away. **The nesting law prices the coordination side only**, and the standing warning is that a strict tree — which is what `g^d` describes — is the wrong shape for exactly this reason: a semilattice, in which a unit belongs to more than one parent, preserves the cross-links a tree amputates [Alexander, 1965]. Those cross-links are where `u` lives, and the weak ties that bridge otherwise separated clusters are the ones carrying non-redundant information [Granovetter, 1973, Burt, 1992]. **Overlapping nests cost more paths than a tree and preserve the cross-links a tree destroys. The computation above is the tree's price list. It is the floor, not the recommendation.**

A parallel ceiling, reached from the cost side rather than the path-count side. Curzi [2026] derives a roster ceiling `m(m−1) <= 2 eta ln(N) / kappa` on the number of simultaneously maintained relations a body can carry, and reports a constructed commons sitting exactly at it — 30 against a ceiling of 30.7225, with a seventh member making the case structural rather than incidental. **That is the same trade this section computes, with the quadratic charged against pairs of maintained relations rather than against communication paths**, and the two arrive at the same conclusion by different arithmetic: the logarithmic ceiling is overtaken by a quadratic charge at a computable size, and the only structural escape is to change the exponent.

25.6.5 6.5 Why trust alone cannot rescue a low-reciprocity regime

This is the most useful result in the first half of the paper and it falls straight out of the steady-state theorem.

Take a relation with `eta S < C`. The steady state is `Q_inf = (eta S − C)/delta` and the numerator is negative. **Lowering `delta` — that is, raising trust — makes `Q_inf` more negative, not less.** The model is stating, in the plainest available language, that a relation losing order faster than it makes it cannot be repaired by making it lose order more slowly. It can only be repaired by raising `eta S` or lowering `C`.

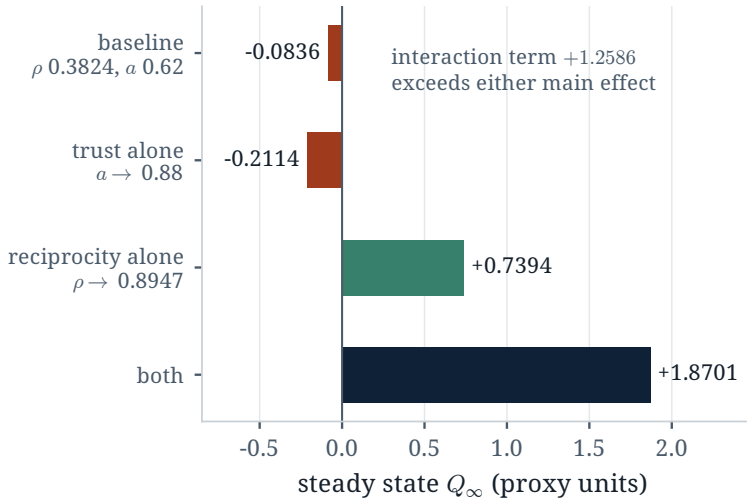

Figure 25.4: **A trust intervention alone moved the equilibrium the wrong way, and the interaction term is larger than either main effect.** One-at-a-time decomposition of the consortium's fixed point: baseline `−0.0836`, reciprocity alone `+0.7394`, trust alone `−0.2114`, both `+1.8701`, leaving an interaction of `+1.2586`. Trust alone is negative because at `rho = 0.38` the numerator `eta S − C` is negative and dividing a negative number by a smaller denominator produces a larger negative number. Modelled from the parameters stated in Sections 6.5 and 9.1; generated by `figs/src/CCP-025_fig04.py`.

Concretely, from the consortium of Section 9.1. Before: `rho = 0.3824`, `a = 0.62`, so `eta = 0.1721`, `delta = 0.4300`, `eta S = 0.2641`, `C = 0.30`, `Q_inf = −0.0836`. After the full intervention: `rho = 0.8947`, `a = 0.88`, `eta = 0.4026`, `delta = 0.1700`, `Q_inf = +1.8701`. Decompose the gain of `+1.9537` by moving one parameter at a time:

move	`Q_inf`	gain over baseline
baseline (both before)	-0.0836	—
reciprocity alone (`rho` to 0.8947, `a` still 0.62)	+0.7394	**+0.8229**
trust alone (`a` to 0.88, `rho` still 0.3824)	-0.2114	**-0.1278**
both	+1.8701	+1.9537
interaction term		+1.2586

Trust alone made it worse. Not marginally — it moved the equilibrium further into the region where the model declares the regime unsustainable, because at `rho = 0.38` the numerator was negative and dividing a negative number by a smaller denominator produces a larger negative number. And the interaction term, `+1.2586`, is larger than either main effect: **the two interventions are strongly complementary and neither is close to sufficient alone.** Curzi [2026] carries this inversion in the corpus's demotion register as R15 — the fixed point moving from `−0.0836` to `−0.2114` under trust alone against `+0.7394` under reciprocity — alongside the demotion of the moment equation on scale and the inversion of a tradition's stated order.

Read it as an operating rule. **Fix the numerator first.** Reciprocity, conversion, cost — the input side — before trust. A trust programme run in a body that is not converting its interactions into anything durable will produce a slower, more polite decline, and it will produce survey results saying the intervention worked.

25.6.6 6.6 Measurement protocols

Three protocols, one per quantity. Each is written to be executable by someone who did not write it, and each states its ethics constraint, because all three involve observing people.

Protocol A — the reliance rate `a`. *Estimates:* the probability that an unverified commitment in domain `d` on relation `(i,j)` is honoured within one period.

1. **Enumerate the commitment population.** List every commitment in domain `d` made on the relation in the last `k` periods. A commitment must have a date, a content, and a party. If the records cannot produce this list, that fact is itself the first finding: **a body that cannot enumerate its commitments cannot measure its trust, and its stored order is smaller than it believes.**
2. **Stratify by consequence** into low, medium and high tiers using a pre-declared rule.
3. **Randomise verification within the low tier only.** Select a random subset of the low-consequence commitments and do not verify them for one period. Verify all others as normal.
4. **Score.** `a_hat = (honoured, unverified) / (total, unverified)`. Compute a Wilson interval; with fewer than about 30 unverified commitments the interval will be wider than the effect being looked for, and the honest report is the interval.
5. **Repeat per domain.** Do not pool across domains.

Ethics constraint, binding. Randomised non-verification is permitted only in the tier where non-verification causes no harm the party has not already accepted, and **every party must be told in advance that verification is sampled rather than universal.** Constructing a hidden test of someone's reliability is a covert manipulation and is prohibited under the declination constraint — the party cannot decline what they are not told about. **The disclosure does not spoil the measurement**: what is concealed is *which* commitments are unverified, not that sampling occurs. The disclosure has a second and independent justification: participation in a study changes behaviour, and the effect is neither negligible nor uniformly directed [McCambridge et al., 2014], while an observer's undisclosed expectation is itself a known source of measured effect [Rosenthal and Jacobson, 1968, Rosenthal and Fode, 1963]. A concealed reliability test is therefore both prohibited and unsound.

Common failure: estimating `a` from complaints. Complaints measure the honoured rate of high-consequence commitments among parties who complain. That is three selection effects stacked.

Protocol B — the reciprocity index `rho`. *Estimates:* the matched fraction of interaction volume on a relation, over a declared window.

1. **Declare the unit.** Flows must be counted in a unit that is at least ratio-scaled with a true zero and that is *symmetric* — the same unit in both directions. Hours, items, referrals, review comments, defined favour-units. **If the unit is not symmetric — if "advice given" is counted one way and "money given" the other — there is no ratio and `rho` is not defined.** Demote to a paired ordinal comparison and say so.
2. **Declare the window before looking.** Default `w = 1/delta` periods (Section 5.3).
3. **Build the matrix** `x_ij` for every ordered pair.
4. **Compute** `rho_ij` per dyad, and `rho_group = sum matched / sum total` over all ordered pairs.
5. **Report the window sensitivity curve**, not only the point estimate.
6. **Report density alongside.** A network with three edges can have `rho = 1`. Reciprocity on a sparse network is a statement about the few edges that exist.

Common failure: computing `rho` from the node balances `b_i` instead of the dyad flows. That gives `1 − B`, which by Section 5.4 is an upper bound and is biased toward good news.

Protocol C — the obligation ledger. *Estimates:* the standing directed debt between every pair, and the network's imbalance.

1. **Same matrix as Protocol B.** One data collection serves both.
2. **Compute** `Skew_ij = (x_ij − x_ji)/2`, `b_i = sum_j (x_ij − x_ji)`, and `B = sum |b_i| / (2 * total)`.
3. **Rank the dyads by `|Skew|`, not by `Sym`.** The largest relations are not the most imbalanced ones, and it is imbalance that predicts breakdown.
4. **Check the sign structure.** A network with a small number of large net creditors and many small net debtors is a patron-client structure regardless of what it calls itself. A network with `b_i` near zero everywhere and high `Sym` is a horizontal association. These are the two cases of Putnam et al. [1993] and they are distinguishable in one afternoon of arithmetic.
5. **Do not publish individual balances without consent.** A ledger of who owes whom, made public inside a group, is a coercive instrument: it converts a private accounting into a public pressure and removes the ability to decline the accounting. Publish the *distribution*, and report dyad-level findings to the dyad.

25.6.7 6.7 Design specifications

Numbered, checkable requirements. A system claiming to have engineered trust, obligation or reciprocity must satisfy all of these or state which it fails and why. **These are renumbered from the source material's `S49.x` series as `S1`–`S12`; the scope specifications of Section 8.12 continue as `S13`–`S22` and the formulary specifications of Appendix B as `S23`–`S32`.**

S1 — Domain-indexed reliance. `a` shall be measured and reported per relation and per domain. A single organisation-wide trust figure shall not be published. Any report quoting one number shall state the domain it applies to.

S2 — Verification policy stated against `a*`. For each domain, `c_v`, `delta_0` and `K = eta S − C_0` shall be estimated, `a*` computed, and the verification rate set on the correct side of it. A verification policy never priced against `a*` is an unpriced recurring charge on `C`.

S3 — Sunset by default. Every commitment entering `Q` shall carry a review date. Absent one, the commitment inherits the relation's `a`, which for a well-run relation is high, and **an obsolete commitment in a high-`a` relation is immortal.**

S4 — Reciprocity window declared in advance. `w` shall be preregistered before flows are tabulated, with its justification. Post-hoc window selection can move `rho` from 0.13 to 0.87 on identical data (Section 5.3) and shall be treated as the researcher degree of freedom that it is.

S5 — Symmetric unit. The flow unit shall be identical in both directions of every dyad. Where no symmetric unit exists, `rho` shall be reported as undefined and the relation assessed by paired ordinal comparison, explicitly demoted.

S6 — Both indices reported. Any report of network reciprocity shall carry `rho` (dyad-level) and `B` (node-level), with the note that `1 − B >= rho`. Reporting only `B` is prohibited.

S7 — Numerator before denominator. No trust intervention shall be commissioned in a system whose measured `eta S − C` is negative. In that regime the intervention is predicted to worsen the equilibrium (Section 6.5). The order is: raise `rho` and `eta`, cut `C`, confirm the numerator is positive, then invest in `a`.

S8 — Graduated sanction as default. Sanctions shall be graduated, with expulsion reserved and its price stated in advance as `ln N − ln(N−1)` of surplus ceiling plus the lost `Sym` volume, and with the departure-fragility profile of Appendix A.1 (IF-05) computed rather than assumed away. A proposal to expel shall carry that computation.

S9 — Nesting above the crossover. Where flat membership exceeds the computed crossover `n` at the measured `c_1`, the body shall be nested, and the nesting shall be a semilattice — units belonging to more than one parent — rather than a strict tree [Alexander, 1965]. The tree figures of Section 6.4 are the cost floor, not the design.

S10 — Exit preserved. No obligation instrument shall bind a party who has not consented and may not withdraw. **This is not negotiable, and by Section 5.5 it is also the test that distinguishes a trust network from a capture network.** A network whose measured `a` is high and

whose measured `rho` is near zero shall be reported as a capture structure.

S11 — No covert reliability testing. Sampling of verification shall be disclosed. Which commitments are sampled need not be.

S12 — Ledger privacy. Individual obligation balances shall not be published within the group. Distributions only, and dyad-level findings to the dyad.

25.6.8 6.8 Failure modes

Ten named faults, renumbered from the source material's `FM-49.x` series as `F1–F10`. Section 8.12 continues with `F11–F18` and Appendix B with `F19–F26`.

F1 — The trust programme in a negative regime. *Signature:* an engagement or culture initiative running in a body whose meetings produce no artefacts and whose coordination cost is unmeasured; survey trust scores rise and nothing else does. *Damages:* wastes the budget and lowers `delta` while `eta S < C`. *Measurement:* compute `eta S − C` before commissioning. *Fix:* S7. *Confusable with:* F4.

F2 — Scalar trust. *Signature:* a dashboard with one trust number, usually from an annual survey, usually on a five-point ordinal scale, usually averaged. *Damages:* destroys the domain structure that makes `a` actionable; produces uniform policy where differentiated policy is required. *Measurement:* attempt to reconstruct `a_ij^(d)` for three domains; if the pooled figure lies between them and predicts none of them, the diagnosis is confirmed. *Fix:* S1 — and note that averaging ordinal responses was not licensed in the first place [Stevens, 1946].

F3 — Verification creep. *Signature:* a breach occurred, controls were added, the controls were never removed, `C` has been rising for three years and nobody can say by how much. *Damages:* `C`, permanently; frequently pushes `h` negative on its own. *Measurement:* price the current `v` against `a*` (S2). *Fix:* recompute `a*`; sunset every control added in response to a specific incident more than `1/delta` periods ago and not re-justified. *Confusable with:* legitimate monitoring, which lowers `c_v`. **The distinguishing test is whether the monitors are the users**: if monitoring is done by a separate function it is a `C` line; if it is a by-product of use it is a `c_v` reduction.

F4 — Reciprocity theatre. *Signature:* high interaction volume, celebrated; newsletters about collaboration; `rho` unmeasured. *Damages:* `eta`, invisibly — the dashboard measures `Sym` and the store depends on `rho`. *Measurement:* Protocol B. In the worked consortium, a volume of 68 units per quarter concealed `rho = 0.3824`. *Fix:* publish the matched fraction alongside the volume, always.

F5 — The node-balance illusion. *Signature:* a network reported as reciprocal because everyone's give and take roughly match in aggregate. *Damages:* conceals dyad-level one-directionality. *Measurement:* compute both; in the worked case, 0.4412 against 0.3824. *Fix:* S6.

F6 — Window shopping. *Signature:* a reciprocity figure that improved after the analyst "refined the measurement period." *Damages:* the credibility of the whole measurement. *Measurement:* ask when the window was chosen relative to seeing the data. *Fix:* S4, and report the sensitivity curve.

F7 — The immortal commitment. *Signature:* a rule everyone follows that nobody can date, justify, or find the author of; usually discovered when a newcomer asks why. *Damages:* `C`, and `u` — because an unexamined rule is a framing nobody is permitted to contradict. *Measurement:* sample the commitment population and score each for last review date; a distribution with a long right tail is the signature. *Fix:* S3. **A system with no forgetting cannot revise.**

F8 — Capture mistaken for culture. *Signature:* very high compliance, very high measured reliability, members who do not leave, flows one-directional toward a small number of nodes, and departure described as betrayal. *Damages:* everything, and the model will not show it if only `a` is measured. *Measurement:* `rho` and the sign structure of `b_i` (Protocol C, step 4). *Fix:* **there is no parameter fix. This is the failure mode the framework refuses to optimise.** The finding is a finding, and the required action is to restore exit.

F9 — Expulsion as first resort. *Signature:* a governance body whose only sanction is removal. *Damages:* `N`, at `ln N − ln(N−1)` per removal, charged whether or not the removal was justified. *Measurement:* the table of Section 6.3 — `−7.7` per cent of `eta S` for one of eight, and more where the departing member carries divergent framing. *Fix:* S8. **A sanction ladder cannot be constructed during the incident it is needed for.**

F10 — Flat above crossover. *Signature:* a body of sixty-plus that still meets as one room and still decides as one room, whose members describe the meetings as necessary and useless. *Damages:* `C`, quadratically. *Measurement:* estimate `c_1` from the observed per-path cost and find the crossover (Section 6.4). *Fix:* S9, with the semilattice caveat.

25.7 7 The internal/external correspondence

25.7.1 7.1 The master table and how to read it

The claim under audit is short enough to state before it is defended: **the internal and external scopes are not two subjects but one set of relations measured at two scopes.** The proven part of that claim is exactly one thing, and it is a statement about form. The recursion `Q_{t+1} = (1−delta)Q_t + eta S_t − C_t` with `S_t = ln(1 + (N−1)U_t)` contains no term naming a substrate: there is no variable for "person" and no variable for "organisation". Every theorem about it — the exact solution, the one-step growth condition, the uniform bound, the sustainability ceiling, the steady state, the headroom gauge — is a theorem about a first-order linear recursion with a loss term, and holds wherever that recursion holds [Curzi, 2026q, Elaydi, 2005]. **That is a claim about model form, not about physics**, and this paper does not exceed it.

Two further proven facts do the structural work. **Banach's fixed point theorem**: for `delta > 0` the map is a contraction with modulus `1 − delta`, so a unique fixed point exists and iteration converges to it geometrically from any starting value [Banach, 1922]. **Strict concavity of `f` and the hard ceiling `0 <= F <= ln N`**: both are properties of the logarithm and neither knows what `N` is counting.

The thesis, badged as the author's thesis and not as a theorem: the internal and external scopes are the same relational system, and the parameters of one have measurable counterparts in the other. That is stronger than the proven statement and must be kept separate from it. The proven statement says the *equation* transfers. The thesis says the *phenomena* correspond — that forgetting and turnover are one parameter at two scopes, that character and institution are one store, that cognitive load and coordination overhead are one dissipation. **A modelling thesis of this kind is not established by exhibiting a table. It is established by cross-scope replication**: the same operationalisation, applied at both scopes, recovering parameters that stand in the predicted relation, with the prediction able to fail. Section 8.11 states exactly what would kill it. Until that programme is run, the correspondence is a research hypothesis with a good structural argument behind it and no cross-scope replication behind it, and this paper says so in those words.

Term	INTERNAL (personal)	EXTERNAL (interpersonal)
`N`	distinguishable categories in one mind	distinct domains held in a group
`u`	non-parallelism between one's own framings	non-parallelism between members
`N_eff`	how many genuinely different views are held	how many genuinely different members
`F`	internal surplus	group surplus
`Q`	character, skill, memory, internalised structure	institution, culture, infrastructure

Term	INTERNAL (personal)	EXTERNAL (interpersonal)
`delta`	forgetting, skill atrophy, drift of self	turnover, decay of practice, lost tradition
`eta`	how experience becomes character	how interaction becomes institution
`C`	cognitive load, effort, maintenance of self	coordination overhead, friction
`h`	personal capacity for the new	organisational headroom
`M`	the moment as lived	the situation as the group constructs it
`D/P`	frame-to-intake ratio	doctrine-to-data ratio

One reading instruction before the rows. The correspondence is not that the two columns describe the same thing. It is that they occupy the same position in the same equation. Internal `delta` and external `delta` are different phenomena — forgetting is not turnover — but they enter the recursion identically, are estimated by the same procedure, and have the same consequences for the trajectory. That is the whole claim, and it is both weaker and more useful than the claim that a company is a mind.

25.7.2 7.2 The counting rows: `N`, `u`, `N_eff`

Row `N`. Internally, `N` is the number of distinguishable categories the mind holds in the domain under analysis — not the number of thoughts, the number of *kinds* it can tell apart. *Measurement:* a free-sort task; present 40–60 items from the domain, ask for as many groups as feel natural with a name per group, and take `N` as the count of groups surviving a re-sort a week later. **The re-sort is the whole protocol**: categories that do not reappear were produced by the task, not held by the person. Report test-retest agreement; below about 0.6 the count is not a measurement [Cronbach, 1951]. Externally, `N` is the number of distinct domains the group holds — not headcount. *Measurement:* the capability inventory; enumerate the domains in which at least one member can act without consulting anyone outside the group, each verified by an observed independent instance.

Where the two diverge in kind. External `N` is enumerable from public evidence and can be audited by a third party. Internal `N` is a modelling choice about how finely to carve, and two competent analysts will return different counts from the same person. **The external count has a fact of the matter that the internal count does not**, and the asymmetry runs opposite to most intuitions: it is easier to count what a team can do than what a mind can distinguish.

Row `u`. Internally, the degree to which a person's own framings of a situation are genuinely different rather than the same framing in different words, `u = 1 − (x.y)^2` per pair with the mean over pairs. *Measurement:* the independent-prediction test — produce `k` framings of one situation, then, separately and without re-reading, ask each framing for a prediction about a specific future observable, and estimate `u` from the disagreement structure. **Framings that predict identically are the same framing.** That is the only defensible operationalisation, because framings stated in words are trivially made to look different and non-trivially made to be different. Externally: the same instrument with different subjects, members predicting independently before discussing.

Where the two diverge in kind. Internally all framings are held by one processor and share its priors; they are correlated by construction and `u` is bounded well below 1 in practice. Externally `u` near 1 is achievable because members can be independently sourced. **The internal ceiling on `u` is lower than the external one**, and the corpus's result that the second genuinely different framing is the largest gain ever bought is a consequence of that lower ceiling rather than a restatement of the concavity [Curzi, 2026o].

Row `N_eff`. `N_eff = 1 + (N−1)u` at both scopes without modification — **the framework's own**

affine effective count, not a Hill number (Section 3.1). This row is the cleanest correspondence in the table because it is pure arithmetic on the two rows above it. With `N = 7` at either scope:

u	N_eff	S = ln N_eff	share of ceiling ln 7 = 1.9459
0.15	1.900	0.6419	33.0%
0.35	3.100	1.1314	58.1%
0.55	4.300	1.4586	75.0%
0.75	5.500	1.7047	87.6%
0.95	6.700	1.9021	97.7%

Seven framings held by one person at `u = 0.15` and seven people in a room at `u = 0.15` are both worth 1.9 of anything. The arithmetic does not care which. That is the correspondence in its most literal and least contestable form: **the audit for redundancy is scope-independent**, because redundancy is a geometric property and geometry does not know what it is measuring. `N_eff` is derived and is never to be measured by a separate instrument.

25.7.3 7.3 The dynamical rows: `F`, `Q`, `delta`, `eta`, `C`

Row `F`. Ceiling at both scopes: `ln N`. **Here the correspondence produces a result neither scope would produce alone.** Since the moment normalises into `[0, ln N]` to serve as `S_t`, the maximum possible moment is `ln N`, which is the law of requisite variety [Ashby, 1956, 1958] appearing in first-person experience: **the richest available moment is bounded by the log of how many kinds of thing the perceiver can distinguish.** That statement was not chosen. It follows from putting the internal and external ceilings in the same equation, and it is the strongest single piece of evidence for the thesis. `F` is derived at both scopes and never measured directly.

Row `Q`. Internally: character, skill, memory, internalised structure — what persists in the person when the situation that built it has gone. *Measurement:* the unprompted-retention probe; sample the domain, wait one period without input, test performance without cues. **The essential feature is the absence of prompting**: capability appearing only when scaffolded is not in `Q`, it is in the scaffold, which belongs to the environment. Externally: institution, culture, infrastructure — what persists in the group when the people who built it have gone. *Measurement:* the identical probe with the identical essential feature, the substitution test: replace the individual and see whether the capability survives. Star and Ruhleder [1996] supplies the diagnostic principle for both scopes — **infrastructure becomes visible only on breakdown** — so `Q` is most accurately measured during a disruption and is systematically underestimated during normal operation.

Where the two diverge in kind. Internal `Q` has a hard terminus. External `Q` does not: an institution's store can in principle outlive every person who has held it, and often does. **A mind's store is bounded by a lifetime and a group's is not, so the two scopes have different upper limits on the time constant `1/delta` and therefore different meaningful ranges for `delta` itself.** That is the first crack, and Section 8 develops it.

Row `delta`. Internally: forgetting, skill atrophy, drift. *Measurement:* measure `Q` at two times under zero input, `delta = 1 − Q_1/Q_0`, half-life `ln 2 / −ln(1−delta)`. Externally: turnover, decay of practice, lost tradition — **and here the external scope has a term with no internal counterpart**, which must be composed rather than assumed:

```
delta_total = 1 − (1 − delta_internal)(1 − tau)
```

where `tau` is the per-period turnover rate. The two losses are independent, so their survivals multiply. **The independence is a postulate, badged**, and it is violated in the specific case where departures are *caused by* the decay — the exit feedback of Section 8.1 — in which case the composition understates the loss.

delta_int	tau	delta_total	Q_inf relative to tau = 0
0.05	0.00	0.0500	100.0%
0.05	0.05	0.0975	51.3%
0.05	0.10	0.1450	34.5%
0.05	0.20	0.2400	20.8%
0.05	0.30	0.3350	14.9%
0.05	0.50	0.5250	9.5%

Five per cent turnover halves steady-state stored order and ten per cent cuts it to a third, before anyone has written a single bad document. This row is where the external scope is strictly harder than the internal one: knowledge does not resign. *Shared caution:* `delta` is per period, and the period lengths at the two scopes typically differ by one to two orders of magnitude. Any cross-scope comparison without normalisation is meaningless; Section 8.7 computes exactly how meaningless.

Row `eta`. Internally, how experience becomes character; `eta = dQ_attributable / M_input`. Externally, how interaction becomes institution; `eta = dQ_attributable / S_input`. Same estimator, same difficulty — attribution is the whole difficulty at either scope — and one external advantage: **the artefacts are countable.** A decision log exists or it does not. **Meetings with no artefact have `eta` approximately 0**, and that is checkable from outside in a way that "did that experience change you" is not.

Where the two diverge in kind, and this is a real asymmetry rather than a measurement inconvenience. Section 5.2 established that at group scope `eta = eta_max rho`: only the reciprocated fraction converts, because structure only one party holds is a debt. **There is no internal analogue of `rho`, because framings cannot renege.** A framing has no interests, cannot defect, and cannot fail to return a favour. The entire apparatus of reciprocity, sanction and obligation transfers inward as metaphor only (Section 8.4).

Row `C`. Internally: cognitive load, effort, the ongoing maintenance of a self — the cost of holding the structure up, paid every period whether or not anything is built. *Measurement:* dual-task interference, or time-on-maintenance sampling. Both are indirect, and **the honest position is that internal `C` is the least well-measured parameter in the table.** Externally: coordination overhead, friction, conflict, compliance. *Measurement:* direct — coordination cost is a line item — and it has a known scaling law that the internal scope does not obviously share, `n(n−1)/2` communication paths [Brooks, 1975, Conway, 1968], giving the computable crossover of Section 6.4. The stock-and-flow vocabulary for the whole row is standard [Forrester, 1961, Sterman, 2000], and the behaviour of `h` near exhaustion has the same shape as utilisation approaching one in a queue, where waiting time diverges [Kingman, 1962, Hopp and Spearman, 2011].

Where the two diverge in kind. External `C` has the quadratic term because members must coordinate pairwise. Internally the framings do not negotiate with each other in that way — a mind is not paying `n(n−1)/2` in inter-framing meetings. **The external scope has a cost law with an exponent; the internal scope, as far as the framework can currently say, does not, and this is a structural difference rather than a difference in parameter value.**

25.7.4 7.4 The gauge rows: `h`, `M`, `D/P`

Row `h`. `h = eta ln N − delta Q − C` at both scopes, unmodified, with the three regimes identical: `h < 0` unsustainable in this model and no geometry saves it; `h = 0` maintenance only; `h > 0` growth available with any requested increment `r <= h`. Internally, the reason a person at high `Q` and high `C` cannot take on one more thing is not weakness of will; it is `h < 0`, and the structural result holds identically at both scopes: **success consumes its own headroom**, because `delta Q` grows with `Q`. Externally, the ossification of successful institutions is the same sentence with different nouns; the reserve that lets a body absorb variation is what Cyert and

March [1963] called organisational slack. *Measurement, both scopes:* derived from the four parameters, **never surveyed.** "Do you have capacity" is a question about perceived `h`, and perceived `h` is exactly the quantity the doctrine-to-data fault distorts. Curzi [2026h] supplies the identity that closes this row: at equilibrium, headroom is unused variety, `h_inf = eta(ln N − F(u*))`, verified to six decimals at `eta = 0.35`, `delta = 0.015`, `N = 6`, `u* = 0.55` giving `Q_inf = 2.840970` and `h_inf = 0.164501`. **This row is where the correspondence pays for itself most directly, because the same diagnostic question — is the maintenance term eating the ceiling — is asked identically of a person and of a department and answered by the same arithmetic.**

Row `M`. `M = (D/P) E`, the moment as lived internally and the situation as the group constructs it externally, with `D` the shared doctrine, `P` the collective perception and `E` the environment. **Magnitudes on this row are demoted (Section 3.4); what follows is the structure, which is not.** The four limiting cases are the diagnostic instrument and they are identical at both scopes:

```
P -> 0    M -> infinity   frame with no intake   internal: dogma, apophenia
                                                 external: a body that has stopped listening
D -> 0    M -> 0          intake with no frame   internal: sensation without experience
                                                 external: a body that measures everything
                                                           and concludes nothing
E -> 0    M -> 0          no environment         both: no situation, no moment
D = P     M = E           THE FIXED POINT        both: undistorted contact
```

The fixed point `D = P` is the same fixed point at both scopes, and it means the same thing: when the frame matches the intake, the moment equals the environment.

Row `D/P`. `r = D/P`, distortion `Delta = |ln r|`, in the same logarithmic register as everything else. Internally, frame-to-intake: `r > 1` over-framed (seeing the expected), `r < 1` under-framed (flooding). Externally, doctrine-to-data: **an over-framed institution is one whose doctrine outruns its intelligence; an under-framed institution drowns in data it cannot read.** Bands at both scopes:

`|ln r|`	`r` (over)	`r` (under)	reading
< 0.10	< 1.105	> 0.905	calibrated
0.10–0.40	1.105–1.492	0.905–0.670	drift
0.40–1.00	1.492–2.718	0.670–0.368	fault
> 1.00	> 2.718	< 0.368	severe

The band table is a construction showing how the measure reads, not a set of measurements, and `Delta` is an ordinal quantity pending instrumentation: it ranks bodies and periods by distance from contact and does **not** license the claim that one distortion is twice another. **The sign of `ln r` is unaffected by the demotion and is the operationally decisive part**, because over-framing and under-framing take opposite corrections [Curzi, 2026]. *Measurement, both scopes:* the prediction-surprise ledger — record predictions with confidence before the observation, score them after. Over-framing shows as high confidence with flat accuracy; under-framing as low confidence with accuracy that would have supported more.

Where the two diverge in kind. An institution's `D` is a public document and its `P` is a measurable throughput; a person's `D` and `P` are both private. **The external version of this row is the more measurable one, which is the reverse of the intuitive expectation: doctrine-to-data is easier to measure than frame-to-intake, because doctrine is written down.**

Two things transfer with this row and both correct how `r = 1` reads in the band table.

First: at the fixed point, headroom is exactly zero, at either scope. Put `r = 1` into the contact relation and the input sits at its ceiling, `S = ln N`. The steady state is then `Q_inf = (eta ln N − C)/delta`, and the headroom gauge reads

```
h = eta ln N − delta Q_inf − C = eta ln N − (eta ln N − C) − C = 0
```

with `delta` and `C` cancelling out. **Perfect contact drives the input to its maximum, the maximum input drives the store to its maximum, and the maximum store spends the entire budget on maintenance.** That this comes out identically at both scopes is among the cleaner pieces of evidence for the thesis: it is a cancellation in the algebra, not a resemblance in the prose. **The consequence at both scopes: `r = 1` is not an unqualified target.** It maximises fidelity and leaves nothing to build with. Room at a settled state requires shedding `Q` deliberately or holding a declared `r != 1` as policy.

At external scope the fixed point acquires an exact join to the surplus functional, `ln r = ln D − ln p_bar − F`. **The group's surplus enters the doctrine-to-data ratio one nat for one nat**, so calibration becomes a geometry requirement rather than an attitude: a body carrying doctrine load `D/p_bar` cannot reach `r = 1` at all unless `D/p_bar <= N`, and the residual floor `Delta_min = ln(D/p_bar) − ln N` is where heavy institutions live. **This join is available only at external scope** — the internal analogue would need a decomposition of one person's intake into countable channels, which Section 8.3's aggregation disanalogy says is not on offer. Record it as a place where the correspondence is **asymmetric in what can be computed**, not merely in what can be measured. Both sides of the join carry the demotion of Section 3.4.

Second: the ledger this row drives must be kept in two tracks, at both scopes. Over-framing **increases** stored order — the storage law integrates the moment as lived and contains no term asking whether it was earned — so the instrument is `Q` against veridical `Q^V`, with stored error `Z_{t+1} = (1−delta)Z_t + eta(M_t − V_t)` (the cost term cancels exactly) and correction load `C_t = c_0 + kappa Z_t`. **Dogma banks faster than knowledge, and the bill arrives on a lag.** Because `V = E min(r,1)` is flat above the fixed point while `M = rE` keeps climbing, **anyone optimising raw `Q` is driven away from `r = 1`, actively and by arithmetic**: a person accumulating a confident self-account, an institution accumulating doctrinal coverage, identically. The knife edge is `kappa = delta` — below it raw `Q_inf` rises without bound in `r`. **Row `Q` should therefore be read as two rows**, and a report of total store without `Z` beside it is a report of a number that grows fastest when the reporter is most wrong. This is the framework's own instance of the general result that a measure which becomes a target ceases to be a measure [Goodhart, 1975, Campbell, 1979].

25.7.5 7.5 What the eleven rows share: one trajectory shape

Every row above is a parameter of the same recursion, and the recursion is a contraction whenever `delta > 0`. Banach therefore guarantees that both scopes converge geometrically to their own fixed points, and that **after normalising time by the time constant `tau = 1/delta`, the two trajectories are the same curve.**

Computed. Internal: period one day, `delta = 0.02`, `eta = 0.30`, `M = 1.20`, `C = 0.15`, so `tau = 50` days and `Q_inf = 10.5000`. External: period one quarter, `delta = 0.16`, same `eta`, `S` and `C`, so `tau = 6.25` quarters and `Q_inf = 1.3125`. Both from `Q_0 = 0`, with `t` rounded to whole periods at each normalised point:

`t / tau`	internal `Q/Q_inf`	external `Q/Q_inf`	continuous limit `1 − e^−k`
0.5	0.3965	0.4073	0.3935
1.0	0.6358	0.6487	0.6321
2.0	0.8674	0.8766	0.8647
3.0	0.9517	0.9636	0.9502
4.0	0.9824	0.9872	0.9817
5.0	0.9936	0.9955	0.9933

The two columns agree to within two per cent at every point and both track the continuous exponential. **The steady states differ by a factor of exactly eight and the shape is identical. The form transfers; the clock does not, and the levels do not.**

A correction to the source material, disclosed rather than absorbed. The source states that "the clocks differ by a factor of about a hundred and forty." **That figure is not recoverable from the stated parameters.** The time constants are 50 days and 6.25 quarters: a ratio of **8** measured in each scope's own periods, and a ratio of **11.4** in absolute time at 91 days to the quarter. Neither is 140, and no combination of the stated parameters produces 140. The corrected figures are printed above and the erroneous one is not repeated.

25.8 8 Where the correspondence breaks: nine audited failures

Nine failures: three severe, four structural but manageable, one a matter of measurement practice, and one absolute. Each is stated as sharply as it can be stated, with its computation where it has one, and with the transfer restriction it implies. **The labels B1–B9 are carried from the source material unchanged, since they do not collide with any result label in this paper.**

25.8.1 8.1 B1 — Exit. A group's members can leave; a mind's parts cannot. SEVERE

This is the deepest disanalogy and everything else in this section is downstream of it.

A framing does not resign. A category does not withdraw its labour. A memory does not accept an offer from a competitor. But every member of a group is a separately deciding agent with an outside option, **and that fact changes the type of the model, not just its parameters.**

Consequence 1: `N` is endogenous externally and exogenous internally. In the internal model `N` is set by the analyst's carving and stays fixed while the trajectory runs. In the external model `N` is an outcome of the trajectory: a group whose `Q` falls loses members, which lowers `N`, which lowers the ceiling `eta ln N`, which lowers `Q` further. **The external system has a feedback loop through `N` that the internal system does not have at all.** Every theorem in the corpus's dynamical core is proved for fixed `N`. **None of them is proved for the closed loop.** That loop is also precisely where the identification problem of Section 3.3 bites hardest, since membership is then simultaneously cause and effect [Manski, 1993].

Consequence 2: group-level sustainability does not imply member-level sustainability. Headroom is computed for the body; each member has their own,

```
h_i = eta ln N / N − delta Q / N − c_i
```

Computed for `N = 9`, `eta = 0.35`, `delta = 0.08`, `Q = 4.0`, with heterogeneous cost shares. The per-member share of the ceiling is `0.35 ln 9 / 9 = 0.08545`; the per-member share of maintenance is `0.08 x 4.0 / 9 = 0.03556`; so the critical private cost is `c_i* = 0.04989`:

member	`c_i`	`h_i`	status
1	0.02	+0.02989	ok
2	0.03	+0.01989	ok
3	0.05	-0.00011	unsustainable
4	0.09	-0.04011	unsustainable
5	0.14	-0.09011	unsustainable
6	0.22	-0.17011	unsustainable

Four of the six tabulated members are individually below water in a body that may well be reporting positive aggregate headroom. They will leave, and they will leave in cost order — the highest-cost members first, which are frequently the members carrying the highest `u`, because carrying a divergent framing in a converged room is expensive. **The internal model**

has no equation that can even express this, because a mind's subsystem cannot have a private balance sheet.

A defect in the source material, disclosed. The per-member shares above are computed at `N = 9`, but only **six** members are tabulated, and the source then reports the result as "four of six". **The denominator of the headroom shares and the denominator of the reported fraction are different numbers.** The arithmetic of each row is correct as printed and is reproduced unchanged; what is wrong is the reading. The defensible statement is that **four of the six members whose private costs are exhibited are below water**, and the fraction of the nine-member body below water is not determined by the table. The source also states `u = 0.6` for this computation, which does not enter `h_i` at all — `h_i` is built from `ln N`, the ceiling, not from `ln N_eff`.

Transfer restriction: **no result derived at internal scope may be transferred outward without checking member-level headroom separately. The aggregate is not sufficient.**

Named in the literature: Hirschman [1970] is the standing treatment of the three options open to a dissatisfied member of an organisation. Two of the three — exit, and loyalty as a mediator of exit — have no internal counterpart at all.

25.8.2 8.2 B2 — Heterogeneity. A group's parameters are distributions; a scalar model is a mean field. SEVERE

The storage law as written has one `delta`, one `eta`, one `C`. A group has one per member. Writing a single value is a **mean-field approximation**, and mean-field approximations fail in a specific, computable way when the underlying distribution is not tight. The general objection is old and unresolved: the behaviour of an aggregate is not the behaviour of a representative member [Kirman, 1992], and the same warning attaches to every aggregated social model [Durlauf, 2005].

Computation 1: the aggregate `delta` is not any member's `delta`, and it is not even constant. Take a store split evenly between two compartments, `Q_A = 50` at `delta_A = 0.05` and `Q_B = 50` at `delta_B = 0.50`. The `Q`-weighted mean is `delta_bar = 0.275`. Run both with no input:

t	true total	mean-field prediction	error	error %	implied aggregate `delta`
0	100.0000	100.0000	0.0000	0.00%	—
1	72.5000	72.5000	0.0000	0.00%	0.2750
2	57.6250	52.5625	+5.0625	+8.79%	0.2052
3	49.1187	38.1078	+11.0109	+22.42%	0.1476
5	40.2515	20.0304	+20.2211	+50.24%	0.0821
8	33.3663	7.6332	+25.7332	+77.12%	0.0550
12	27.0302	2.1089	+24.9213	+92.20%	0.0504

The mean-field model is exactly right for one period and wrong by 92 per cent after twelve. The reason is structural: the fast compartment empties, so the surviving store is increasingly the slow one, and the implied aggregate `delta` drifts from 0.275 down toward 0.05. **A single `delta` fitted to early data will catastrophically over-predict decay, and a single `delta` fitted to late data will catastrophically under-predict it. Neither is a parameter of the system; both are artefacts of when the analyst looked.**

Computation 2: aggregate `u` does not identify the structure, and the structures differ in fragility. Model each member as `v_i = cos(th_i) e_0 + sin(th_i) f_i`, with `e_0` the shared direction and the `f_i` mutually orthonormal private directions. Then `u_ij = 1 − c_i c_j` with `c_i = cos^2(th_i)`, and the mean pairwise `u` follows in closed form.

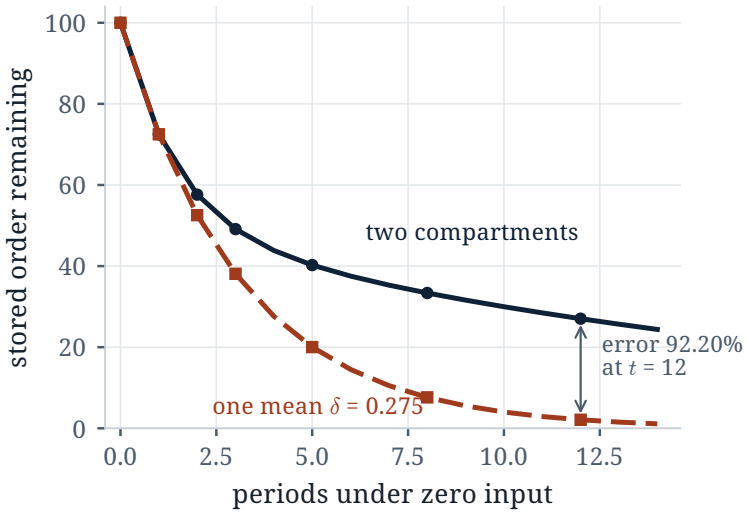

Figure 25.5: **The mean-field scalar is exactly right for one period and wrong by 92 per cent after twelve.** A store of 100 split evenly between a slow compartment at `delta = 0.05` and a fast one at `delta = 0.50`, run under zero input, against the single Q-weighted rate `delta_bar = 0.275`. The fast compartment empties, the surviving store becomes increasingly the slow one, and the implied aggregate rate drifts from 0.2750 at `t = 1` down to 0.0504 at `t = 12`. Modelled from the parameters stated in Section 8.2; generated by `figs/src/CCP-025_fig05.py`.

configuration	composition	mean `u`	`S` at `N = 9`
A, homogeneous	nine members all at `c = 0.6325`	0.5999	1.7578
B, heterogeneous	six at `c = 0.95`, three at `c = 0.0501`	0.5999	1.7578

Identical aggregate `u`. Identical surplus. Now remove three members:

configuration	which three	remaining `u`	remaining `S` at `N = 6`
A	any three	0.5999	1.3862
B	the three divergent	0.0975	**0.3971**
B	three conformists	0.7904	1.5998

Configuration A is departure-invariant in `u`. **Configuration B loses 77.4 per cent of its surplus to the departure of three of nine, where configuration A loses 21.1 per cent** — and B *gains* if the right three leave instead. The two systems are indistinguishable from the aggregate.

A second defect in the source material, disclosed. The source reports the ratio of the two damages as "three and a half times", and Appendix A.1 (IF-05) states it as "3.49 times the damage". **That figure is the ratio of the two *surviving* surpluses, `1.3862 / 0.3971 = 3.4909`, not the ratio of the two losses.** The losses are `1.7578 - 1.3862 = 0.3716` and `1.7578 - 0.3971 = 1.3607`, so **the damage ratio is `1.3607 / 0.3716 = 3.66`**, which is also what the paired percentages `77.4%` and `21.1%` printed in the same paragraph imply. The corrected figure is 3.66 and it is used from here on. The same entry computes its *other* ratio — targeted against random single removal, `0.2599 / 0.1144 = 2.27` — correctly on losses, so the two ratios in that entry are computed by two different methods.

This is a failure of identifiability at external scope only, because it is a failure about who leaves, which is B1 again. The parallel result in network science is standard: heterogeneous structures are robust to random failure and fragile to targeted removal [Albert et al., 2000, Cohen et al., 2000, Callaway et al., 2000], and the arithmetic above is that result appearing in surplus geometry rather than in a connectivity graph. **The transfer is a modelling assumption; the arithmetic is exact.**

Transfer restriction: **at external scope, `u` shall be reported with its distribution across members, never as a scalar alone.** At internal scope the scalar is defensible because the framings cannot separate.

25.8.3 8.3 B3 — Aggregation is not always well defined. SEVERE

The `D/P` row assumes a group *has* a doctrine — that there is a coherent `D` to put in a numerator. For a single mind this is usually approximately true. For a group it can be false as a matter of arithmetic rather than of sloppiness.

Three members, three options, these preference orders:

```
member 1:  A > B > C
member 2:  B > C > A
member 3:  C > A > B
```

Pairwise majorities, computed:

```
A vs B:  2–1  ->  A
B vs C:  2–1  ->  B
A vs C:  1–2  ->  C
```

The group prefers A to B, B to C, and C to A. There is no transitive collective ordering to extract. This is the Condorcet cycle, and Arrow's impossibility theorem generalises it: no rule aggregating three or more ordinal preferences can simultaneously satisfy unrestricted domain, non-dictatorship, the Pareto criterion, and independence of irrelevant alternatives. **Neither result has a bibliography entry available to this paper, so both are stated as classical results without a citation key rather than attached to a source that does not support them; the cycle above is arithmetic a reader can redo in three lines.**

The consequence is exact: the group's `D` may not exist as a well-defined object, in which case `D/P` is not merely hard to measure but undefined. A group can be cyclically incoherent while every member is individually coherent.

The honest counter-weight, stated because the disanalogy should not be overclaimed: individual preferences also exhibit intransitivity, and preference reversals under reframing are among the more robust findings in judgement research. So the disanalogy is one of degree and of mechanism rather than of kind. **But the mechanism differs in a way that matters: individual intransitivity is an error, and collective intransitivity can be the correct output of a faultless procedure applied to faultless inputs.** No amount of member-level rationality removes it.

Transfer restriction: **before computing a group `D/P`, test for cyclicity.** If the collective ordering over the relevant options is cyclic, report `D` as undefined and diagnose by member-level `D_i/P_i` distributions instead.

25.8.4 8.4 B4 — Reciprocity has no internal analogue. STRUCTURAL

Section 7.3 stated it: `eta = eta_max rho` externally, and internally there is no `rho`, because a framing cannot renege. Extending the machinery of Sections 5 and 6 inward requires positing internal agents with interests — and then a second layer of agents to explain the first.

The trap is easy to fall into precisely because the equations permit it. The storage law will accept an "internal reciprocity" parameter without complaint; the equation has no way to object. **What objects is the measurement:** `rho` requires a flow matrix `x_ij` between agents, and there are no internal agents whose flows can be counted.

The partial exception, stated honestly: intertemporal-choice research does model a person as a sequence of selves whose interests conflict, and the technology of precommitment has an obvious structural resemblance to a contract between parties. That is a real modelling tradition and it is not obviously wrong. **But the resemblance is to contract, not to reciprocity: the later self did not choose to enter the arrangement and cannot decline it, which is B1 again.** A framework whose governing refusal is *never remove a person's ability to decline* must notice that precommitment is precisely the removal of a future person's ability to decline, and that this is permitted only because the two persons are the same person. **No entry in this corpus's bibliography supports the intertemporal-choice literature referred to here, so it is named descriptively and left uncited rather than attached to a source that does not carry it.**

Transfer restriction: **Sections 4 to 6 transfer outward-to-inward as metaphor only.** Nothing in their arithmetic — `rho`, the obligation ledger, the sanction ladder, `a*` — has an internal measurement, and none of it should be given one.

25.8.5 8.5 B5 — The observation asymmetry. STRUCTURAL

Internal measurement has privileged access and unreliable instruments: introspection is available continuously, at no cost, and is **biased in a direction correlated with the quantity being measured.** A person who is over-framed (`r > 1`) is by definition seeing what their frame predicts, including when they look at their own frame. **The error is not noise; it is signal-dependent distortion**, and the unreliability of self-report about the causes of one's own judgements is well established [Nisbett and Wilson, 1977].

External measurement has public access and sparse, noisy instruments: behaviour observed at cost, at intervals, through selection filters. **The error is large but comparatively unbiased**, or at least biased in ways that are themselves observable.

The consequence is that the same parameter has different identifiability profiles at the two scopes and therefore requires different estimators — not the same estimator with a different sample size. Internal `C` is the clearest case: Section 7.3 conceded it is the least well-measured quantity in the table, and the reason is that the cost of maintaining a self is paid by the same apparatus that would report it.

Transfer restriction: **an operationalisation validated at one scope is not thereby validated at the other.** Validation is per scope, and it is the specific gate most often skipped [Campbell and Fiske, 1959, Cronbach and Meehl, 1955].

25.8.6 8.6 B6 — Boundary definition runs the opposite way at the two scopes. STRUCTURAL

Noted in Sections 7.2 and 7.4 and collected here because it is systematic and counter-intuitive:

quantity	easier internally	easier externally
`N`		yes — capability inventory is auditable
`u`		yes — independent prediction rounds
`Q`		yes — substitution test
`delta`	yes — no turnover term to disentangle	
`eta`		yes — artefacts are countable
`C`		yes — coordination cost is a line item
`M`	yes — the observer is the one having it	
`D/P`		yes — doctrine is written down

quantity	easier internally	easier externally

Six of eight are easier externally. The common assumption is the reverse — that we know our own minds and can only guess at institutions. **The framework's measurement requirements invert that assumption almost completely**, and this is one of the more useful things the correspondence produces: to learn how to measure an internal parameter, look at how the external version is measured, because the external version is usually the better-instrumented one.

25.8.7 8.7 B7 — Timescale. `delta` is per period and the periods differ by two orders of magnitude. PRACTICE

The scope transform is `delta_T = 1 - (1 - delta)^T` for aggregating `T` short periods into one long one. **It is exact and it is routinely omitted.**

`delta` per period	`T = 7`	`T = 30`	`T = 52`	`T = 365`
0.001	0.0070	0.0296	0.0507	0.3059
0.005	0.0345	0.1396	0.2295	0.8395
0.010	0.0679	0.2603	0.4070	0.9745
0.020	0.1319	0.4545	0.6503	0.9994
0.050	0.3017	0.7854	0.9306	1.0000
0.100	0.5217	0.9576	0.9958	1.0000

And the trap, stated with its number. A `delta` of 0.02 at internal scope with a daily period, and a `delta` of 0.02 at external scope with a quarterly period, print identically:

```
internal 0.02/day     compounded over 91 days   ->  0.8409 per quarter
external 0.02/quarter expressed per day         ->  0.000222 per day
ratio of implied daily rates                    ->  90.1x
```

Two numbers that print identically differ by a factor of ninety.

Transfer restriction: **`delta` and `eta` shall never be quoted without their period; `Q`, `C` and `h` inherit the requirement.** Only `N`, `u`, `N_eff` and `F` are period-free.

25.8.8 8.8 B8 — Rival versus non-rival stored order. STRUCTURAL, with no internal counterpart

Whether members exit depends on what they get, and what they get depends on whether `Q` is rival.

Rival case (the store is divided): each member's per-period return is `eta ln(N_eff)/N - c_i`. With `eta = 0.35`, `c_i = 0.020`, `u = 1` so that `N_eff = N`, and outside option `w = 0.030`:

`N`	`S = ln N`	per-capita	return	decision
3	1.0986	0.12817	+0.10817	stay
6	1.7918	0.10452	+0.08452	stay
12	2.4849	0.07248	+0.05248	stay
20	2.9957	0.05243	+0.03243	stay
30	3.4012	0.03968	+0.01968	**exit**

`ln(x)/x` is maximised at `x = e = 2.71828`. **Under equal division of a logarithmic surplus, the per-capita return is maximised at a group of about three, and every additional member reduces everyone's share.** Rival stored order pushes groups toward the smallest size that clears the outside option.

Non-rival case (a standard, a piece of infrastructure, a body of practice): each member's return is `eta ln N − c_i`, increasing without bound in `N`:

`N`	3	5	8	12	20	30
return	+0.3645	+0.5433	+0.7078	+0.8497	+1.0285	+1.1704

The same group, the same surplus, the same members — and the sign of the size gradient flips entirely depending on whether the stored order is divided or shared. This is a fork in the external model with no internal counterpart whatever, because a mind's stored order is not shared with anyone and the question does not arise. It is the same fork that separates common-pool resources from public goods in the governance literature [Ostrom, 1990, 2010], and it is why the design principles that work for one do not transfer unaltered to the other.

Transfer restriction: **any external application must declare whether `Q` is rival or non-rival before predicting anything about group size.** Predictions about optimal `N` transferred from internal reasoning are unsupported.

25.8.9 8.9 B9 — The ethical asymmetry. ABSOLUTE

The mathematics is symmetric. The permissions are not.

A person may restructure their own `N`, force their own `u`, raise their own `delta` on a habit they want gone, and spend their own `h` however they like. **They may not do any of those things to another person, and the framework's governing refusal is exactly this: no intervention may remove a person's ability to decline.**

Every internal result in this corpus is written for a practitioner working on themselves, and every external result for an engineer working on a circumstance that other people are free to enter and leave. Those are different licences, and the correspondence does not transfer the licence with the equation. **A technique that is legitimate self-discipline internally becomes coercion externally by the simple substitution of a second person, and the substitution is exactly what the correspondence otherwise licenses.**

Section 5.5 supplied the measurable form of the boundary: **an obligation network that removes exit is not a trust system but a capture system, and the two are distinguished by `rho`, which the first has and the second does not.** The ethical rule and the engineering rule agree here, which is fortunate but not necessary, and where they disagree the ethical rule wins without argument. Curzi [2026] states the corpus's boundary in the form this paper is bounded by, including the concession that the case where the feedback loop runs through another person's will remains an unsettled seam.

No entry in this corpus's bibliography establishes consent as a precondition for measuring or restructuring another person's relationships. The constraint is a normative stipulation of the framework, badged as such here and again in Section 12. What the literature does supply is the narrower and purely methodological result that covert study changes what is measured [McCambridge et al., 2014, Rosenthal and Jacobson, 1968], which makes concealed measurement unsound as well as prohibited but does not by itself carry the ethical claim.

25.8.10 8.10 What survives all nine

Something does, and it is worth stating precisely rather than defensively.

The recursion transfers. `Q_{t+1} = (1−delta)Q_t + eta S_t − C_t` holds at both scopes, and every theorem about it holds at both scopes, because none of them mentions a substrate. Section 7.5 demonstrates the shared trajectory to within two per cent.

The geometry transfers. `N_eff = 1 + (N−1)u` and `S = ln N_eff` are arithmetic on a redundancy audit, and redundancy is scope-independent.

The ceiling transfers, and produces a new result in doing so. `F <= ln N` at both scopes forces `M <= ln N` at internal scope, which is requisite variety in first-person form. That result was not available at either scope alone.

The diagnostic questions transfer. *Is the maintenance term eating the ceiling? Is the frame outrunning the intake? Is the interaction leaving anything behind?* These are the same three questions with different nouns.

What does not transfer is anything involving agency of the parts. Exit, heterogeneity of interests, aggregation of preferences, reciprocity, sanction, rivalry of the store. **The correspondence is a correspondence of dynamics and geometry, not of agency.** Stated that way it is defensible. Stated as "a company is a mind" it is a slogan that will be wrong in precisely the six places listed above, all of which are the places where somebody can walk out.

25.8.11 8.11 What would falsify the correspondence

A framework that cannot fail cannot be trusted, and this is how this one fails.

Test 1 — cross-scope parameter recovery. Take one operationalisation of `delta` — the two-time zero-input estimator — and apply it to twenty individuals learning a skill and twenty teams maintaining a practice. Preregister. **The correspondence predicts that after normalisation by period length the two `delta` distributions occupy the same functional role**, meaning that `Q_inf = (eta S − C)/delta` predicts held-out `Q` equally well at both scopes with no scope-specific correction term. *If a scope-specific correction term is needed and does not shrink with sample size, the correspondence is false as an equality of role and must be demoted to an analogy of form.*

Test 2 — the shape test. Fit the trajectory shape, not the levels. **The correspondence predicts that normalised trajectories at the two scopes are the same curve** (Section 7.5). *If internal trajectories are systematically non-exponential in normalised time while external ones are exponential, or the reverse, the shared-dynamics claim fails and the material reduces to a notational convenience.*

Test 3 — the four baselines, both scopes. Persistence, direct input, matched autoregression, and a shuffled-input control [Curzi, 2026i]. *If shuffled `U` predicts `Q` as well as real `U` at either scope, the causal story at that scope is a trend.* **The control is weak and must be calibrated before use**: its measured false-rejection rate is 0.108 for iid permutation and 0.120 for circular shift against a nominal 0.05, with only block permutation near nominal at 0.060, so it is **anti-conservative by a factor of about two**; it passed a filtered repackaging at `p = 0.0005` that was caught only by the structural ceiling test, at 38.5 times the admissible one-step maximum; and against a confound driving both series it passed 98.35 per cent of the time while detecting the clean case only 48.17 per cent of the time [Curzi, 2026i]. **Design controls, not more surrogates.**

Test 4 — the breakdown predictions. Section 8 is not only a list of caveats; it is a list of predictions. **B2 predicts that a heterogeneous group's fitted `delta` drifts downward over an unmaintained interval while a homogeneous one's does not.** That is directly testable and is the sharpest available discriminator between the mean-field model and the real one. *If fitted `delta` does not drift in heterogeneous groups, the mean-field caution is wrong; and if it drifts in individuals too, then B2 is not a disanalogy at all and the correspondence is stronger than this paper claims.*

Test 5 — reproducibility across investigators. Same operationalisation, different investigators, different populations. **This gate decides the hard-science question and it is the one most often skipped. Nothing in this material has passed it** [Open Science Collaboration, 2015].

25.8.12 8.12 Scope specifications and failure modes

S13 — Scope declared. Every application shall declare its scope (internal or external), its period length, and its unit for `Q`, before any parameter is estimated.

S14 — Period stated with every rate. `delta`, `eta`, `C` and `h` shall never be reported without their period. Cross-scope comparison shall use `delta_T = 1 - (1-delta)^T` (B7).

S15 — Distribution, not scalar, at external scope. `delta`, `eta`, `C` and `u` shall be reported with their across-member distribution at external scope. **A scalar alone is a mean-field claim and shall be labelled as one** (B2).

S16 — Member headroom computed. Any external application reporting `h > 0` shall also report the distribution of `h_i` and name the members below zero (B1). **A body may not be described as sustainable while a quarter of its members are not.**

S17 — Rivalry declared. Before any prediction about group size, the analyst shall state whether `Q` is rival or non-rival and justify it (B8).

S18 — Cyclicity tested before `D/P`. Group-scope `D/P` shall not be computed until the collective ordering has been tested for intransitivity over the relevant option set (B3).

S19 — No inward transfer of agency machinery. `rho`, obligation ledgers, sanctions and verification budgets shall not be given internal operationalisations (B4). Their internal use is metaphorical and shall be labelled.

S20 — Per-scope validation. An instrument validated at one scope shall be re-validated at the other before use (B5).

S21 — Licence not transferred. Techniques licensed for self-application shall not be applied to another person on the strength of the correspondence (B9).

S22 — The thesis carries its badge. In any document quoting this correspondence it shall be identified as the author's thesis, with Section 8 cited, and not as a proven result. **The proven result is the scale-freeness of the form, and it is a much smaller claim.**

F11 — The slogan. *Signature:* "a company is just a big brain," offered as an explanation rather than as a model with limits. *Damages:* everything downstream, because it licenses transfers through all nine breakdowns at once. *Measurement:* ask which of the nine breakdowns the speaker has checked; the usual answer is none. *Fix:* S22.

F12 — Unnormalised period comparison. *Signature:* a table comparing an individual's `delta` to a department's with no period column. *Damages:* conclusions wrong by up to two orders of magnitude (B7: 90.1x on a realistic pair). *Measurement:* look for the period column; if absent, the comparison is void. *Fix:* S14.

F13 — Mean-field complacency. *Signature:* one `delta` for a group with obviously heterogeneous members; a decay forecast that keeps being wrong in the same direction. *Damages:* forecast error rising to 92 per cent over twelve periods (B2). *Measurement:* fit `delta` on early data and on late data separately; divergence is the diagnosis. *Fix:* S15, and compartment the model.

F14 — Aggregate `u` complacency. *Signature:* a diverse-on-paper body reporting a healthy `u` with no distribution. *Damages:* invisible fragility — configuration B loses 77.4 per cent of its surplus to the departure of three of nine against configuration A's 21.1 per cent, and reports identically beforehand. *Measurement:* compute `u` with each member removed in turn; the spread of that vector is the fragility. *Fix:* S15. **This computation costs nine subtractions and should be standing practice.**

F15 — The group mind that cannot decide. *Signature:* a body that reverses itself in a cycle, each reversal individually well argued, members each believing the others inconsistent. *Damages:* `D` is undefined and every doctrine-to-data diagnostic returns nonsense. *Measurement:* elicit member orderings and check pairwise majorities for a cycle (B3). *Fix:* S18 — restrict the option set or change the aggregation rule, noting that one of the four conditions must be given up whichever is chosen.

F16 — The sustainable body with departing members. *Signature:* positive aggregate headroom, rising attrition, and genuine bewilderment at the attrition. *Damages:* loses the highest-

`c_i` members first, who are frequently the highest-`u` members (B1). *Measurement:* the `h_i` table; it takes an afternoon. *Fix:* S16 — reduce `c_i` for the members below zero, or accept the loss with its `ln N` price computed (F9).

F17 — Inward transfer of the sanction ladder. *Signature:* a self-improvement scheme built on internal contracts, penalties and rewards, with an internal agent doing the enforcing. *Damages:* imports a model whose central parameter has no internal referent (B4). *Measurement:* ask what the flow matrix is between which agents. There is no answer. *Fix:* S19.

F18 — Introspective validation. *Signature:* an internal instrument validated by asking the subject whether it seems right. *Damages:* the error in introspection is correlated with the quantity being measured, so agreement is evidence of nothing (B5). *Measurement:* check whether the validation criterion is independent of the instrument; usually it is not. *Fix:* S20, with behavioural criteria [Nisbett and Wilson, 1977].

25.9 9 Results: three systems worked end to end

All three systems are constructed, not observed. Every number below is the output of the stated parameters under the model developed above, carried through so that a reader can re-derive it. They demonstrate that the procedure runs and that it reports its own failures; they are not evidence that any organisation behaves this way and must not be cited as such.

25.9.1 9.1 An eight-firm regional supplier consortium

Eight independent manufacturing firms in one region, formed to share tooling, qualified staff, emergency capacity and test equipment; nine quarters old; membership voluntary with one quarter's notice. **Two members, firms 1 and 2, are substantially larger than the rest.** The presenting complaint: participation is good but the consortium never gets anywhere — every quarter it agrees things and every quarter it starts over.

Encoding. Period one quarter. `N = 8` firms; measured non-parallelism across their capability and market framings `u = 0.52`, so `S = ln(1 + 7(0.52)) = 1.5347` against a ceiling `ln 8 = 2.0794`. **The consortium is operating at 73.8 per cent of its surplus ceiling, which is respectable and is not the fault.** `eta_max = 0.45`, estimated from the three shared assets that became permanent in the first two quarters. `C_0 = 0.30` per quarter (secretariat, meeting time, legal). `delta_0 = 0.05` per quarter, mostly staff movement inside member firms.

Baseline measurement, Protocols B and C. One quarter's flow matrix in documented favour-units (loaned tooling days, seconded staff days, test slots, referrals), all symmetric and ratio-scaled. Rows are givers:

to:	F1	F2	F3	F4	F5	F6	F7	F8
F1	–	1	1	0	0	0	0	0
F2	1	–	1	1	0	0	0	0
F3	6	7	–	3	2	1	1	0
F4	4	5	2	–	2	1	0	0
F5	3	4	1	1	–	1	0	0
F6	2	3	1	1	1	–	1	0
F7	2	2	0	0	0	1	–	1
F8	1	2	0	0	0	0	1	–

Directed volume 68 favour-units per quarter; matched volume 26; `rho_group = 26/68 = 0.3824`. Node balances `b_i` (given minus received):

firm	F1	F2	F3	F4	F5	F6	F7	F8
b_i	**-17**	**-21**	+14	+8	+5	+5	+3	+3

B = 76/(2 x 68) = 0.5588, so 1 − B = 0.4412. As S6 requires, note that 1 − B = 0.4412 exceeds rho = 0.3824: **the node index flatters the network by 15.4 per cent.** The sign structure is unambiguous — two large net receivers, six net givers, and the worst dyads are one-directional:

dyad	x	y	volume	rho
(1,4)	0	4	4	0.0000
(1,5)	0	3	3	0.0000
(2,5)	0	4	4	0.0000
(2,6)	0	3	3	0.0000
(2,3)	1	7	8	0.2500
(1,3)	1	6	7	0.2857

This is the vertical patron-client pattern of Section 5.5, measured. It is not what anyone intended; firms 1 and 2 are the largest and were the natural first call, and nine quarters of natural first calls produced a star.

Protocol A, reliance rate. Domain: commitments to supply capacity when asked. Sixty-two low-consequence commitments over four quarters, of which 21 were left unverified by the sampling rule; honoured unverified 13. a_hat = 13/21 = 0.619, taken as **a = 0.62**. With 21 trials the 95 per cent Wilson interval is approximately [0.41, 0.79], which is wider than several of the differences the diagnosis turns on and is the honest report.

Diagnosis.

```
eta   = eta_max * rho   = 0.45 * 0.3824 = 0.1721
delta = delta_0 + (1−a) = 0.05 + 0.38   = 0.4300
S     = 1.5347          eta S = 0.2641          C = 0.30
Q_inf = (0.2641 − 0.30) / 0.4300 = −0.0836
```

The steady state is negative, which is the theorem stating its own failure mode: the regime is unsustainable in this model, or the linear model must be replaced. The complaint — "we agree things and every quarter we start over" — is Q_inf < 0 in plain English. Headroom at the current Q = 1.20:

```
h = eta ln N − delta Q − C = 0.3578 − 0.5160 − 0.3000 = −0.4582
```

Negative, and **no arrangement of the interaction geometry rescues it**: the consortium could raise u to 1.0 and still fail, because the ceiling eta ln N = 0.3578 is below delta Q + C = 0.8160 on its own. Curzi [2026] reaches the same shape in a different domain and with a cleaner cancellation: at a 15 per cent annual hard-currency drag, a local-currency allocation of 25.17 per cent of protected capital drives the headroom coefficient to exactly −0.500000 and cancels the whole eta ln(N) = 0.377583 diversification gain, with a 10 per cent allocation costing 0.150000, or 39.73 per cent of the gain. **A cost term consuming a logarithmic gain is the same arithmetic here as there; only the nouns differ.** Trajectory from Q_0 = 1.20 with no intervention:

quarter	0	1	2	3	4	5	6
Q	1.2000	0.6481	0.3335	0.1542	0.0520	-0.0063	-0.0395

Admissibility requires `Q >= (0.30 − 0.2641)/0.57 = 0.0630`. **The trajectory breaches that between quarter 3 and quarter 4.** What the model predicts past that point is not negative stored order — that is meaningless — but the exit of the model's validity, which in this system means dissolution. On this measurement the consortium had about four quarters left.

What is required. By S7 the numerator comes first. Required `eta` for a positive numerator at current `S` and `C`: `eta > 0.30/1.5347 = 0.1955`, so `rho > 0.4344`. **The consortium is 5.2 points of reciprocity away from not dying, and 51 points away from working.**

The intervention. Three changes, each attached to a parameter. **I-1 (raises `rho`): the reciprocal-call rule** — firms 1 and 2 commit that for each favour received they originate one outbound offer to the same partner within the quarter, from a published list. This is the congruence principle implemented literally as a balance condition on the flow matrix. **I-2 (raises `rho` and volume): the capability register** — every firm publishes what it can lend; the small firms did not know what the large ones had. **I-3 (raises `a`): the standing-commitment ledger with quarterly sunset** — every commitment recorded with a date and a twelve-month review, which is deliberately a `delta`-raising device on obsolete items and an `a`-raising device on live ones, because most of the unhonoured unverified commitments in the baseline turned out to be commitments neither party could state precisely. **Deliberately not done:** expulsion of the two large firms, or any sanction; per Section 6.3 that would cost 7.7 per cent of `eta S` at minimum, and the ladder should exist before it is needed.

Post-intervention measurement, fourth quarter after.

```
to:      F1  F2  F3  F4  F5  F6  F7  F8
F1        –   3   4   3   2   1   1   1
F2        3   –   5   4   3   2   2   1
F3        6   7   –   3   2   1   1   1

F5        3   4   2   2   –   1   1   1
F6        2   3   1   1   1   –   1   1
F7        2   2   1   1   1   1   –   1
F8        1   2   1   1   1   1   1   –
```

Directed volume 114 (from 68); matched volume 102; `rho_group = 102/114 = 0.8947`. Balances are now `[−6, −6, +4, +2, +2, +2, +1, +1]`, so `B = 24/228 = 0.1053` and `1 − B = 0.8947`. **The bound `1 − B >= rho` is met with equality here**, which happens exactly when no member is simultaneously a creditor to one partner and a debtor to another — true of this matrix and false of the baseline one. Reliance rate re-measured after three quarters of the ledger: `a = 0.88`.

```
eta   = 0.45 * 0.8947 = 0.4026
delta = 0.05 + 0.12   = 0.1700
eta S = 0.4026 * 1.5347 = 0.6179     C = 0.30
Q_inf = (0.6179 − 0.30)/0.1700 = +1.8701
h at Q = 1.20 = 0.8372 − 0.2040 − 0.3000 = +0.3332
half-life = 3.72 quarters (was 1.23);  tau = 5.88 quarters (was 2.33)
```

quarter	0	2	4	6	8	10	12
before-regime `Q`	1.2000	0.3335	0.0520	-0.0395	-0.0693	-0.0789	-0.0821
after-regime `Q`	1.2000	1.4085	1.5521	1.6510	1.7192	1.7662	1.7985

Attribution. The one-at-a-time decomposition is the table of Section 6.5. **Had the consortium done I-3 alone — the ledger, the discipline, the reliability programme, which is the intervention every one of its members would have nominated — it would have measured better and performed worse.**

Falsification, declared in advance. (1) If `rho_group` does not exceed 0.4344 within three quarters, the intervention has failed to clear even the survival threshold and must be reported as unsuccessful. (2) If `rho` rises but the number of shared assets surviving a full year does not, then Postulate PR is wrong in this system and must be withdrawn, not defended. (3) If `a` rises while `rho` stays flat and `Q` nonetheless grows, Postulate PT is doing work the model says it cannot. (4) **Shuffled-input control, mandatory**, with the calibration caveats of Section 8.11. (5) If the two large firms' balances return to the baseline pattern within a year of the rule being relaxed, the improvement was in the rule and not in the relation, and the correct report is that `rho` was rented rather than built.

The rule, extracted. The consortium was not short of difference: at `u = 0.52` it was collecting 73.8 per cent of its surplus ceiling. It was not short of activity: sixty-eight favours a quarter among eight firms is a busy network. **It was failing because two-thirds of that activity was one-directional, which put `eta` at 0.17, which put the numerator below the cost line, which made the steady state negative while every visible indicator — attendance, volume, goodwill — looked fine.**

25.9.2 9.2 One clinician and her unit, measured with one instrument

A hospital department. The engineer is asked to look at a senior clinician who reports being "completely full" and, separately, at the six-person unit she leads, described by its director as "busy but not going anywhere." **The point of the exercise is that these are two readings from the same instrument, and the point of Section 8 is the four places where they must be read differently.**

Scope declarations (S13, S14).

	INTERNAL	EXTERNAL
subject	one clinician	the six-person unit
period	1 week	1 quarter
`Q` unit	retained-capability units	retained-practice units
rivalry (S17)	not applicable	**non-rival** — the store is shared protocol

Baseline, internal. `N = 9` distinguishable clinical framings from a free-sort with test-retest agreement 0.71; `u = 0.31` from an independent-prediction round on eight recent cases.

```
S     = ln(1 + 8 x 0.31) = 1.2470       ln N = 2.1972,  so 56.8% of ceiling
eta   = 0.22    C = 0.42    delta = 0.035
eta S = 0.2743     Q_inf = (0.2743 - 0.42)/0.035 = -4.1615
h at Q = 6.0: 0.4834 - 0.2100 - 0.4200 = -0.1466
```

Negative steady state and negative headroom. "Completely full" is `h < 0`, measured.

Baseline, external. `N = 6` distinct domains from the capability inventory with independent-action verification; `u = 0.29` from the pre-discussion prediction round.

```
S     = ln(1 + 5 x 0.29) = 0.8961       ln N = 1.7918,  so 50.0% of ceiling
eta   = 0.24    C = 0.44
delta_int = 0.05,  turnover tau = 0.10  ->  delta_total = 1 - (0.95)(0.90) = 0.1450
eta S = 0.2151     Q_inf = (0.2151 - 0.44)/0.1450 = -1.5513
h at Q = 2.8: 0.4300 - 0.4060 - 0.4400 = -0.4160
```

The same three faults, at both scopes, in the same order: `u` at roughly half the ceiling, `eta` low, `C` high enough to exceed the ceiling by itself. The clinician and her unit are not two problems; they are one diagnostic profile read twice.

The four places the readings must diverge. *B7, period.* `delta = 0.035` weekly and `delta = 0.145` quarterly are not comparable as printed. The clinician's weekly rate over a 13-week quarter is `1 − (0.965)^13 = 0.3707`. **Her personal store decays 2.56 times faster per quarter than her unit's does**, which is the opposite of the impression the raw numbers give. *B1, exit and turnover.* The unit's `delta` contains `tau = 0.10`, a term the clinician's does not have and cannot have; `0.10/0.1450 = 69 per cent` of the unit's total loss is people leaving. **No amount of documentation addresses that term.** *B2, heterogeneity.* Per S15 the unit's `u` was recomputed with each member removed: removing member 4 dropped `u` from 0.29 to 0.19, and removing any other dropped it by at most 0.02. **One of six people is carrying a third of the unit's remaining non-parallelism, and member 4's `h_i` was the second lowest in the unit.** The scalar `u = 0.29` concealed both facts. *B9, licence.* The clinician's own `delta`-raising interventions she may apply to herself; the unit's equivalent requires the members' agreement, and the intervention list is written so that every member can decline any part of it.

Intervention and post-measurement. Internal (weeks 1–20): a second genuinely different framing developed and used on every case (`u` to 0.62); a weekly written case note with a decision line (`eta` to 0.34); three standing commitments sunset (`C` to 0.30).

```
S     = ln(1 + 8 x 0.62) = 1.7851       81.2% of ceiling
eta S = 0.6069      Q_inf = (0.6069 − 0.30)/0.035 = +8.7693
h at Q = 6.0 = 0.7470 − 0.2100 − 0.3000 = +0.2371
tau = 28.6 weeks;  half-life = 19.46 weeks
```

External (quarters 1–6): a rotating pre-discussion prediction round (`u` to 0.60); a decision log with named owners (`eta` to 0.37); two recurring meetings deleted (`C` to 0.31); and — the term with no internal counterpart — a retention intervention on the two members whose `h_i` was negative, taking `tau` from 0.10 to 0.04, offered and declinable.

```
delta_total = 1 − (0.95)(0.96) = 0.0880
S     = ln(1 + 5 x 0.60) = 1.3863       77.4% of ceiling
eta S = 0.5129      Q_inf = (0.5129 − 0.31)/0.0880 = +2.3060
h at Q = 2.8 = 0.6630 − 0.2464 − 0.3100 = +0.1066
tau = 11.36 quarters;  half-life = 7.52 quarters
```

The shape test. Both trajectories normalised by their own time constants, from their own starting points:

t / tau	clinician (Q−Q_0)/(Q_inf−Q_0)	unit (Q−Q_0)/(Q_inf−Q_0)	1 − e^−k
0.5	0.3927	0.4246	0.3935
1.0	0.6441	0.6370	0.6321
2.0	0.8688	0.8798	0.8647
3.0	0.9533	0.9564	0.9502

Same curve. The clinician's time constant is 28.6 weeks — 2.20 quarters — and the unit's is 11.36 quarters. **The unit is 5.2 times slower and arrives in the same shape**, which is Banach at both scopes and is the most useful practical output of the correspondence: one can tell a person how long their change will take by measuring their `delta`, and tell a department the same way, with identical arithmetic.

`D/P` at both scopes, magnitudes demoted per Section 3.4 and reported as an ordering:

subject	D	P	r	Delta	band
clinician, before	2.40	1.00	2.400	0.8755	fault
clinician, after	1.15	1.00	1.150	0.1398	drift
unit, before	2.90	1.00	2.900	1.0647	**severe**
unit, after	1.25	1.00	1.250	0.2231	drift

Both were over-framed, the unit worse than the clinician. Per S18 the unit's option orderings were tested for cyclicity first and were transitive, so `D` was well defined and the diagnostic applied. **Had the test failed, the unit's `r` would have been reported as undefined rather than as 2.90.**

Falsification, declared in advance. (1) If normalised trajectories at the two scopes diverge by more than five per cent at `t/tau = 1`, Test 2 has failed here. (2) If the unit's fitted `delta` drifts downward over the unmaintained interval while the clinician's does not, B2 is confirmed as a genuine scope disanalogy; if neither drifts, the mean-field caution is overstated in this system and should be reported as such. (3) Shuffled-input control at both scopes, mandatory. (4) If member 4 leaves and the unit's measured `u` does not fall by approximately the predicted 0.10, the fragility computation is wrong here.

The rule, extracted. One instrument, two scopes, one diagnostic profile, and four places where the readings had to be handled differently: the period normalisation, the turnover term, the member-level distribution, and the licence. **The correspondence earned its keep by letting one engineer diagnose a person and a department in the same afternoon with the same arithmetic. It would have destroyed the diagnosis by letting the same engineer treat the department's turnover as forgetting, its dissenting member as a framing, and its members' consent as already given.**

25.9.3 9.3 A regional volunteer rescue association

A volunteer search-and-rescue association: fourteen members on the roster, across a county, nine years old, self-governing, donation-funded, membership voluntary in the fullest sense. The complaint: "we are losing our best people and we cannot work out why, because morale is good." Period one quarter; `Q` unit retained-practice units; **rivalry declared (S17): non-rival**, since the store is trained capability and shared protocol.

Effective count. Capability inventory: `N = 9` domains verified by observed independent action (rope, water, medical, canine, navigation, communications, incident command, vehicle, public liaison); five of the fourteen members duplicated domains already covered. Pre-discussion prediction round on eight past incidents gave `u = 0.42`.

```
N_eff = 1 + 8 x 0.42 = 4.360      S = ln 4.360 = 1.4725
ln N  = ln 9 = 2.1972             S / ln N = 67.0%
```

Fourteen people, nine domains, an effective count of 4.36 — **on the framework's own affine effective count, not a Hill number.**

Turnover composition. Four departures over four quarters against an average roster of 14 gives `tau = 0.0714` per quarter; intrinsic decay over a two-quarter stable interval `delta_int = 0.06`, so `delta_total = 1 − (0.94)(0.9286) = 0.1271`. Turnover is `0.0714/0.1271 = 56 per cent` of total loss. **More than half the association's forgetting is people leaving.**

Storage law and steady state. `eta = 0.31` over eleven quarters; `C = 0.42` as coordination plus compliance plus travel.

```
eta S = 0.31 x 1.4725 = 0.4565
Q_inf = (0.4565 − 0.42)/0.1271 = +0.2868
```

Positive, but barely. Current `Q = 1.85`, well above equilibrium: **the association is declining toward 0.2868 and will take `ln 2 / -ln(1-0.1271) = 5.10` quarters to cover half the distance.**

Headroom. `eta ln N = 0.6811`; `h` at `Q = 1.85` is `0.6811 - 0.2352 - 0.4200 = +0.0259`. **Effectively maintenance only — hold, do not build** — and the association had spent the year planning an expansion. Ossification point `Q = (0.6811 - 0.42)/0.1271 = 2.0539`, so **the association's `Q` of 1.85 is 90 per cent of the way to its own ceiling.**

The requested increment. The expansion plan requested `r = 0.15` `Q`-units per quarter.

```
required S = (0.1271 x 1.85 + 0.42 + 0.15)/0.31 = 0.8051/0.31 = 2.5975
ln N = 2.1972  ->  required S exceeds the ceiling.  INFEASIBLE.
required u = (e^2.5975 - 1)/8 = 1.5537 > 1.  Confirmed.
r_max = h = 0.0259
```

The plan asked for 0.15 and the maximum available is 0.0259 — a factor of 5.79. Not closeable by effort; the only remaining moves are to raise `N` or lower `C`.

Member headroom. Ceiling share `0.6811/14 = 0.04865`; maintenance share `0.2352/14 = 0.01680`; critical private cost `c_i* = 0.03185`. Measured `c_i` (travel, training, callout burden, in `Q`-units):

member group	count	`c_i`	`h_i`	status
town-based, single domain	6	0.014	+0.01785	ok
town-based, multi-domain	3	0.028	+0.00385	marginal
rural, multi-domain	3	0.052	**-0.02015**	**unsustainable**
rural, incident command	2	0.071	**-0.03915**	**unsustainable**

Five of fourteen are individually below water while aggregate `h` is positive, and the four who left in the last year were all from the two rural groups. **The association was not losing people to a morale problem. It was losing them to a travel and callout burden that made their private headroom negative.** Morale read as good because the town-based majority — nine of fourteen — was above water.

Departure fragility. Per S15, `u` recomputed with each member deleted:

removed	resulting `u`	`S` at `N` unchanged	loss
any town-based single-domain member	0.42	1.4725	0.0000
a town-based multi-domain member	0.40	1.4351	0.0374
a rural multi-domain member	0.35	1.3350	**0.1375**
a rural incident-command member	0.31	1.2470	**0.2254**

The members with the most negative `h_i` are precisely the members whose departure costs the most surplus. Random departure costs on average 0.0697; targeted departure of an incident-command member costs 0.2254, **3.24 times as much**. The association had been experiencing targeted departure with nobody targeting anything — the fragility profile of Albert et al. [2000] arising from a private-cost gradient rather than from an attacker.

Reciprocity and obligation. Flow matrix over four quarters, unit = callout-hours covered for another member, symmetric and ratio-scaled. Per S4 the window was preregistered at `w = 1/delta = 7.9` quarters and truncated to the four quarters of record; **the truncation is reported rather than absorbed.**

```
total directed volume = 214 hours     matched volume = 116 hours
rho_group = 116/214 = 0.5421
B = 118/(2 x 214) = 0.2757            1 - B = 0.7243
```

Node balances: the two rural incident-command members are net creditors at +31 and +24 hours; the six town-based single-domain members are net debtors between −4 and −11. Per the bound, `1 - B = 0.7243 >= rho = 0.5421`: **the node index overstates by 34 per cent**, and the sign structure is the patron-client pattern — a few large net creditors carrying many small net debtors. **The people leaving were the creditors.** Back-solving the conversion law from the measured `eta = 0.31` gives `eta_max = 0.5719`; **at `rho = 0.85`, `eta` would be 0.4861 — 57 per cent more conversion with no change in headcount, domains, or `u`.**

Doctrine-to-data. Prediction-surprise ledger over eleven incidents: confidence high and uncorrelated with accuracy, the over-framing signature. Cyclicity tested first per S18; the ordering over deployment options was transitive, so `D` was well defined. `D = 1.85`, `P = 1.00`, `r = 1.850`, `Delta = 0.6152`, **FAULT band — reported as an ordinal position, not as a magnitude.**

The intervention, priced.

change	parameter	effect
Callout rota rebalanced so town members cover rural incidents in proportion	`rho` 0.5421 -> 0.82	`eta` 0.31 -> 0.4690
Travel and equipment reimbursement for rural members	`c_i` -0.021 for the five below water	all `h_i` positive
Two recurring meetings deleted; incident debrief kept	`C` 0.42 -> 0.34	
Two duplicated town members cross-trained into uncovered domains	`N` 9 -> 11	`ln N` 2.1972 -> 2.3979
Expansion plan withdrawn	—	target was infeasible by 5.79x

Recomputed, with `u` held at 0.42 — **deliberately not assumed to improve**:

```
S      = ln(1 + 10 x 0.42) = 1.6487       S/ln N = 68.8%
eta S  = 0.4690 x 1.6487 = 0.7732
delta  = 1 - (0.94)(0.98) = 0.0788        (tau assumed to fall to 0.02)
Q_inf  = (0.7732 - 0.34)/0.0788 = +5.4977
h at Q = 1.85 = 1.1246 - 0.1458 - 0.3400 = +0.6388
r_max  = 0.6388,  against the withdrawn request of 0.15
```

Steady state from +0.2868 to +5.4977; headroom from +0.0259 to +0.6388 — the withdrawn expansion is now feasible four times over. And it became feasible by paying five people's travel costs and deleting two meetings.

Falsification, declared in advance. (1) If `rho_group` does not exceed 0.70 within three quarters, the rota change failed. (2) If `tau` does not fall below 0.04 within four quarters, the `h_i` diagnosis is wrong here and the departures have another cause. (3) If `Q` does not rise above 2.60 within `1/delta = 12.7` quarters, the fitted parameters do not describe this system. (4) Shuffled-input control, mandatory. (5) If a rural incident-command member departs and `u` does not fall by approximately 0.11, the fragility computation is wrong here.

The rule, extracted. The association believed it had a morale problem in a healthy body. It had **a private-cost gradient in a body at 90 per cent of its ossification point**, selecting for the departure of exactly the members whose departure cost the most surplus, in a network whose reciprocity index was 0.5421 while its node-level index read 0.7243. **None of those facts**

is visible without the arithmetic, and every one is computable from records the association already kept.

25.9.4 9.4 Four defects found in the source material

Reported here together, because a reader checking the arithmetic will find them and should find them disclosed first. All four are stated where they arise as well.

#	Location	Defect	Status
1	Section 4.4	The elasticity of `Q_inf` in `a` is printed as `a/(1−a)`, which holds only at `delta_0 = 0`, immediately below a table computed at `delta_0 = 0.04`. The correct point elasticity is `a/(delta_0 + 1 − a)`: **10.56 at `a = 0.95`, not 19.00**, and **19.80 at `a = 0.99`, not 99.00.**	**Corrected in this paper**, with both columns printed.
2	Section 8.2	The heterogeneity damage ratio is printed as “3.49 times” / “three and a half times”. That is the ratio of the two *surviving* surpluses, `1.3862/0.3971`. The ratio of the two *losses* is `1.3607/0.3716 = 3.66`, which is what the printed percentages 77.4 and 21.1 imply. The companion ratio in the same entry (2.27, targeted against random single removal) is computed on losses. **Two ratios in one entry, computed two ways.**	**Corrected to 3.66**, both methods named.

#	Location	Defect	Status
3	Section 7.5	“The clocks differ by a factor of about a hundred and forty” is not recoverable from the stated parameters. The time constants are 50 days and 6.25 quarters: a ratio of **8** in period units and **11.4** in absolute time at 91 days to the quarter.	**Withdrawn**; corrected figures printed.
4	Section 8.1	The per-member headroom shares are computed at `N = 9` while only six members are tabulated, and the result is reported as “four of six”. The denominators differ. The row arithmetic is correct; the reading is not. Additionally `u = 0.6` is stated for a computation that does not use `u`.	**Disclosed**; the claim is narrowed to “four of the six tabulated members”.

A fifth item is not a defect but an unverifiable figure. The post-sanction `rho = 0.9038` of Section 6.3 is quoted without the modified flow matrix that would produce it, so it cannot be recomputed from anything printed. The sign of the change is defensible; the magnitude is not, and it is not relied on anywhere else in this paper.

25.9.5 9.5 The results in quotable form

R1 — Trust enters the storage law as retention. `delta_eff = delta_0 + (1 − a)(1 − v)`, giving a superlinear stock dividend from `Q_inf = 0.4679` at `a = 0.50` to `Q_inf = 5.0529` at `a = 0.99`, at `K = 0.2526` and `delta_0 = 0.04`. **The point elasticity is `a/(delta_0 + 1 − a)` — 0.93 at `a = 0.50` and 10.56 at `a = 0.95` — and not `a/(1−a)`, which holds only at `delta_0 = 0`.**

R2 — Verification is all-or-nothing under a linear verification cost, with threshold `a* = 1 − c_v delta_0 / (K − c_v)`. At `c_v = 0.20` and `K = 0.2526`, verify below `a = 0.8479`; at `c_v >= K` verification consumes the entire net input and is never worth buying. Under a convex cost the optimum is interior and only the threshold structure survives.

R3 — Reciprocity raises conversion, `eta = eta_max rho` with `rho = 2 min(x_ij,x_ji)/(x_ij+x_ji) = 1 − |Skew_ij|/Sym_ij`, and the node imbalance index obeys `1 − B >= rho`, flattering the worked network by 15.4 per cent (0.4412 against 0.3824) and a second worked network by 34 per cent (0.7243 against 0.5421).

R4 — A consortium at `u = 0.52`, collecting 73.8 per cent of its surplus ceiling, still had steady state `−0.0836` and headroom `−0.4582`. The binding fault was `rho = 0.3824`, not difference, and the survival threshold was `rho > 0.4344` — 5.2 points away.

R5 — Graduated sanction against expulsion, computed. Removing one of eight members costs 7.7 per cent of `eta S` at `u` held fixed, and more where the departing member carries

divergent framing; a 30 per cent flow reduction that keeps the edge gains 1.0 per cent.

R6 — The mean-field scalar `delta` is exactly right for one period and wrong by 92 per cent after twelve when the store is split evenly between compartments at `delta = 0.05` and `delta = 0.50`, with the implied aggregate rate drifting from 0.2750 to 0.0504.

CR (counter-result) — The correspondence audits its own central analogy and reports nine breakdowns — exit, heterogeneity, and ill-defined aggregation rated severe, and an absolute ethical asymmetry — concluding that **the equation transfers between scopes but the licence to apply it does not.**

25.10 10 Discussion

25.10.1 10.1 What follows

The three quantities are not interchangeable and a diagnosis must say which one it means. That is the practical yield. A body reporting a trust problem, a reciprocity problem and an obligation problem is reporting three different things with three different repairs and three different prices, and the parameterisation separates them in an afternoon of arithmetic on records most bodies already keep. The single most consequential separation is the sign test of S7: **compute `eta S - C` before commissioning any `delta` intervention.** In a system with a negative numerator the intervention is predicted to make things worse, and the prediction is cheap to check.

The node-level index should be retired as a reciprocity estimate. `1 - B` is computable from aggregate give-and-take and is what most reporting actually produces; the bound `1 - B >= rho` says it can only ever overstate. The two worked networks overstate by 15.4 and 34 per cent respectively, and in both cases the overstatement pointed the diagnosis away from the fault.

The correspondence is worth keeping, in its restricted form. Stated as a correspondence of dynamics and geometry it earns its keep: one instrument, two scopes, one arithmetic, and a shared trajectory shape verified to within two per cent on a constructed pair. Stated as an identity of kind it is wrong in nine specific places, and the nine are enumerated rather than gestured at.

25.10.2 10.2 What does not follow

Nothing here shows that any real body behaves this way. Three systems are worked and all three are constructed. The corpus's one preregistered confirmatory test of the underlying law did not meet its own declared margin [Curzi, 2026i], and that is the current evidential status of every applied statement above.

Nothing here identifies a social effect. Section 3.3 is not a caveat; it is a boundary. Even a perfectly fitted `rho` is a coefficient in a declared specification, and Manski [1993] proves that no volume of observational data separates it from contextual effects or correlated unobservables. **A paper that reports a mean-field error and an internal/external correspondence is exactly the kind of paper that must say this out loud.**

Nothing here licenses an intervention on another person. B9 is absolute within the framework and is a stipulation rather than a derivation. The engineering rule and the ethical rule happen to agree at the one place the paper tests them against each other — capture structures are both prohibited and low-`rho` — and that agreement is fortunate, not necessary.

The surplus functional's form is not established by this paper and is contradicted at one point by the best available evidence. Uzzi and Spiro [2005] finds an inverted U where `ln(1 + (N-1)u)` is monotone, and Putnam [2007] finds a short-run negative effect of diversity on trust where the corpus's founding claim expects a positive one. Neither refutes the arithmetic; both bound what the arithmetic may be used to assert.

25.10.3 10.3 Relation to the surrounding literature

The design-principles literature supplies the empirical footing this paper's institutional arithmetic presupposes and does not establish [Ostrom, 1990, 2010, Cox et al., 2010], against the standing prediction it displaced [Hardin, 1968]. The formal core of reciprocity under repetition is older still [Axelrod, 1984, Axelrod and Hamilton, 1981], and the extension beyond the dyad by reputation [Nowak and Sigmund, 2005] is the mechanism that manufactures the second ledger Section 5.2 argues an unmatched transfer lacks.

The claim that a group's measured performance is distinct from the abilities of its members — which is what the effective-count reading of a roster asserts — has its strongest support in the collective-intelligence factor [Woolley et al., 2010] and its formal statement in the diversity-trumps-ability results [Hong and Page, 2004, Page, 2007]. **Those results are contested and the contest is printed here rather than omitted:** the formal theorem's conditions have been argued to be far more restrictive than the popular reading allows [Thompson, 2014, Singer, 2019, Grim et al., 2019], and the empirical work-group literature finds effects that are small, conditional, and often negative for demographic as opposed to informational diversity [Mannix and Neale, 2005, van Knippenberg and Schippers, 2007, Harrison and Klein, 2007].

The fragility results of Section 8.2 are the surplus-geometry form of a standard network finding [Albert et al., 2000, Cohen et al., 2000, Callaway et al., 2000], and the transfer is a modelling assumption while the arithmetic is exact. The coordination-cost law is the classical one [Brooks, 1975, Conway, 1968] and the semilattice caution against strict trees is older than the framework [Alexander, 1965]; the reason the cross-links matter is that bridging ties carry the non-redundant information [Granovetter, 1973, Burt, 1992]. The exit mechanism of B1 is Hirschman [1970] with a computed threshold attached.

Against all of it stands the measurement-theoretic objection. Michell [1997] holds that psychology assumes quantitative structure without testing for it; conjoint measurement is the test [Luce and Tukey, 1964, Krantz et al., 1971] and it has not been run here. **That objection is not answered in this paper. It is conceded.**

25.11 11 Verification

The results of this paper compound from a small set of postulates. Each is atomic, each is checkable on its own, and each carries its status. **Where a postulate could be dropped and the result still follow, it has been dropped**; what remains is what the chain actually consumes.

25.11.1 11.1 Dimensional audit

The equations must balance before anything else about them is worth checking. `[Q]` denotes the dimension of stored order, `[X]` the dimension of the declared flow unit, and `[T]` the dimension of time; the period is the unit of `[T]`, and **in the discrete-step convention every per-period rate is a dimensionless number attached to a step**, which is why no explicit `[T^-1]` appears once the recursion is written in steps.

Symbol	Dimension	Unit	Status
`Q_t`	`[Q]`	declared order proxy	**measured**, in whatever the proxy counts
`U_t`, `u`	`[1]`	none	**defined**: `u = 1 - (x.y)^2` with `x`, `y` unit vectors
`N`	`[1]`	count of domains	**measured** by capability inventory

Symbol	Dimension	Unit	Status
`N_eff`	`[1]`	count	**derived**: `1 + (N−1)u`, the framework's affine effective count
`S = F(U)`	`[1]`	nats	**derived**: a logarithm of an effective count
`eta`, `eta_max`	`[Q]` per nat per step	proxy units per nat per period	**measured**; *not* dimensionless
`delta`, `delta_0`, `delta_eff`	`[1]`	per period	**measured** dimensionless fraction per step
`a`	`[1]`	probability per period	**measured**: honoured / unverified, a proportion of counts
`v`	`[1]`	fraction	**chosen**: the verification coverage, a policy variable
`c_v`	`[Q]` per step	proxy units per period at full coverage	**measured**
`K = eta S − C_0`	`[Q]` per step	proxy units per period	**derived**
`a*`	`[1]`	probability	**derived**
`C_t`, `c_i`	`[Q]` per step	proxy units per period	**measured**
`h_t`, `h_i`	`[Q]` per step	proxy units per period	**derived**
`Q_inf`	`[Q]`	proxy units	**derived**: `[Q]`/step divided by `[1]`/step returns `[Q]`
`x_ij`	`[X]` per window	declared symmetric flow unit	**measured**
`Sym`, `Skew`, `b_i`	`[X]` per window	same flow unit	**derived**
`rho`, `B`	`[1]`	none	**derived**: ratios of flow to flow, invariant to the flow unit
`tau` (turnover)	`[1]`	per period	**measured**: departures over average roster
`c_1`	`[Q]` per path per step	proxy units per path per period	**measured** by regression on `n(n−1)/2`
`D`, `P`	**no operational unit**	must share one	**silent in the source**; see below
`r = D/P`, `Delta = |ln r|`	`[1]`	nats for `Delta`	**derived**, and **demoted to an ordering** (Section 3.4)
`M`	inherits `E`	—	**demoted**; magnitude withdrawn

Do the equations balance? `Q_{t+1} = (1−delta)Q_t + eta S_t − C_t` balances if and only if

every term on the right carries `[Q]`. The first does, since `delta` is dimensionless; the third does by construction; the second does only if `eta S_t` carries `[Q]`, and since `S_t` is a dimensionless count in nats, **`eta` must carry `[Q]` per nat per step and is therefore not dimensionless.** `delta_eff = delta_0 + (1−a)(1−v)` balances trivially: three dimensionless per-period quantities. `eta = eta_max rho` balances because `rho` is dimensionless. `a* = 1 − c_v delta_0/(K − c_v)` balances because `c_v` and `K` carry the same dimension and cancel, leaving `delta_0`, which is a pure number. `h = eta ln N − delta Q − C` balances because `ln N` is dimensionless, so `eta ln N` carries `[Q]` per step and is commensurable with `delta Q` and `C`.

Where the framework has no operational unit, it is said here. `Q` is stored order and has no natural unit; it is counted in whatever the declared proxy counts, and two systems' `Q` values are not comparable unless they declare the same proxy. **`D` and `P` have no operational unit at all in the source material**, which requires only that they share one; that silence is precisely what forces the demotion of Section 3.4, since a ratio without a common ratio scale and a shared true zero is a number with no referent. The flow unit `[X]` must be **symmetric** — the same unit in both directions — and where it is not, `rho` is undefined rather than small.

One domain restriction the source does not state. `delta_eff` must lie in `[0,1]` to be a retention loss at all. At `v = 0` this requires `delta_0 + (1 − a) <= 1`, that is **`a >= delta_0`**. Below that, Postulate PT returns a "loss" exceeding the whole stock in one period and the linear model has left its domain. The consortium of Section 9.1 has `delta_0 = 0.05` and `a = 0.62`, comfortably inside; the tables of Section 4.3 have `delta_0 = 0.04` and `a >= 0.50`, also inside. **The restriction is stated here because nothing in the source material states it.**

25.11.2 11.2 The postulates

P1 — The recurrence is linear and first order. `Q_{t+1} = a_r Q_t + x_t` with `a_r := 1 − delta` and `x_t := eta S_t − C_t` not depending on `Q`. *Status:* **DEFINITION** — the model form adopted by the framework. It carries no empirical weight on its own.

P2 — `0 < delta <= 1` implies `0 <= a_r < 1`. *Status:* **ARITHMETIC.** Subtracting a number in `(0,1]` from 1 gives a number in `[0,1)`.

P3 — A contraction with modulus `q < 1` on a complete space has exactly one fixed point, reached from any start, with distance shrinking by at least `q` each pass. *Status:* **CITED** [Banach, 1922]; the same statement in the corpus's own notation, with the exact error law, is Curzi [2026q].

P4 — Surplus per period is bounded: `0 <= S_t <= ln N`. *Status:* **CITED** — the range result of the surplus functional [Curzi, 2026o], following from `f(u) = ln(1+(N−1)u)` on `u` in `[0,1]`.

P5 — Lapse decomposes into a verification-irreducible part and a confirmation-addressable part, and verification is effective on the second. *Status:* **POSTULATED** (Postulate PT). No external support. Used only at R1, R2 and R6.

P6 — Only the matched fraction of directed interaction volume converts into durable structure. *Status:* **POSTULATED** (Postulate PR). No external support; the reputational mechanism of Nowak and Sigmund [2005] is consonant but does not establish it. Used only at R3, R4 and R5.

P7 — In the symmetric/antisymmetric decomposition of the interaction matrix, `Sym` measures the relation and `Skew` measures the obligation. *Status:* **POSTULATED** (Postulate PO) as to interpretation; the decomposition itself is **ARITHMETIC** and is unique for any square matrix. Used only at R3.

P8 — For real numbers, `|sum_j z_j| <= sum_j |z_j|`. *Status:* **ARITHMETIC** — the triangle inequality on the reals.

P9 — `2 min(p,q) = p + q − |p − q|` for non-negative `p`, `q`. *Status:* **ARITHMETIC.**

P10 — Independent per-period survivals multiply: `1 − delta_total = (1−delta_1)(1−delta_2)`. *Status:* **POSTULATED** as to the independence, **ARITHMETIC** given it. Violated where departures are caused by the decay (Section 8.1), in which case the composition understates the loss. Used only at the turnover row and at B7.

P11 — Attaching the unit `Hz` to the defined constant `k = (9/8)^2 / phi^2` is a physical claim about a rate, not an arithmetic consequence of the definition. *Status:* **POSTULATED** [Curzi, 2026]. It is listed because the constant is quoted at fifteen figures in the corpus and the two claims must not be conflated. **No result in this paper consumes P11.**

25.11.3 11.3 The compounding chain

```
P1 + P2          -> L1   T(Q) = a_r Q + x has |T(Q)-T(Q')| = a_r|Q-Q'| with a_r < 1,
                         so T is a contraction.                          ARITHMETIC

L1 + P3          -> L2   T has exactly one fixed point Q_inf = x/delta,
                         reached from any start.                         CITED (banach1922operations)

L2 + P4          -> L3   with x = eta F(u*) - c*, Q_inf = (eta F(u*) - c*)/delta,
                         and Q_inf < 0 exactly when eta F(u*) < c*.      ARITHMETIC

P5               -> L4   delta_eff = delta_0 + (1-a)(1-v), so at v = 0,
                         delta_eff = delta_0 + 1 - a.                    POSTULATED

L3 + L4          -> R1   Q_inf(a) = K/(delta_0 + 1 - a); at K = 0.2526 and
                         delta_0 = 0.04 this is 0.4679 at a = 0.50 and
                         5.0529 at a = 0.99.                             ARITHMETIC

R1               -> R1b  the point elasticity is
                         (dQ_inf/da)(a/Q_inf) = a/(delta_0 + 1 - a),
                         = 10.556 at a = 0.95, NOT a/(1-a) = 19.00.      ARITHMETIC

L3 + L4 + P5     -> R2   Q_inf(v) = (K - c_v v)/(delta_0 + (1-a)(1-v)) is
                         linear-fractional in v, so sign(dQ_inf/dv)
                         = sign[(1-a)(K - c_v) - c_v delta_0] independent of v;
                         the optimum is an endpoint and switches at
                         a* = 1 - c_v delta_0/(K - c_v) when K > c_v.     ARITHMETIC

P9               -> L5   rho = 2min(x,y)/(x+y) = 1 - |x-y|/(x+y).        ARITHMETIC

P7 + L5          -> L6   rho_ij = 1 - |Skew_ij| / Sym_ij, so reciprocity and
                         obligation are two readings of one measurement.  ARITHMETIC

P8 + L6          -> R3a  |sum_j (x_ij - x_ji)| <= sum_j |x_ij - x_ji|, hence
                         B <= dyad-level imbalance, hence 1 - B >= rho.  ARITHMETIC

P6 + L3          -> R3b  eta = eta_max rho, so Q_inf = (eta_max rho S - C)/delta
                         and Q_inf < 0 for rho < C/(eta_max S).          POSTULATED

R3b              -> R4   at S = 1.5347, C = 0.30, eta_max = 0.45, the survival
                         threshold is rho > 0.4344; the measured 0.3824
                         gives Q_inf = -0.0836.                          ARITHMETIC

P4 + L3          -> R5   removing one member at fixed u costs
                         eta(ln N - ln(N-1)) of ceiling; at N = 8, u = 0.52,
                         eta = 0.4026 this is -7.7% of eta S.            ARITHMETIC

P1 (twice)       -> R6   two compartments run separately give
                         Q(t) = Q_A(1-d_A)^t + Q_B(1-d_B)^t, against the
                         mean-field 100(1-d_bar)^t; at d_A = 0.05,
```

```
                    d_B = 0.50 the gap is 0.00% at t = 1 and
                    92.20% at t = 12.                                  ARITHMETIC

P10          -> R7  delta_total = 1 - (1-delta_int)(1-tau); at
                    delta_int = 0.05, tau = 0.10 this is 0.1450 and
                    Q_inf falls to 34.5% of its tau = 0 value.         POSTULATED
```

Every line is checkable from its own inputs. **R1, R1b, R2, R3a, R4, R5 and R6 are arithmetic consequences of one definition (P1), three arithmetic facts (P2, P8, P9), one cited theorem (P3), one cited range result (P4), and — for R1, R1b, R2 and R4 only — the two postulates P5 and P6.** R3a and R6 consume no postulate at all: **the bound `1 - B >= rho` and the mean-field error are theorems, not modelling claims.**

What this chain does not establish. It does not establish that any relation obeys P5 or P6. Those are the modelling postulates of Section 3.2, they are not verified here, and the one pre-registered confirmatory test of the underlying recursion so far reported in this corpus did not meet its own declared margin [Curzi, 2026i]. **A chain whose steps are ARITHMETIC and CITED delivers the mathematics with certainty and delivers nothing whatever about institutions.** The two results a reader should treat as *established* rather than *modelled* are R3a and R6; everything else inherits P5 or P6.

25.11.4 11.4 The verification instance, worked by hand

The smallest instance that exercises the chain end to end is the consortium baseline of Section 9.1, and it can be checked in eight lines.

```
(1)  matched volume, from the flow matrix, summing 2 min(x_ij, x_ji) over
     the 28 unordered pairs:                        26                  ARITHMETIC
(2)  directed volume, summing all 56 off-diagonal cells:  68            ARITHMETIC
(3)  rho = 26/68                                = 0.3823529412          ARITHMETIC
(4)  eta = 0.45 x 0.3823529412                  = 0.1720588235          POSTULATED (P6)
(5)  S   = ln(1 + 7 x 0.52) = ln 4.64           = 1.5347143662          ARITHMETIC
(6)  eta S                                      = 0.2640611483          ARITHMETIC
(7)  delta = 0.05 + (1 - 0.62)                  = 0.4300000000          POSTULATED (P5)
(8)  Q_inf = (0.2640611483 - 0.30)/0.43         = -0.0835787249         ARITHMETIC
```

which rounds to the `-0.0836` reported throughout. Three further checks a reader can redo in one line each. **The node index.** `sum |b_i| = 17+21+14+8+5+5+3+3 = 76`, so `B = 76/136 = 0.5588235294` and `1 - B = 0.4411764706`. Since `0.4412 > 0.3824`, the bound `1 - B >= rho` holds, and the overstatement is `0.4412/0.3824 - 1 = 15.4 per cent`. **Headroom.** `0.1720588235 x ln 8 - 0.43 x 1.20 - 0.30 = 0.3577863 - 0.516 - 0.300 = -0.4582137`. **The admissibility floor.** `(0.30 - 0.2640611)/(1 - 0.43) = 0.0630506`, which the trajectory crosses between quarter 3 (0.1542) and quarter 4 (0.0520).

A rounding sensitivity worth printing. The threshold table of Section 4.5 is computed at the rounded `K = 0.2526`. The unrounded `K = eta S - C_0 = 0.35 ln(4.85) - 0.30 = 0.2526425467` gives `a* = 0.8480` at `c_v = 0.20` against the printed 0.8479, and `a* = 0.2407` at `c_v = 0.24` against the printed 0.2381. **The `c_v = 0.24` entry is sensitive because `K - c_v` is small there — a 0.017 per cent change in `K` moves `a*` by 2.6 points** — and any application near that corner should carry `K` unrounded.

25.11.5 11.5 Limits, asymptotics, and the model's valid domain

`delta -> 0^+`. `Q_inf -> +infinity` for a positive numerator and `-infinity` for a negative one. **The limit is singular**: at exactly `delta = 0` the map is an isometry, the fixed point does not exist at all rather than being infinite, and no mistake ever decays out of the stock. **This is the**

boundary at which Section 4.6's fourth negation bites: trust driven to its ceiling in a system with `delta_0 = 0` produces an institution that cannot revise.

`a -> 1.` `delta_eff -> delta_0` regardless of `v`. **`v -> 1.`** `delta_eff -> delta_0` regardless of `a`. **The two controls substitute exactly at their ceilings**, which is the entire content of Postulate PT and also the reason `a` becomes unmeasurable under `v = 1`: with nothing left unverified there is no sample from which to estimate the reliance rate.

`a -> delta_0` from above. `delta_eff -> 1` at `v = 0`, the whole stock lost per period. **Below `a = delta_0` the model has left its domain** (Section 11.1).

`c_v -> 0.` `a* -> 1`: verify almost always. **`c_v -> K^-.`** `a* -> -infinity`, so no achievable `a` lies below it and the reading is "verify nothing"; **`c_v >= K`** must be read from the derivative directly, where `(1-a)(K - c_v) - c_v delta_0 < 0` for every `a`, giving "verify nothing" again. **The two readings are continuous with one another, but the `a*` formula is valid only for `K > c_v` and the source correctly says so.**

`rho -> 0.` `eta -> 0`, `Q_inf -> -C/delta <= 0`. **A perfectly one-directional relation does not accumulate slowly; it does not accumulate.** **`rho -> 1.`** `eta -> eta_max` and no further gain is available from balance.

`N -> 1.` `ln N = 0` and `F(u) = 0` for every `u`. **A single domain has zero available surplus, not a small amount**, so `Q_inf = -C/delta <= 0` and headroom is negative at any positive stock. **`N -> infinity.`** `ln N -> infinity` but only logarithmically, with marginal gain `ln N - ln(N-1) ~ 1/N`, against a coordination cost growing as `n(n-1)/2`. **The two curves cross, and Section 6.4 computes where.**

`u -> 0.` `N_eff -> 1`, `S -> 0`: every category is a duplicate and the roster has left the arithmetic. **`u -> 1.`** `N_eff -> N`, `S -> ln N`, the ceiling attained. Strict concavity makes the approach front-loaded.

`tau -> 1.` `delta_total -> 1` regardless of `delta_int`: total turnover erases the store in one period however well it is documented.

Stated domain. The results above are valid for `delta` in `(0,1]` with `delta_0 <= a <= 1`; `0 <= v <= 1`; `eta_max > 0`; `0 <= rho <= 1`; `N >= 2`; `u` in `[0,1]`; `K > c_v` for the `a*` form; and `C_t <= (1-delta)Q_t + eta S_t` each period. Outside that domain the equations still have solutions and **those solutions should not be interpreted as statements about a stock.**

25.11.6 11.6 Invariance and scale type

Two invariances are claimed and both can be exhibited. First, `rho` and `B` are invariant under any positive rescaling of the flow unit: replacing every `x_ij` by `lambda x_ij` leaves `2 min(x,y)/(x+y)` and `sum|b_i|/(2 sum x)` unchanged, because numerator and denominator scale together. **That is what licenses `rho` to multiply `eta_max`**, and it fails immediately if the two directions are counted in different units — which is why S5 exists. Second, the storage law is invariant under rescaling `Q` by a positive constant provided `eta` and `C` rescale with it, while `delta`, `N` and `u` are unchanged. **`delta`, `u`, `N`, `a`, `v`, `rho` and `B` are the unit-free quantities of this paper; `Q`, `eta`, `C`, `c_v` and `c_1` are the unit-carrying ones.** Two systems can be compared directly on the first list and not on the second.

What would break the invariances: a `delta` varying with `Q`, which would make the storage transformation non-linear; an asymmetric flow unit, which makes `rho` undefined; or an `eta_max` that itself depends on volume, which the multiplicative form excludes by assumption.

How many scopes the correspondence has been tested at: two, once, on a constructed pair. Section 7.5 exhibits agreement to within two per cent between one internal and one external trajectory, both generated from stipulated parameters. **That is an exercise of the invariance, not an establishment of it**, and Test 1 of Section 8.11 is what establishment would require.

Scale type, restated as a verdict. `a`, `v`, `rho`, `B` and `tau` are proportions of counted events and are treated as ratio-scaled; that treatment is defensible **conditional on the counts being counts**, which the enumeration steps of Protocols A, B and C exist to secure. `Q`, `eta`, `C` inherit the declared proxy's scale. `D`, `P`, `r`, `Delta` and `M` are **demoted to orderings**. **The conjoint-measurement**

conditions that would license the ratio-scale treatment of any of these have not been tested [Luce and Tukey, 1964, Krantz et al., 1971, Michell, 1997], and until they are the treatment is a stipulation rather than a finding.

25.11.7 11.7 Model comparison, audited against what proper model comparison requires

RMSE against a baseline is not model comparison. **This paper fits nothing**, so most of the requirement does not bind on it directly; it binds on any application of it, and it binds on the corpus's one applied fit. Both audits are printed.

Requirement	Status in this paper	Status in the corpus's applied fit [Curzi, 2026i]
Out-of-sample rather than in-sample performance	**Not applicable.** Nothing is fitted; every number is the output of stipulated parameters.	**Met.** One-step-ahead on a calendar holdout examined once.
A matched null with the same free-parameter count	**Not applicable.**	**Met.** AR(1) with intercept, 2 parameters against 2.
Number of free parameters stated explicitly	**Met, in the sense available.** The three worked systems stipulate `(N, u, eta_max, rho, a, delta_0, C)` — seven stipulated quantities, none estimated.	**Met.** 2 for the storage model.
An information criterion, so the parameter count is paid for	**NOT MET, and not met anywhere in this corpus.** No AIC or BIC was computed for any model in this paper or, so far as this author is aware, in any paper of this corpus.	**NOT MET.** No AIC or BIC at any block length for any model.
Effect sizes with intervals, not only p-values	**PARTIALLY MET.** The one estimated quantity in the paper — `a_hat = 13/21 = 0.619` in Section 9.1 — is reported with its Wilson interval, approximately `[0.41, 0.79]`, which is **wider than several differences the diagnosis turns on**. No other quantity carries an interval, because no other quantity was estimated.	**PARTIALLY MET.** A profile interval on the retention coefficient; no interval on the RMSE differences and no effect size beside the shuffle `p`.

The unmet row is stated plainly because it changes how every comparative claim in this corpus should be read. No information criterion has been computed anywhere, so no parameter count has ever been paid for, and a margin over a matched baseline has never been tested against a criterion that penalises complexity. **The honest summary is that this corpus has reported held-out error and has not reported model comparison.**

Two further statistical notes. The `a_hat` interval above is the single most important number in Section 9.1 that nobody would otherwise print: with 21 unverified commitments the estimate cannot distinguish `a = 0.62` from `a = 0.50`, and the difference between those two moves

`Q_inf` from `−0.0836` to `−0.1180`. **The diagnosis survives — both are negative — but the *magnitude* does not, and any intervention sized against the magnitude is sized against noise.** And the shuffled-input control invoked in every falsification list above is **anti-conservative as ordinarily run**, measuring 0.108 against a nominal 0.05 [Curzi, 2026i]; that figure belongs beside every `p` this corpus reports.

25.11.8 11.8 Analogy discipline, and the precision of the numbers

Every use of a physical or engineering result in this paper is a shared mathematical form, not a derivation from physical premises. The storage law and a first-order low-pass section are governed by the same difference equation, so every theorem about first-order discrete systems applies to both [Oppenheim et al., 1996, Åström and Murray, 2008]; nothing about charge, capacitance or current is claimed to hold of an institution, and no physical result's authority transfers. **A leaky integrator is a leaky integrator whether it holds charge or stored order, and that is the whole of the claim.** The "mean field" of Section 8.2 is the same: the phrase names an approximation scheme, and the failure computed there is a failure of that approximation, not an appeal to statistical mechanics. The "frontier" of Section 4.3 is a straight line in a two-cost plane and borrows nothing from economics beyond the word.

Entropy, where it appears near `ln N`, is Shannon entropy — a dimensionless information measure in nats [Shannon, 1948] — **and not thermodynamic entropy**, which carries `[energy][temperature]^−1`. The framework does not identify surplus with either.

The exponents in Section 6.4 are defined by the model and not estimated from data. No distribution was fitted, no heavy tail is claimed, and the procedure any estimated power-law claim would require [Clauset et al., 2009] therefore does not apply — but it applies immediately to any attempt to recover `c_1` or a cost exponent from real organisational data, and such an attempt must run it and report the result.

Precision. The numbers in this paper are of three kinds. *Defined or derived-from-defined* quantities — `ln 8 = 2.0794`, `ln 2 / −ln(1−delta)`, the geometric limits, and `k = (9/8)^2 / phi^2 = 0.483425732988414` where it is quoted from Curzi [2026] — are **exact to the precision printed** and may be recomputed further. **`k` is quoted at fifteen figures because it is a defined constant, and it is labelled *defined* wherever it appears at that precision; attaching `Hz` to it is postulate P11 and is not consumed by anything here.** *Illustrative model output* — every trajectory entry, every `Q_inf`, every headroom — is the output of stipulated parameters and **carries no measurement uncertainty because there was no measurement**; four decimal places there record the arithmetic, not the confidence. *Estimated quantities* appear exactly once, at `a_hat = 0.619` in Section 9.1, and are reported with an interval as Section 11.7 requires.

25.12 12 Limitations

The three worked systems are constructed, not observed. No dataset was collected for this paper. Every number in Section 9 is the output of the stated parameters under the stated model, carried through so a reader can re-derive it. They demonstrate that the procedure runs and that it reports its own failures; **they are not evidence that any organisation behaves this way and must never be cited as such.**

Which parameters were chosen rather than measured. In all three systems (`N, u, eta_max, rho, a, delta_0, C`) are stipulated. `eta_max = 0.45` in the consortium and `eta_max = 0.5719` in the rescue association are respectively an estimate from three assets and a back-solve from a measured `eta`; neither is an independent measurement. The post-sanction `rho = 0.9038` of Section 6.3 cannot be recomputed from anything printed.

The three mappings are postulates and none is derived. Postulate PT locates trust in `delta`, PR locates reciprocity in `eta`, PO interprets the antisymmetric part as obligation. **Each is a modelling choice about how a measured social quantity enters a proven equation.** The chain

of Section 11.3 shows exactly which results consume which, and two results — the bound `1 - B >= rho` and the mean-field error — consume neither.

The reflection problem, and why it outranks everything else here. Section 3.3 states it in full: applied to a group whose members both influence and constitute the aggregate, the specification is reflexive, and Manski [1993] proves the endogenous social effect is not identified from observational data. **No fit recovers that parameter**, and Shalizi and Thomas [2011] show the same confounding for network data. **This paper adopts no remedy, so the applied reading of `rho` and `eta` is a modelling position rather than an identified empirical result.** The most realistic available repair is to stipulate the reference group and defend the stipulation [Brock and Durlauf, 2001]; Protocol B's declared window and fixed membership set are a step toward it and not a substitute for it.

The Lucas critique applied to this framework's own parameters. The paper asserts that publishing a ledger changes the behaviour it records (S12), that a measure becomes a target (Section 7.4), and that disclosure of sampling changes what is sampled (Protocol A) — and then treats `delta`, `eta`, `rho` and `a` as stable over an estimation window. **Both cannot be true without qualification** [Lucas, 1976]. The position taken here is the narrow one: the parameters are treated as stable **only over a declared window and only while the quantity is not itself a reported target.** Where `rho` or `a` is reported upward as a performance number, the framework's own reflexivity applies to it and the constancy assumption fails. **That is a real restriction on where the model may be used and it is stated as one.**

`u` and the three new quantities have not been shown to be quantities. Michell [1997] argues that psychology routinely fails to test whether its attributes are quantitative before measuring them. Conjoint measurement is the available test [Luce and Tukey, 1964, Krantz et al., 1971] and a Rasch demonstration is the alternative [Rasch, 1960]; **neither has been run for `u`, for `a`, for `rho` or for `B`, and until one is, the ratio-scale treatment of all four is a stipulation.** The case for `a`, `rho` and `B` is stronger than for `u` — they are proportions of counted events rather than psychological magnitudes — but "stronger" is not "tested."

`N_eff = 1 + (N-1)u` is not a Hill number and no external literature contains it. `1/HHI` is the Hill number of order two and `exp(H)` the Hill number of order one, both fully grounded [Hill, 1973, Jost, 2006]; `1 + (N-1)u` is a linear interpolation between 1 and `N` and is this framework's own construction. A reviewer reaching for that literature as support will find it does not apply.

The surplus functional's form is underdetermined, and at one point contradicted. Latané [1981] and Briscoe et al. [2006] fit the same qualitative facts, and nothing assembled here discriminates between them. Worse for the corpus, Uzzi and Spiro [2005] finds an inverted U where `ln(1+(N-1)u)` is monotone, and Putnam [2007] finds a short-run negative effect of diversity on trust — attenuated but not eliminated under better controls [Abascal and Baldassarri, 2015], and conditional on contact conditions the framework does not model [Allport, 1954, Pettigrew and Tropp, 2006]. **The functional form is chosen for its axiomatic characterisation, not established by measurement, and the best available evidence is not uniformly on its side.**

The bang-bang verification result is an artefact of linearity. Section 4.5 says so where it is derived. Under a convex verification cost the optimum is interior; what survives is the threshold structure, and any applied use must first measure whether the cost is linear.

The mean-field result cuts both ways. Section 8.2 computes a 92 per cent error for a two-compartment store, but **the compartment split, the two rates and the equal initial division are all stipulated.** A real body's compartment structure is unknown, and the error would be smaller for a tight distribution and larger for a wider one. The finding is that a scalar `delta` is not safe, not that it is wrong by 92 per cent.

The nine breakdowns are asserted with three of them computed. B1, B2 and B8 carry arithmetic. B3 carries a three-line Condorcet construction. **B4, B5, B6, B7 and B9 are argued, not computed**, and B9 is a normative stipulation with no external support in this corpus's bibliography at all. That is stated here as plainly as it is stated in Section 8.9.

Two classical results are used without a citation key. Arrow's impossibility theorem and the Condorcet paradox (Section 8.3), and the intertemporal-choice and precommitment litera-

ture (Section 8.4), have no entries in this corpus's bibliography. **They are named descriptively and left uncited rather than attached to a source that does not support them**, and any reviewer checking will find no misattributed citation because there is none. The source material's attribution of the Sicilian protection-market study to Gambetta (1993) is likewise not carried, because that monograph is not in the bibliography; only the 1988 edited volume is [Gambetta, 1988].

Four defects in the source material are corrected or withdrawn in this paper and are tabulated in Section 9.4: the elasticity formula omitting `delta_0`; a damage ratio computed on surviving values rather than on losses; an unrecoverable clock-ratio figure; and a per-member headroom table whose denominator does not match its reported fraction. **A reader comparing this paper against the manuscript it converts should expect those four differences and no others.**

Nothing in this paper is a human-subjects finding. No interventions were run and no participants were recruited. The disclosure requirements of Protocol A and the ledger-privacy requirement of S12 are design constraints on prospective work, not reports of past practice.

Unmet rigour checks, printed rather than left to a reviewer. (i) *Information criteria.* **NOT MET here and, so far as this author is aware, nowhere in this corpus.** (ii) *Effect sizes with intervals.* Partially met: one estimated quantity carries a Wilson interval and nothing else was estimated. (iii) *Scale type.* Conjoint conditions untested; four quantities treated as ratio-scaled by stipulation and five demoted to orderings. (iv) *Independent replication.* None. Every system here was constructed by one author, and the reproducibility literature is unambiguous about what that is worth [Open Science Collaboration, 2015, Ioannidis, 2005]. (v) *Directional versus point prediction.* Meehl [1967] observes that directional predictions are nearly costless in the social sciences; H2, H4 and H6 make point predictions with constants, which is the right answer to that objection, but none has been put at risk. (vi) *Identification.* Unaddressed by design, and stated as such in Section 3.3.

25.13 13 Conclusion

Trust, reciprocity and obligation enter the storage law at three different positions, and the positions are why the three behave differently. Trust enters as retention: `delta_eff = delta_0 + (1 − a)(1 − v)`, where `a` is the measured rate at which unverified commitments are honoured. At `K = eta S − C_0 = 0.2526` and `delta_0 = 0.04` the steady stock rises from `Q_inf = 0.4679` at `a = 0.50` to `Q_inf = 5.0529` at `a = 0.99`, and **the point elasticity of the stock in the reliance rate is `a/(delta_0 + 1 − a)` — 0.93 at `a = 0.50` and 10.56 at `a = 0.95` — not `a/(1−a)`, which holds only in the limit `delta_0 -> 0` and is corrected here.** Under a linear verification cost the verification budget's optimum is always at an endpoint, switching at `a* = 1 − c_v delta_0/(K − c_v)`: at `c_v = 0.20` verify below `a = 0.8479`, and at `c_v >= K` verification consumes the entire net input and is never worth buying. **Trust is valuable exactly in proportion to the cost of the verification it displaces.**

Reciprocity enters as conversion, `eta = eta_max rho` with `rho = 2 min(x_ij,x_ji)/(x_ij+x_ji) = 1 − |Skew_ij|/Sym_ij`, so reciprocity and obligation are two readings of one measurement rather than two measurements. **The node-level imbalance index obeys `1 − B >= rho` and is therefore an upper bound on reciprocity, never an estimate of it**: it flattered one worked network by 15.4 per cent (0.4412 against 0.3824) and a second by 34 per cent (0.7243 against 0.5421), in both cases in the direction of comfort.

An eight-firm consortium at `u = 0.52` was collecting 73.8 per cent of its surplus ceiling and still had a steady state of `−0.0836` and headroom of `−0.4582`. The binding fault was `rho = 0.3824`, not difference, and the survival threshold was `rho > 0.4344` — 5.2 points away. Raising `rho` to 0.8947 and `a` to 0.88 moved the fixed point to `+1.8701`, and the one-at-a-time decomposition shows why the order of operations matters: **reciprocity alone gave `+0.7394`, trust alone gave `−0.2114` — worse than doing nothing — and the interaction term of `+1.2586` exceeded either main effect.** Where the numerator `eta S − C` is negative, lowering `delta` moves the equilibrium

further from zero. **Fix the numerator first.** Graduated sanction against expulsion prices out at `+1.0` per cent against `−7.7` per cent of `eta S`, and the `−7.7` is a floor rather than an estimate because it holds `u` fixed across the removal.

The mean-field scalar `delta` is exactly right for one period and wrong by 92 per cent after twelve when the store is split evenly between compartments at `delta = 0.05` and `delta = 0.50`, with the implied aggregate rate drifting from 0.2750 down to 0.0504. That is a theorem about compartments, not a modelling claim, and it is the sharpest available discriminator between a scalar model of a heterogeneous body and the body.

The correspondence between one head and one group is audited here rather than asserted, and it breaks in nine named ways — exit, heterogeneity and ill-defined aggregation rated severe, four structural, one a matter of measurement practice, and an absolute ethical asymmetry. What survives is precise: the recursion transfers, because it names no substrate; the redundancy geometry transfers, because geometry does not know what it is counting; the ceiling transfers and produces requisite variety in first-person form; and the three diagnostic questions transfer. **What does not transfer is anything involving agency of the parts. The equation transfers between scopes; the licence to apply it does not.**

None of this identifies a social effect. The reflexive specification the framework rests on is not identified from observational data, no remedy is adopted here, and every applied statement above is therefore a modelling position rather than a measured result. **The arithmetic is certain and the institutions are not, and a paper that says which is which is worth more than one that lets the certainty of the first stand in for evidence about the second.**

25.13.1 Declarations

Data and code availability

No external dataset was collected for this paper. All numerical results are computed from the stated parameters under the model developed in the text, and every table can be re-derived from the equations and parameter values printed beside it. The three systems worked in Section 9 are constructed examples with declared parameters, not field observations; the two flow matrices in Section 9.1 are printed in full precisely so that `rho`, `B` and every derived quantity can be recomputed by hand. The figures are generated by the scripts named in each caption; those scripts contain no data beyond the numbers printed in this paper and the model equations of Sections 3 to 8.

Funding

This research received no external funding.

Conflicts of interest

The author declares no conflicts of interest.

Author contributions

Single author. Michael Laurence Curzi conceived the work, derived the results, produced the worked examples and figures, and wrote the paper.

Ethics

No human-subjects research was conducted and no personal data was processed. The three worked systems are constructed. The measurement protocols of Section 6.6 carry binding disclosure and privacy constraints — sampling of verification must be disclosed to every party,

and individual obligation balances must not be published within a group — and those are **design constraints on prospective work, not reports of any study performed.** The declination constraint invoked throughout is a normative stipulation of the framework; **no entry in this corpus's bibliography establishes it**, and it is badged as a stipulation in Sections 2, 3.5, 8.9 and 12.

Preregistration

This paper reports no preregistered test of its own; its results are derivations and constructed worked examples. Falsification rules are declared in advance for each of the three worked systems in Sections 9.1, 9.2 and 9.3, and for the correspondence in Section 8.11, but **none has been executed.** The preregistered protocol for testing the underlying storage law against a real system, together with the confirmatory application that **failed** its second falsification rule — a 2.8 per cent held-out RMSE advantage over a matched AR(1) against a declared margin of 10 per cent — is reported in Curzi [2026i]. Any applied claim resting on this paper inherits that result.

25.14 Appendix A — The interpersonal formulary

25.14.1 A.0 How the formulary is organised, and two standing verdicts

This appendix collects every formula developed above, plus the group-scope forms of the framework's core, in one reference with a fixed entry format: **statement**, **derivation** with its badge, **worked number**, and **named failure modes**. The seven validation gates `G1`–`G7` (Section 3.4) are consolidated into the single matrix of Section A.7 rather than repeated twenty-five times; **every non-`PASS` verdict is spelled out there, and an entry quoted without its gate row is an entry quoted without its limits.** Entries are labelled `IF-01` to `IF-25`; the labels do not collide with the results `R1`–`R6`, the specifications `S1`–`S32`, the failure modes `F1`–`F26`, or the breakdowns `B1`–`B9`.

Standing verdict 1 — every `M`-derived entry is demoted on gate G2. `D` and `P` are not instrumented on a common ratio scale with a shared true zero, and division without a true zero produces a number with no referent. This governs **IF-14, IF-15, IF-16 and IF-17**. A count supplies a zero and a unit inside one declared encoder and supplies no linkage between encoders, so the magnitude of `r` moves when the encoder moves.

> **Withdrawn as measured quantities:** the magnitude of `D/P`; `Delta = |ln r|` as a number; and the quantitative form of the join from the moment into the storage law. The worked numbers under those four entries are **illustrative constructions demonstrating the arithmetic of each measure.**
>
> **In force, untouched:** the limiting cases; the `D = P` fixed point; the ordering *over-framed / calibrated / under-framed*; and the **sign** of `ln r`, which is the operationally decisive part because the two faults take opposite corrections. **What is demoted is magnitude, not structure.**

The route out is constructive, specific and priced. Measuring `D` and `P` as Rasch measures on one common linked scale makes `Delta = |ln(D/P)| = |theta_D − theta_P|` genuinely ratio-scaled, with Rasch separation supplying the true zero that division requires [Rasch, 1960, Andrich, 1988]; the corpus prices that instrument at approximately **123 items per term to establish a half-logit distortion at 95 per cent confidence**, and about **31 items for a full logit**. At group scope the items are decisions with later-observable answers, so **a body that already keeps a decision log is already accumulating the item bank** — the one respect in which the interpersonal version of the study is cheaper than the personal one. **A formulary that demotes four of its own entries, names exactly what survives, and prices the study that would restore**

the rest is the protocol working. It is not an apology. Curzi [2026] carries the demotion in the corpus's register.

Standing verdict 2 — the shuffled-input control has three measured failure modes, and every G6 verdict below inherits all three.

#	Failure mode	Measured
1	**Anti-conservative as ordinarily run.** Against nominal `alpha = 0.05` over 500 null trials: iid permutation false-rejected at **0.108, 2.2x nominal**; circular shift 0.120; block permutation 0.060, near nominal	[Curzi, 2026i]
2	**Blind to repackaging.** A filtered repackaging passed all four baselines including the shuffle at `p = 0.0005`, and was caught **only by the structural ceiling test** — its single-step jump was **38.5x** the theoretical maximum	[Curzi, 2026i]
3	**Blind to shared slow drivers.** Across 4,000 trials the shuffle detected the clean case 48.17% of the time and **passed 98.35% of the time against a confound driving both series**	[Curzi, 2026i]

> **The rule, superseding any earlier statement of it: the shuffle is a weak, miscalibrated empirical audit. Repackaging is caught only by the structural ceiling test; confounding by a shared slow driver is caught only by design controls — blinding, channel separation, prospective sampling, a yoked control. No surrogate catches either.** Calibrate the surrogate by simulation on the design in hand before using it, and **build design controls, not more surrogates.**

Index by parameter. `N`: IF-02, IF-04, IF-05, IF-22. `u`: IF-01, IF-02, IF-03, IF-05. `S/F`: IF-01, IF-02, IF-03, IF-04. `Q`: IF-06, IF-07, IF-08. `delta`: IF-11, IF-18, IF-19, IF-25. `eta`: IF-20, IF-21. `C`: IF-12, IF-13, IF-19. `h`: IF-09, IF-10, IF-22. `M`, `D/P`: IF-14, IF-15, IF-16, IF-17. Thresholds: IF-23, IF-24.

Index by symptom. "lots of people, no new ideas" — IF-02 then IF-05. "we agree things and start over every quarter" — IF-08 then IF-20. "meetings are necessary and useless" — IF-12 then IF-13. "we're busy but nothing accumulates" — IF-20, IF-21. "we keep being surprised by the same thing" — IF-16, IF-17. "good people keep leaving" — IF-22, IF-11. "the reorganisation didn't help" — IF-09, IF-10. "one person left and everything got worse" — IF-05. "we cannot get the change to stick" — IF-24. "the numbers from the team and the person disagree" — IF-25.

25.14.2 A.1 Class A — geometry of difference

IF-01 · The pair surplus.

```
S_2 = ln(1 + u),     u = 1 − (x . y)^2  in [0,1],     ceiling ln 2 = 0.693147
```

Derivation: the surplus functional at `N = 2` [Curzi, 2026o]; not a special case requiring separate proof. **Extremality: `S_2 = 0` if and only if the framings are parallel**, which is the formal content of the statement that the pairing of like with like is a non-event. *Protocol:* choose and justify the framing space; each party independently predicts `k >= 8` observables without conferring; encode as unit vectors and compute `u = 1 − (x.y)^2`; repeat after one period and report test-retest, below 0.6 the estimate is not a measurement.

u	0.00	0.10	0.25	0.50	0.75	0.90	1.00
S_2	0.0000	0.0953	0.2231	0.4055	0.5596	0.6419	0.6931
% of ln 2	0.0	13.8	32.2	58.5	80.7	92.6	100.0

Half the available surplus of a pair is bought by the first quarter of the way to orthogonality — strict concavity arriving as a design fact. *Failure modes:* similarity mistaken for compatibility, where a pair chosen for agreement has `S_2 = 0` exactly; encoded difference, where vocabulary differences register as `u > 0` while predicting identically, which the independent-prediction step excludes; **conscripted difference**, where an instructed disagreement produces `u` with no informational content and is prohibited where the partner cannot decline the role.

IF-02 · The effective count and the group surplus.

```
N_eff = 1 + (N − 1)u,     S = ln N_eff = ln(1 + (N−1)u),     0 <= S <= ln N
```

Derivation: the surplus functional, with the effective count coming from the affine design axiom. **That axiom is chosen, not derived, and this entry must not be used without saying so** [Curzi, 2026o]. What it buys is that surplus is the log of a headcount *after the headcount has been audited for redundancy*. **It is not a Hill number** (Section 3.1). *Protocol:* capability inventory for `N`; pre-discussion prediction round for `u`; compute `N_eff` and `S`; **never measure `N_eff` directly**; report `S / ln N` alongside `S`.

u	0.00	0.10	0.20	0.35	0.50	0.65	0.80	1.00
N_eff at N = 12	1.000	2.100	3.200	4.850	6.500	8.150	9.800	12.000
S	0.0000	0.7419	1.1632	1.5790	1.8718	2.0980	2.2824	2.4849
% of ln 12	0.0	29.9	46.8	63.5	75.3	84.4	91.8	100.0

Twelve people at `u = 0.10` are worth 2.1 people. Not "somewhat redundant" — 2.1. *Failure modes:* headcount substituted for `N`, the single commonest error in this subject; reporting `S` without `S / ln N`, which is half a diagnosis since ceiling and realised fraction are different levers; reporting `N_eff` from a survey, when it is derived and cannot be asked about.

IF-03 · The two-source decomposition.

```
u = u_cross + u_div,    u_cross = beta^2,   u_div = alpha^2 sin^2(gamma)
max( f(u_cross), f(u_div) )  <=  f(u)  <=  f(u_cross) + f(u_div)
```

Derivation: the two-source theorem for a pure block vector. **The upper bound is subadditivity on the parameter `u` and is not a triangle inequality** — the triangle inequality fails for geometric triples, and **this entry must not be chained** (S31). *Protocol:* declare the category partition **before** measuring, from an external criterion; a partition chosen after seeing the data is not a partition, it is a fit. Compute `u` within and across blocks separately, then verify the bound; **a violation means the block assignment is wrong, not that the theorem is.** *Worked:* `N = 12`, `u_cross = 0.24`, `u_div = 0.16`, so `u = 0.40`:

```
f(u)       = ln(1 + 11 x 0.40) = 1.6864
f(u_cross) = ln(1 + 11 x 0.24) = 1.2920
f(u_div)   = ln(1 + 11 x 0.16) = 1.0152
bound:  1.2920 <= 1.6864 <= 2.3072      satisfied
subadditivity slack = 2.3072 − 1.6864 = 0.6208
```

The slack of 0.6208 nats is the amount by which naive addition of the two sources would overstate the surplus — **36.8 per cent of the true value.** *Failure modes:* chaining across three parties, prohibited; post-hoc partition; summing the sources.

IF-04 · Requisite variety at group scope.

```
required:  N_eff >= N_env,     hence  u >= (N_env − 1)/(N − 1),
feasible only if N >= N_env, since u <= 1
```

Derivation: only variety absorbs variety [Ashby, 1956, 1958]. **The transfer into this parameterisation is a modelling assumption, badged.** What is proven here is only the algebra. *Protocol:* enumerate the environment states requiring **distinct** responses, merging any two whose correct response is identical; compute `N_eff` per IF-02; if `N_eff < N_env` the shortfall is the number of states the group must handle by guessing.

`N_env`	required `u` at `N = 8`	at `N = 12`	at `N = 20`
4	0.4286	0.2727	0.1579
8	1.0000	0.6364	0.3684
16	infeasible	infeasible	0.7895
32	infeasible	infeasible	infeasible

An eight-member body facing an eight-state environment must be perfectly orthogonal to be adequate, which is not achievable in practice. *Failure modes:* inflated `N_env`; treating the requirement as sufficient, when it is necessary only — the group must also convert and afford.

IF-05 · Departure fragility: targeted versus random removal.

```
u_ij = 1 − c_i c_j,   c_i = cos^2(th_i)
mean u = 1 − [ (sum c)^2 − sum c^2 ] / (2 ∗ C(N,2))
fragility = S(N,u) − S(N−1, u after removing a named member)
```

Derivation: definition plus the surplus functional. **The one-parameter geometry is a modelling choice, badged**: each member holds a shared direction plus one private orthogonal direction, the minimal structure producing heterogeneous `c_i`. *Protocol:* estimate each `c_i` from the member's prediction vector against the group centroid; compute mean `u`; **recompute `u` with each member deleted in turn**; report the maximum, not the mean. *Worked:* `N = 9`, six members at `c = 0.95` and three at `c = 0.0501`, giving `u = 0.5999` and `S = 1.7578`:

removal	resulting `S` at `N = 8`	loss
random member (expectation)	1.6434	0.1144
a conformist (`c = 0.95`)	1.7162	0.0416
the most divergent (`c = 0.0501`)	**1.4979**	**0.2599**

Targeted removal costs 2.27 times random removal, which is the standard network result — heterogeneous structures robust to random failure and fragile to targeted attack [Albert et al., 2000] — appearing in surplus geometry rather than in a connectivity graph. **The transfer is a modelling assumption; the arithmetic is exact.** And the deeper case: two nine-member groups can have identical `u = 0.5999` and `S = 1.7578`, and be left with either 1.3862 or 0.3971 of surplus when three members leave, **losing 0.3716 or 1.3607 respectively — a damage ratio of 3.66, not the 3.49 obtained by dividing the surviving values** (Section 9.4, defect 2). *Failure modes:* scalar `u` reporting, which conceals the entire profile; assuming the loudest member is the most divergent, when divergence is measured by prediction disagreement and not by volume; retention policy by seniority, which is uncorrelated with `c_i` — subject always to the constraint that **retention is an offer and never a restriction**.

25.14.3 A.2 Class B — storage and dynamics

IF-06 · The institutional storage law. Statement, derivation, protocol and honesty clauses are those of Section 3.1 and are not repeated. **The mathematics is proven; the mapping of an institution onto a single scalar `Q` is a postulate, badged.** *Worked:* `N = 12`, `u = 0.45`, `eta = 0.40`, `C = 0.55`, `delta = 0.10`, `Q_0 = 0`, so `S = 1.7834`, `eta S = 0.7134` and `Q_inf = 1.6336`:

t	0	1	2	3	5	8	10	12
Q	0.0000	0.1634	0.3104	0.4427	0.6690	0.9304	1.0640	1.1722

Half-life 6.579 periods; 95 per cent settling at 28.43. *Failure modes:* ordinal `Q`, since a five-point survey cannot enter this equation; `S` inferred from `Q`, which destroys identifiability; **declaring success at `t = 3`, when the system is 27 per cent of the way to its own equilibrium.**

IF-07 · The exact solution and the contraction.

```
Q_t = (1−delta)^t Q_0 + sum_{k=0}^{t−1} (1−delta)^{t−1−k} (eta S_k − C_k)
|Q_t − Q_inf| = (1−delta)^t |Q_0 − Q_inf|      under constant input
tau = 1/delta periods;   t_half = ln 2 / −ln(1−delta)
```

Derivation: induction for the solution; the contraction follows because the map is affine with slope `(1−delta)`, and Banach then guarantees a unique fixed point and convergence from any start [Banach, 1922, Curzi, 2026q]. *Protocol:* measure `Q` at two times under zero input, `delta = 1 − Q_1/Q_0`; **verify geometry with a third point — `Q_2/Q_1` must equal `Q_1/Q_0` within measurement error, and if it does not, the system is not single-compartment** (B2).

delta	tau	half-life	95% at t	99% at t
0.05	20.00	13.51	58.40	89.78
0.10	10.00	6.58	28.43	43.71
0.20	5.00	3.11	13.43	20.64
0.35	2.86	1.61	6.95	10.69

Failure modes: two-point `delta` on a heterogeneous store, which gives a number that is neither compartment's and drifts with when the analyst looked; measuring under non-zero input, which conflates `delta` with `eta S − C`.

IF-08 · The group steady state. `Q_inf = (eta F(u*) − c*)/delta` for `delta > 0` and constant input; **if `eta F(u*) < c*` the equilibrium is negative.** *Derivation:* set `Q_{t+1} = Q_t`. **The theorem states its own failure mode and this entry must reproduce it:** a negative `Q_inf` means the regime is unsustainable in this model, or the linear model must be replaced. It does not mean negative stored order, which is meaningless. *Protocol:* confirm the input is approximately constant over at least `3/delta` periods; fit from the transient; **check the sign of `eta F − c` first, and if it is negative, stop and report unsustainability rather than presenting a negative equilibrium as a small number.** *Worked:* `N = 12`, `eta = 0.40`, `C = 0.55`, `delta = 0.10`:

u	S	eta S	Q_inf
0.45	1.7834	0.7134	+1.6336
0.70	2.1633	0.8653	+3.1533

Raising `u` from 0.45 to 0.70 nearly doubles the equilibrium: **+1.5197 units for a change costing nothing in headcount.** *Failure modes:* reporting a negative `Q_inf` as a forecast; applying the formula to a non-stationary input.

IF-09 · Organisational headroom. `h_t = eta ln N − delta Q_t − C_t`, with the three regimes of Section 7.4 and `h = 0` at `Q = (eta ln N − C)/delta`. *Derivation:* the headroom gauge. **Note that headroom uses `ln N`, the ceiling, while the growth condition uses `S = ln N_eff`, the realised value. Half of all misdiagnosis turns on that distinction**: a system can have large positive headroom and shrink every period, because it operates far below its own ceiling. *Protocol:* derive from the four parameters; **never survey it.** *Worked:* `N = 12`, `eta = 0.40`, `C = 0.55`, `delta = 0.10`, so `eta ln N = 0.9940`:

Q	0	1	2	3	4	5	7
h	+0.4440	+0.3440	+0.2440	+0.1440	+0.0440	-0.0560	-0.2560

Ossification at `Q = 4.4396`. **The organisation runs out of headroom by succeeding, and the number at which it happens is computable in advance.** *Failure modes:* using `S` instead of `ln N`; reporting `h` without `S / ln N`; treating `h < 0` as a motivation problem, when **no arrangement of people prevents decline in that regime.**

IF-10 · The target increment and the maximum step.

```
Q_{t+1} − Q_t >= r_t   iff   S_t >= (delta Q_t + C_t + r_t)/eta
feasible only if  delta Q_t + C_t + r_t <= eta ln N
r_max = eta ln N − delta Q_t − C_t = h_t
required u = (e^{S_required} − 1)/(N − 1),   feasible only if u <= 1
```

Derivation: the growth condition rearranged. **No policy based on interaction geometry alone can guarantee more than `r_max`.**

The concavity correction, required before either feasibility test is read. The statement is written as though `U` were constant every period, and it never is. What accumulates is `sum eta F(U_t)`, so **the operative quantity is the mean of `F(U_t)`, never `F` of the mean `U`.** Because `F` is strictly concave, Jensen's inequality gives `mean of F(U_t) <= F(mean of U_t)`, with equality only if `U` is constant. **A body whose geometry varies delivers strictly less surplus than one sitting at its own average every period, so testing feasibility on `F(mean U)` approves increments that cannot be delivered.** In the corpus's worked office the penalty is 0.0761 nats — mean `F` of 1.1501 against `F(mean U)` of 1.2262, **a loss of 6.2 per cent of the surplus purely to variability** — and it was enough there to turn a feasible-looking plan into a shortfall. Report `u_req` for legibility; do not test against it.

Worked: `N = 12`, `eta = 0.40`, `C = 0.55`, `delta = 0.10`, `Q_t = 2.0`, requested `r_t = 0.30`:

```
required S = (0.10 x 2.0 + 0.55 + 0.30)/0.40 = 2.6250
ln N = 2.4849  ->  required S exceeds the ceiling. INFEASIBLE.
required u = (e^2.6250 − 1)/11 = 1.1641 > 1.  Confirmed infeasible.
r_max = 0.9940 − 0.2000 − 0.5500 = 0.2440
```

The most the body can deliver is 0.2440 and it was asked for 0.3000. The gap is 23 per cent and is not closeable by effort, exhortation, or reorganisation of the same twelve domains. *Failure modes:* accepting an unpriced target; re-planning instead of re-scoping when required `u > 1`; feasibility tested on `F(mean U)`.

IF-11 · Turnover composition. `delta_total = 1 − (1 − delta_int)(1 − tau)`, survivals multiplying because the two losses are independent. *Derivation:* definition plus an independence assumption. **The independence is a postulate, badged** (P10), and it is violated where departures are caused by the decay, in which case the composition understates the loss. *Protocol:* measure `tau` from the roster; measure `delta_int` during an interval with no departures; compose; **check the independence assumption by testing whether departures cluster after `Q` declines, and if they do, use the composed value as a lower bound only.** *Worked:* the table of Section 7.3. **Five per cent turnover halves steady-state stored order.** Not reduces — halves. *Failure modes:* adding the rates, which gives 0.15 where the truth is 0.1450 — small there and

large at high tau; attributing the loss to documentation quality, when at tau = 0.20 some 79 per cent of the total loss is people leaving; assuming replacement restores Q, when it restores N and Q must be rebuilt at rate eta S.

25.14.4 A.3 Class C — cost and structure

IF-12 · The coordination cost law and the crossover. paths(n) = n(n−1)/2 [Brooks, 1975]; C(n) = c_0 + c_1 n(n−1)/2; crossover n* the least n with C(n) > eta ln n. *Derivation:* the path count is exact combinatorics; **the linear-in-paths cost model is a postulate, badged.** *Protocol:* measure coordination cost per period across sub-units of differing size in one body and regress on n(n−1)/2 to recover c_1, reporting the fit; **a poor fit means the group is not all-to-all connected**, which is the good case and points to IF-13. *Worked:* the two tables of Section 6.4, with n* = 61 at c_1 = 0.0009. **A twenty-fold difference in per-path cost moves the viable group size from 85 to 16**, which is why "what is the right team size" has no context-free answer. *Failure modes:* assuming a universal team size; measuring c_1 from meeting hours only, which omits the asynchronous coordination cost and is usually the larger part; adding people to a late project, where the added C is immediate and the added S is delayed.

IF-13 · The nesting law. N = g^d, groups = (g^d − 1)/(g − 1), paths = groups x g(g−1)/2, paths per member tending to g/2; flat cost O(N^2), nested O(N). *Derivation:* exact combinatorics on a g-ary tree. **The mapping onto the nested- enterprises design principle is a modelling assumption, badged**: nesting was reported as an empirical regularity among long-enduring institutions [Ostrom, 1990], and the cost arithmetic is the framework's. *Protocol:* map the actual communication structure, not the published chart — the two diverge and the actual one is the one that costs [Conway, 1968]; count paths carrying real traffic; compare with the nominal structure, and **the excess is the cost of the informal cross-links, which is not waste.** *Worked:* the table of Section 6.4. **This is the only entry in the formulary that changes an exponent rather than a coefficient**, and the ceiling eta ln N is untouched, so nesting is a pure reduction of C. **The mandatory caveat:** a g^d tree is exactly the structure identified as wrong for this purpose — **a strict tree amputates the cross-links a semilattice preserves, and those links are where u lives** [Alexander, 1965]. The figures are the tree's cost floor, not a recommendation. *Failure modes:* nesting as a tree; nesting the chart without nesting the traffic; adding depth without limit, since depth is a delay and distortion term appearing in IF-16 and not in C.

IF-14 · The group launch budget. L = max(0, M − C), with L the group's capacity to imagine and pursue an alternative to its present arrangement. *Derivation:* **the claim that collective alternatives are generated only from surplus is a postulate, badged.** The max(0, .) is the model's statement that there is no negative imagination. **G2: DEMOTE** (standing verdict 1) — the subtraction requires an interval scale at minimum and the normalisation into [0, ln N] requires ratio, so **L is reportable as a threshold condition — is the moment above the cost line or not — and not as a magnitude.**

M	C	L	reading
1.20	0.55	0.6500	alternatives available
2.00	0.55	1.4500	ample
0.80	0.90	0.0000	none — fully consumed
0.55	0.55	0.0000	exactly at the line

A body at L = 0 will not propose a change to its own arrangement, and this is not a failure of vision. It is the arithmetic of a group whose whole moment is consumed by its own maintenance; the instruction to leave one's comfort zone reverses the order of operations, since the departure is planned from surplus rather than from its absence. *Failure modes:* demanding innovation from an L = 0 body, where the correct move is to cut C first; reading L = 0 as complacency, when it is capacity, measured; ordinal M.

25.14.5 A.4 Class D — the lens at group scope

IF-15 · The group moment. `M = (D/P) . E`, with `D` shared doctrine, `P` collective perception, `E` the environment; `D` and `P` must share units so that `r = D/P` is dimensionless, and `M` inherits `E`'s units. *Derivation:* **this is the author's formula and it is a postulate, badged.** What is not postulated is the dimensional requirement, which is forced. **G2: DEMOTE** (standing verdict 1) — division requires `D` and `P` ratio-scaled with a true zero on a **common** scale, and no such instrument exists; channel-counting gives a zero within one encoder and no linkage between encoders. **The formula stands as the ordering over-framed / calibrated / under-framed, plus its limits and its fixed point; its magnitudes are withdrawn.** *Protocol:* prediction-surprise ledger; estimate `D` from confidence held and `P` from information actually supplied; **test for cyclicity first (B3) — if the collective ordering is intransitive, `D` is not a well-defined object and this entry does not apply.** *Worked, illustrative construction with `E = 10.0`:*

D	P	r	M	reading
1.0	1.0	1.000	10.0000	calibrated: `M = E`
2.5	1.0	2.500	25.0000	over-framed
3.0	1.0	3.000	30.0000	over-framed, severe
1.0	3.0	0.333	3.3333	under-framed, severe
0.4	1.0	0.400	4.0000	under-framed

Failure modes: ordinal inputs; cyclic `D`, where the numerator does not exist; confusing `M` with `E`, which are equal only at the fixed point and the whole diagnostic concerns the cases where they are not.

IF-16 · Doctrine-to-data and the group distortion. `r = D/P`, `Delta = |ln r|`, with `r > 1` over-framed, `r = 1` calibrated, `r < 1` under-framed. *Derivation:* definition from IF-15. **The log-ratio form is chosen because ratios compose multiplicatively**, which makes over-framing and under-framing by the same factor equal distortions, as the raw ratio does not. **G2: inherits IF-15's DEMOTE. `Delta` is an ordinal quantity pending instrumentation — it ranks bodies and periods by distance from contact and does not license the claim that one distortion is twice another. The sign of `ln r` is unaffected and is the part that decides the correction.** The band table of Section 7.4 is a construction showing how the measure reads, not a set of measurements. A body at `r = 2.90` has `Delta = 1.0647`, severe over-framing; correcting to `r = 1.25` gives `Delta = 0.2231`, drift. **Calibration is not the goal; the achievable goal is drift, and a body reporting `Delta < 0.05` is more likely to be mismeasuring than to be perfect.** The two structural reasons why `r = 1` is not an unqualified target — the exact-zero headroom at the fixed point, and the fact that a body optimising raw `Q` is driven away from `r = 1` by arithmetic — are developed in Section 7.4 and are not repeated. *Failure modes:* correcting the wrong direction, since under-framing treated by adding doctrine becomes over-framing; reporting `Delta` alone, which loses the sign; confusing over-framing with confidence, when the diagnostic is confidence **uncorrelated with accuracy**, not confidence as such.

IF-17 · The group return difference. `Delta_R = |ln(M'/M)|`, with `M` the moment the group sent into the world and `M'` the moment that came back; convertible to octaves by `x 2.885390`. *Derivation:* **the claim that the world's answer over what was sent is the informative quantity is a postulate, badged.** The log form is forced by the same reasoning as IF-16. **G2: DEMOTE. Amplification, null return and attenuation are findings; the number of nats is not.** The octave conversions below are exact arithmetic on an illustrative construction, not measurements. *Protocol:* record `M` at the moment of sending, **before** any response; record `M'` when the response is complete, same instrument; report magnitude **and sign**. *Worked, `M = 10`:*

M'	Delta_R (nats)	octaves	reading
10	0.0000	0.0000	**zero return difference: no information**

M'	Delta_R (nats)	octaves	reading
12	0.1823	0.5261	mild amplification
7	0.3567	1.0291	attenuation
25	0.9163	2.6439	strong amplification
3	1.2040	3.4739	strong attenuation

A response identical to what was sent is an echo, and an echo carries no information about the world. A body whose consultations return exactly its own proposal has learned nothing, and the measurement says so with a zero. *Failure modes:* treating `Delta_R = 0` as success, the commonest misreading, when it means the channel is a mirror; mismatched instruments; ignoring the sign.

25.14.6 A.5 Class E — trust, reciprocity, obligation

IF-18 · Trust as retention reduction. `delta_eff = delta_0 + (1 − a)(1 − v)`. Statement, derivation, protocol, ethics constraint and worked half-life table are those of Sections 4.2, 4.3 and 6.6 and are not repeated. **Derivation: Postulate PT, badged.** The decomposition of lapse into irreducible and confirmation-addressable causes is the substantive content; the postulate is that verification is effective on the second class. **`a` and `v` are separately identifiable only if some commitments are genuinely left unverified: under `v = 1`, `a` is unmeasurable.** The elasticity is `a/(delta_0 + 1 − a)` and **not** `a/(1−a)` (Section 4.4). *Failure modes:* scalar trust; trust from survey, an ordinal self-report prohibited from entering the equation; **maximising `a`**, when `delta` is not a fault to be minimised and high `a` on a commitment that ought to lapse is how obsolete procedure becomes immortal.

IF-19 · The verification budget and the trust threshold. `C_v(v) = c_v v`; `Q_inf(v) = (K − c_v v)/(delta_0 + (1−a)(1−v))` with `K = eta S − C_0`; `sign(dQ_inf/dv) = sign[(1−a)(K − c_v) − c_v delta_0]`, independent of `v`; and `a* = 1 − c_v delta_0/(K − c_v)` valid when `K > c_v`. Derivation, worked table and the linearity caveat are Section 4.5. *Protocol:* estimate `c_v` as the full-coverage verification cost; estimate `delta_0` from an interval with `v = 1`, where the residual loss is irreducible; estimate `K`; compute `a*` and compare against measured `a`. *Failure modes:* verification creep; **monitoring mistaken for trust-building — monitoring lowers `c_v`, which raises `a*`; it does not raise `a`** (Section 6.2).

IF-20 · The reciprocity index and the conversion law. `rho_ij = 2 min(x_ij,x_ji)/(x_ij+x_ji) = 1 − |x_ij − x_ji|/(x_ij + x_ji)`; `rho_group = matched / total`; `eta = eta_max rho`. **The index is a definition; `eta = eta_max rho` is Postulate PR, badged. G5: FAIL as stated — `rho` depends on the accounting window, and the same relation measures 0.1333 at one month and 0.8667 at twenty-four. The window must be preregistered and the sensitivity curve reported** (S4). Protocol is Section 6.6, Protocol B. *Worked:* the tables of Sections 5.2 and 5.3. **A relation at `rho = 0.29` does not accumulate slowly; it fails to accumulate at all** — while fourteen transfers a period look perfectly healthy on a dashboard. *Failure modes:* window shopping; asymmetric units; volume mistaken for reciprocity; ignoring density, since `rho` on a sparse network is a statement about the few edges that exist.

IF-21 · The obligation decomposition and the imbalance index. `X = Sym + Skew`; `b_i = sum_j (x_ij − x_ji)` with `sum_i b_i = 0`; `B = sum_i |b_i|/(2 x total volume)`; and the theorem `1 − B >= rho`. *Derivation:* the decomposition is exact and unique for any square matrix; **the interpretation is Postulate PO, badged**; **the bound is proved** from the triangle inequality on the reals (P8). Protocol is Section 6.6, Protocol C. **Ethics, binding: individual balances shall not be published within the group** (S12). *Worked:* the eight-firm consortium, total directed volume 68, `b_i = [−17, −21, +14, +8, +5, +5, +3, +3]`, so `B = 76/136 = 0.5588`, `1 − B = 0.4412` against a measured `rho = 0.3824`. **The node index flatters the network by 15.4 per cent, systematically, in the direction of comfort.** *Failure modes:* reporting `B` alone; publishing the ledger; reading a large `Sym` as health, when volume and balance are independent.

25.14.7 A.6 Class F — members and thresholds

IF-22 · Member headroom and the exit condition. `h_i = eta ln N / N − delta Q / N − c_i`, with critical private cost `c_i* = (eta ln N − delta Q)/N`; **member `i` is individually unsustainable when `h_i < 0` regardless of the group's `h`.** *Derivation:* IF-09 divided by `N`, with `c_i` replacing the per-capita average. **The equal division of the ceiling and of maintenance is a postulate, badged**; unequal division is the general case and requires member-specific shares. *Protocol:* measure `c_i` per member — their own time, travel, compliance burden, in the group's `Q`-unit; compute `h_i`; **report the names below zero, not just the count**; address by reducing `c_i`, **never by restricting exit — retention is an offer, never a restriction.** *Worked:* the table of Section 8.1, with its disclosed denominator defect. **They leave in cost order — highest `c_i` first — and the highest-cost members are frequently the highest-`u` members, because carrying a divergent framing in a converged room is expensive. Combined with IF-05, the body loses its most divergent members first and therefore loses surplus faster than headcount.** *Failure modes:* aggregate headroom quoted as sufficient; attributing exit to commitment when `h_i < 0` is arithmetic; retention by restriction, prohibited.

IF-23 · Rival versus non-rival return.

```
RIVAL     (store divided):    return_i = eta ln(N_eff)/N  −  c_i
NON-RIVAL (public good):      return_i = eta ln(N_eff)    −  c_i
ln(x)/x is maximised at x = e = 2.71828
```

Derivation: definition of the two allocation regimes applied to the surplus of IF-02. **The maximum of `ln(x)/x` at `x = e` is elementary calculus and is exact.** *Protocol:* **declare rivalry first** (S17) — is the store divided among members or held whole? Tooling access is rival; a published standard is not. **G5: rivalry must be declared from the nature of the store, not inferred from the data, since both regimes fit small-`N` data equally well.** *Worked:* the two tables of Section 8.8, at `eta = 0.35`, `c_i = 0.020`, `u = 1` and outside option `w = 0.030`. **The same group, the same surplus, the same members — and the sign of the size gradient flips entirely depending on whether the store is divided or shared.** *Failure modes:* undeclared rivalry; treating a mixed store as one regime, when most real institutions hold both and the correct move is to split `Q` into two accounts; **reading the `x = e` result as a recommendation**, when it is the rival regime's arithmetic and not a design rule.

IF-24 · The tipping threshold and the cascade. A committed minority near **25 per cent** of `N` was **measured** to overturn an established social convention in a controlled experimental paradigm [Centola et al., 2018]; the threshold-model fixed-point construction, in which the equilibrium active count `x*` is the smallest fixed point of `x -> #{ i : T_i <= x }`, is Granovetter [1978]. **Both are real results; the transfer to any particular body is a modelling assumption, badged. G6: the 25 per cent figure is one well-conducted experimental paradigm, not a constant of nature, and must be stated as a measured tipping point in that paradigm. G7: PARTIAL — the design is clear and published, but broad cross-context replication of the specific value is not established and must not be claimed.** This is the only entry in the formulary whose G7 is better than `OPEN`. *Protocol:* count `N` for the convention in question — the population the convention actually binds; treat `ceil(0.25 N)` as an order-of-magnitude guide, not a target; **estimate the threshold distribution by observing partial adoptions, because the distribution matters more than the mean.**

`N`	8	12	20	25	40	100	150
committed needed at 25%	2	3	5	7	10	25	38

The threshold result, computed. Ten people with thresholds `0,1,2,3,4,5,6,7,8,9` cascade to **10 of 10**. Change one threshold — the person at 1 becomes a 2 — and the equilibrium is **1 of 10**. **One person's threshold moving by one unit changes the outcome from complete adoption to none.** The mean threshold moved by 0.1; the outcome moved by 90 per cent of the population.

This is why aggregate measures of readiness for change have almost no predictive value and why the distribution is the only useful object.

Complex-contagion caveat, mandatory. Behaviours requiring social reinforcement spread differently from simple contagion: **they need multiple reinforcing contacts, and clustered topology beats random long ties** [Centola and Macy, 2007, Centola, 2010]. A change requiring reinforcement will not propagate along the weak-tie shortcuts that carry information [Granovetter, 1973], and a plan built on information diffusion will fail for that reason without the failure being visible. *Failure modes:* quoting 25 per cent as a law; **manufacturing the committed minority**, which is conscripted difference (IF-01) and is prohibited where members cannot decline the role; planning simple diffusion for a reinforcement-dependent change.

IF-25 · The scope transform. `delta_T = 1 - (1 - delta)^T` and its inverse `delta = 1 - (1 - delta_T)^{1/T}`. Period-free quantities: `N`, `u`, `N_eff`, `F`. Period-bearing: `delta`, `eta`, `C`, `h`, and `Q` if it is a flow rather than a stock. *Derivation:* survival compounds multiplicatively; **exact, not an approximation.** *Protocol:* convert **before** comparing any two rates; never compare `delta` values whose periods differ. *Worked:* the table and the 90.1x trap of Section 8.7. *Failure modes:* unnormalised comparison, the commonest cross-scope error; adding rates instead of compounding, which at `delta = 0.10` and `T = 7` gives 0.70 where the truth is 0.5217; applying the transform to a heterogeneous store, where a departure from the prediction is the diagnosis and not a rounding problem.

25.14.8 A.7 The consolidated gate matrix

`P` = PASS, `Pc` = PASS (conditional), `F` = FAIL as stated, `D` = DEMOTE, `O` = OPEN, `Pt` = PARTIAL. **Every non-`P` verdict is spelled out beneath the table.**

Entry	G1	G2	G3	G4	G5	G6	G7
IF-01 pair surplus	P	P	P	P	Pc	Pc	O
IF-02 effective count	P	Pc	P	P	Pc	Pc	O
IF-03 two-source	P	P	P	P	**F**	Pc	O
IF-04 requisite variety	P	Pc	P	P	Pc	P	O
IF-05 departure fragility	P	P	P	P	**F**	P	O
IF-06 storage law	P	Pc	P	P	Pc	P	O
IF-07 exact solution	P	Pc	P	P	P	P	O
IF-08 steady state	P	Pc	P	P	Pc	P	O
IF-09 headroom	P	Pc	P	P	Pc	P	O
IF-10 target increment	P	Pc	P	P	Pc	P	O
IF-11 turnover composition	P	P	P	P	P	P	O
IF-12 coordination cost	P	Pc	P	P	P	P	O
IF-13 nesting	P	P	P	P	P	P	O
IF-14 launch budget	Pc	**D**	P	P	Pc	P	O

IF-17 return difference	Pc	**D**	P	P	Pc	P	O
IF-18 trust as retention	P	P	P	P	Pc	P	O
IF-19 verification budget	P	P	P	P	Pc	P	O
IF-20 reciprocity index	P	Pc	P	P	**F**	P	O
IF-21 obligation decomposition	P	Pc	P	P	Pc	P	O
IF-22 member headroom	P	Pc	P	P	Pc	P	O
IF-23 rival / non-rival	P	Pc	P	P	Pc	P	O
IF-24 tipping threshold	P	P	P	P	Pc	Pc	**Pt**
IF-25 scope transform	P	P	P	P	P	P	O

The three G5 failures. IF-03: many `(u_cross, u_div)` pairs give the same `u`, so the aggregate does not identify the split — **the split must be measured from the block assignment, not inferred from `u`.** IF-05: distinct `{c_i}` vectors give identical mean `u`, so **the aggregate does not identify the fragility, and that is the entry's whole point.** IF-20: `rho` depends on the accounting window, moving from 0.1333 to 0.8667 on identical data, so **the window must be preregistered and the sensitivity curve reported.**

The four G2 demotions are standing verdict 1 and are stated in A.0. **The G2 conditionals** require in every case a ratio-scaled measure with a true zero: `N` enumerable by the independent-action test rather than headcount (IF-02, IF-04, IF-09); `Q` on the substitution test rather than a Likert culture survey (IF-06 through IF-10, IF-22); a ratio-scaled cost measure (IF-12, IF-23); and a **symmetric** ratio-scaled flow unit (IF-20, IF-21) — **if advice is counted one way and money the other, `rho` is undefined.**

The G1 conditionals (IF-14, IF-15, IF-17) all require that `D` and `P`, or `M` and `M'`, be in the same unit, which is the hard requirement because the answer often arrives in a different currency from the question.

The G6 conditionals require a preregistered encoding (IF-01), a shuffled-input control with the calibration of standing verdict 2 (IF-02), an independently specified block structure (IF-03), independent measurement of both terms (IF-15), and the paradigm restriction on the 25 per cent figure (IF-24).

G7 is `OPEN` for twenty-four of twenty-five entries and `PARTIAL` for the twenty-fifth. `OPEN` is a debt, not a pass. Nothing here has been through a cross-lab reproducibility trial [Open Science Collaboration, 2015].

25.15 Appendix B — Specifications and failure modes of formulary use

S23 — Gate row mandatory. No formula shall be used in a report without its gate row reproduced or cited. **An entry quoted without its gates is an entry quoted without its limits.**

S24 — `OPEN` is a debt, not a pass. Twenty-four of twenty-five entries have G7 `OPEN` and the twenty-fifth has it only `PARTIAL`. Any claim of established measurement shall state that.

S25 — Demote on scale failure. Where G2 fails — ordinal data entering a division or a ratio — the formula shall be demoted in print to a heuristic ordering, labelled as such, and its numerical output shall not be published. This governs IF-14, IF-15, IF-16 and IF-17 most often.

S26 — Badge every postulate in the sentence that states it. IF-04, IF-05, IF-11, IF-13, IF-14, IF-15, IF-17, IF-18, IF-20, IF-21, IF-22, IF-23 and IF-24 all rest on at least one postulate. **The modelling is permitted; it is permitted in the open, with its badge on.**

S27 — Report the ceiling and the realised fraction together. Any use of IF-09 shall be accompanied by `S / ln N` from IF-02. **Half of all misdiagnosis turns on confusing the ceiling with the realised value.**

S28 — Preregister windows and partitions. IF-03's block partition and IF-20's accounting window shall be declared before the data are seen, with justification [Nosek et al., 2018].

S29 — Distribution, not scalar. IF-05, IF-11, IF-20 and IF-22 shall be reported with their across-member distributions. A scalar alone is a mean-field claim.

S30 — Consent constraints carried. IF-18's disclosure requirement, IF-21's ledger-privacy requirement, IF-22's no-restriction requirement, and IF-24's no-conscription requirement travel with those entries and shall not be dropped in citation.

S31 — No chaining across triples. IF-03 shall not be composed across three parties. The triangle inequality fails for geometric triples.

S32 — Adding an entry. A new formula enters this formulary only with: a stated derivation identifying it as theorem, definition or postulate; all seven gates with verdicts; a measurement

protocol executable by someone who did not write it; at least one computed worked number; and named failure modes. **A formula without a failure mode has not been thought about.**

F19 — The quoted number. *Signature:* a figure from a worked example reappearing in someone's report as a finding about their own system. *Damages:* every downstream conclusion. *Diagnostic:* ask which of their own measurements produced it; usually none. *Fix:* **every worked number in this paper is an illustration of the arithmetic, not a benchmark. Measure.**

F20 — Gate skipping. *Signature:* an entry applied with its gate row omitted, most often G2. *Damages:* produces confident numbers from ordinal data. *Diagnostic:* ask for the scale type of every term; if the answer is "a one-to-five rating", the division is invalid. *Fix:* S23 and S25.

F21 — Postulate laundering. *Signature:* a badged postulate quoted at second hand without its badge, then treated as following from a theorem. *Damages:* misattributes a modelling choice to a proof, which makes it unarguable. *Diagnostic:* trace the claim to its entry and check the derivation field. *Fix:* S26.

F22 — The single lever. *Signature:* a diagnosis naming one parameter and an intervention on that parameter alone. *Damages:* Section 6.5 computes a case where a single-lever trust intervention **moved the equilibrium the wrong way** while every survey measure improved. *Diagnostic:* compute the one-at-a-time decomposition; if the interaction term exceeds either main effect, single-lever intervention is contraindicated. *Fix:* check the sign of `eta S − C` before any `delta` intervention.

F23 — Ceiling / realised confusion. *Signature:* a body reported as having ample headroom and shrinking every period. *Damages:* sends the engineer to the wrong lever entirely. *Diagnostic:* `h` uses `ln N` and the growth condition uses `ln N_eff`; compute both, always. *Fix:* S27.

F24 — Scalar reporting. *Signature:* one `u`, one `delta`, one `rho` for a group with visibly heterogeneous members. *Damages:* conceals the fragility profile (IF-05) and the exit profile (IF-22), both computable in an afternoon. *Diagnostic:* recompute with each member deleted in turn; a wide spread means the scalar was hiding it. *Fix:* S29.

F25 — Consent stripping. *Signature:* IF-18 used to run hidden reliability tests; IF-21 used to publish a debt ledger; IF-22 used to justify retention clauses; IF-24 used to assemble a committed minority by instruction. *Damages:* violates the declination constraint, and in three of the four cases also invalidates the measurement. *Diagnostic:* ask whether the affected person could have declined and been told they could. *Fix:* S30. **This is the one failure mode with no parameter fix and no acceptable trade-off.**

F26 — Reference material read as argument. *Signature:* this appendix cited as though the density of formulas were itself evidence. *Damages:* the credibility of everything else. *Diagnostic:* count the `OPEN` gates — twenty-four of twenty-five G7s are `OPEN` and the twenty-fifth is only `PARTIAL`. *Fix:* S24. **Formulas do not make a field hard. Ratio-scale, reproducible, falsifiable measurement of the formulas' terms does.**

Chapter 26

The Formula Validation Protocol, Scale Type, and Specific Objectivity: Demoting the Corpus's Own Moment Equation and Pricing Its Restoration

Abstract. This paper specifies a seven-gate protocol — dimensions, scale type, limiting cases, fixed points, identifiability, falsification, reproducibility — and runs it on the corpus's own moment equation $M = (D/P)E$. **The protocol does not pass it.** The equation clears gate 1, names all four limiting cases at gate 3, and its $D = P$ invariant is shown at gate 4 to be static rather than attracting. Gate 5 exhibits two invariance groups, so only the ratio r is identifiable. Gate 6 was run on preregistered simulated data: the frozen log-linear model scored held-out $R^2 = 0.8091$ against a shuffled control at 0.0059, while data generated additively triggered the division kill condition, the coefficient on the denominator returning a 95 per cent interval of $[-0.2009,\ 0.0590]$ against a target of -1. Gate 7 exposed a pooled fiction: a true between-person spread $\tau = 0.2534$ against a pooled standard error of 0.0257, a ratio of 9.9. **Gate 2 is the demotion.** Theorem 7.1 establishes that a quotient is meaningful only on a ratio scale, and four demonstrations show that admissible relabelling moves a reported D/P by 25 per cent, reverses orderings across occasions, produces any ratio one likes via $g(x) = x^k$, and can make the ratio negative or undefined. **The magnitude of D/P, the distortion as a number, and the quantitative moment-to-storage join are therefore withdrawn as measured quantities**, and the same gate demotes five of the nine entries of the corpus's personal formulary. Rasch separability supplies the constructive route, priced at roughly 123 items per term for a half-logit.

Keywords: formula validation; scale type; meaningfulness; magnitude estimation; cross-modality matching; specific objectivity; Rasch separation; kill conditions

26.1 1 Introduction

A framework that writes its claims as equations has to answer a question before any of those equations can be assessed: what would have to be true of the quantities in them for the arithmetic to be about anything? Writing `M = (D/P)E` does not make the study of moments a science.

An equation is a claim about relations among *measured* quantities, and if the quantities are not measured on a scale that supports the operations the equation performs on them, the equation is a diagram of an intuition in mathematical clothes.

This paper specifies the instrument the corpus uses to answer that question and then turns the instrument on the corpus's own central formula. The Formula Validation Protocol (FVP) is a seven-gate procedure — dimensions, scale type, limiting cases, fixed points, identifiability, falsification, reproducibility — which every formula in the framework is required to pass in print, with its per-gate verdict stated. **Run on the moment equation `M = (D/P)E`, the protocol returns DEMOTE at gate 2 and NOT YET RUN at gates 6 and 7.** The magnitude of `D/P`, the distortion $\Delta = |\ln r|$ as a number, and the quantitative join between the moment equation and the storage law are withdrawn as measured quantities and relabelled illustrative constructions. The same protocol, applied across the corpus's personal formulary, demotes **five of that formulary's nine entries** on the same gate [Curzi, 2026q].

That result is the paper's principal contribution, and it is deliberately reported at the front. A validation procedure that passes everything it tests is worthless as a certificate that anything passed: **a protocol that nothing fails is measuring nothing**, which is Goodhart's and Campbell's observation applied to a methodology rather than to a policy target [Goodhart, 1975, Campbell, 1979]. The corpus's pass rate under its own protocol is therefore reported here as a headline number rather than as an appendix entry.

The motivation for building such a protocol is external and quantitative. The Open Science Collaboration attempted direct replications of one hundred psychological studies: 97 of the originals reported a statistically significant result and about 36 of the replications did, with effect sizes roughly halved [Open Science Collaboration, 2015]. That is 37 per cent of the originally significant findings recovered, and — because a correlation's explained variance goes as its square — a halving of `r` is a quartering of `r^2`. The diagnosis is not fraudulence. It is a publication filter selecting on something other than truth [Ioannidis, 2005], fed by flexibility in analysis [Simmons et al., 2011, Gelman and Loken, 2013] whose standard remedies are preregistration and held-out prediction [Nosek et al., 2018].

The observation that makes the protocol possible is that one branch of the same discipline does not have this problem. Weber's ratio law has been reproduced continuously since 1834 [Weber, 1834]; Fechner's logarithmic relation since 1860 [Fechner, 1860, 1966]; Stevens' magnitude-estimation exponents replicate across laboratories and decades, and where they vary they vary in known and documented ways with method, range and instruction [Stevens, 1957, Teghtsoonian, 1971, Krueger, 1989]. Psychophysics studies subjective experience — the loudness of a tone, the heaviness of a weight — which is exactly the class of quantity the sceptic says cannot be measured. **The discriminating variable is therefore not subjectivity. It is how the quantity is put on a scale.**

Four things are contributed here relative to the surrounding literature rather than relative to the framework. First, the seven gates are ordered by cost, so that the cheap structural gates run before the expensive empirical ones, and the ordering is defended with the observation that running gate 6 on a formula that fails gate 1 spends a year to learn what an afternoon would have taught. Second, an invariance theorem — that a quotient is meaningful only on a ratio scale — is stated with a three-line proof and then *executed* as four constructive demonstrations on the corpus's own data structures, showing that an admissible relabelling moves a reported `D/P` by 25 per cent, reverses the ordering of two occasions, delivers any ratio one likes, and can make the ratio negative and the distortion undefined. Third, the demotion that follows is stated as a withdrawal of specific quantities, with an explicit list of what survives it. Fourth, the restoration is **priced**: given a badged identification postulate, Rasch person measures supply the true zero that division requires, and the arithmetic of person measurement says how many items that costs — approximately 31 per term to detect a one-logit distortion, 123 for half a logit, and 342 for 0.3.

None of this is a claim about human beings. The empirical portions of gates 6 and 7 are run on **simulated** data throughout, and that label is load-bearing: what is demonstrated is the *protocol* — what the analysis looks like when the formula is true, what it looks like when it is

false, and what the numbers would have to be for a reader to be entitled to believe it.

The framework's static half — the surplus functional `F(u) = ln(1 + (N−1)u)` and its affine effective count — is presupposed rather than re-derived [Curzi, 2026]. The storage law `Q_{t+1} = (1−delta)Q_t + eta S_t − C_t`, its fixed point and its geometric convergence, which gate 4 checks candidate formulas against, are presupposed from Curzi [2026a]. The moment equation itself and its self-imposed demotion to ordinal scale are stated in Curzi [2026m]; the logarithmic register in which the whole corpus is written is established in Curzi [2026n].

Section 2 states the hypotheses. Section 3 states the protocol and what is presupposed, including the identification problem the framework cannot answer. Sections 4 to 6 define the seven gates, their requirements and their failure modes. Sections 7 to 9 develop gate 2 in full, because scale type is where the corpus's own central formula is most exposed. Sections 10 to 12 develop the deep form of gate 7. Section 13 reports the protocol run end to end. Sections 14 to 17 discuss what follows, verify the chain, state the limitations, and conclude.

26.2 2 Hypotheses

Some of what follows are theorems about transformation groups and about a probabilistic model, and they cannot be falsified by observation; they are labelled as derivations where they appear. What can be falsified is the claim that the protocol is *discriminating* — that it separates formulas that measure something from formulas that do not — and the claim that the corpus's own formulas have the status the protocol assigns them. The hypotheses below separate the two, and each names the observation that would defeat it.

H1 — The protocol has teeth. A validation protocol applied to a body of formulas whose author constructed both will return a pass rate materially below one. **Predicted:** applied to the corpus's own formulary, the protocol demotes a substantial fraction of the entries, and the corpus's central formula is among the demoted. **Falsified by:** every formula in the corpus passing every gate. That outcome would not be evidence that the formulas are sound; it would be evidence that the protocol is a compliance exercise, which is failure mode FM-6.8.

H2 — Scale type, not sample size, is what licenses a quotient. For quantities measured on a scale admitting transformations beyond $x \mapsto ax$, the value of a reported ratio is a property of the labelling rather than of the world. **Predicted:** an admissible relabelling of an ordinal instrument changes a reported `D/P` by an arbitrary factor, reverses the ordering of two occasions, and can render the distortion undefined; and no quantity of data alters this, because it is an algebraic property of the transformation group. **Falsified by:** exhibiting a strictly increasing `g` under which `g(X)/g(Y) = X/Y` for all positive `X`, `Y` without `g` being linear through the origin. Section 15 shows this cannot be done, so H2 is in fact a **theorem**, not a hypothesis; it is stated here as a hypothesis only to make the boundary between the two explicit, and it is recorded as `DEFINITION/ARITHMETIC` in the verification chain rather than as an empirical claim.

H3 — A preregistered rival functional form is necessary, and a null is not sufficient. A misspecified functional form can beat every simpler baseline on held-out data. **Predicted:** data generated additively and fitted with the multiplicative log-linear model will still return a respectable held-out `R^2` — high enough to be reported as confirmation against persistence, direct-input and autoregressive baselines — while the correct additive model scores materially higher. **Falsified by:** the misspecified form failing conspicuously against the simple baselines, which would make the rival-form preregistration redundant.

H4 — Pooling across persons manufactures apparent precision. Where a parameter varies between persons, a pooled regression returns an interval far narrower

than the true spread of the individuals it purports to describe. **Predicted:** with true between-person spread τ and pooled standard error s, the ratio τ/s is large and grows with the number of pooled observations, so the pooled analysis looks *more* precise the *more* wrong it is about every individual in it. **Falsified by:** a pooled interval whose width tracks the between-person spread rather than the observation count.

H5 — Invariance dominates fit as a diagnostic. Split-sample parameter invariance detects instrument defects that model-fit statistics miss. **Predicted:** on an instrument with planted defects, the split-sample invariance test flags strictly more of them than the fit statistics do, and at least one defect returns fit statistics in the nominal range. **Falsified by:** fit statistics catching every defect the invariance test catches, which would make gate 7 a footnote to model fit rather than a separate gate.

H1 is confirmed and H3, H4 and H5 are confirmed on simulated data; H2 is a theorem. The confirmations of H3, H4 and H5 are confirmations *about the protocol*, on data whose generating process is known, and they carry no implication whatever about human subjects. That distinction is maintained throughout and is restated in Section 16.

26.3 3 The validation problem and the protocol

The three parts of this paper are the scientific warrant of Series B of the corpus. Everything before them is a construction. Everything after them depends on whether the construction is allowed to stand. If this paper fails, the applied sections of the framework are an elaborate notation for opinions, and the honest thing to do would be to say so and stop.

So it is worth being exact about what is being claimed, and about what the objection actually is.

26.3.1 3.1 The objection, stated fairly

The objection is not that psychology and sociology are pseudoscience. **That charge is false, it is lazy, and this paper does not make it.** It is worth spelling out why, because a great deal of sloppy work — including sloppy work that flatters the corpus's own project — hides behind the sloppiness of the charge.

Psychology and sociology are sciences. They have theories that make predictions, experimental methods, measurement instruments, institutions of criticism, and findings that hold. The contact hypothesis is a real finding, with four stated conditions [Allport, 1954] and a meta-analysis over more than five hundred studies attached to it [Pettigrew and Tropp, 2006]. The collective intelligence factor is a real finding [Woolley et al., 2010]. The tipping point at roughly twenty-five per cent is a measured quantity from a controlled experiment [Centola et al., 2018]. Ostrom's design principles were extracted from field data across decades [Ostrom, 1990]. These are not vibes.

What these fields have is **a measurement problem and a replication problem**, and those are different diseases from fraudulence, with different treatments.

26.3.2 3.2 The replication numbers, stated exactly

The Open Science Collaboration's *Estimating the reproducibility of psychological science* (*Science*, 2015) attempted direct replications of one hundred studies published in three high-ranking psychology journals. The headline result, as recorded in the corpus's canon:

```
originals reporting a statistically significant result:      97 of 100
replications reporting a statistically significant result:   about 36 of 100
replication effect sizes:                                    roughly half the originals
```

Three pieces of arithmetic on those figures, computed:

```
36 / 97   = 0.3711        of the originally significant findings, about 37% replicated
97 - 36   = 61            percentage-point gap between claimed and recovered
halving r: r -> r/2  =>  r^2 -> r^2 / 4       variance explained falls to 25%
```

That last line is the one people miss. **Effect sizes "roughly halved" means variance explained roughly quartered**, because the variance a correlation accounts for goes as its square. An effect that explained 16% of variance in the original explains 4% in the replication, whatever the p-value says. Verified across the plausible range:

original `r`	original `r^2`	halved `r`	halved `r^2`	ratio
0.20	0.0400	0.100	0.0100	0.250
0.30	0.0900	0.150	0.0225	0.250
0.40	0.1600	0.200	0.0400	0.250
0.50	0.2500	0.250	0.0625	0.250

26.3.3 3.3 What the numbers are evidence of, and what they are not

They are **not** evidence that psychology is fake. Some failed replications are themselves false negatives, some are context-sensitivity rather than error, and one replication is not a verdict. They are also not evidence about sociology, which was not the sample.

They are evidence of something narrower and more actionable. **A field in which 97% of published results are significant and 36% of them survive a direct redo is a field whose publication filter is selecting on something other than truth.** That is a process fault, and process faults have process fixes: preregistration, adequate power, held-out prediction, and — the concern of these this paper — better measurement.

Here is the observation that makes the whole of this paper possible, and it is the load-bearing observation of the section. **Psychophysics does not have this problem.** Weber's ratio law has been reproduced continuously since 1834. Fechner's logarithmic relation since 1860. Stevens' magnitude-estimation exponents replicate across laboratories, across decades, and across languages, and where they vary they vary in known and documented ways with method, range and instruction [Stevens, 1957, Teghtsoonian, 1971, Krueger, 1989]. Psychophysics studies *subjective experience* — the loudness of a tone, the heaviness of a weight, the brightness of a light — which is exactly the class of quantity the sceptic says cannot be measured. And it replicates.

So the discriminating variable is not subjectivity. Psychophysics is as subjective as anything in Series B of the corpus. The discriminating variable is **how the quantity is put on a scale.** Psychophysics built ratio scales, with a true zero, using procedures that recover the same exponent from different observers on different days in different rooms. Much of the rest of the field uses seven-point ratings, treats them as though they were metres, and averages them.

26.3.4 3.4 The claim of this paper, stated so it can be checked

Formulas do not make a field hard. Ratio-scale, reproducible, falsifiable measurement of the formulas' terms does.

That sentence is the thesis of this paper, and it cuts against the corpus as much as for it. Writing `M = (D/P)E` does not make the study of moments a science. Nothing about the typographic dignity of an equals sign confers empirical status. An equation is a claim about relations among *measured quantities*, and if the quantities are not measured — really measured, on a scale that supports the operations the equation performs on them — then the equation is a diagram of an intuition wearing mathematical clothes.

This is achievable. Psychophysics achieved it for sensory magnitude, and Rasch measurement achieved a version of it for attainment and attitude (Section 10). The Formula Validation Protocol is the route, and it is deliberately harsh: a protocol the corpus's own formulas cannot fail would be worthless as a certificate that they passed.

26.3.5 3.5 The protocol, badged

Postulate FVP (methodological). **A formula in the corpus is admissible if and only if it passes all seven gates below, in print, with its results stated.** This is a house standard, not a theorem. It is not derived from the foundations papers of the corpus, and no result in the corpus depends on it. It is a rule the author has adopted and by which the author asks to be judged. Its components are drawn from established measurement theory and established replication practice; the choice to require all seven, together, of every formula, is the author's.

```
FVP-1  DIMENSIONS       Units of every term; both sides agree; ratios dimensionless.
FVP-2  SCALE TYPE       Stevens' typology per term. Division and multiplication REQUIRE a
                        ratio scale with a true zero. If only ordinal data exist, say so:
                        the formula is a heuristic ordering, not an equation, and is
                        DEMOTED in print.
FVP-3  LIMITING CASES   Behaviour as each term -> 0 and -> infinity. Every divergence must
                        correspond to a real, nameable phenomenon or the formula is wrong.
FVP-4  FIXED POINTS     Solve for the invariant. State what it means.
FVP-5  IDENTIFIABILITY  Can the parameters be recovered from obtainable data? If two distinct
                        parameter sets predict identical observations, the formula is not
                        testable as written.
FVP-6  FALSIFICATION    Preregister; fit on training; FREEZE; report held-out; beat four
                        baselines (persistence, direct-input, matched autoregressive,
                        SHUFFLED-INPUT control). State in advance what result kills it.
FVP-7  REPRODUCIBILITY  Same operationalisation, different people, different laboratories:
                        do the parameters recover?
```

26.3.6 3.6 Why seven, and why in this order

Each gate kills a distinct class of error, and the classes do not overlap. A formula can be dimensionally perfect and scale-illegal. It can be scale-legal and unidentifiable. It can be identifiable and unfalsifiable. It can pass every one of the first six and still be a private fact about one person's rating habits, which is what FVP-7 is for.

Gate	Class of error it kills	Cost to run	What passing buys
FVP-1	Category error: adding unlike things	Hours	The equation is *about* something coherent
FVP-2	Operation error: arithmetic the data cannot support	Hours to years	The operations performed are meaningful
FVP-3	Structural error: behaviour with no referent	Hours	The formula's extremes describe real states

Gate	Class of error it kills	Cost to run	What passing buys
FVP-4	Vacuity: no invariant, therefore no content	Hours	The formula says something at equilibrium
FVP-5	Aliasing: distinct causes, identical predictions	Days	The parameters are recoverable in principle
FVP-6	Overfitting and post-hoc rescue	Months	The formula beat the alternatives on data it never saw
FVP-7	Idiosyncrasy: a result true of one person only	Years	The formula is about people, not about a person

The order is a cost ordering and it must be respected. Gates 1 through 4 are armchair work: they cost an afternoon and they kill most bad formulas. Gate 5 costs days. Gate 6 costs months. Gate 7 costs years and multiple laboratories. Running gate 6 on a formula that fails gate 1 is a way of spending a year to learn something an afternoon would have taught. In the corpus's experience the ratio is stark: **the cheap gates kill most candidates, and the expensive gates are where the surviving candidates are actually decided.**

26.3.7 3.7 FVP-7 is the gate that decides, and the gate that gets skipped

Every one of the first six gates can be passed by a result true of exactly one person on exactly one instrument. A single subject, densely measured, can produce beautiful held-out prediction that beats all four baselines, and the whole thing can still be an artefact of how that one person uses the word "vivid."

FVP-7 is where the hard-science question is actually settled, and it is the gate the literature most often omits. It is omitted because it is expensive, because it requires coordination with people who do not share your priors, and because — the real reason — it is the gate most likely to return a negative. A framework that has passed gates 1 through 6 feels finished. It is not. The 36% figure is what the world looks like when a field routinely stops at gate 6.

Section 7 is FVP-2 in full, because scale type is where the corpus's own central formula is most at risk. Section 10 is the deep form of FVP-7, because invariance across persons and instruments is what "reproducible measurement" actually means. The falsification suite is FVP-6 in full [Curzi, 2026u]. Sections 3 to 6 define all seven gates, and Section 13.1 runs the complete protocol, end to end, on `M = (D/P)E`.

26.3.8 3.8 What is presupposed

Four results are used here and not re-derived.

The **surplus functional** `F(u) = ln(1 + (N−1)u)`, its axiom set, and the affine effective count `N_eff = 1 + (N−1)u` are established in Curzi [2026] and are used at gate 1 as the worked dimensional check. **That effective count is a linear interpolation between 1 and `N` and is the corpus's own construction; it is not a Hill number of any order.** Where an effective count appears below it is this one, and the Hill numbers proper — `1/HHI` at order 2 and `exp(H)` at order 1 [Hill, 1973, Jost, 2006] — are the different quantities used in the corpus's concentration work [Curzi, 2026], not here.

The **storage law** `Q_{t+1} = (1−delta)Q_t + eta S_t − C_t`, its unique fixed point `Q_inf = (eta S − C)/delta`, and the geometric error law `|Q_t − Q_inf| = (1−delta)^t |Q_0 − Q_inf|` are established in Curzi [2026a], whose result that `delta = 0` is a pathology rather than an ideal — no contraction, no unique fixed point, an error-persistence column of ones — is the behaviour gate 4 checks a candidate formula's invariant against. The contraction itself is stated exactly in Curzi [2026]: a contraction with modulus `q < 1` on a complete space has exactly one fixed point, reached from any start, with distance shrinking by at least `q` each pass [Banach, 1922, Elaydi, 2005].

The **moment equation** `M = (D/P)E` and its calibration ratio `r = D/P` are stated in Curzi [2026m], together with the demotion rule this paper executes: because the equation contains a division and a multiplication, ordinal data for frame or intake demote it to a heuristic ordering that may not be printed as a fraction or computed.

The **logarithmic register** — that the corpus's quantities are differences of logarithms, reported in nats — is established in Curzi [2026n], whose ratio-invariance test is the licence claimed for a ratio scale there: two fourfold physical steps returned 2.5100 and 2.5000, agreeing to 0.40 per cent and matching the fitted `4^0.6569 = 2.4859`.

The corpus's classification of its own claims into established mathematics, established psychology and declared postulates is Curzi [2026]; every badge used below is a badge in that scheme.

26.3.9 3.9 Identification: what no amount of fitting can recover

Gate 5 asks whether distinct parameter values imply distinct observable predictions. There is a prior identification problem which gate 5 as stated does **not** catch, which is more serious than anything gate 5 does catch, and which this paper cannot answer.

The framework's central formal claim is a reflexive loop `T(x) = W(x, M(x))`: the group influences the member and the members constitute the group. **That is exactly a linear-in-means reflexive specification, and Manski [1993] proves that the endogenous social effect in such a specification is not identified from observational data.** It cannot be separated from contextual effects or from correlated unobservables however much data is collected. Shalizi and Thomas [2011] reinforce the point for networks: influence and selection are generically confounded in observational network data.

The known remedies are randomisation of the treatment, an instrument, partial-population variation, or stipulating the reference group by prior information and defending the stipulation — Brock and Durlauf [2001] being the template for the last and the most realistic route here. **None of them is free, and this paper adopts none of them.** The protocol specified below therefore validates *formulas*, and validation of a formula is not identification of a social effect. Where the framework's reflexive claims are concerned, the honest statement is that they are a **modelling position rather than an identified empirical result**, and the FVP row of any formula resting on the loop should carry that statement at gate 5 in addition to the invariance list.

Two further objections in the same family are recorded here because they bear directly on gate 7. The **Lucas critique** applies to the corpus reflexively: parameters estimated in a population that has not read the storage law cannot be assumed stable in a population that has [Lucas, 1976]. Hacking [1995] states the same problem philosophically — classifications of people interact with the people classified, so the referent moves — and Ferraro et al. [2005] supplies the warning case. Against this, MacKenzie and Millo [2003] documents a reflexive fixed point *observed in the field*, with dates and price data, which is the corpus's own mechanism caught happening; the corpus proposes to give people laws to manage their own comfort by, and is therefore building an engine as well as a camera [MacKenzie, 2006, Callon, 1998]. **The corpus asserts reflexivity for its subject matter and cannot consistently exempt its own parameters from it.** Gate 7 as specified below tests stability across persons and instruments; it does not test stability across *publication*, and no gate in the protocol does.

26.3.10 3.10 Analogy discipline, and what the protocol borrows

The corpus draws on physics and on information theory for its form. Every such borrowing is one of three things and is labelled at first use: a **derivation**, where the system genuinely satisfies the physical premises; a **shared mathematical form**, where the same equation governs both with no claim that the underlying physics applies; or an **analogy**, legitimate as motivation and never as evidence.

Everything this paper borrows is of the second kind, and the second kind is respectable. The dimensional rules R1–R3 of gate 1 are the algebra of dimensional homogeneity and carry no physics. The invariance argument of gate 2 is group theory applied to labelling conventions [Stevens, 1946, Krantz et al., 1971]. The fixed-point language of gate 4 is the elementary theory of first-order difference equations [Elaydi, 2005]. The **entropy** that appears in the treatment of nominal scales is Shannon entropy of a partition, measured in nats or bits [Shannon, 1948], not a thermodynamic quantity, and no thermodynamic consequence is claimed for it. The **logit** of the Rasch model is a log-odds, not a physical potential.

Two limits on the borrowing are recorded now rather than in Limitations. First, the corpus's `Q` is a stock that accumulates, leaks and is spent — the grammar of a conserved quantity — and Mirowski [1989] shows that importing the notation of a conserved quantity without the conservation law is the characteristic failure of exactly this genre. **The corpus owes a statement of what is conserved, in what units, and under what invariance, and it does not have one.** Cartwright [1999] offers the escape route the corpus should take: specify the arrangement within which each law is claimed to hold and stop claiming a universality it does not need. Second, Anderson [1972] is the charter for writing laws at the psychological and social level and, read carefully, an equally strong argument that such laws must be *derived* at that level rather than imported from a lower one.

The functional form of the corpus's surplus law is underdetermined by the evidence, and the protocol below does not repair that. Latané [1981] proposes influence growing as a power of the number of sources with exponent below one; Briscoe et al. [2006] argues for `n log n`; the corpus asserts `ln(1 + (N−1)u)`. All three are decelerating and all three fit the qualitative facts, and Stumpf and Porter [2012] states the general problem: many mechanisms produce indistinguishable curves. The corpus's uniqueness-under-axioms argument establishes that its form follows from *its axioms*; it does not establish that its axioms are the ones the data support. Gate 6's requirement to preregister a rival functional form (KILL-5 below) is the corpus's answer to this in miniature, and Section 13.1.6 shows what it catches. One genuine strengthening is available and should be taken wherever the logarithm is justified: Peters and Gell-Mann [2016] derives a logarithmic form from multiplicative dynamics with **no psychological assumption at all**, which is a stronger warrant than Fechner's because it does not require the perceptual story to be true.

Finally, **no scaling, power-law or heavy-tail claim is made anywhere in this paper.** The one power law that appears — Stevens' `psi = k I^a` in Section 7.10 — is fitted by ordinary least squares in log-log coordinates over a bounded, experimenter-chosen stimulus range with the `R^2` reported, and it is a *response function*, not a distributional tail. Where a distributional claim is made elsewhere in the corpus, the procedure of Clauset et al. [2009] is binding and this paper does not substitute for it.

26.3.11 3.11 Standing honesty clauses

Three clauses govern every number reported below and are stated once here.

Simulated is said, every time. The empirical portions of gates 6 and 7 are run on data whose generating process is known and chosen. They demonstrate the protocol's behaviour under a true model and under two false ones. They are not evidence about people, and no sentence below should be read as such.

Significant figures follow epistemic status. Quantities that are exact by construction — a transformation group, a ratio of integers, the elementary symmetric functions of a stated pa-

rameter vector — are quoted to whatever precision is useful and said to be exact. Quantities estimated from the simulated series are quoted with a standard error or an interval. Quantities that are illustrative model output are rounded and labelled.

A gate not run is reported NOT YET RUN, never blank and never passed. The corpus's own formulas mostly report NOT YET RUN at gates 6 and 7. Printing the honest status is what makes the passed gates worth anything.

26.4 4 The seven gates in detail

26.4.1 4.1 FVP-1 — Dimensions

Dimensional analysis is the cheapest true statement you can make about an equation, and it is astonishing how often it is skipped in the human sciences. It requires no data — only that you write down, beside each symbol, what a unit of that symbol *is*. Three rules, none negotiable:

```
R1  Only like-dimensioned quantities may be added or subtracted.
R2  The argument of ln, exp, sin, or any transcendental function must be dimensionless.
R3  Both sides of an equation must carry identical dimensions.
```

R2 does the most work in this corpus, because this corpus is logarithmic throughout. You cannot take the logarithm of three metres. You can take the logarithm of a *ratio* of metres, and the result is dimensionless — measured in nats, a unit of information, not of length.

Worked check: the surplus law.

```
u = 1 - (x . y)^2 = ||x ^ y||^2        x, y are UNIT vectors -> u dimensionless, in [0,1]
N                                       a count -> dimensionless
1 + (N-1)u                              dimensionless + dimensionless -> OK by R1
F = ln(1 + (N-1)u)                      argument dimensionless -> OK by R2; F in nats
```

Passes. Note what the check enforces: `x` and `y` must be *unit* vectors, or `u` is not dimensionless and the construction fails at R2. That is the reason the surplus functional is defined on normalised states [Curzi, 2026].

Worked check: the storage law.

```
Q_{t+1} = (1 - delta) Q_t + eta S_t - C_t

Q      units of stored order     [q]
S      nats
eta    [q] per nat                       -> eta S has units [q]        OK
delta  dimensionless per period          -> (1-delta) Q has units [q]  OK
C      [q] per period                    -> subtractable from [q]      OK
h = eta ln N - delta Q - C               all three terms in [q]        OK by R1
```

Passes, and the check *earns something*: `eta` is not a pure number. **Eta is a conversion constant with units — the exchange rate between nats of interaction and units of durable structure.** Anyone reporting an eta without saying what `[q]` is has reported half a number. The storage law's conversion constant is named in words in Curzi [2026a]; FVP-1 says it in units.

Worked check: the Moment equation.

```
M = (D / P) . E

For D/P to be dimensionless (R2 is not invoked here, but the interpretation demands it),
```

```
D and P must carry the SAME units.  Then:

r = D/P            dimensionless
M = r E            M inherits E's units exactly

Distortion:  Delta = |ln r|      argument dimensionless -> OK by R2, Delta in nats
```

Passes, **conditionally** — and the condition is the whole content of the gate here. If perspective is measured in "confidence points" and perception in "cues detected per minute", the ratio is not dimensionless, it is a rate with units, and `M` does not inherit `E`'s units. The formula would then be false as written, not merely unmeasured.

FVP-1 therefore imposes a design requirement on the whole of the moment-equation material: D and P must be instrumented on one common scale. That is a hard constraint and it is where most naive operationalisations of the Moment equation die. It is also the constraint that makes cross-modality matching (Section 7, §7.11) relevant rather than ornamental.

26.4.2 4.2 FVP-2 — Scale type

Section 7 is this gate, in full, and nothing here substitutes for it. The summary that belongs in the protocol definition:

```
NOMINAL    identity only        admissible transforms: any 1–1 relabelling
ORDINAL    order               admissible transforms: any strictly increasing g
INTERVAL   order + distance    admissible transforms: x -> a x + b,  a > 0
RATIO      order + distance
           + a true zero       admissible transforms: x -> a x,      a > 0
```

The rule that governs the corpus: division and multiplication are meaningful only on a ratio scale. The reason is exactly the invariance structure above. A statement survives as a claim about the world only if it is unchanged under every transformation the scale admits. On a ratio scale, `g(D)/g(P) = (aD)/(aP) = D/P`: the ratio is invariant, so it carries information. On an interval scale, `(aD+b)/(aP+b)` depends on `b`, which was arbitrary. On an ordinal scale, `g(D)/g(P)` depends on the entire shape of `g`, and `g` was arbitrary.

FVP-2 returns one of three verdicts:

```
PASS       ratio-scaled with a demonstrated true zero -> the equation stands as an equation
DEMOTE     ordinal or interval only -> the formula is printed as a HEURISTIC ORDERING,
           with the demotion stated in the same paragraph as the formula
FAIL       the quantity has no defensible scale at all -> the term is not admissible
```

The DEMOTE verdict is the honest middle, and the corpus uses it. A demoted formula is still useful: it can order occasions, flag directions, and structure attention. What it cannot do is carry a number that is then multiplied by something else. Section 7 §7.13 specifies exactly what survives demotion and what does not.

26.4.3 4.3 FVP-3 — Limiting cases

Take every term to zero and to infinity, one at a time, and read what the formula says. Then ask, for each result, **is there a real phenomenon with that name?**

This gate is a structure test, not a data test, and it is unreasonably effective. Formulas built by analogy almost always have a limit that is nonsense, and the nonsense stays invisible until someone takes the limit.

```
RULE FVP-3a   A divergence (a term going to infinity) must correspond to a real, nameable
              phenomenon. If it does not, the formula is wrong at the singularity, and
              almost always wrong well before it.

RULE FVP-3b   A zero must correspond to a real, nameable phenomenon. "It just goes to zero"
              is not an interpretation.

RULE FVP-3c   Where the limit is a genuine impossibility rather than a phenomenon, the
              formula must state its DOMAIN OF VALIDITY and stop there. Restricting the
              domain is legitimate. Pretending the limit is meaningful is not.
```

The Moment equation is the exemplar and it passes with unusual grace; §13.1 runs the numbers. The storage law also passes, and the passing is instructive: as `delta -> 0` the model gives `Q_t <= Q_0 + t eta ln N` [Curzi, 2026a, Theorem 3.3] — unbounded linear growth with no fixed point. That is not a defect; it is the exact description of a system with no forgetting, which is the subject of the storage law's zero-loss pathology [Curzi, 2026a], and which really does fail to converge. **The limit named a real phenomenon, so the gate passes.**

26.4.4 4.4 FVP-4 — Fixed points

Solve for the invariant. Two distinct objects go by this name and confusing them is a common error:

```
FIXED POINT OF A MAP        x* such that T(x*) = x*.  Dynamic. Banach guarantees existence and
                            convergence when T is a contraction.
                            Example: Q_inf = (eta F(u*) - c*) / delta   [the storage law]

INVARIANT OF AN EQUATION    the parameter configuration at which the equation reduces to an
                            identity. Static. No dynamics required.
                            Example: D = P  =>  M = E
```

Both must be reported. The map's fixed point tells you where iteration arrives; the equation's invariant tells you what the formula is *for*.

A formula with no invariant is usually vacuous. If no configuration of the parameters reduces it to something simpler and interpretable, it is a curve-fit rather than a law — laws are compressions, and compressions have degenerate cases.

FVP-4 also requires that the fixed point's *stability* be stated. `Q_inf` is attracting whenever `delta > 0`, with `|Q_t - Q_inf| = (1-delta)^t |Q_0 - Q_inf|` — geometric convergence, Curzi [2026q]. `D = P` is *not* dynamically attracting in the Moment equation as written, because the Moment equation is not a map: it is an instantaneous relation. Saying so is part of passing the gate. Nothing in `M = (D/P)E` makes `r` drift toward 1. That drift, if it exists, is a separate postulate about learning, and the calibration-ratio paper states it separately and badges it [Curzi, 2026m].

26.4.5 4.5 FVP-5 — Identifiability

A formula is identifiable if distinct parameter values imply distinct observable predictions. If two different parameter sets predict exactly the same data, no amount of data will ever distinguish them, and the formula is not testable as written. This is a property of the *model*, not of the sample size, and it is checked algebraically before anything is measured.

Two kinds:

```
STRUCTURAL identifiability   distinct parameters -> distinct predictions, in principle,
                             with infinite noiseless data. An algebraic property.
```

```
PRACTICAL  identifiability   the parameters can be recovered with useful precision from the
                             data you can actually obtain. A statistical property.
```

Structural failure is fatal and no quantity of data repairs it. Practical failure can sometimes be fixed by better design.

The Moment equation has a structural identifiability problem, and it is severe. `M = (D/P)E` is invariant under two separate transformations, computed here on concrete values:

case	D	P	E	M = (D/P)E
A (reference)	8.0	4.0	3.0	**6.0000**
B (`D`,`P` both scaled by 2.5)	20.0	10.0	3.0	**6.0000**
C (`r` doubled, `E` halved)	16.0	4.0	1.5	**6.0000**
D (`r` quartered, `E` quadrupled)	2.0	4.0	12.0	**6.0000**

Four different worlds. One observation. **From `M` alone, none of `D`, `P`, `E` or even `r` is recoverable.** The first invariance (rows A and B) is benign in a sense — it says the ratio `r` is what matters and the common scale of `D` and `P` is free — but it means you cannot report `D` as a number without an anchor. The second invariance (rows A, C, D) is the dangerous one: **`r` and `E` trade off exactly, so a large distortion with a thin environment is observationally identical to undistorted contact with a rich one.**

This is not a fatal objection but a specification of what the instrument must supply. Three remedies, in ascending order of cost:

```
REMEDY I5-a   ANCHOR the common scale. Fix a standard stimulus and define D and P relative
              to it. This removes the (cD, cP) freedom by convention. Cost: a standard.

REMEDY I5-b   MEASURE E INDEPENDENTLY of M, by an instrument that does not pass through the
              observer. Physical measures of the environment; a second observer; a record.
              This breaks the r-E trade. Cost: an external instrument. THIS ONE IS ESSENTIAL.

REMEDY I5-c   VARY the terms independently across occasions and use the TIME SERIES. If D
              and P and E move independently over time, the log-linear design matrix has
              full column rank and the exponents are recoverable. Cost: repeated measures,
              and the requirement that the terms genuinely decorrelate.
```

Remedy I5-c has a checkable condition, and it is the practical form of the gate. Writing the Moment equation in the logarithmic register [Curzi, 2026n] gives

```
ln M = b0 + bD ln D + bP ln P + bE ln E + noise
```

with the theoretical prediction `(bD, bP, bE) = (1, −1, 1)`. The parameters are recoverable if and only if the matrix of `[1, ln D, ln P, ln E]` has full column rank. **If `D` and `P` co-vary perfectly across occasions — if your frame always tracks your intake — the columns are collinear and no data set of any size will separate `bD` from `bP`.** That is a real risk, not a hypothetical one, because a well-adapted person's frame *does* track their intake. The design must therefore include occasions that break the coupling, and the analysis must report the collinearity diagnostics. A protocol that measures only ordinary days will fail FVP-5 in practice while passing it in principle.

26.4.6 4.6 FVP-6 — Falsification

The template is the preregistration protocol of Curzi [2026i], and it is stated as a sequence because the order is what makes it work:

Preregistration with a frozen model is the open-science literature's own prescription [Nosek et al., 2018, Simmons et al., 2011], and the corpus's one confirmatory application of this sequence to a real system — together with its failure — is Curzi [2026i].

```
1.  PREREGISTER      Write the operationalisation, the model, the exponent targets, the
                     baselines, the held-out split, and THE KILL CRITERIA. Deposit it
                     before collecting data. The kill criteria are the point.
2.  FIT              Estimate parameters on the training partition ONLY.
3.  FREEZE           Write the parameters down. They do not change again. Not for a better
                     fit, not for an outlier, not for a discovered confound.
4.  HELD-OUT         Apply the frozen parameters to data never used in fitting. Report the
                     out-of-sample statistic.
5.  BASELINES        Beat all four:
                        (i)   PERSISTENCE       yhat_t = y_{t-1}
                        (ii)  DIRECT-INPUT      the environment term alone
                        (iii) MATCHED AR        an autoregressive model of the same order
                        (iv)  SHUFFLED-INPUT    the same model, inputs permuted across time
6.  REPORT           Publish the failures alongside the successes, at the same prominence.
```

The shuffled-input control matters most and is most often absent. Every other baseline asks whether your model beats a simpler model. The shuffle asks a sharper question: *does the model's performance depend on the inputs being matched to the right occasions at all?* A model with enough free parameters, fitted to autocorrelated data, can post a respectable held-out score purely from the marginal distributions. Shuffling destroys the pairing while preserving every marginal. If the shuffled model does nearly as well as the real one, the real one learned nothing about the relation.

The kill criteria must be numeric and must be written before the data exist. For the Moment equation, the corpus preregisters:

```
KILL-1   The 95% confidence interval for bP excludes -1.0  ->  the DIVISION is not there.
KILL-2   The 95% confidence interval for bD excludes  1.0  ->  the frame term is misspecified.
KILL-3   Held-out R^2 of the model fails to exceed the best baseline by at least 0.10.
KILL-4   Held-out R^2 of the SHUFFLED-INPUT control exceeds 0.20.
KILL-5   The model is beaten by a purely additive form M = D - P + E on the same held-out set.
```

KILL-5 deserves comment because it is the specific alternative most likely to be true. Nothing about the phenomenology of perception forces a *multiplicative* combination. If frame and intake combine additively, the log-linear model will still fit reasonably — §13.1 computes exactly how reasonably — and only a direct comparison against the additive form exposes it. **Preregistering the rival functional form, not merely a null, is what separates a falsification test from a ritual.**

26.4.7 4.7 FVP-7 — Reproducibility

The gate: **same operationalisation, different people, different laboratories — do the parameters recover?**

There are three possible answers and they are not equally good, but only one of them is fatal:

```
OUTCOME A   UNIVERSAL CONSTANT
            The parameter takes the same value across persons, within sampling error.
            Strongest outcome. Rare. This is what a physical constant looks like.

OUTCOME B   PERSON-LEVEL CONSTANT
```

```
            The parameter varies between persons but is STABLE WITHIN a person across
            occasions and instruments. This is still measurement, and it is the normal
            case for psychological quantities. A person's height varies between persons
            too. What matters is that it is stable and that it predicts.

OUTCOME C   UNSTABLE
            The parameter varies within a person across occasions or instruments by as
            much as it varies between persons. FATAL. There is no quantity here; there
            is a fitting artefact.
```

Outcome B is a pass, and this must be said clearly, because the sceptic's demand for Outcome A is a demand physics itself would fail for most of its quantities. The mass of an object is not a universal constant. What makes mass a measurement is that the same object gives the same mass on different balances in different laboratories. The psychological analogue: the same person gives the same exponent on different instruments on different days — which is the convergent half of a multitrait-multimethod design [Campbell and Fiske, 1959] and the operational form of construct validation [Cronbach and Meehl, 1955]. That is what Section 10 calls *specific objectivity*, and it is the real criterion.

The statistic that separates B from C is the between-person variance component. Given per-person estimates `b_i` with standard errors `se_i`:

```
tau^2  =  Var(b_i)  −  mean(se_i^2)          the true between-person variance
```

If `tau^2` is at or below zero, the parameter is a universal constant to within your precision (Outcome A). If `tau^2` is large and positive *and* the within-person estimates are stable across instruments, Outcome B. If `tau^2` is large and the within-person estimates are *not* stable across instruments, Outcome C, and the framework dies for that term.

The single most dangerous mistake at this gate is pooling. §13.1 computes the exact damage: pooling twelve heterogeneous subjects produced a confidence interval on `bD` about ten times narrower than the actual spread of the individuals' true values. The pooled analysis looked *more* precise the *more* wrong it was about every individual in it. Pooling is not a way of running FVP-7. It is a way of avoiding it.

26.4.8 4.8 The FVP row — the required print format

Every formula in the applied sections of the framework carries this block. It is a specification artefact, not a summary: a reader must be able to check each cell against the section that produced it.

```
FVP ROW  ——  <formula name>
  FVP-1  DIMENSIONS      <units of each term; verdict>
  FVP-2  SCALE TYPE      <scale required per term; scale available; PASS / DEMOTE / FAIL>
  FVP-3  LIMITING CASES  <each limit, its named phenomenon, domain of validity>
  FVP-4  FIXED POINTS    <invariant, meaning, stability>
  FVP-5  IDENTIFIABILITY <invariances; remedies required; rank condition>
  FVP-6  FALSIFICATION   <kill criteria; baselines; status: TESTED / UNTESTED>
  FVP-7  REPRODUCIBILITY <status: OUTCOME A / B / C / NOT YET RUN>
```

A gate that has not been run is reported as NOT YET RUN, never as blank and never as passed. The corpus's own formulas mostly report NOT YET RUN at gates 6 and 7, and the costed programme for changing that is Curzi [2026u]. Printing the honest status is not an embarrassment; it is the only thing that makes the passed gates worth anything.

26.5 5 The validation requirements

Numbered, checkable requirements. A formulary entry satisfying V-1 through V-22 has been validated to the corpus's standard. An entry that does not satisfy them is not a formula in the corpus; it is a note.

V-1 — No formula without an FVP row. The row appears in the same section as the formula, not in an appendix, not in a footnote. A formula printed without its row is a specification defect regardless of how well it performs.

V-2 — Units before symbols. Before any manipulation, tabulate every symbol with its dimension and its unit. Symbols whose unit cannot be stated are not admissible terms.

V-3 — Verify R1, R2 and R3 explicitly. State, in one line each: which additions are like-to-like, which transcendental arguments are dimensionless, and that both sides agree.

V-4 — Declare the common scale for every ratio. Any expression of the form `X/Y` must name the single scale on which both `X` and `Y` are measured, and the instrument that produces it.

V-5 — Classify each term on Stevens' typology, with evidence. The classification must cite the procedure that establishes it — magnitude estimation, cross-modality matching, ratio production, a Rasch calibration — not an assertion. "Treated as ratio" without a procedure is a FAIL, not a PASS.

V-6 — Demote in the same paragraph, not later. Where FVP-2 returns DEMOTE, the demotion appears in the paragraph that introduces the formula, in the same typeface, and the formula is thereafter written with an ordering relation rather than an equals sign wherever the text permits.

V-7 — Take every limit. For each term: the limit to zero, the limit to infinity, and the behaviour at any interior singularity. Report all of them, including the boring ones.

V-8 — Name the phenomenon at every limit. A limit reported without a named phenomenon fails FVP-3. If no phenomenon exists, restrict the domain and say where the formula stops applying.

V-9 — Report the invariant and its stability. State whether the fixed point is a fixed point of a map (and whether the map is a contraction) or an invariant of a relation (and therefore non-dynamic). Do not let the reader assume dynamics that the formula does not contain.

V-10 — Enumerate the invariance group. List every transformation of the parameters that leaves the predictions unchanged. This is FVP-5's core deliverable and it is algebra, not statistics. If the list is non-trivial, state the anchoring convention that removes each freedom.

V-11 — State the rank condition. For any formula to be estimated by regression, state the design condition under which the parameters are separable, and the collinearity diagnostic that will be reported.

V-12 — Preregister before data. Operationalisation, model, exponent targets, split, baselines, and kill criteria, deposited and timestamped. A preregistration written after the first look is not a preregistration; report it as an exploratory analysis and label it so.

V-13 — Freeze and never unfreeze. Parameters estimated on training data are written down before the held-out partition is touched. Any subsequent change to the model converts the study to exploratory and it must be relabelled throughout.

V-14 — All four baselines, always, including the shuffle. Persistence, direct-input, matched autoregressive, shuffled-input. Report all four scores whether or not the model beat them.

V-15 — Kill criteria are numeric and prior. No kill criterion may contain the words "materially", "substantially", or "clearly". A number and a comparison operator, or it is not a criterion.

V-16 — Preregister the rival functional form. At minimum, the additive analogue of any multiplicative formula and the multiplicative analogue of any additive one. Beating a null is not evidence for a specific functional form.

V-17 — Report per-subject parameters, never only the pool. Publish the individual esti-

mates and their standard errors as a table. A pooled estimate may accompany them; it may not replace them.

V-18 — Compute and report `tau^2`. The between-person variance component, corrected for within-person sampling variance, with the FVP-7 outcome letter (A, B or C) stated.

V-19 — Test within-person stability across instruments, not only across occasions. Outcome B requires that the same person's parameter recovers on a *different* operationalisation. Occasion stability alone does not distinguish a measurement from a habit of responding.

V-20 — Report NOT YET RUN honestly. Any gate not executed is marked NOT YET RUN with a one-sentence statement of what running it would require. Blank cells are prohibited.

V-21 — Publish failures at equal prominence. A formula that failed a gate is reported in the section where it would have appeared, with the failure stated in the opening paragraph. Failed formulas are not silently removed between editions.

V-22 — Guard the protocol against itself. No FVP result may become a target [Goodhart, 1975, Campbell, 1979]. Where an FVP statistic is used to select among candidate formulas, the selection must be disclosed and the winning formula must be re-run on fresh data before it is reported as validated.

26.6 6 Failure modes of formula validation

Each entry: name, clinical description, damaged gate, diagnostic signature, detecting measurement, fix.

26.6.1 FM-6.1 · THE DRESSED-UP METAPHOR

Damages: FVP-1 and FVP-3.

An intuition is written with an equals sign and thereby acquires an unearned authority. The symbols have no units, the terms cannot be added, and no limit was ever taken. The formula is a diagram of a feeling.

Diagnostic signature: the author cannot say what a unit of any term is; every term is described qualitatively; taking a limit produces nonsense. A reliable tell: the formula never appears with numbers in it, anywhere, ever.

Detecting measurement: attempt V-2. Tabulate the units. The tabulation either completes or it does not.

Fix: either instrument the terms or rewrite the relation in words. **A well-written sentence is not a lesser thing than a badly-founded equation; it is a more honest one.**

26.6.2 FM-6.2 · THE UNANCHORED RATIO

Damages: FVP-5.

A ratio is reported as a number without any convention fixing the common scale, so the number means nothing across contexts. Two reports of `r = 1.4` from two instruments are not comparable and are nonetheless compared.

Diagnostic signature: `r` values drift systematically between studies, between instruments, or between the same person's sessions on different apparatus, with no substantive account of why.

Detecting measurement: run the same subject on two operationalisations in one sitting and regress one `r` on the other. A slope far from 1 with a high correlation is the signature: the quantity is real, the anchor is missing.

Fix: Remedy I5-a. Adopt and publish a standard stimulus. The choice of standard is arbitrary; the existence of one is not.

26.6.3 FM-6.3 · THE R-E TRADE

Damages: FVP-5, specifically.

The environment term is estimated from the same report that produced the moment, so `r` and `E` absorb each other and the model fits perfectly while identifying nothing. This is the single largest threat to the Moment equation and it is the reason Remedy I5-b is marked essential.

Diagnostic signature: excellent in-sample fit; `bE` and the intercept strongly correlated in the parameter covariance matrix; held-out performance collapses when the environment measure is replaced by an external one.

Detecting measurement: compute the correlation between estimated `ln r` and estimated `ln E` across occasions. Strong negative correlation is the trade appearing directly.

Fix: measure `E` by an instrument that does not pass through the observer. A physical record, a second observer, a logged event stream. Without this, the Moment equation is not testable.

26.6.4 FM-6.4 · THE MISSING SHUFFLE

Damages: FVP-6.

Three baselines are reported and the shuffled-input control is not. The model beats persistence, beats direct-input and beats an AR(1), and none of that establishes that it used the pairing between inputs and outcomes.

Diagnostic signature: the baselines reported are all *simpler models*, none is a *destroyed-pairing control*. The word “shuffle” or “permutation” does not appear in the methods.

Detecting measurement: run it. It costs one line of code and one refit.

Fix: run it, and report the number whatever it is. In the demonstration of §13.1, the real model scored `R^2 = 0.8091` held-out and the shuffled control scored `0.0059`. That gap is what a working model looks like. A gap of `0.81` versus `0.55` would have meant something very different.

26.6.5 FM-6.5 · THE POOLED FICTION

Damages: FVP-7, fatally, while appearing to strengthen it.

Individual subjects are pooled into one regression. The pooled confidence interval is narrow because `n` is large. The narrowness is reported as precision. It is not precision; it is a statement about the *average* of a population, presented as though it were a statement about the *members*.

Diagnostic signature: per-subject estimates are not reported; `n` in the results is the number of observations rather than the number of subjects; the confidence interval is implausibly tight for a psychological quantity.

Detecting measurement: fit every subject separately and compute `tau^2` (V-18). In §13.1’s heterogeneous case, `tau = 0.2534` against a pooled standard error of `0.0257`. **The pooled interval was about ten times narrower than the real spread.**

Fix: V-17 and V-18. Publish the per-subject table. Report `tau`. If the target is a group-level claim, use a model with an explicit random effect and report the variance component, not only the mean.

26.6.6 FM-6.6 · THE SILENT DEMOTION

Damages: FVP-2, and everything downstream of it.

Ordinal data are collected, arithmetic that requires a ratio scale is performed on them, and the scale question is never raised. This is the most common failure in the entire human-sciences literature and it is invisible because it is universal.

Diagnostic signature: seven-point ratings entering a multiplication or a division; means and standard deviations of Likert items [Likert, 1932]; ratios of Likert means reported to two decimal places. The rating instrument is separately exposed to question-wording and focusing-illusion effects [Schwarz, 1999, Kahneman et al., 2006], so the arithmetic is performed on a response whose level is itself unstable.

Detecting measurement: the re-labelling test of Section 7.9. Apply an arbitrary strictly increasing transformation to the raw responses, recompute the result, and see whether the conclusion survives. If it does not, the conclusion was about the labels.

Fix: build a real scale (Section 7.10-7.12) or demote in print (V-6). There is no third option, and the pretence that there is one is what the 36% figure is partly made of.

26.6.7 FM-6.7 · THE EPICYCLE

Damages: FVP-6.

A prediction fails and the model acquires a term. The new term is justified post hoc and is never itself preregistered. Repeat, and the model becomes unfalsifiable by accretion rather than by design.

Diagnostic signature: the model has more free parameters than it had last year; every added parameter was added after a specific failure; there is no held-out test that postdates the last addition.

Detecting measurement: count parameters against the preregistration. Compare held-out performance of the current model to the *original* frozen model on *new* data.

Fix: freeze, and re-run the full FVP-6 suite on fresh data with the amended model preregistered. An amended model is a new model and inherits none of the old one's credit.

26.6.8 FM-6.8 · GOODHART CAPTURE OF THE PROTOCOL

Damages: all seven, by making them a target.

The FVP becomes a compliance exercise. Formulas are constructed to pass the gates rather than tested by them; kill criteria are written loose enough to survive; the shuffle control is run on a version of the data with the pairing partially preserved.

Diagnostic signature: every formula in the corpus passes every gate. This is the tell. **A protocol that nothing fails is measuring nothing** [Goodhart, 1975, Campbell, 1979].

Detecting measurement: the pass rate. In an honest corpus it is well below one.

Fix: V-21 and V-22. Publish failures. Re-run selected formulas on fresh data. And keep the pass rate itself on the dashboard, because a rising pass rate is the earliest signal of capture.

26.7 7 Scale type: why a quotient requires a ratio scale

This is the crux of Series B of the corpus. Every other result in the applied sections of the framework either survives this gate or is demoted by it.

The Moment equation divides. `M = (D/P)E` takes perspective, divides it by perception, and multiplies the result by environment. **Division and multiplication are not universally available operations. They are licensed by the scale type of the quantities involved, and they are**

licensed only on a ratio scale with a true zero. If `D` and `P` are not ratio-scaled, the expression `D/P` does not fail to be accurate — it fails to be *about anything*, because its value can be set to whatever you like by a relabelling that changes nothing in the world.

That is the claim of this section, and it is not a matter of taste. It is a theorem about invariance, and the theorem is proved in three lines.

26.7.1 7.1 Stevens' typology

Stevens [1946] classified measurement scales by **the group of transformations under which the scale's information is preserved.** A scale is not a set of numbers; it is a set of numbers *together with the class of relabellings that leave what the numbers mean unchanged.* That class is the scale.

```
SCALE      WHAT IS PRESERVED           ADMISSIBLE TRANSFORMATIONS g
--------   -------------------------   ---------------------------------------------
NOMINAL    identity / distinctness     any one-to-one map          x -> g(x), g injective
ORDINAL    identity + order            any strictly increasing g   x -> g(x), g' > 0
INTERVAL   + equality of differences   positive affine             x -> a x + b,  a > 0
RATIO      + a true zero               similarity                  x -> a x,      a > 0
ABSOLUTE   + the unit itself           identity only               x -> x
```

Each row's transformation group is a *subgroup* of the row above it. Nominal admits the most relabellings and therefore carries the least information; absolute admits none and carries the most. Moving down the table is buying information by giving up freedom.

26.7.2 7.2 The meaningfulness criterion

A statement made in terms of scale values is meaningful if and only if its truth value is unchanged under every admissible transformation of the scale.

This is the operative definition and it is the whole of this section's logic. It is not a philosophical preference. It follows from what a scale *is*: if `g` is admissible, then `g(x)` and `x` encode the same empirical facts by definition, so any statement true of one and false of the other is a statement about the labelling, not about the world.

The criterion is mechanical to apply. Write the statement. Apply an admissible `g`. See if it survives.

26.7.3 7.3 The division theorem

Theorem 7.1 (the division theorem; designated *Theorem 53.1* in the source manuscript and cited under that designation elsewhere in the corpus)**.** *Let `X` and `Y` be measured on a common scale with admissible transformation group `G`. The statement "`X/Y = k`" is meaningful if and only if `G` is the similarity group `{g(x) = ax : a > 0}` or a subgroup of it — that is, if and only if the scale is ratio or absolute.*

Proof. Three cases.

```
RATIO.     g(x) = a x,  a > 0.
           g(X)/g(Y) = (aX)/(aY) = X/Y.
           The ratio is invariant under every admissible g. MEANINGFUL.

INTERVAL.  g(x) = a x + b,  a > 0.
           g(X)/g(Y) = (aX + b)/(aY + b).
           Take X = 20, Y = 10. Under g = identity the ratio is 2.000.
           Under g(x) = 1.8x + 32 the ratio is 68/50 = 1.360.
```

```
          The value depends on b, which the scale leaves free. NOT MEANINGFUL.

ORDINAL.  g strictly increasing, otherwise arbitrary.
          g(X)/g(Y) can be given ANY value greater than 1 (for X > Y > 0) by a suitable
          choice of g. Demonstrated constructively in section 7.9. NOT MEANINGFUL.
```

The converse direction is immediate: if `g(X)/g(Y) = X/Y` for all admissible `g` and all positive `X, Y`, then taking `Y` fixed shows `g` is linear through the origin, so `G` is contained in the similarity group. QED.

Therefore: `D/P` is meaningful if and only if `D` and `P` are ratio-scaled with a true zero. There is no third possibility, no partial credit, and no way to get there by having a lot of data. A million observations on an ordinal scale is a million ordinal observations.

26.7.4 7.4 What an interval scale does license

The theorem is often misread as saying interval scales are useless. They are not. **On an interval scale, ratios of *differences* are meaningful, and this is exactly the claim the scale supports.** Verified on the values `x = (10, 20, 35, 40)` under four admissible affine transformations:

transformation	values	`(x2−x1)/(x4−x3)`	`x2/x1`
identity	10, 20, 35, 40	**2.000000**	2.000000
`g(x) = 1.8x + 32`	50, 68, 95, 104	**2.000000**	1.360000
`g(x) = 2x − 7`	13, 33, 63, 73	**2.000000**	2.538462
`g(x) = 0.4x + 100`	104, 108, 114, 116	**2.000000**	1.038462

The ratio of differences is rock stable at 2.000000 under every admissible relabelling. The ratio of values takes four different answers. That contrast is the whole distinction, and it is why interval-scaled temperature supports “the rise from Monday to Tuesday was twice the rise from Wednesday to Thursday” but not “Tuesday was twice as warm as Monday.”

26.7.5 7.5 The badge

Note on the status of Stevens’ typology. Stevens’ four-way classification is a **proposal about scientific practice**, not a theorem, and it has been criticised — most sharply by Michell, who argues that psychology largely assumed its attributes were quantitative rather than testing whether they are [Michell, 1997, 1999]. The representational theory of measurement puts the whole subject on axiomatic footing and treats Stevens’ types as special cases [Krantz et al., 1971].

None of that weakens Theorem 7.1, which is an invariance argument and holds within any of these frameworks. Whatever you call the scale, if the admissible relabellings include anything beyond `x -> ax`, ratios of values are not invariant, and a formula that divides is reporting a property of the labelling. The badge is on the *typology*. The theorem stands unbadged.

26.7.6 7.6 The four scales, in operational detail

NOMINAL. Numbers as names. Jersey numbers, diagnostic codes, room identifiers, the numbering of the twelve nodes of the foundations series.

```
Permissible:      counting members of a class; mode; chi-square; contingency tables;
                  entropy of the partition; "same or different"
NOT permissible:  order, mean, median, difference, ratio, correlation
```

A nominal scale still carries real information — the entropy of a partition is a genuine quantity, and the corpus's lineage census uses exactly that [Curzi, 2026]. **You can do serious quantitative work on nominal data; you cannot do arithmetic on the labels.**

ORDINAL. Order without spacing. Rankings, hardness scales, seniority, most rating scales as they are actually used, "how anxious do you feel, 1 to 7."

```
Permissible:      median; percentiles; rank correlation (Spearman, Kendall); order statistics;
                  monotone regression; "greater than"; sign tests
NOT permissible:  mean; standard deviation; difference; ratio; Pearson correlation;
                  any arithmetic on the labels
```

INTERVAL. Equal differences, arbitrary zero. Celsius, Fahrenheit, calendar dates, standardised scores, and — importantly for Section 10 — properly constructed Rasch measures in logits.

```
Permissible:      mean; standard deviation; Pearson correlation; differences; ratios of
                  DIFFERENCES; linear regression; t-tests and ANOVA
NOT permissible:  ratios of VALUES; "twice as much"; multiplication of two measures;
                  proportional statements
```

RATIO. Equal differences plus a non-arbitrary zero denoting genuine absence. Length, mass, duration, count, Kelvin, frequency in hertz, and — the existence proof this volume depends on — Stevens' magnitude estimates of sensory intensity.

```
Permissible:      everything above, plus ratios of values, multiplication, division,
                  geometric mean, coefficient of variation, logarithms of the values,
                  "twice as loud"
```

Note the last two entries. **The geometric mean and the logarithm are ratio-scale operations, and this entire manual runs on both.** `ln N_eff`, `ln M`, `|ln r|`, the octave, the nat: every one of them presupposes ratio-scaled inputs. That is not an incidental fact about the notation. **The logarithmic register of the corpus [Curzi, 2026n] is available only because ratio scales support it, and this section is the price of admission.**

26.7.7 7.7 What a true zero actually is

"True zero" is not "the smallest number on the form". It is a specific empirical claim:

```
A scale has a TRUE ZERO if the value 0 denotes the complete ABSENCE of the attribute, and
that absence is an empirically identifiable state rather than a chosen origin.
```

Three tests, in ascending order of strength:

Test Z1 — describability. Can you describe the state the zero denotes, and would a second person recognise it? Zero mass is describable. Zero degrees Celsius is not a state of absence; it is the freezing point of water, chosen for convenience. **This test is necessary and cheap and almost nobody runs it.**

For the Moment equation's terms, the zeros pass Z1 and they pass it well:

```
P = 0    total absence of intake. Sensory deprivation, dissociation, the closed eye.
D = 0    total absence of frame. Raw sensation with no interpretive structure at all.
E = 0    total absence of environment. No situation to have a moment about.
```

Test Z2 — additivity / concatenation. Is there an operation that concatenates two instances of the attribute such that the scale values add? Two one-kilogram masses on a pan read two kilograms. This is the classical criterion and it is why length, mass and duration are unproblematic. For subjective quantities there is generally no physical concatenation operation, which is precisely Michell's objection [Michell, 1997] and the historical reason psychology's measurement claims were contested; the axiomatic statement of what must hold before a quantity can be said to exist is Krantz et al. [1971].

Test Z3 — ratio consistency. Do judgements of ratio behave consistently? If an observer says `B` is twice `A` and `C` is twice `B`, do they say `C` is four times `A`? Does halving compose with halving to give quartering? **This is the test that replaces concatenation for subjective quantities, and it is the test magnitude estimation is built on.** It is weaker than Z2 but it is empirical, it is checkable, and it either holds or it does not.

A scale that passes Z1 and Z3 is admissible as ratio for the corpus's purposes, with the provenance stated. That is the standard adopted here, it is the standard psychophysics adopted, and it is badged: Z3 is a behavioural consistency criterion, not a concatenation, and a critic who holds out for Z2 is not being unreasonable.

26.7.8 7.8 What goes wrong on an interval scale

Temperature is the canonical demonstration because everyone already knows the answer and almost nobody carries the lesson into their own data.

Celsius pair	`C` ratio	Fahrenheit values	`F` ratio	Kelvin values	`K` ratio
20 / 10	2.000	68.0 / 50.0	1.360	293.15 / 283.15	1.0353
25 / 5	5.000	77.0 / 41.0	1.878	298.15 / 278.15	1.0719
15 / -5	-3.000	59.0 / 23.0	2.565	288.15 / 268.15	1.0746
10 / 0	**undefined**	50.0 / 32.0	1.562	283.15 / 273.15	1.0366

Read the rows across. **The same physical pair of temperatures produces the ratio 2.000, 1.360 and 1.0353 depending on nothing but the labelling convention.** Row three produces a *negative* ratio in Celsius and a positive one in Fahrenheit — the two labellings disagree about the sign. Row four is undefined in Celsius and perfectly finite in Fahrenheit.

Only the Kelvin column is a real quantity, because Kelvin has a true zero and its admissible transformations are similarities alone. **The ratio 1.0353 is a fact about the world. The ratio 2.000 is a fact about Anders Celsius.**

Now transpose this. A questionnaire scored 1 to 7 has its zero at "1", chosen because forms usually start at one. A scale scored 0 to 6 measuring the same thing has its zero at "0". These two instruments differ by `g(x) = x − 1`, a perfectly admissible affine transformation. A `D/P` of `6/3 = 2.0` on the first instrument is `5/2 = 2.5` on the second. **Nothing changed but the printer's choice, and the reported distortion moved by 25%.**

26.7.9 7.9 What goes wrong on an ordinal scale — the demonstrations

Ordinal is worse than interval, and it is worse in a way that surprises people who have absorbed the temperature lesson. On an interval scale, at least the *family* of possible ratios is constrained by a two-parameter group. **On an ordinal scale the admissible transformations form an infinite-dimensional family, and the ratio can be sent anywhere.**

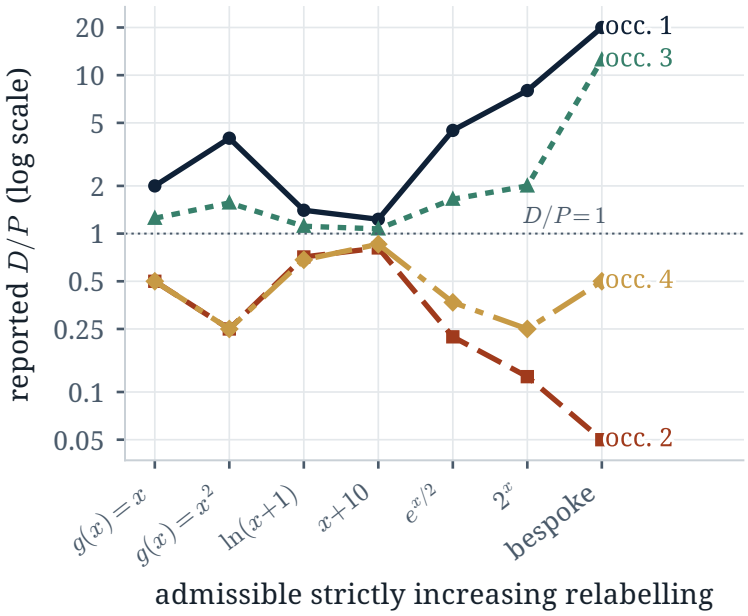

Figure 26.1: **A quantity settable by relabelling is not a measurement:** the same four responses, `D = (6, 3, 5, 2)` and `P = (3, 6, 4, 4)`, report occasion 1's distortion as anything from 1.231 to 20.000 — a factor of 16.25 — under seven strictly increasing relabellings, every one of them admissible on an ordinal scale. Occasions 2 and 4 are tied under two relabellings, and the tie is then broken in *both* directions by others. Values transcribed from the Demonstration 1 table of Section 7.9; generated by `figs/src/CCP-026_fig01.py`.

Demonstration 1 — the magnitude is arbitrary. Four occasions of a frame/intake report on a seven-point instrument, `D = (6, 3, 5, 2)`, `P = (3, 6, 4, 4)`. Apply admissible strictly increasing relabellings and recompute `D/P`:

relabelling `g`	`D/P` across the four occasions	ranking, most over-framed first
`g(x) = x` (raw)	2.000, 0.500, 1.250, 0.500	1, 3, then 2 and 4 TIED
`g(x) = x^2`	4.000, 0.250, 1.562, 0.250	1, 3, then 2 and 4 TIED
`g(x) = ln(x+1)`	1.404, 0.712, 1.113, 0.683	1, 3, **2, 4**
`g(x) = x + 10`	1.231, 0.812, 1.071, 0.857	1, 3, **4, 2**
`g(x) = e^(x/2)`	4.482, 0.223, 1.649, 0.368	1, 3, **4, 2**
`g(x) = 2^x`	8.000, 0.125, 2.000, 0.250	1, 3, **4, 2**
bespoke monotone	20.000, 0.050, 12.500, 0.500	1, 3, **4, 2**

The last column is the alarming one. Under three admissible relabellings occasions 2 and 4 are tied, under one occasion 2 is worse, and under four occasion 4 is worse. **The tie is broken in both directions by relabellings that changed nothing about what the respondent reported.**

Occasion 1's distortion is reported as anything from 1.231 to 20.000 — a factor of sixteen — with no change to a single response. **Every one of these relabellings is admissible. The instrument recorded the same thing in every row.**

Demonstration 2 — the ordering across occasions reverses. Take `D = (7, 4)` and `P = (4, 2)`:

relabelling `g`	`r` occasion 1	`r` occasion 2	verdict
`g(x) = x`	1.7500	2.0000	occasion 2 more over-framed
`g(x) = x^2`	3.0625	4.0000	occasion 2 more over-framed
`g(x) = x^3`	5.3594	8.0000	occasion 2 more over-framed
`g(x) = ln(x+1)`	1.2920	1.4650	occasion 2 more over-framed
`g(x) = 2^x`	8.0000	4.0000	**occasion 1 more over-framed**
`g(x) = e^x`	20.0855	7.3891	**occasion 1 more over-framed**

Which occasion was more distorted is not a fact about the person. It is a fact about the shape of the response labels. This is the finding that matters clinically, because "which session was worse" is exactly the question a practitioner asks.

Demonstration 3 — the constructive result. For `D > P > 0` on an ordinal scale, *any* target ratio can be achieved by an admissible relabelling. With `D = 7`, `P = 4`, use `g(x) = x^k`, which is strictly increasing on the positives for every `k > 0`, giving `g(D)/g(P) = (7/4)^k`:

target ratio	required `k`	achieved
1.05	0.0872	1.0500
1.50	0.7245	1.5000
2.00	1.2386	2.0000
5.00	2.8760	5.0000
10.00	4.1146	10.0000
100.00	8.2292	100.0000

A quantity you can set to any value you like by relabelling is not a measurement. It carries exactly zero bits of information beyond the ordering it started with.

Demonstration 4 — the ratio can become negative or undefined. `g(x) = x − 2.5` is strictly increasing and therefore admissible on an ordinal scale. Applied to the four occasions of Demonstration 1, occasion 4 has `D = 2 -> −0.5` and `P = 4 -> 1.5`, so `r = −0.333` and `Delta = |ln r|` is undefined over the reals. **An admissible relabelling turned the distortion measure into a non-number.** No amount of careful statistics downstream repairs this.

26.7.10 7.10 Building a ratio scale: magnitude estimation

The good news, and it is very good news, is that ratio scales for subjective quantity are not hypothetical. Stevens' method of magnitude estimation produces them, it has produced them since 1957 [Stevens, 1957], and it replicates [Stevens, 1956, Krueger, 1989]. Its failure modes are documented at least as thoroughly as its successes: the ones catalogued in Section 9 appear first in Poulton [1968] and Poulton [1979], and the exponent's dependence on the experimenter's chosen stimulus range, which is the reason for requirement S-8, is Teghtsoonian [1971].

The procedure, specified.

```
ME-1   Present stimuli from the continuum in IRREGULAR order, spanning at least 1.5 orders
       of magnitude. A narrow range biases the exponent toward 1.
ME-2   Instruct: "Assign any positive number to the first stimulus. Assign numbers to the
       rest so that the numbers stand in the same RATIO as the sensations. If one seems
       three times as strong, give it three times the number."
ME-3   Impose NO upper bound and NO fixed modulus. The observer's own first number is the
       modulus and it is free.
ME-4   Normalise each observer by their own geometric mean across stimuli. This removes the
```

```
       arbitrary modulus without touching any ratio.
ME-5   Aggregate across observers by the GEOMETRIC mean, never the arithmetic mean.
ME-6   Regress log(response) on log(intensity). The slope is the exponent a.
ME-7   Report the exponent with its interval, the log-log R^2, and the per-observer spread.
```

The prediction being tested is Stevens' power law:

```
psi = k I^a       ->       log psi = log k + a log I
```

A straight line in log-log is not a curve-fitting convenience. **It is the falsifiable content of the claim: if the observer's judgements were not ratio-consistent, the log-log plot would bend, and it does not.**

Worked recovery. Ten simulated observers, seven intensities spanning `1` to `64`, generated with a true exponent of `0.67`, independent free moduli (the largest observer's modulus was `31.15` times the smallest), and 18% log-normal judgement noise.

```
geometric mean across observers, by intensity:
   0.2300   0.4124   0.5753   0.9469   1.7176   2.6619   4.2328

log-log fit on the geometric means:
   a_hat = 0.6987   s.e. 0.0165   95% CI [0.6664, 0.7310]      true a = 0.67
   log-log R^2 = 0.99723
```

The exponent is recovered, and the log-log linearity is essentially perfect. Per-observer exponents, each fitted separately:

```
0.737  0.569  0.694  0.653  0.755  0.774  0.720  0.631  0.728  0.726
mean 0.6987   sd 0.0631
```

Note what this is: FVP-7 Outcome B in miniature. The exponent is a person-level parameter with a real spread of about 0.06, not a single universal number, and that is the normal and acceptable state of a psychological measurement.

Why the geometric mean is mandatory (ME-5). With free moduli, the arithmetic mean is dominated by whichever observer happened to pick large numbers. In the run above, one observer alone contributed **27.5%** of the arithmetic mean at the lowest intensity and **21.1%** at the highest, in a panel of ten where each should carry 10%. Under the geometric mean each observer contributes exactly `1/n` of the log, by construction. **The arithmetic mean of magnitude estimates silently weights observers by their choice of modulus, which is the one thing the method declares arbitrary.**

26.7.11 7.11 The ceiling: why a rating scale cannot do this

Here is the computation that should end the practice of treating slider responses as ratio data. The same magnitude-estimation simulation — same true exponent `0.67`, same observers, same noise — run four times, changing only the response format:

response format	recovered exponent	bias
unbounded, free modulus (proper ME)	0.6678	-0.0022
0-100 slider	0.5763	-0.0937
0-50 slider	0.4076	-0.2624
1-7 rating	**0.0114**	**-0.6586**

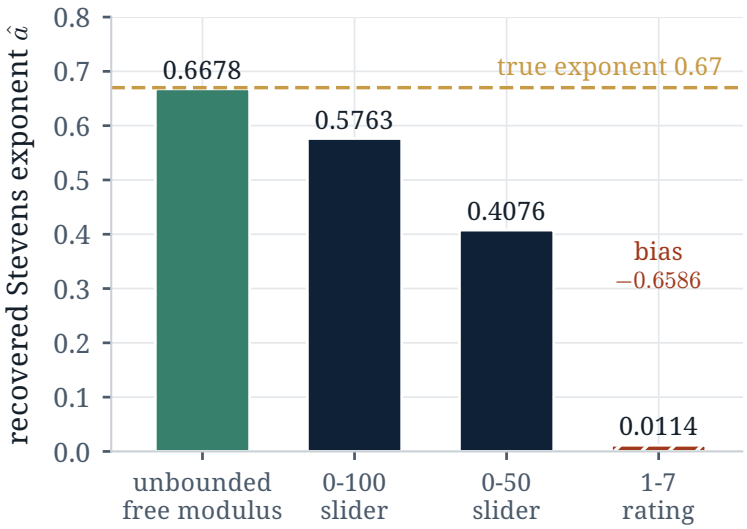

Figure 26.2: **A bounded response format does not degrade the ratio scale, it destroys it:** the same simulated magnitude-estimation panel — ten observers, seven intensities, free moduli, 18 per cent log-normal noise, true exponent 0.67 — recovers 0.6678 unbounded, 0.5763 on a 0–100 slider, 0.4076 on a 0–50 slider and **0.0114** on a 1–7 rating, a bias of −0.6586. Modelled with the parameters stated in Section 7.10; generated by `figs/src/CCP-026_fig02.py`.

A seven-point rating scale recovered an exponent of 0.011 from a process whose true exponent is 0.67. The measured quantity was destroyed almost entirely — not degraded, destroyed. The bound compresses the top of the range, the compression is worst where the signal is strongest, and the log-log slope collapses.

This is not an argument that rating scales are useless. They are excellent ordinal instruments. **It is an argument that a bounded response format cannot produce a ratio scale, ever, and that arithmetic performed on its output is arithmetic on the bound.** A ratio scale must be unbounded above, because doubling must always be possible; a scale with a ceiling has a largest number, and "twice that" has no representation.

26.7.12 7.12 Cross-modality matching — the validation that makes it science

Magnitude estimation on its own could, in principle, be measuring how people use numbers rather than how they experience intensity. **Cross-modality matching is the test that rules this out, and it is the strongest piece of evidence in the whole psychophysical corpus.**

The procedure uses no numbers at all. The observer adjusts one continuum — squeezes a dynamometer, turns a light up — until it *feels* as intense as a stimulus presented on a different continuum. The exponent of that matching function is then a prediction with **no free parameters**:

```
If  psi_1 = k_1 I_1^a   and   psi_2 = k_2 I_2^b,
then matching psi_1 = psi_2 gives  I_2 proportional to I_1^(a/b).

The MATCHING EXPONENT is a/b -- fully determined by two exponents measured in two
separate experiments that never involved matching.
```

The full prediction matrix from the canonical psychophysical exponents [Stevens, 1957, 1956]. Rows are the continuum the observer *adjusts*; columns are the continuum *presented*; entries are the predicted matching exponent `a/b`:

adjusted presented	Loudness 0.67	Bright 0.33	Length 1.00	Salt 1.30	Heavy 1.45	Warmth 1.60	Shock 3.50
Loudness (0.67)	1.0000	0.4925	1.4925	1.9403	2.1642	2.3881	5.2239
Brightness (0.33)	2.0303	1.0000	3.0303	3.9394	4.3939	4.8485	10.6061
Visual length (1.00)	0.6700	0.3300	1.0000	1.3000	1.4500	1.6000	3.5000
Taste, salt (1.30)	0.5154	0.2538	0.7692	1.0000	1.1154	1.2308	2.6923
Heaviness (1.45)	0.4621	0.2276	0.6897	0.8966	1.0000	1.1034	2.4138
Warmth (1.60)	0.4188	0.2062	0.6250	0.8125	0.9062	1.0000	2.1875
Electric shock (3.50)	0.1914	0.0943	0.2857	0.3714	0.4143	0.4571	1.0000

Every cell is a testable prediction. And the matrix carries an internal consistency requirement that is itself a falsification test — **transitivity**:

```
match loudness -> heaviness   = 0.4621
match heaviness -> brightness = 4.3939
product                       = 2.0303
direct loudness -> brightness = 2.0303       AGREES

match brightness -> warmth    = 0.2062
match warmth -> loudness      = 2.3881
product                       = 0.4925
direct brightness -> loudness = 0.4925       AGREES
```

This is what a ratio scale looks like from outside. Three experiments, no shared parameters, and the third one's answer is forced by the first two. When that holds, the scale is not a story about how people use numbers; it is a measurement, because a measurement is exactly a set of numbers whose relations compose.

An honest note is required here: the canonical exponents are nominal, they vary with method, range and instruction, and they are properly reported as *constants of a procedure* rather than constants of nature. Empirically, cross-modality matching exponents recover the predicted `a/b` well but not perfectly, and the residual discrepancies are a known and studied feature of the literature. **The transitivity test is a real test that can fail, which is what makes passing it worth something.**

26.7.13 7.13 Ratio production — the third instrument

Magnitude estimation asks for a number given a stimulus. **Ratio production inverts it: give the observer a number and a standard, and have them produce the stimulus.** "Adjust this until it is half as bright." "Set this until it is three times as heavy."

Production is the strongest of the three because it is the direct behavioural test of Z3, and it composes:

```
RP-1   halve, then halve again -> should equal a single quartering
RP-2   double, then double again -> should equal a single quadrupling
RP-3   triple, then take a third -> should return to the standard
RP-4   the production function and the estimation function should be inverse,
       giving exponents that are reciprocals
```

RP-4 is the sharpest check and it is a genuine falsification opportunity: estimation and production are known to yield systematically slightly different exponents — the "regression effect", in which observers under-use whichever variable they control, catalogued with the rest of the method's biases by Poulton [1979]. **Report both, report the discrepancy, and take the geometric mean of the two exponents if a single figure is needed.** Concealing the discrepancy would be the error; it is a known property of the method and it is documented.

26.7.14 7.14 The other route: additive conjoint measurement

There is a second path to metric structure and it deserves a full hearing, because it is the path that rescues ordinal data — and it is the path Section 10 walks.

Luce and Tukey [1964] proved a remarkable thing. **Suppose you have only an ORDINAL ordering of outcomes, but the outcomes are produced by two factors crossed with each other. If that ordinal table satisfies certain purely ordinal axioms, then interval scales for both factors exist and are essentially unique.** The metric is not assumed. It is *derived from order*, and its existence is a testable consequence of the ordering.

The central axiom is **double cancellation**:

```
if   (a1, b2) >= (a2, b1)   and   (a2, b3) >= (a3, b2)
then (a1, b3) >= (a3, b1)
```

Every symbol is an ordinal comparison. Nothing is added or multiplied. Verified on two 3x3 tables, all 36 antecedent-satisfying triples tested in each:

```
Table A = [[1, 2, 4], [2, 4, 8], [4, 8, 16]]     (a_i * b_j: additive in logs)
   36 triples tested, 0 violations       -> additive structure available

Table B = [[1, 2, 4], [2, 9, 3], [4, 3, 16]]     (non-additive)
   36 triples tested, 3 violations       -> additive structure REFUTED
```

This is the honest answer to "but all I have is ordinal data". You may still have metric structure — but you have to earn it by testing the cancellation conditions, not by assuming them. Double cancellation, together with solvability and an Archimedean condition, is what licenses the interval scale. **Michell's objection [Michell, 1997] is answered not by assertion but by running the test [Luce and Tukey, 1964, Krantz et al., 1971].**

The deterministic form above is brittle: one noisy observation produces a violation. The probabilistic form of the same idea — which tolerates noise, and which is the reason Section 10 exists — is the Rasch model. **Rasch measurement is additive conjoint measurement with error, and the person-by-item table is the two-factor crossing.** That is the connection between these two two treatments and it is not decorative: it is the same theorem, made usable.

26.7.15 7.15 The honest demotion — what to do when you only have ordinal data

Most of the time, in most real settings, you will have ordinal data. This section specifies exactly what you may then do, and it is the section a practitioner needs most.

What SURVIVES demotion. Given `D` and `P` recorded on the *same* ordinal scale with the *same* labels:

```
SURVIVES-1   The SIGN of the comparison. If D > P on the raw labels, then g(D) > g(P) for
             every strictly increasing g. So "this occasion was over-framed" is an
             admissible ordinal claim, PROVIDED both terms use one instrument.
SURVIVES-2   Within-occasion direction of change over time, if the instrument is fixed.
             "The gap narrowed between March and June" is ordinal and admissible.
SURVIVES-3   Rank correlations. Spearman and Kendall are invariant under monotone
             relabelling by construction.
SURVIVES-4   Medians, percentiles, order statistics, sign tests, monotone regression.
SURVIVES-5   The QUALITATIVE structure of the formula: the limiting cases, the fixed point
             D = P as a describable condition, and the three-regime classification
             (over-framed / calibrated / under-framed). These are order facts.
```

What DOES NOT survive.

```
DIES-1   The magnitude of r. Demonstration 3: settable to anything.
DIES-2   The ordering of r ACROSS occasions. Demonstration 2: reverses.
DIES-3   Delta = |ln r| as a number. Demonstration 4: can become undefined.
DIES-4   Any arithmetic that feeds r into another formula. In particular, M as an input
         to the self-storage law Q_{t+1} = (1-delta)Q_t + eta M_t - C_t is NOT available
         from ordinal D and P. The join between the two central formulas requires
         ratio scales.
DIES-5   Means and standard deviations of the raw responses.
DIES-6   Pearson correlations of the raw responses.
```

DIES-4 is the expensive one. **The join between the Moment equation and the storage law [Curzi, 2026m] is the architectural keystone of Series B of the corpus, and it is available only on ratio scales.** That is stated here, in the section that establishes it, and not buried.

The Spearman/Pearson demonstration, on forty paired ordinal responses, computed under four admissible relabellings:

relabelling	Pearson `r`	Spearman `rho`
identity	0.6474	**0.6692**
`g(z) = z^2`	0.5167	**0.6692**
`g(z) = e^(z/2)`	0.4370	**0.6692**
`g(z) = ln(z+1)`	0.7223	**0.6692**

Pearson moves from 0.44 to 0.72 — a range wide enough to change any conclusion — while Spearman is identical to four decimal places in every row, as it must be. **If your data are ordinal, the rank statistic is not a conservative choice. It is the only correct one.**

The print convention (FVP-2 DEMOTE, per V-6). A demoted formula is printed with an ordering relation and an explicit statement, in the same paragraph:

```
DEMOTED FORM:

    Over-framed  <=>  D > P          Calibrated  <=>  D = P
    Under-framed <=>  D < P

    On ordinal D and P the classification above is admissible. The magnitude D/P is NOT,
    and no value of D/P from this instrument may be multiplied, averaged, or entered into
    any downstream formula.
```

Where an interval scale is wanted and respondents cannot be asked to use numbers at all, Thurstone [1927] is the classical alternative route and it predates all of this.

This is not a defeat. It is a considerable amount of usable structure — three named regimes, a fixed point, a direction of correction — obtained honestly and stated in a way a critic can check. What it is not is an equation, and it is not printed as one.

26.8 8 Requirements for scale construction

S-1 — Classify every term before any arithmetic. For each symbol, record: the scale type, the instrument that produced it, and the transformation group that instrument admits. A term whose group cannot be stated is not admissible.

S-2 — Apply the meaningfulness test explicitly. For every statement the analysis will make, apply an admissible `g` and check invariance. Record the check. This costs minutes.

S-3 — Never divide or multiply below ratio. No exception, no “approximately ratio”, no “close enough for practical purposes”. Theorem 7.1 has no epsilon in it.

S-4 — Establish the true zero by Z1 and Z3, and say which. Describe the state the zero denotes in one sentence. Report the Z3 ratio-consistency check with its numbers. If Z2 concatenation is available, use it and say so; if not, say that too.

S-5 — Both terms of a ratio on one instrument. `D` and `P` must come from the same scale with the same anchor. Two instruments, however similar, do not license division of one by the other without a demonstrated common calibration.

S-6 — Response formats for ratio data must be unbounded above. No sliders, no fixed maxima, no “1 to 10”. The ceiling table in §7.11 is the reason: a seven-point format recovered `0.011` where the truth was `0.67`.

S-7 — Free modulus, always. The observer chooses their own first number. Anchoring the first response imposes a scale and destroys the ratio property being measured.

S-8 — Span at least 1.5 orders of magnitude in the stimulus. Narrow ranges bias exponents toward 1 and can manufacture apparent linearity out of nothing.

S-9 — Irregular presentation order. Monotone sequences invite response strategies and produce sequential dependencies that masquerade as the function being measured.

S-10 — Aggregate by geometric mean. Never the arithmetic mean of magnitude estimates. §7.10 quantifies the damage: one observer of ten carrying 27.5% of the weight.

S-11 — Report the log-log `R^2`. Linearity in log-log is the falsifiable content of the power law. A curved log-log plot is a finding and must be reported as one, not smoothed.

S-12 — Report per-observer exponents and their spread. The panel mean is not the result. The distribution is the result, and it determines the FVP-7 outcome letter.

S-13 — Validate by cross-modality matching. Where two continua have independently measured exponents, run the matching experiment and compare against the predicted `a/b`. This is the test that distinguishes measurement from number-usage habit.

S-14 — Run at least one transitivity triangle. Three continua, three matching experiments, and the composition check of §7.12. Report the agreement, or the failure.

S-15 — Run ratio production as a cross-check. RP-1 through RP-4. Report the estimation and production exponents separately and report their discrepancy; do not silently average.

S-16 — Where only ordinal data exist, test double cancellation before assuming metric structure. Report the number of antecedent-satisfying triples tested and the number of violations. A table with violations does not support an additive structure.

S-17 — Demote in print, in the same paragraph. Requirement V-6 of Section 5. The demotion appears with the formula, in the same typeface, not in a footnote and not in an appendix.

S-18 — Use rank statistics on ordinal data. Spearman or Kendall, never Pearson; median, never mean. §7.15 quantifies the alternative.

S-19 — Never feed a demoted quantity into another formula. DIES-4. A heuristic ordering cannot be an input to the storage law, cannot be averaged across people, and cannot be differenced across time as a number.

S-20 — State the scale provenance beside every reported number. The form is: `r = 2.14 [ratio scale, magnitude estimation, free modulus, geometric-mean aggregation, n = 14 observers, a_hat = 0.71 (0.04)]`. A number without provenance is not admissible in the corpus.

26.9 9 Failure modes of scale treatment

26.9.1 FM-9.1 · THE LIKERT METRE

Damages: FVP-2, and everything downstream.

Seven-point responses [Likert, 1932] are treated as though the intervals between them were equal and the bottom of the scale were a true zero. Means are computed, ratios are taken, and the results are reported to two decimal places.

Diagnostic signature: a mean of 4.73 on a 1-7 scale, reported without a distributional summary; a ratio of two such means; a standard deviation of ordinal responses; any Pearson correlation on raw Likert items.

Detecting measurement: the relabelling test. Recompute the headline result under `g(x) = x^2` and `g(x) = 2^x`. If the conclusion moves, it was a conclusion about the labels.

Fix: build a real scale (§7.10-7.13), earn an interval scale by conjoint or Rasch analysis (§7.14, Section 10), or demote (§7.15). **These are the only three options and the third one is respectable.**

26.9.2 FM-9.2 · THE ARBITRARY ZERO

Damages: FVP-2 specifically at the ratio boundary.

An interval scale is treated as ratio because its numbers happen to be positive. Positivity is not a true zero. Fahrenheit is positive across most of the inhabited world and is not a ratio scale.

Diagnostic signature: the author cannot describe the state that "0" denotes; the zero coincides suspiciously with the bottom of a form, the start of a study, or a sample mean.

Detecting measurement: Test Z1. Ask what the zero *is*. Then shift the origin by one unit and see whether any reported ratio survives.

Fix: locate a describable zero and re-anchor, or restrict all claims to differences and ratios of differences (§7.4), which interval scales genuinely support.

26.9.3 FM-9.3 · THE MODULUS LEAK

Damages: the aggregation step of a magnitude-estimation study.

Magnitude estimates are averaged arithmetically. The observers who chose big numbers dominate. The group exponent becomes a weighted statistic where the weights are the very quantity the method declared arbitrary.

Diagnostic signature: group means much larger than the median observer's values; the group exponent shifting when a single observer is removed; a modulus range across observers exceeding a factor of five with no normalisation step reported.

Detecting measurement: compute each observer's share of the group mean at each stimulus level. Under correct aggregation each carries `1/n`. In §7.10's run, arithmetic aggregation gave one of ten observers 27.5%.

Fix: S-7 and S-10. Normalise by the observer's own geometric mean, then aggregate geometrically.

26.9.4 FM-9.4 · THE CEILING

Damages: FVP-2, invisibly and catastrophically.

The response format has an upper bound. The upper part of the stimulus range compresses against it. The recovered exponent is biased toward zero, and the bias grows as the bound tightens.

Diagnostic signature: responses piling up at the maximum; a log-log plot that is straight at low intensities and bends flat at high ones; a recovered exponent implausibly close to zero.

Detecting measurement: the proportion of responses at the maximum. Any nonzero proportion is disqualifying for ratio claims. Compare the exponent fitted on the lower half of the range to the exponent fitted on the whole.

Fix: S-6. Remove the bound. If the bound cannot be removed — some field instruments cannot — the data are ordinal and must be demoted. **The 1-7 row of the table in §7.11 is what happens otherwise: the true exponent 0.67 recovered as 0.011.**

26.9.5 FM-9.5 · THE SILENT PROMOTION

Damages: all of FVP-2, and the reader's ability to check.

Ordinal data are promoted to ratio by fiat somewhere in the middle of an analysis pipeline, usually at the point where a mean is taken, and the promotion is never stated.

Diagnostic signature: the methods section describes a rating scale; the results section reports ratios; no sentence connects the two. The word "assume" does not appear.

Detecting measurement: trace every reported number back to its instrument. The promotion happens at a specific line and it can be found.

Fix: S-1 and S-20. Provenance beside every number. If the promotion is deliberate, badge it as a postulate with its justification and its consequences, under the corpus's badging convention [Curzi, 2026].

26.9.6 FM-9.6 · THE CROSS-INSTRUMENT DIVISION

Damages: FVP-1 and FVP-2 jointly.

`D` is measured by one instrument and `P` by another, and the two are divided. Even if both are ratio scales, their units differ, so the quotient is a rate with units rather than a dimensionless calibration ratio, and the fixed point `D = P` has no meaning.

Diagnostic signature: the two terms come from different sections of a protocol, different response formats, or different modalities; `r` clusters implausibly far from 1 across all subjects, which is the units mismatch showing.

Detecting measurement: the distribution of `r` across a healthy sample. A systematic offset in `ln r` common to everyone is a unit conversion, not a population-wide distortion.

Fix: S-5. One instrument, one anchor, or an explicit cross-modality calibration (§7.12) converting one to the other with the conversion exponent reported.

26.9.7 FM-9.7 · THE UNTESTED CANCELLATION

Damages: FVP-2 via the conjoint route.

Additive conjoint measurement or a Rasch analysis is invoked to justify treating ordinal data as metric, and the cancellation conditions are never actually tested. The theorem is cited; its hypothesis is not checked.

Diagnostic signature: "we used a Rasch model, so the measures are interval" with no fit statistics, no invariance test, no violation count.

Detecting measurement: S-16 for the deterministic case; the fit statistics of Section 10 and split-sample invariance test for the probabilistic one.

Fix: run the test. **A conjoint or Rasch analysis that does not report its fit is a promotion by fiat wearing a better suit.**

26.10 10 Specific objectivity: invariance as the criterion of measurement

Section 7 established what a ratio scale is and why `D/P` needs one. It ended with a construction — magnitude estimation, cross-modality matching, ratio production — and with the honest

verdict that the construction has not been carried out for perspective and perception.

Section 10 develops the second route, and it is the one that answers the harder question. A ratio scale built by magnitude estimation is still a scale built by *one instrument on one occasion*. FVP-7 asks something more: **does the measure survive a change of instrument and a change of population?** That is the real criterion of hard measurement, and there is a body of theory that addresses it directly, achieves it, and can be checked.

26.10.1 10.1 The requirement, stated by Rasch

Rasch [1960] set out the condition he called **specific objectivity**, developed into a working measurement practice by Andrich [1988]:

```
The comparison of two persons must be independent of WHICH ITEMS were used to compare them.
The comparison of two items must be independent of WHICH PERSONS were used to compare them.
```

Read those two lines slowly, because they are more demanding than they look. The first says that if instrument A and instrument B both measure the same attribute, then A's verdict on whether Alice exceeds Bob must agree with B's — not approximately, not on average, but as a structural property of the model, holding for every pair of persons and every pair of items.

This is the property physical measurement has and psychological measurement usually does not. A kitchen scale and a laboratory balance agree about which of two objects is heavier, and they agree about *by how much* once the units are matched. They agree regardless of what else was weighed that day. Two questionnaires purporting to measure the same construct routinely disagree, and the disagreement is normally reported as "modest convergent validity" — the language of Campbell and Fiske [1959] and Cronbach and Meehl [1955] — rather than as the failure of measurement it is.

Specific objectivity is precisely the property Series B needs, because the internal/external correspondence [Curzi, 2026s] claims that the same parameters describe a mind and a city. That claim is empty unless the parameters mean the same thing when measured by different instruments at different scopes. **Invariance is not a nice-to-have property of a good measure. Invariance is what "measure" means.**

26.10.2 10.2 The model

For a dichotomous response `X_ni` of person `n` to item `i`:

```
                     exp(theta_n − beta_i)
P(X_ni = 1) = ---------------------------------
                1 + exp(theta_n − beta_i)

theta_n   the person's location on the latent continuum   (logits)
beta_i    the item's location on the same continuum       (logits)
```

Equivalently, and more revealingly:

```
     P(X_ni = 1)
ln  -------------  =  theta_n − beta_i
     P(X_ni = 0)
```

The log-odds of success is the DIFFERENCE between a person parameter and an item parameter, and nothing else. No item discrimination, no guessing parameter, no interaction term. That austerity is the entire point: it is what buys separability, and every parameter added to the model to improve fit destroys it.

Note also where this places us. `theta − beta` is a *difference on a logarithmic register*, which is the register Curzi [2026n] identifies as the one everything in this corpus lives in. The Rasch model was derived in the 1950s from a requirement about invariance, with no reference to surplus, pitch, or Fechner. **It arrived at the same register by an independent route, and §10.17 shows that the arrival is not a coincidence.**

26.10.3 10.3 Item separability (Theorem 10.1)

The difference in log-odds between two items is independent of the person parameter.

```
ln[P_ni/(1−P_ni)] − ln[P_nj/(1−P_nj)]  =  (theta_n − beta_i) − (theta_n − beta_j)
                                       =  beta_j − beta_i
```

`theta_n` cancels identically. Not approximately — identically, for every person. Verified numerically with `beta_i = −0.80` and `beta_j = +0.60`:

theta	P_i	P_j	logit P_i	logit P_j	difference	odds ratio
-3.0	0.0998	0.0266	-2.2000	-3.6000	**+1.4000**	4.0552
-2.0	0.2315	0.0691	-1.2000	-2.6000	**+1.4000**	4.0552
-1.0	0.4502	0.1680	-0.2000	-1.6000	**+1.4000**	4.0552
0.0	0.6900	0.3543	+0.8000	-0.6000	**+1.4000**	4.0552
1.0	0.8581	0.5987	+1.8000	+0.4000	**+1.4000**	4.0552
2.0	0.9427	0.8022	+2.8000	+1.4000	**+1.4000**	4.0552
3.0	0.9781	0.9168	+3.8000	+2.4000	**+1.4000**	4.0552

The success probabilities range from 3% to 98%. **The comparison between the items is 1.4000 in every row.** Ask a struggling person or an expert; the items stand in the same relation.

26.10.4 10.4 Person separability (Theorem 10.2)

The difference in log-odds between two persons is independent of the item parameter. By the same cancellation, with `theta_1 = 1.10` and `theta_2 = −0.30`:

item beta	logit P_1 - logit P_2
-2.0	**+1.4000**
-1.0	**+1.4000**
0.0	**+1.4000**
+1.0	**+1.4000**
+2.0	**+1.4000**

`theta_1 − theta_2 = 1.4000`, whichever item you use. **This is the half of specific objectivity that matters for Series B of the corpus: a person's measure does not depend on which items were used.**

26.10.5 10.5 The badge, and the methodological inversion

Note on status. The Rasch model is **a model**, and the theorems above are theorems *about the model*, not about people. They say: *if* responses follow this model, *then* separability holds. They say nothing about whether any real response set does follow it.

This produces the methodological inversion that defines Rasch measurement and separates it from mainstream item response theory:

```
ITEM RESPONSE THEORY:   choose the model that fits the data.
                        Add parameters until fit is acceptable.
                        Goal: describe the data well.

RASCH MEASUREMENT:      require the data to fit the model.
                        Where they do not, revise the INSTRUMENT.
                        Goal: obtain measurement, or find out you cannot.
```

Neither position is foolish, and the choice between them is a choice about what you are trying to do. If you want the best description of a data set, fit the richest model. If you want a *measuring instrument* — something whose readings transfer between contexts — you must insist on the model that has the invariance property, and treat misfit as a defect of the instrument rather than as a licence to elaborate the model. Theorem 7.1 is the reason: the properties that make numbers usable are properties of the *scale*, and they are lost the moment the model allows item-by-person interaction.

This paper takes the Rasch position, and badges it as a position. The reason is stated plainly in §10.14 and demonstrated with numbers: models with free discrimination parameters fit better and do not measure.

26.10.6 10.6 The connection to Section 7

Section 7.14 introduced additive conjoint measurement (Luce & Tukey 1964): a purely ordinal table on two crossed factors, satisfying double cancellation, licenses interval scales for both factors. The deterministic form is brittle — a single noisy response produces a violation.

The Rasch model is the probabilistic form of exactly that structure. Persons and items are the two crossed factors; the response table is the outcome; `theta_n − beta_i` is the additive combination; the logistic function supplies the error model that deterministic cancellation lacks. Fit statistics (§10.16) are the stochastic replacement for counting cancellation violations.

Rasch measurement is additive conjoint measurement with error, and that is why it delivers interval scales from ordinal data honestly rather than by fiat. It is the answer to Michell's objection, and it is the answer to a practitioner who has only ratings to work with.

26.10.7 10.7 Sufficiency — why separation is possible at all

Separability is not luck. It follows from a property of the model's likelihood, and the property is worth deriving because it is the mechanism.

For one person answering `k` items, with `xi = exp(theta)` and `eps_i = exp(−beta_i)`:

```
                       prod_i  (xi eps_i)^{x_i}          xi^r * prod_i eps_i^{x_i}
P(x_1..x_k | theta) = -------------------------  =  -------------------------------
                       prod_i  (1 + xi eps_i)           prod_i (1 + xi eps_i)

where r = sum_i x_i  is the RAW SCORE.
```

The person parameter enters only through `xi^r`. The response pattern enters only through `prod eps_i^{x_i}`. The likelihood factorises, and by the factorisation criterion **the raw score `r` is a sufficient statistic for `theta`.**

The consequence is the machinery of the whole method. Condition on `r`:

```
                           prod_i eps_i^{x_i}
P(x_1..x_k | r)  =  --------------------------
                             gamma_r(eps)
```

where `gamma_r` is the **elementary symmetric function** of order `r` in the `eps_i` — the sum of all products of `r` distinct `eps` values. **The person parameter has vanished completely.** The conditional distribution of the response pattern given the raw score depends on the item parameters alone.

Verified numerically. Five items with `beta = (−1.2, −0.5, 0.0, 0.6, 1.4)`, a person at `theta = 0.4`, four different response patterns all scoring `r = 3`:

pattern	r	P(pattern | theta)	P(pattern | r)
1 1 1 0 0	3	0.142349	0.375236
1 0 1 1 0	3	0.047384	0.124905
0 1 1 1 0	3	0.023530	0.062026
1 1 0 1 0	3	0.078123	0.205934

The middle column depends on `theta`. **The right-hand column does not — it is computable from the item parameters alone, and it is the quantity conditional estimation maximises.**

26.10.8 10.8 The gamma recursion

`gamma_r` looks expensive — it is a sum over all `C(k, r)` subsets — but there is a recursion that computes the whole vector in `O(k^2)`. Add items one at a time; each new item either contributes to the product or does not:

```
gamma_r^(m)  =  gamma_r^(m−1)  +  eps_m * gamma_{r−1}^(m−1)
```

Worked in full for the five items above, `eps = (3.32012, 1.64872, 1.00000, 0.54881, 0.24660)`:

```
after item 1:  1.00000  3.32012
after item 2:  1.00000  4.96884   5.47395
after item 3:  1.00000  5.96884  10.44279   5.47395
after item 4:  1.00000  6.51765  13.71855  11.20507  3.00417
after item 5:  1.00000  6.76425  15.32579  14.58802  5.76730  0.74082

check:  gamma_1 = sum(eps)  = 6.76425     OK
        gamma_5 = prod(eps) = 0.74082     OK
```

The two checks at the bottom are the ones to run in any implementation: the first-order symmetric function is the sum, the top-order one is the product. **Numerical instability in these functions is the commonest bug in Rasch software and the two checks catch most of it.**

26.10.9 10.9 Conditional maximum likelihood

Maximise the product of conditional probabilities over persons:

```
                  N   [    prod_i eps_i^{x_ni}   ]
ln L_C  =  ln  prod   [ ------------------------ ]
                 n=1  [      gamma_{r_n}(eps)   ]

        =  − sum_i  s_i beta_i  −  sum_n ln gamma_{r_n}(eps)

where s_i = sum_n x_ni  is the ITEM SCORE.
```

Three properties of this estimator matter and should be stated:

```
CML-1   No person parameters appear. There are N of them and they are ALL eliminated.
        This is why CML is consistent as N grows -- unlike joint estimation, where the
        number of nuisance parameters grows with the sample and the estimator is biased.

CML-2   The item score s_i is a sufficient statistic for beta_i. Symmetric to the person
        side, as specific objectivity requires.

CML-3   Persons with extreme scores (r = 0 or r = k) contribute nothing: gamma_0 and
        gamma_k are constants and the conditional likelihood is degenerate. They are
        EXCLUDED, and the exclusion must be reported.
```

The atom of the whole procedure is visible in the two-item case. Among persons who got exactly one of items `i` and `j` right:

$$P(\text{item } i \text{ right} \mid r = 1) = \frac{\exp(-\beta_i)}{\exp(-\beta_i) + \exp(-\beta_j)} = 0.802184$$

with $\beta_i = -0.80$, $\beta_j = +0.60$. Log odds $= \beta_j - \beta_i = 1.4000$.

No `theta` appears anywhere in that expression. The relative difficulty of two items is estimated from the persons who split them, and how able those persons are does not enter. That is specific objectivity as an estimation procedure rather than as a theorem.

26.10.10 10.10 Calibration — a worked recovery

Twelve items with true difficulties evenly spaced from `-2.00` to `+2.00` logits (centred), 2000 simulated persons drawn `Normal(0, 1.2)`, 1945 usable after excluding extreme scores. CML estimates:

item	true `beta`	CML `beta`	error
1	-2.0000	-1.8690	+0.1310
2	-1.6364	-1.5544	+0.0820
3	-1.2727	-1.3236	-0.0509
4	-0.9091	-0.9090	+0.0001
5	-0.5455	-0.6309	-0.0854
6	-0.1818	-0.1432	+0.0386
7	+0.1818	+0.1336	-0.0482
8	+0.5455	+0.5250	-0.0204
9	+0.9091	+0.9072	-0.0019
10	+1.2727	+1.4011	+0.1284
11	+1.6364	+1.5664	-0.0699
12	+2.0000	+1.8967	-0.1033

```
RMS error = 0.0764 logits      max |error| = 0.1310 logits
correlation(true, estimated) = 0.998382
```

26.10.11 10.11 Separation and reliability — how much measurement you actually have

Estimation accuracy is not the same as measurement precision, and Rasch practice reports both.

```
person SE_n  =  1 / sqrt( sum_i P_ni (1 - P_ni) )
item   SE_i  =  1 / sqrt( sum_n P_ni (1 - P_ni) )

true SD    = sqrt( observed SD^2  -  mean SE^2 )
SEPARATION index G = true SD / RMSE
RELIABILITY        = G^2 / (1 + G^2)
distinct STRATA    = (4G + 1) / 3
```

For the calibration above:

```
observed SD of person measures  = 1.3675 logits
RMSE of person measures         = 0.7576 logits
true SD                         = 1.1385 logits
person separation G             = 1.5028
person reliability              = 0.6931
distinct strata                 = 2.34

item separation                 = 22.0854
item reliability                = 0.9980
mean item SE                    = 0.0578 logits
```

Read the last line of the person block: 2.34 strata. Twelve items, two thousand people, and the instrument distinguishes roughly two and a third levels of the attribute. It can tell high from low and not much else. The item side is superb — 0.0578 logits of item error — because two thousand people calibrated twelve items. **Item precision and person precision are bought by different resources: items are calibrated by persons, persons are measured by items.**

This is the number practitioners most often fail to report, and it is the number that determines whether the instrument can do the job. **An instrument with a person reliability of 0.6931 cannot support individual decisions.** It can support group comparisons. Saying which is a professional obligation. The separation index is the informative statistic here and a coefficient alpha is not [Cronbach, 1951]; the reasons not to stop at alpha are set out by Sijtsma [2009].

26.10.12 10.12 The invariance test — running FVP-7 on an instrument

The theorems in §10.3 and §10.4 are about the model. The test is about the data. **Split the persons into disjoint groups that differ substantially on the attribute, calibrate the items separately in each, and compare.**

The person sample above was split at the median ability (lower half mean `theta = −0.949`, upper half mean `theta = +0.872` — a separation of 1.82 logits, so the two groups are genuinely different populations):

item	`beta` (low sample)	`beta` (high sample)	difference
1	-1.8684	-1.8714	-0.0030
2	-1.4895	-1.7360	-0.2465
3	-1.3595	-1.2439	+0.1156
4	-0.9382	-0.8568	+0.0814
5	-0.7165	-0.5056	+0.2109
6	-0.1480	-0.1363	+0.0118
7	+0.1505	+0.1203	-0.0302
8	+0.5995	+0.4763	-0.1232
9	+1.0241	+0.8481	-0.1760

item	beta (low sample)	beta (high sample)	difference
10	+1.4439	+1.3856	-0.0582
11	+1.5202	+1.5849	+0.0647
12	+1.7820	+1.9349	+0.1529

```
mean difference = +0.0000    sd of difference = 0.1360    max |difference| = 0.2465
correlation(low, high) = 0.994399
```

Two disjoint populations, differing by 1.82 logits in ability, produced item calibrations correlating at 0.9944 with a mean difference of exactly zero and no difference exceeding a quarter of a logit. That is what specific objectivity looks like in data. **This single table is the strongest form of evidence available in psychometrics, and it is the exact analogue of FVP-7.**

The formal statistic is a per-item invariance `t`:

```
t_i  =  ( beta_i^{high} − beta_i^{low} )  /  sqrt( SE_i^{high 2} + SE_i^{low 2} )
```

Flag at `|t| > 2.58` (roughly a 1% two-sided criterion, appropriate under multiple testing across a short instrument). §10.18 runs it on data with planted defects.

26.10.13 10.13 What breaks separability — the two-parameter model

The two-parameter logistic model — due to Birnbaum, and given its standard statement in Lord and Novick's *Statistical Theories of Mental Test Scores* of 1968, neither of which is present in this corpus's verified external bibliography and neither of which is therefore given a citation key here — adds a discrimination parameter per item:

```
P(X_ni = 1) = exp( a_i (theta_n − beta_i) ) / [ 1 + exp( a_i (theta_n − beta_i) ) ]
```

It fits real data better. It fits real data better because it has more parameters. **And it destroys specific objectivity outright**, which is not a subtle statistical cost but a total loss of the property that made the numbers measurements.

The item log-odds difference under 2PL:

```
a_i (theta − beta_i)  −  a_j (theta − beta_j)  =  (a_i − a_j) theta  +  (a_j beta_j − a_i beta_i)
```

The `theta` term does not cancel unless `a_i = a_j`. The same two items as §10.3, now with `a_i = 1.8` and `a_j = 0.6`:

theta	P_i	P_j	logit P_i	logit P_j	difference	odds ratio
-3.0	0.0187	0.1034	-3.9600	-2.1600	**-1.8000**	0.1653
-2.0	0.1034	0.1736	-2.1600	-1.5600	**-0.6000**	0.5488
-1.0	0.4110	0.2769	-0.3600	-0.9600	**+0.6000**	1.8221
0.0	0.8085	0.4110	+1.4400	-0.3600	**+1.8000**	6.0496
1.0	0.9623	0.5597	+3.2400	+0.2400	**+3.0000**	20.0855
2.0	0.9936	0.6985	+5.0400	+0.8400	**+4.2000**	66.6863
3.0	0.9989	0.8085	+6.8400	+1.4400	**+5.4000**	221.4064

The difference sweeps from `−1.80` to `+5.40` and **changes sign at**

```
theta* = (a_i beta_i − a_j beta_j) / (a_i − a_j) = −1.5000
```

Below `theta = −1.5`, item `i` is harder. Above it, item `j` is harder. Which item is more difficult is not a property of the items. It depends on who you ask. The odds ratio moves by a factor of over 1300 across the range.

This is the whole argument in one table. **A model that fits better and cannot answer "which item is harder" without naming a person has not measured the items.** The 2PL is a perfectly good descriptive model and a perfectly bad measuring instrument, and Series B needs a measuring instrument.

26.10.14 10.14 The 2PL under the invariance test

The theoretical point becomes an empirical diagnostic. Data were generated from a 2PL — items 1-6 with `a = 1.8`, items 7-12 with `a = 0.6`, same difficulties as before — and then put through exactly the Rasch calibration and split-sample procedure of §10.12:

item	`beta` (low)	`beta` (high)	difference	true `a`
1	-2.2508	-3.5274	-1.2766	1.8
2	-1.6428	-2.3178	-0.6750	1.8
3	-1.1397	-1.9441	-0.8043	1.8
4	-0.5026	-1.3115	-0.8089	1.8
5	+0.0621	-0.6818	-0.7438	1.8
6	+0.7035	-0.0222	-0.7257	1.8
7	+0.2261	+0.9978	+0.7717	0.6
8	+0.4828	+1.3075	+0.8248	0.6
9	+0.7755	+1.4943	+0.7189	0.6
10	+0.8497	+1.8437	+0.9940	0.6
11	+1.1991	+2.0240	+0.8249	0.6
12	+1.2371	+2.1374	+0.9002	0.6

```
mean |difference|  =  0.8391   (Rasch data: 0.1062)   ->  7.9 times larger
max  |difference|  =  1.2766   (Rasch data: 0.2465)
```

Look at the sign column. Every high-discrimination item drifted negative. Every low-discrimination item drifted positive. Not one exception in twelve. **The drift is not noise; it is a signature, and the signature reads out the discrimination structure directly.** The test does not merely detect the violation, it tells you what kind of violation it is.

That is the practical value of the invariance test and the reason it belongs in every FVP-7 report. A global fit index would have said "acceptable". The split-sample table says "your items have heterogeneous discriminations, the high ones are items 1 through 6, and your scale is not a scale."

26.10.15 10.15 Fit statistics — what misfit tells you

The residual of a single response, standardised:

```
z_ni = ( x_ni − P_ni ) / sqrt( P_ni (1 − P_ni) )     mean 0, variance 1 under the model
```

Two summaries, per item:

```
                1
OUTFIT MNSQ  =  ---  sum_n  z_ni^2                    UNWEIGHTED mean square
                N
```

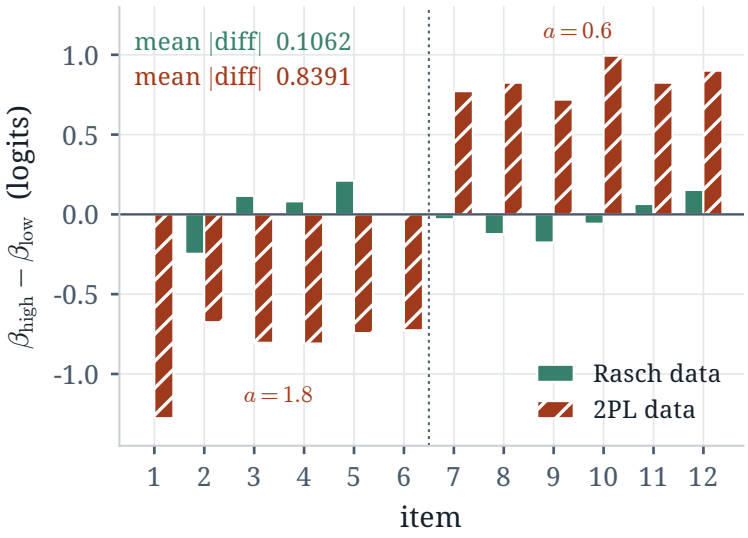

Figure 26.3: **Invariance is a criterion and fit is only a screen:** item calibrations from two disjoint person samples split at the median. On Rasch-generated data the mean absolute difference is 0.1062 logits with no difference exceeding a quarter of a logit; on 2PL-generated data it is 0.8391, 7.9 times larger, and the sign of the drift reads out the discrimination structure directly — every one of items 1–6 (`a = 1.8`) negative and every one of items 7–12 (`a = 0.6`) positive, without exception. Both data sets are simulated with the item parameters stated in Sections 10.12 and 10.14; generated by `figs/src/CCP-026_fig03.py`.

```
                  sum_n ( x_ni - P_ni )^2
INFIT MNSQ    =  -------------------------          INFORMATION-WEIGHTED mean square
                  sum_n  P_ni (1 - P_ni)
```

Both have expectation 1 under the model. The difference between them is which responses dominate:

```
OUTFIT is OUTLIER-SENSITIVE. Its denominator P(1-P) is tiny for far-off-target responses,
       so a single unexpected response from a badly mismatched person can move it a lot.
       Use it to detect: guessing, careless errors, miskeys, lucky hits.

INFIT is INLIER-SENSITIVE. It weights each residual by the information that response
       carries, so on-target responses dominate.
       Use it to detect: problems with the items people are actually well matched to --
       the failures that matter for the measure.
```

Interpretation of the mean square, with the two directions carrying entirely different diagnoses:

```
MNSQ >> 1     UNDERFIT -- more randomness than the model predicts.
              Off-construct item, ambiguous wording, guessing, careless responding,
              multidimensionality. THIS IS THE DANGEROUS DIRECTION: it degrades measurement.

MNSQ << 1     OVERFIT -- LESS randomness than the model predicts.
              Responses too predictable: item dependency, redundancy, a Guttman-like
              over-discriminating item. Does not degrade measurement, but it INFLATES
              reliability and makes the instrument look better than it is.
```

The asymmetry is the practically important part and it is routinely inverted by newcomers, who treat MNSQ = 0.4 as a triumph. It is not. It means an item is telling you something you already knew, and it means your reported reliability is a fiction.

Standardised versions (ZSTD) convert the mean square to an approximate normal deviate via the Wilson-Hilferty cube-root transformation. Report both: **the mean square says how much misfit, the ZSTD says how sure you are it is real.** With large samples, trivial misfit becomes highly significant, so ZSTD alone will condemn everything.

26.10.16 10.16 Fit statistics on data with planted defects

Twelve items, 2958 usable persons, nine clean Rasch items and three deliberately broken ones.

item	beta	OUTFIT MNSQ	ZSTD	INFIT MNSQ	ZSTD	pt-measure r	planted defect
1	-1.851	0.859	-1.92	0.911	-1.96	+0.419	clean
2	-1.571	0.897	-1.57	0.886	-2.68	+0.465	clean
3	-1.291	0.925	-1.26	0.939	-1.47	+0.465	clean
4	-1.522	0.936	-0.98	1.000	+0.00	+0.404	**guessing, c = 0.30**
5	-0.587	0.918	-1.76	0.944	-1.45	+0.519	clean
6	-0.210	0.953	-1.06	0.936	-1.70	+0.535	clean
7	+0.168	0.887	-2.64	0.915	-2.29	+0.556	clean
8	+0.158	**1.411**	**+8.23**	**1.252**	**+6.14**	+0.328	**low discrimination, a = 0.35**
9	+0.896	0.913	-1.74	0.947	-1.31	+0.510	clean
10	+1.302	0.850	-2.68	0.924	-1.80	+0.496	clean
11	+2.599	**0.404**	**-7.45**	**0.683**	**-6.09**	+0.487	**over-discriminating, a = 3.0**
12	+1.909	0.788	-2.99	0.894	-2.24	+0.451	clean

Item 8 is caught cleanly: `OUTFIT = 1.411`, `ZSTD = +8.23`, and the point-measure correlation drops to `+0.328` against a clean-item range of `0.40` to `0.56`. Classic underfit — the item is noisy relative to the construct.

Item 11 is caught in the other direction: `OUTFIT = 0.404`, `ZSTD = −7.45`. **Severe overfit. Its responses are far too predictable, and if you read low mean squares as good news you would have called it your best item.** Note also its estimated difficulty, `+2.599` — well outside the true range — because forcing a slope-3 item into a slope-1 model displaces its location.

Item 4 is the finding of the section, and it is a negative one. The guessing item, with a 30% lower asymptote, posted `OUTFIT = 0.936` and `INFIT = 1.000`. **Both statistics say "perfect".** By fit statistics alone, item 4 is the best-behaved item on the instrument. It is broken.

No single fit statistic is sufficient, and the invariance test is the criterion that fit statistics only approximate. §10.18 runs the invariance `t` on this same data set and catches item 4 at `t = +4.14`. That is why FVP-7 is a separate gate rather than a footnote to model fit, and it is why Section 3 insisted it is the gate that decides.

An honest caveat about the mean squares. The clean items in the table average `OUTFIT = 0.888`, not `1.000`. This is not evidence that they misfit. It is the deflation caused by estimating both `theta` and `beta` from the same responses: fitted parameters absorb some residual variance. The same data scored against the *true* parameters gives:

```
mean OUTFIT with true theta and true beta = 0.9995     (expectation 1.000)
mean INFIT  with true theta and true beta = 0.9988
```

The expectation of 1.000 is exact for the model, and the shortfall to 0.888 is an artefact of estimation, not a property of the items. Anyone comparing observed mean squares to a nominal 1.000 without accounting for this will systematically over-diagnose overfit. Compare items to the *instrument's own* mean, and to each other.

26.10.17 10.17 Why this is exactly what Series B needs

Now the payoff, and it is a structural result rather than an analogy.

Step 1. Rasch measures live on an interval scale in the log-odds register. The model `ln[P/(1−P)] = theta − beta` determines `theta` up to an additive constant: the origin is arbitrary (fixed by convention, usually by centring the items at zero), and the *unit* is fixed by the model, because the discrimination is constrained to 1. Choosing a different logarithm base rescales all measures by one common factor — exactly the way nats and bits differ [Curzi, 2026n] — and is a change of unit, not a change of scale.

Step 2. Identify the quantity with the exponential of the measure. *Postulate SO1, badged as a postulate:* if `D` and `P` are calibrated as Rasch measures `theta_D` and `theta_P` on one common scale, then the corresponding magnitudes are `D = exp(theta_D + b)` and `P = exp(theta_P + b)`, where `b` is the scale's arbitrary common origin. This identification is a modelling choice. It is not derived, and it is badged here.

Step 3. The arbitrary origin cancels from the ratio. Verified across four wildly different origin choices, with `theta_D = 1.45` and `theta_P = 0.62`:

origin `b`	`D`	`P`	`D/P`	`Delta = |ln r|`
+0.0	4.2631	1.8589	**2.293319**	**0.830000**
-3.0	2.1225e-01	9.2551e-02	**2.293319**	**0.830000**
+2.5	5.1935e+01	2.2646e+01	**2.293319**	**0.830000**
+100.0	1.1460e+44	4.9970e+43	**2.293319**	**0.830000**

```
D/P  =  exp(theta_D − theta_P)  =  exp(0.8300)  =  2.293319
```

The magnitudes `D` and `P` range over forty-four orders of magnitude and the ratio does not move. The arbitrary constant that makes the logit scale merely *interval* is exactly the constant that cancels in a ratio.

Step 4. The distortion measure is on a genuine ratio scale.

```
Delta  =  | ln(D/P) |  =  | theta_D − theta_P |
```

Its true zero is not a convention: `Delta = 0` if and only if `theta_D = theta_P`, which is the calibrated state, and that identity holds in every unit and under every origin. The only remaining freedom is the unit:

```
Delta in logits (nats) = 0.830000
Delta in bits          = 1.197437        (divide by ln 2 = 0.693147)
ratio                  = 0.693147        a pure multiplicative constant
```

A quantity with a fixed true zero and a free multiplicative unit is a ratio scale, by the definition of Section 7.7. Therefore:

> **Theorem 10.3** (designated *Theorem 54.3* in the source manuscript; item and person separability above are *Theorems 54.1 and 54.2* there)**, given Postulate SO1.** *If `D` and `P` are measured as Rasch person-measures on one common scale, then `Delta = |ln(D/P)| = |theta_D − theta_P|` is ratio-scaled with a true zero at perfect calibration, and `D/P` is determined up to the choice of unit.*

This is the single most important result in this paper for the corpus's own formulas. Section 7 showed that ordinal data cannot support `D/P`. Section 10 shows there is a constructive route from ordinal responses to a properly scaled distortion measure: build a Rasch instrument, calibrate `D` and `P` on a *common* scale, and read the distortion off as a logit difference. **The raw ordinal responses never became ratio data. The measure derived from them did, because the model earned it.**

And note where this lands. Distortion is a *difference of logarithms* — which is what the corpus's logarithmic register requires [Curzi, 2026n], and what the lens theorem [Curzi, 2026n] said perception operates in. **Rasch arrived at the logarithmic register in 1960 from a pure invariance requirement about test items, with no reference to Fechner, to surplus, or to anything in this book.** Two independent derivations, one register. That convergence is worth stating and worth not overstating: it is a structural correspondence between formalisms, exactly like the predictive-processing correspondence noted in Curzi [2026m], and structural similarity is not identity.

26.10.18 10.18 What it would cost — the precision arithmetic

The result above is constructive, which means it can be costed. Person measurement error in the best case (every item targeted at the person, `P = 0.5`, information `0.25` per item):

```
SE(theta)  =  1 / sqrt( k * 0.25 )  =  2 / sqrt(k)
SE(Delta)  =  SE(theta_D) * sqrt(2)          (two independent measures)
```

items per term `k`	best-case `SE(theta)`	`SE(Delta)`	smallest detectable `Delta` (95%)
5	0.8944	1.2649	2.4792
10	0.6325	0.8944	1.7531
12	0.5774	0.8165	1.6003
20	0.4472	0.6325	1.2396
30	0.3651	0.5164	1.0121
44	0.3015	0.4264	0.8357
60	0.2582	0.3651	0.7157
100	0.2000	0.2828	0.5544
150	0.1633	0.2309	0.4526
200	0.1414	0.2000	0.3920

Inverted, so it can be read as a design requirement:

distortion to detect	ratio `r`	items required per term
1.00 logits	2.718	31
0.50 logits	1.649	123
0.30 logits	1.350	342
0.20 logits	1.221	769
0.10 logits	1.105	3074

This table is sobering and it is meant to be. A twenty-item instrument can only detect distortions above about `1.24` logits — a frame-to-intake ratio of about 3.5. Anything subtler is inside the noise. To resolve a ratio of `1.35` you need three hundred and forty-two items per term, which no one will sit through in one session and which therefore implies adaptive testing, item banking, or repeated measurement across occasions.

A practitioner reporting `r = 1.2` from a twelve-item pair of scales is reporting noise, and the arithmetic above says so exactly. That is the kind of statement the Formula Validation Protocol exists to make available before the study is run rather than after.

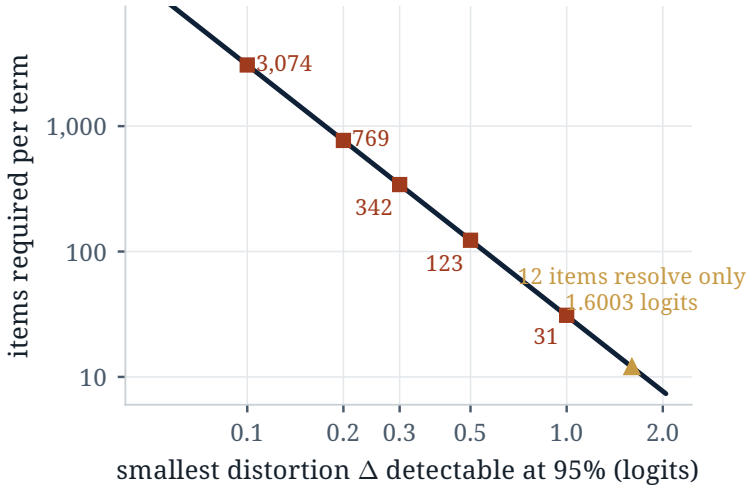

Figure 26.4: **The restoration is priced, and the price is steep:** the best-case relation $k = (5.543717/\Delta)^2$, derived at R5 of the verification chain, plotted against the five design targets printed in Section 10.18 — 31 items per term to detect a one-logit distortion, 123 for half a logit, 342 for 0.3, 769 for 0.2 and 3,074 for 0.1. A twelve-item pair of scales sits at the ochre marker and resolves nothing finer than 1.6003 logits. Derived, assuming every item perfectly targeted (information 0.25 per item), so every count is a lower bound; generated by `figs/src/CCP-026_fig04.py`.

26.11 11 Requirements for specific objectivity

SO-1 — State the model and its constraint. Report that the discrimination is fixed at 1 and that this is a deliberate measurement choice, not an oversight. Anyone using a 2PL or 3PL must state that specific objectivity has been abandoned and say why.

SO-2 — Estimate by conditional maximum likelihood where feasible. CML eliminates the person parameters and is consistent as `N` grows. Where marginal or joint methods are used instead, report the choice and its bias implications.

SO-3 — Report the gamma checks. `gamma_1 = sum(eps)` and `gamma_k = prod(eps)`. Numerical failure in the elementary symmetric functions is the commonest implementation bug.

SO-4 — Exclude and report extreme scores. Persons at `r = 0` or `r = k` and items answered correctly by everyone or no one contribute nothing to CML. State how many were excluded. A large exclusion count means the instrument is mistargeted.

SO-5 — Report person AND item separation, reliability, and strata. Not reliability alone. `(4G+1)/3` strata is the number that tells a reader what the instrument can actually distinguish. An instrument reported without its strata count is not specified.

SO-6 — Never claim individual-level decisions below person reliability 0.90. The 0.69 example in §10.11 supports group comparison and nothing finer.

SO-7 — Run the split-sample invariance test, always. Split on the attribute itself, not on convenience. Report the full item-by-item table, the mean difference, the sd of differences, the maximum, and the correlation. **This is the FVP-7 deliverable and it is not optional.**

SO-8 — Split on a second variable too. Attribute-based splitting detects discrimination heterogeneity. Splitting on group membership detects differential item functioning. Both must be run and both reported.

SO-9 — Report the invariance `t` per item. `t_i = (beta_i^A - beta_i^B) / sqrt(SE_A^2 + SE_B^2)`, with the flagging threshold stated in advance and justified against the number of items tested.

SO-10 — Report OUTFIT and INFIT, mean square and standardised, for every item. Four

numbers per item. Not a global fit index, not a selection of the good ones.

SO-11 — Interpret overfit as a defect. `MNSQ` well below 1 means dependency or redundancy and it inflates reliability. Treat it as a finding, never as a success.

SO-12 — Correct for estimation deflation before diagnosing. Compare items to the instrument's own mean mean-square, not to the nominal 1.000. §10.16 measured the artefact at roughly `0.11`.

SO-13 — Report the point-measure correlation. It catches things the mean squares miss and it is free.

SO-14 — Do not rely on fit statistics alone. Item 4 of §10.16 passed both mean squares and was broken. Fit statistics are a screen; invariance is the criterion.

SO-15 — Test unidimensionality explicitly. Principal-components analysis of the standardised residuals, with the variance explained by the first residual contrast reported. Rasch fit does not by itself establish that one dimension is present.

SO-16 — Calibrate `D` and `P` on ONE common scale. Either one item bank measuring both, or two banks linked by common items or common persons, with the linking constants and their errors reported. **Two independently centred scales cannot be differenced**, because each has its own arbitrary origin and the origins do not cancel. This is requirement S-5 in Rasch form and it is the single most likely point of failure in an applied study.

SO-17 — Report `Delta` in logits with its standard error. `SE(Delta) = sqrt(SE_D^2 + SE_P^2)`. A distortion is not reportable unless its interval excludes zero.

SO-18 — Use the precision table before the study, not after. §10.18. Decide what magnitude of distortion matters, read off the item count, and either build that instrument or narrow the claim.

SO-19 — Badge Postulate SO1 wherever the exponential identification is used. The step from a Rasch logit measure to a magnitude `D = exp(theta + b)` is a modelling choice and carries its badge under the corpus's badging convention [Curzi, 2026].

SO-20 — State the unit. Logits (nats) or bits. `Delta` is unit-dependent by a multiplicative constant and a reported number without its unit is not a number.

26.12 12 Failure modes of Rasch practice

26.12.1 FM-12.1 · THE 2PL ESCAPE

Damages: specific objectivity, totally, in exchange for a better fit index.

Items misfit. A discrimination parameter is added per item. Fit improves. The report says the model now describes the data well, and it does — and the scale is gone.

Diagnostic signature: the model was chosen after inspecting fit; the discrimination parameters vary substantially across items; no invariance test is reported; the phrase "better model fit" appears without the phrase "loss of parameter separation".

Detecting measurement: §10.13's table on your own items. Compute the item log-odds difference at `theta = −2` and at `theta = +2`. If it moves, item difficulty is person-dependent.

Fix: revise the instrument, not the model. Remove or rewrite the items whose discriminations deviate. **If you genuinely need the 2PL to describe your data, say that you have a description and not a measure, and stop reporting the numbers as if they transferred.**

26.12.2 FM-12.2 · THE UNTESTED INVARIANCE

Damages: FVP-7 and SO-7.

A Rasch analysis is run, fit statistics are reported, and no split-sample calibration is ever performed. The theorem is cited in the introduction; its empirical test is absent from the results.

Diagnostic signature: the words "specific objectivity" appear in the introduction and nowhere in the methods. No table compares calibrations across samples.

Detecting measurement: look for the table. There either is one or there is not.

Fix: run it. It costs one extra estimation and it is the most informative table in the report. §10.12 and §10.14 show what a pass and a failure look like side by side, and they are not subtle.

26.12.3 FM-12.3 · THE FIT-STATISTIC ALIBI

Damages: SO-14, and the credibility of everything downstream.

Acceptable mean squares are treated as proof of measurement. They are not. §10.16's item 4 — a guessing item with a 30% lower asymptote — returned `OUTFIT = 0.936` and `INFIT = 1.000`, the best numbers on the instrument.

Diagnostic signature: the conclusion "the data fit the Rasch model" rests entirely on mean squares in a conventional range; no invariance test; no residual dimensionality analysis.

Detecting measurement: the invariance `t` (SO-9). On §10.16's data it flags item 4 at `t = +4.14` where both mean squares said nothing.

Fix: SO-7 through SO-15. Three independent checks — fit, invariance, dimensionality — and no one of them substitutes for another.

26.12.4 FM-12.4 · READING OVERFIT AS SUCCESS

Damages: reported reliability, and the instrument's real precision.

An item posts `MNSQ = 0.40` and is celebrated. It is over-discriminating or dependent on another item. Reliability is inflated because the responses are more predictable than the construct warrants.

Diagnostic signature: mean squares clustered well below 1; unusually high reliability for a short instrument; items that are near-paraphrases of one another.

Detecting measurement: residual correlations between item pairs. Strong positive residual correlation is local dependence and it is the usual cause.

Fix: combine or remove the dependent items and recalibrate. Expect reliability to fall; the fall is the correction, not the damage.

26.12.5 FM-12.5 · THE UNLINKED SCALES

Damages: SO-16, and with it every `Delta` the study reports.

`D` and `P` are calibrated by two separate Rasch analyses, each centred on its own items at zero. The difference `theta_D − theta_P` is then computed as though the origins were shared. They are not, and each was set arbitrarily.

Diagnostic signature: two calibrations, each reported with mean item difficulty exactly zero, and no linking design described. The mean `Delta` across a population comes out implausibly close to zero, or implausibly far from it, with no substantive explanation.

Detecting measurement: look for the linking constant. If there is no common item set and no common person set, there is no link.

Fix: a linking design — common items across both banks, or a common person sample taking both — with the linking constant and its standard error reported. **Without a link, `Delta` is the difference of two arbitrary constants and means nothing.** This is the same defect as Section 7's FM-9.6, arriving through a different door.

26.12.6 FM-12.6 · THE MISTARGETED INSTRUMENT

Damages: person precision, silently.

The items sit at difficulties far from where the persons sit. Everyone scores near the top or near the bottom. Extreme scores are excluded, the remaining sample is small and unrepresentative, and person standard errors are enormous.

Diagnostic signature: a large excluded fraction; a person-item map with the two distributions barely overlapping; person separation below 1.5 and strata below 2.

Detecting measurement: SO-4 and SO-5. The exclusion count and the strata count together are diagnostic.

Fix: add items at the person distribution's location. **Item precision is bought with persons and person precision is bought with items; a mistargeted instrument buys neither.**

26.12.7 FM-12.7 · CENTRING CONTAGION

Damages: every item estimate, by a common shift.

The scale's origin is set by centring the item difficulties. One badly misfitting item drags the mean, and therefore shifts every other item's estimate. Clean items are then flagged as misbehaving.

Diagnostic signature: several items flagged at moderate `t` alongside one flagged at extreme `t`; the moderate flags disappear when the extreme item is removed and the scale recentred.

Detecting measurement: remove the worst-fitting item, recalibrate, and re-run the invariance test. In §10.18's run, item 5 was flagged at `t = +3.71` in the presence of three planted defects; the flag is contamination, not a property of item 5.

Fix: anchor the origin on a stable subset of items rather than on the full-set mean, and always re-run diagnostics after removing an item. **Never remove several items at once: each removal moves the scale.**

26.12.8 FM-12.8 · THE ASSUMED DIMENSION

Damages: the meaning of the measure, entirely.

Fit statistics are acceptable, invariance holds, and the instrument is nonetheless measuring two things at once whose mixture happens to be stable in the sample studied. The measure will not transfer to a population where the mixture differs.

Diagnostic signature: residual principal components with a first contrast explaining substantial variance; items clustering by content in the residual space; measures that behave differently in a new population despite fitting in the old one.

Detecting measurement: SO-15. Principal-components analysis of the standardised residuals, with the first-contrast eigenvalue reported.

Fix: split the instrument along the contrast and calibrate each dimension separately. Two honest measures beat one composite whose composition is unknown.

26.13 13 Results

Three demonstrations are reported. Section 13.1 runs the complete seven-gate protocol end to end on the moment equation `M = (D/P)E`, including the empirical gates on simulated series generated from the model and from two false alternatives. Section 13.2 specifies and demonstrates the construction of a ratio scale for the divided terms, and delivers the gate-2 verdict.

Section 13.3 runs the specific-objectivity procedure on a twelve-item instrument with three planted defects and applies the result to `D/P`.

Every empirical number below comes from simulated data whose generating process is stated beside it. Nothing here is a claim about human beings, and the verdicts for the moment equation as applied to people are NOT YET RUN at gates 6 and 7 throughout.

26.13.1 13.1 The protocol run end to end on the moment equation

The complete protocol, run end to end on the Moment equation, with every number computed.

```
M = (D / P) . E        D perspective, P perception, E environment, M moment
```

The empirical portions (FVP-6 and FVP-7) are run here on **simulated data**, and that label is load-bearing. **No claim is made here about human beings.** What is demonstrated is the *protocol*: what the analysis looks like when the formula is true, what it looks like when it is false, and what the numbers have to be for a reader to be entitled to believe it. Curzi [2026u] costs out the programme that would run this on people.

13.1.1 FVP-1 — Dimensions

term	meaning	dimension	unit
`D`	perspective / frame strength	`[s]`	one common subjective magnitude scale, anchored
`P`	perception / intake strength	`[s]`	the same scale, same anchor
`r = D/P`	calibration ratio	dimensionless	pure number
`E`	environment magnitude	`[e]`	environmental units, externally instrumented
`M`	moment magnitude	`[e]`	inherits `E` exactly
`Delta = |ln r|`	distortion	dimensionless	nats

R1: no unlike additions occur. R2: `ln r` takes a dimensionless argument. R3: left side `[e]`, right side `dimensionless x [e] = [e]`.

VERDICT: PASS, conditional on `D` and `P` sharing one anchored scale. The condition is not cosmetic; it forces the instrument design and it is the reason Section 7.12 matters.

13.1.2 FVP-2 — Scale type

`D` and `P` are divided, so both require a ratio scale with a true zero. `E` is multiplied, so it too requires a ratio scale. `M` inherits.

The true zeros are interpretable, which is a necessary condition and a good sign: `P = 0` is total absence of intake, `D = 0` is total absence of frame, `E = 0` is total absence of environment. Each is a state one can describe. **A quantity whose zero cannot be described does not have a true zero, and the ratio scale is unavailable.**

Whether ratio-scaled `D` and `P` can actually be *built* is the subject of Section 7. The honest verdict for the corpus, today:

VERDICT: DEMOTE, pending instrumentation. Magnitude estimation gives a validated route (Section 7.10), and the route has produced ratio scales for sensory magnitudes for seventy years. It has not yet been applied to `D` and `P` by anyone. Until it has, `M = (D/P)E` is printed in the corpus as a **heuristic ordering with a demonstrated structure**, not as a measured equation. Everything below shows what passing would look like; it does not show that we have passed.

13.1.3 FVP-3 — Limiting cases

With `D = 6`, `E = 2`, sweeping `P` down:

P	r = D/P	M = rE	Delta = |ln r|
4.0000	1.50	3.00	0.4055
2.0000	3.00	6.00	1.0986
1.0000	6.00	12.00	1.7918
0.5000	12.00	24.00	2.4849
0.2500	24.00	48.00	3.1781
0.1000	60.00	120.00	4.0943
0.0500	120.00	240.00	4.7875
0.0100	600.00	1200.00	6.3969
0.0010	6000.00	12000.00	8.6995

With `P = 3`, `E = 2`, sweeping `D` down:

D	r	M	Delta
12.0000	4.0000	8.0000	1.3863
6.0000	2.0000	4.0000	0.6931
3.0000	**1.0000**	**2.0000**	**0.0000**
1.5000	0.5000	1.0000	0.6931
0.7500	0.2500	0.5000	1.3863
0.3000	0.1000	0.2000	2.3026
0.0300	0.0100	0.0200	4.6052
0.0030	0.0010	0.0020	6.9078

The four limits and their named phenomena [Curzi, 2026m]:

```
P -> 0    M -> infinity    frame with no intake      -> hallucination, dogma, apophenia
D -> 0    M -> 0           intake with no frame      -> no moment; sensation is not experience
E -> 0    M -> 0           no environment            -> no moment
D = P     M  = E           THE FIXED POINT           -> undistorted contact
```

Every limit names a real, describable state, and the divergence names the most clinically familiar one of the four. A frame that receives no correcting intake and grows without bound is the structure of dogma, of the closed ideology, and of the psychotic elaboration. The formula's singularity is not a mathematical embarrassment to be excused; it is the formula's most recognisable prediction.

Note also the shape of the `Delta` column. Distortion grows *logarithmically* while `M` grows *linearly* in `r`. Cutting intake by a factor of ten multiplies the moment by ten but adds only `ln 10 = 2.3026` nats of distortion. **In the log register, catastrophic over-framing is a modest number, and that is exactly the register the person inside it experiences.** The lens theorem [Curzi, 2026n] applied to its own pathology.

Domain of validity: the formula is stated for `D >= 0`, `P > 0`, `E >= 0`. At `P = 0` the expression is undefined and the model is replaced by the statement "unbounded", not by a number.

VERDICT: PASS.

13.1.4 FVP-4 — Fixed points

Set `M = E` and solve: `(D/P)E = E` for `E > 0` gives `D/P = 1`, hence `D = P`.

The invariant is `D = P`, and its meaning is veridical contact: the moment equals the environment. Frame matches intake exactly and adds nothing and subtracts nothing. This is the formula's most important content and it is the reason the formula is worth stating at all — it provides an equation for a condition usually described only in adjectives.

Stability: **the Moment equation is a relation, not a map, and `D = P` is therefore not dynamically attracting.** Nothing in `M = (D/P)E` drives `r` toward 1. Any claim that calibration improves with experience is a separate postulate about learning, is not contained in this formula, and is badged separately in Curzi [2026m]. Reporting this is part of passing the gate: **a static invariant presented as though it were an attractor is a real and common misreading, and it is the author's job to forestall it.**

Contrast with the storage law, where the fixed point *is* dynamic: `Q_inf = (eta F(u*) − c*)/delta` [Curzi, 2026a], approached geometrically with `|Q_t − Q_inf| = (1−delta)^t |Q_0 − Q_inf|`, guaranteed by Banach because `delta > 0` makes the map a contraction.

VERDICT: PASS, with the non-dynamic status stated.

13.1.5 FVP-5 — Identifiability

The invariance group, from §4.5: `(D, P, E) −> (cD, cP, E)` for any `c > 0`, and `(D, P, E) −> (kD, P, E/k)` for any `k > 0`. The four-row table in §4.5 exhibits both.

VERDICT: FAIL as written; PASS under Remedies I5-a, I5-b and I5-c jointly. All three are required, and the specification for any study of the Moment equation must include all three. This is a genuine defect of the formula in its bare form and printing it as a failure is the point of having the gate.

The rank condition (V-11): the design matrix `[1, ln D, ln P, ln E]` must have full column rank across occasions. In the demonstration series below, the terms were generated with independent innovations and moderate autocorrelation, so the condition holds. **In a real study it may not, and the collinearity between `ln D` and `ln P` must be reported before any exponent is interpreted.**

13.1.6 FVP-6 — Falsification, run

Preregistered: a single-subject series of `T = 200` occasions; `D`, `P`, `E` each log-normally distributed with first-order autocorrelation (0.55, 0.55, 0.40 respectively, so that persistence and AR baselines are genuine competitors, not straw men); log-normal multiplicative noise on `M` with `sigma = 0.35` in the log register. Model:

```
ln M = b0 + bD ln D + bP ln P + bE ln E + e
targets: (b0, bD, bP, bE) = (0, 1, −1, 1)
```

Split: occasions 1-140 train, 141-200 held out. Parameters frozen after training.

Fitted on training (n = 140), then frozen:

parameter	estimate	s.e.	95% CI	target	`t` vs target
`b0`	-0.0295	0.1191	[-0.2629, 0.2039]	0.0	-0.248

parameter	estimate	s.e.	95% CI	target	t vs target
bD	1.0205	0.0504	[0.9217, 1.1193]	1.0	0.407
bP	-0.9505	0.0627	[-1.0734, -0.8275]	-1.0	0.790
bE	0.8985	0.0725	[0.7563, 1.0407]	1.0	-1.399

All four intervals contain their targets. KILL-1 and KILL-2 are not triggered.

Held out (n = 60), frozen parameters, against all four baselines:

model	held-out R^2	RMSE
the Moment model	**0.8091**	**0.4067**
persistence (yhat_t = y_{t−1})	-0.3322	1.0744
direct-input (E alone)	0.3797	0.7331
matched AR(1)	0.0756	0.8950
shuffled-input control	**0.0059**	**0.9281**

The margin over the best baseline is 0.8091 − 0.3797 = 0.4294, comfortably past KILL-3's threshold of 0.10. The shuffled control returns 0.0059, far below KILL-4's ceiling of 0.20, and its fitted coefficients collapse toward zero (bD = 0.1249, bP = −0.0524, bE = 0.2024) — which is what destroying the pairing is supposed to do.

The persistence baseline's *negative* R^2 is not an error: it means the baseline predicts worse than the training mean, the correct behaviour for persistence against a series whose innovations dominate its autocorrelation.

Now the same suite run against two false worlds — the part that makes the suite worth running.

Counterfactual A — the division is not there. Data generated from M = D.E, with P present in the record but causally inert. Same fitting procedure:

```
bD = 1.0890   CI [0.9448, 1.2332]
bP = −0.0709  CI [−0.2009, 0.0590]     <-- KILL-1 TRIGGERED
bE = 0.9017   CI [0.7485, 1.0549]
```

The bP interval misses −1.0 by 0.799. **The protocol kills the formula, correctly, and it kills it on the specific term that was wrong** — which is more than a global goodness-of-fit statistic would have told anyone.

Counterfactual B — combination is additive, not multiplicative. Data generated from M = D − P + E in raw units. Fitting the log-linear multiplicative model:

```
log-linear fit to additive data:   bD = 1.6477   bP = −1.9381   bE = 1.2322
held-out R^2 of the WRONG multiplicative model  = 0.6758
held-out R^2 of the correct ADDITIVE model      = 0.9694
additive coefficients: 0.930, −0.882, 0.977  (targets 1, −1, 1)
```

This is the important result of the demonstration. The wrong functional form still achieved a held-out R^2 of 0.68. Against persistence, against direct-input, against AR(1) it would have won handsomely. A study that preregistered only a null would have reported the multiplicative Moment equation as confirmed. Only KILL-5 — the preregistered *rival functional form* — exposes it, and it exposes it decisively: 0.9694 against 0.6758.

The exponents also announce the problem to anyone who looks: bD = 1.65 and bP = −1.94 are nowhere near 1 and −1, so KILL-1 and KILL-2 both fire as well. **A formula that predicts its exponents is far more falsifiable than one that merely predicts a direction, and that is an argument for stating exponent targets in the preregistration.**

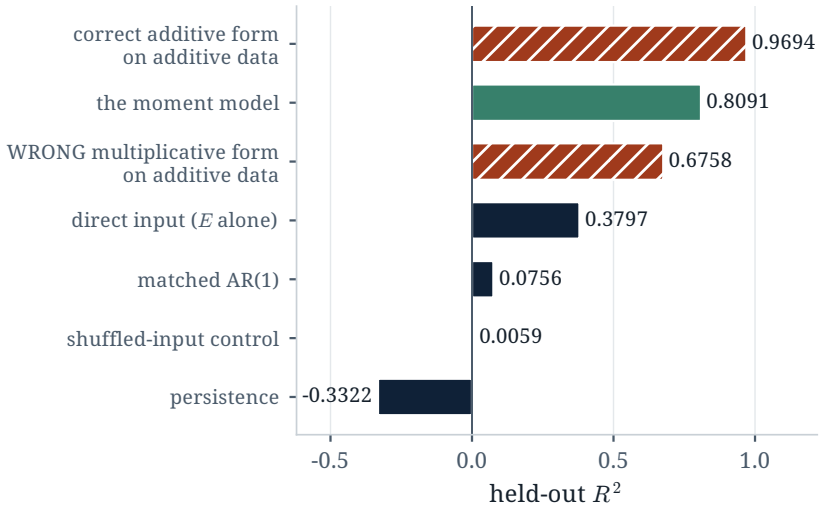

Figure 26.5: **A wrong functional form beats every simple baseline:** held-out `R^2` for the frozen model and its four preregistered baselines, and for the additive counterfactual. The moment model scores 0.8091 against a shuffled-input control at 0.0059 and a best simple baseline of 0.3797, a margin of 0.4294 against KILL-3's threshold of 0.10. But data generated *additively* and fitted with the multiplicative form still returns 0.6758 — enough to be reported as confirmation — while the correct additive model returns 0.9694. Only the preregistered rival functional form (KILL-5) separates them. All series simulated with the parameters stated in Section 13.1.6; generated by `figs/src/CCP-026_fig05.py`.

Power. From the observed `s.e.(bP) = 0.0627` at `n = 140`, the standard error scales as `0.7419 / sqrt(n)`. Required sessions to detect a given deviation from the exponent target:

deviation from target	`n` for 80% power	`n` for 90% power
0.50	18	24
0.40	27	37
0.30	48	65
0.25	70	93
0.20	108	145
0.15	192	258
0.10	432	579
0.05	1728	2314

Read this table before designing the study, not after. Detecting a `0.2` deviation in an exponent needs about 110 sessions from one person; detecting `0.1` needs about 430. A thirty-session pilot can only rule out gross misspecification, and should say so.

VERDICT on the demonstration: PASS on data generated from the model; correctly FAILS on both counterfactuals. VERDICT for the Moment equation as applied to human beings: NOT YET RUN.

13.1.7 FVP-7 — Reproducibility, run

Twelve simulated subjects, 200 occasions each, same operationalisation.

Case 1 — homogeneous population. All twelve subjects generated with true exponents `(1, -1, 1)`.

subject	bD (s.e.)	bP (s.e.)	bE (s.e.)	covers (1, -1, 1)
1	0.950 (0.051)	-0.969 (0.051)	0.997 (0.052)	YYY
2	1.053 (0.055)	-1.024 (0.056)	1.088 (0.050)	YYY
3	1.011 (0.061)	-0.946 (0.046)	0.979 (0.059)	YYY
4	0.964 (0.050)	-1.111 (0.055)	1.071 (0.058)	YnY
5	1.019 (0.053)	-0.937 (0.055)	0.976 (0.060)	YYY
6	1.111 (0.059)	-1.007 (0.052)	1.075 (0.057)	YYY
7	0.951 (0.045)	-0.955 (0.047)	1.048 (0.053)	YYY
8	1.033 (0.046)	-1.026 (0.052)	1.079 (0.059)	YYY
9	1.034 (0.052)	-1.048 (0.050)	1.100 (0.055)	YYY
10	0.977 (0.044)	-1.038 (0.048)	0.985 (0.053)	YYY
11	1.013 (0.049)	-1.028 (0.046)	0.986 (0.066)	YYY
12	0.992 (0.058)	-1.036 (0.058)	0.966 (0.058)	YYY

```

    tau^2 = max(0, 0.00216 − 0.00273) = 0.00000   ->  tau = 0.0000
```

`tau` is zero to numerical precision: the between-subject spread is entirely accounted for by sampling error. **This is OUTCOME A — a universal constant, to within the precision of the study.** The single miss at subject 4 is the expected behaviour of a 95% interval across twelve tests; one miss in twelve is not evidence of heterogeneity, and reporting it as such would be an error in the other direction.

Case 2 — heterogeneous population. True exponents drawn per subject with standard deviation 0.30 around `(1, −1, 1)`.

subject	true (bD, bP, bE)	estimated bD (s.e.)	estimated bP (s.e.)	estimated bE (s.e.)	covers

10	(0.923, -1.294, 0.948)	0.876 (0.045)	-1.332 (0.054)	1.052 (0.052)	nnY

subject	true (bD, bP, bE)	estimated bD (s.e.)	estimated bP (s.e.)	estimated bE (s.e.)	covers
11	(0.613, -0.994, 0.989)	0.653 (0.056)	-1.055 (0.050)	1.016 (0.059)	nYY
12	(0.909, -1.314, 0.881)	0.919 (0.053)	-1.305 (0.051)	0.908 (0.049)	YnY

```
mean bD = 0.9128  sd 0.2587       coverage of bD on 1.0  : 2/12
mean bP = −1.0157 sd 0.2767       coverage of bP on −1.0 : 4/12
mean bE = 0.9106  sd 0.2306       coverage of bE on 1.0  : 5/12

bD: between-subject variance 0.06693 ; mean within-subject variance 0.00270
    ratio 24.78   ->   tau^2 = 0.06423   ->   tau = 0.2534
```

Every subject's own exponents are recovered accurately — compare the true and estimated columns. **The estimates are excellent and the universal constant is absent.** Heterogeneity is roughly 25 times the sampling noise. This is **OUTCOME B**: the exponent is a person-level parameter, not a species-level one.

Outcome B is a pass provided V-19 is also satisfied — provided the same person's exponent recovers on a *different instrument*. If it does, the exponent is that person's and the framework has a measurement. If it does not, the exponent belongs to the instrument and the framework has nothing.

Now the damage from pooling. The same heterogeneous data, fitted as one pooled regression over all 2400 observations:

```
bD = 0.8474   s.e. 0.0257   CI [0.7969, 0.8979]
bP = −1.0451  s.e. 0.0257   CI [−1.0955, −0.9947]
bE = 0.9094   s.e. 0.0267   CI [0.8571, 0.9617]
```

The pooled bP interval contains −1.0, so a pooled analysis would have reported the division confirmed. Meanwhile:

```
tau (true spread of individual bD)        = 0.2534
pooled standard error on bD               = 0.0257
ratio                                     = 9.9
```

The pooled confidence interval is about ten times narrower than the actual spread of the individuals it describes. It is not a wrong interval — it is a correct interval about the wrong quantity. It describes the population mean; it was read as describing a person. That substitution is FM-6.5, it is extremely common, and it is one of the mechanisms behind the replication gap this paper opened with. **An estimate can be simultaneously precise, unbiased about its own target, and useless for every individual in the sample.**

13.1.8 The completed FVP row

```
FVP ROW  --  THE MOMENT EQUATION   M = (D/P).E

  FVP-1  DIMENSIONS      D,P share one anchored scale [s]; r dimensionless; M inherits [e];
                         Delta = |ln r| in nats. R1, R2, R3 all verified.
                         PASS, conditional on the common scale.

  FVP-2  SCALE TYPE      D, P, E all require RATIO scale with true zero. All three zeros are
                         describable states. Instrumentation not yet built.
```

```
                        DEMOTE -- printed in the corpus as a heuristic ordering with
                        demonstrated structure, pending the construction of Section 7.

FVP-3  LIMITING CASES   P->0 unbounded (dogma/apophenia); D->0 zero (sensation without
                        experience); E->0 zero (no environment); D=P gives M=E (contact).
                        All four named. Domain: D>=0, P>0, E>=0.
                        PASS.

FVP-4  FIXED POINTS     Invariant D=P, meaning veridical contact. STATIC, not an attractor;
                        the formula contains no dynamics driving r toward 1.
                        PASS, with non-dynamic status stated.

FVP-5  IDENTIFIABILITY  Two invariances: (D,P,E)->(cD,cP,E) and (D,P,E)->(kD,P,E/k).
                        Bare formula is NOT identifiable. Requires Remedy I5-a (anchored
                        standard), I5-b (independent measurement of E -- ESSENTIAL), and
                        I5-c (independent variation across occasions, with the rank
                        condition reported).
                        FAIL as written; PASS under all three remedies.

FVP-6  FALSIFICATION    Kill criteria KILL-1..KILL-5 preregistered, including the rival
                        additive form. Protocol demonstrated on simulated data: passes on
                        true data (held-out R^2 = 0.8091 vs shuffle 0.0059), correctly
                        kills both counterfactuals. Power table computed.
                        NOT YET RUN on human data.

FVP-7  REPRODUCIBILITY  Protocol demonstrated; Outcome A and Outcome B both exhibited;
                        pooling damage quantified at a factor of ~10.
                        NOT YET RUN on human data.
```

Two of the seven gates report NOT YET RUN and one reports DEMOTE. That is the honest state of the corpus's central formula, and it is printed here, in the paper that defines the standard, so that no reader can mistake the ambition for the achievement.

The ambition is nonetheless achievable, and that is this section's closing claim. The demonstration above is arithmetic on a design that could be run starting Monday with a hundred and forty sessions and a preregistration. What stands between the corpus and a validated moment equation is the scale construction of Section 7, the falsification suite and the costed programme of Curzi [2026u] — not a philosophical obstacle, and not the nature of subjectivity.

Psychology and sociology are not pseudoscience. They are sciences with a measurement problem and a replication problem. Formulas do not fix that. Ratio-scale, reproducible, falsifiable measurement of the formulas' terms does — and that is what Sections 7 and 10 are for.

26.13.2 13.2 Constructing a ratio scale for the divided terms

Constructing a ratio scale for `P`, perceptual intake, and then delivering the FVP-2 verdict on `D/P`. This is a design, costed in effort, that a competent laboratory could run; the numbers below that come from simulation are labelled as such.

13.2.1 The attribute and its zero

`P` is defined as **the magnitude of registered sensory and situational intake during a bounded episode.** The zero state, per Test Z1: complete absence of intake — an episode in which nothing whatever was registered. This is describable, it is recognisable, and observers agree on

instances of near-approach to it (dreamless sleep, deep absorption in an unrelated task, dissociative episodes). **Z1 passes.**

Z2 concatenation is unavailable: there is no operation that physically joins two intakes so their magnitudes add. **Z2 not available, and this is stated, not glossed.** The scale will rest on Z3.

13.2.2 The instrument

```
Stimulus continuum:   recorded episodes of controlled richness, spanning a factor of at
                      least 40 in a pre-measured environmental index (count of distinct
                      events, distinct speakers, distinct objects manipulated -- an
                      EXTERNAL measure, satisfying Remedy I5-b).
Task:                 immediately after each episode, magnitude estimation of "how much
                      you took in", free modulus, unbounded, per ME-1 through ME-7.
Order:                irregular, per S-9.
Aggregation:          geometric, per S-10.
```

Note that the external environmental index does double duty. It is the stimulus variable for the power-law fit here, and it is the independent measure of `E` that FVP-5 declared essential. **One instrument, two gates.**

13.2.3 Expected analysis, demonstrated on simulated data

Using the §7.10 simulation as the template — ten observers, seven levels, free moduli spanning a factor of 31, 18% log-normal noise:

```
a_hat (geometric-mean aggregation)  = 0.6987   s.e. 0.0165   95% CI [0.6664, 0.7310]
log-log R^2                         = 0.99723
per-observer exponents              = 0.737 0.569 0.694 0.653 0.755
                                      0.774 0.720 0.631 0.728 0.726
per-observer mean 0.6987, sd 0.0631
```

What would have to be true for this to count. Not that the exponent takes a particular value — nothing in the corpus predicts the exponent of perceptual intake. What must be true is:

```
C1   the log-log relation is straight (R^2 above about 0.98, no systematic curvature)
C2   no responses at any ceiling, because there is no ceiling
C3   ratio production composes: halve-then-halve equals quarter, within tolerance (Z3)
C4   cross-modality matching against an established continuum recovers the predicted a/b
C5   the same observer's exponent recovers on a second occasion, weeks apart
```

C1 and C2 are properties of a single session. C3 is Z3, the ratio-scale warrant. **C4 is the one that makes it science**, because it is a prediction from two other experiments with no free parameters. C5 is FVP-7 within a person, and it is the precondition for Outcome B.

13.2.4 The same construction for `D`

`D`, perspective, is defined as **the magnitude of interpretive frame brought to the episode** — how much structure the observer supplied. Its zero: raw sensation with no interpretation, which is describable and, at the limit, is what the Moment equation's `D -> 0` case names.

Critically, `D` must be estimated on the same instrument, in the same session, with the same modulus, per S-5. The observer gives one number for intake and one number for frame, both

referred to the same freely chosen first number. This is what makes them commensurable and it is what makes `D/P` dimensionless (FVP-1 above).

This is a real design constraint with a real cost: the observer must hold one modulus across two judgements, which is harder than holding it across one continuum, and the resulting scale will be noisier. **The alternative — two instruments, two anchors, one division — is FM-9.6 and is not admissible.**

13.2.5 The verdict

Assembling everything:

```
FVP-2 -- SCALE TYPE -- THE MOMENT EQUATION  M = (D/P).E

  Term D:  RATIO required (it is divided).
           Zero describable: YES (Z1 passes).
           Concatenation available: NO (Z2 unavailable; stated).
           Ratio-consistency established: NOT YET (Z3 not run).
           Instrument built: NO.
           STATUS: ratio scale is CONSTRUCTIBLE by the design in 13.2.2-13.2.4;
                   NOT YET CONSTRUCTED.

  Term P:  identical status to D.

  Term E:  RATIO required (it multiplies).
           Zero describable: YES. External physical index available: YES.
           STATUS: ratio scale AVAILABLE today via the environmental index.

  VERDICT: DEMOTE.

  Until D and P are instrumented per 13.2.2 and validated per C1-C5, the Moment equation
  is printed in the corpus in its DEMOTED FORM (section 7.15):

      Over-framed <=> D > P ;  Calibrated <=> D = P ;  Under-framed <=> D < P

  The three-regime classification, the four limiting cases, and the fixed point D = P are
  ADMISSIBLE on ordinal data from a single common instrument. The magnitude D/P, the
  distortion Delta = |ln r|, and the join to the storage law via M_t are NOT, and are
  reported nowhere in Series B of the corpus as measured quantities.
```

13.2.6 What the scale-construction demonstration concludes

The crux was never whether subjective quantities can be measured on a ratio scale. Psychophysics settled that affirmatively seventy years ago, and the transitivity table in §7.12 is what the settlement looks like. The crux is whether *these particular* subjective quantities — frame and intake — have been so measured. They have not. The route is specified, the instrument is designed, the validation criteria C1 through C5 are written down, and the work has not been done.

That is a smaller and far more useful claim than the one a less careful account would make, and it has the property that it can be discharged. **Ratio-scale measurement of `D` and `P` is a finite programme of laboratory work, not a philosophical impasse**, and Curzi [2026u] costs it out.

Until then, the demotion stands, in print, in the same paragraph as the formula, every time. That is the discipline the Formula Validation Protocol exists to impose, and Section 7 is the reason it has teeth.

26.13.3 13.3 The specific-objectivity procedure on an instrument with planted defects

The full sequence on the twelve-item instrument with planted defects, ending in the FVP-7 verdict and the application to `D/P`.

13.3.1 Calibration and fit

The instrument, the fit table, and the deflation correction are §10.16. Summary of what the fit screen alone concluded:

```
UNDERFIT flagged:   item 8    OUTFIT 1.411  ZSTD +8.23   pt-measure +0.328
OVERFIT  flagged:   item 11   OUTFIT 0.404  ZSTD -7.45
CLEAN by fit:       all ten others, INCLUDING item 4 (OUTFIT 0.936, INFIT 1.000)
```

Two of three planted defects detected. **The third — the guessing item — passed cleanly.**

13.3.2 The invariance test on the same data

Persons split at the median measure, 1479 in each half, items recalibrated independently in each, with standard errors:

item	b_low	SE	b_high	SE	difference	t	flag
1	-2.056	0.061	-1.972	0.101	+0.084	+0.71	
2	-1.791	0.059	-1.630	0.089	+0.161	+1.51	
3	-1.478	0.057	-1.417	0.083	+0.061	+0.60	
4	-1.816	0.059	-1.395	0.083	+0.421	**+4.14**	**DIF**
5	-0.857	0.057	-0.532	0.066	+0.324	**+3.71**	**DIF**
6	-0.392	0.059	-0.261	0.063	+0.131	+1.51	
7	-0.013	0.063	+0.136	0.060	+0.149	+1.72	
8	-0.645	0.058	+0.705	0.057	+1.350	**+16.55**	**DIF**
9	+0.819	0.076	+0.830	0.057	+0.012	+0.12	
10	+1.129	0.084	+1.292	0.058	+0.163	+1.60	
11	+5.212	0.505	+2.384	0.068	-2.828	**-5.55**	**DIF**
12	+1.887	0.109	+1.860	0.062	-0.028	-0.22	

Flagged at `|t| > 2.58`: **items 4, 5, 8, 11.**
Read this against the planted defects:

```
item 4   guessing, c = 0.30       CAUGHT by invariance (t = +4.14), MISSED by fit
item 8   low discrimination       CAUGHT by both (t = +16.55, OUTFIT 1.411)
item 11  over-discriminating      CAUGHT by both (t = -5.55, OUTFIT 0.404)
item 5   clean                    FALSE FLAG -- centring contagion, FM-12.7
```

The invariance test caught all three planted defects. The fit statistics caught two. That is the empirical basis for SO-14 and for the insistence of Section 3 that FVP-7 is the deciding gate.

Item 5's false flag is instructive and is reported rather than tidied away. Three misfitting items distorted the centring, shifting every estimate, and the shift showed up as apparent DIF in a clean item. **The correct procedure is FM-12.7's fix: remove the worst item, recentre, re-run, and repeat one item at a time.** Removing all four flagged items simultaneously would have discarded a good item on the strength of a contamination artefact.

Item 11's `b_low = +5.212` with `SE = 0.505` is the over-discriminating item behaving exactly as theory predicts: for the low-ability half, a slope-3 item is nearly impossible, so its estimated difficulty runs away and its error explodes. **An item estimate with an error an order of magnitude larger than its neighbours is itself a diagnostic and should never be reported without comment.**

13.3.3 The verdict on the instrument

```
FIT SCREEN            items 8 and 11 fail
INVARIANCE TEST       items 4, 8, 11 fail; item 5 flagged as contagion
DIMENSIONALITY        not run in this demonstration (SO-15 would be required)

INSTRUMENT VERDICT    NOT MEASURING as constituted. Items 4, 8 and 11 must be
                      rewritten or removed, one at a time with recalibration between,
                      and the invariance test re-run on the revised instrument.
```

Three broken items out of twelve is an ordinary result for a first draft of an instrument, and finding them is what the procedure is for. The failure here is not a failure of the method; it is the method working.

13.3.4 Applying it to `D/P`

Suppose the revised instrument survives. Two Rasch banks — one for perspective, one for perception — **linked by a common item set so that the two scales share one origin (SO-16).** A respondent is measured on both.

```
theta_D = +1.45 logits    theta_P = +0.62 logits    (common scale)

Delta   = theta_D - theta_P  =  0.8300 logits
D/P     = exp(0.8300)        =  2.293319
verdict = OVER-FRAMED
```

The origin invariance was verified in §10.17: shifting the common origin by `-3.0`, `+2.5` or `+100.0` leaves `D/P = 2.293319` and `Delta = 0.830000` unchanged to six decimals, while the implied magnitudes range across forty-four orders of magnitude. **The reported quantity is a property of the person, not of the scale's arbitrary centre.**

Now the precision, which is where honesty is required. With person standard errors of `0.30` logits each:

```
SE(Delta) = sqrt(0.30^2 + 0.30^2) = 0.4243 logits
95% CI    = 0.8300 +/- 1.96 * 0.4243 = [-0.0016, 1.6616]
```

The interval includes zero, barely. A distortion of `0.83` logits — a frame-to-intake ratio of 2.29, which is substantial over-framing — **is not distinguishable from perfect calibration at this precision.** From §10.18's table, standard errors of `0.30` logits correspond to roughly 44 targeted items per term.

The correct report, per SO-17 and SO-20, is therefore:

```
Delta = 0.83 logits, 95% CI [-0.00, 1.66], SE 0.42
   [Rasch person measures, common-linked banks, 44 items per term,
    person reliability to be reported, unit = logits (nats)]
   Interval includes zero: over-framing is INDICATED, NOT ESTABLISHED.
   To establish a distortion of this size at 95%, the precision table (10.18)
   requires approximately 123 items per term.
```

That report is worth more than a confident "r = 2.29" would be, and it is worth more precisely because it declines to claim what it cannot support.

13.3.5 What the specific-objectivity demonstration establishes, and what it does not

Established:

1. Specific objectivity is a real, checkable property, and the Rasch model has it exactly (Theorems 10.1 and 10.2).
2. It is testable in data, and the split-sample invariance table is the test. Rasch data: mean difference 0.0000, sd 0.1360, correlation 0.9944. 2PL data: mean |difference| 7.9 times larger, with a systematic sign pattern.
3. Fit statistics are a screen, not a criterion. Three planted defects: fit caught two, invariance caught three.
4. Given Postulate SO1, Delta = |theta_D − theta_P| is RATIO-SCALED with a true zero at calibration, and D/P is determined up to the choice of unit (Theorem 10.3). This is a constructive route to the scale Section 7 demanded.
5. The precision required is large and computable: 31 items per term to detect a 1-logit distortion, 123 for half a logit, 342 for 0.3.

Not established:

1. That any real instrument for perspective or perception fits the Rasch model. Nobody has built one. FVP-7 for D and P: NOT YET RUN.
2. That perspective and perception are unidimensional. This must be tested, not assumed (SO-15), and it is the assumption most likely to fail.
3. That Postulate SO1's exponential identification is correct. It is a modelling choice, badged, and an alternative identification would change the scale type of D/P.
4. Anything at all about the surplus law or the storage law. Those are proved mathematics and stand independently of this section.

The distance between the established list and the unestablished one is the honest measure of the current scientific standing of Series B, and it is a distance measured in laboratory work rather than in argument. The falsification suite and the costed programme are specified in Curzi [2026u].

What this paper has shown is that the route exists. **Psychology and sociology are not pseudoscience; they are sciences with a measurement problem and a replication problem, and the problem is tractable.** Psychophysics built ratio scales for sensation and they replicate. Rasch built parameter separation for attainment and it can be tested in an afternoon on any data set. Neither achievement required abandoning the study of subjective experience. **Both required taking the measurement seriously enough to let it fail.**

That is the whole of the discipline this protocol asks for, and it is the reason this material is placed in the body of the corpus rather than in an appendix.

26.13.4 13.4 The demotion tally

The protocol's own output, collected, is the paper's principal result and is stated here as a count rather than left to be inferred from the gate reports above.

Object audited	Gate	Verdict
Moment equation `M = (D/P)E`	FVP-1 dimensions	**PASS**, conditional on one anchored common scale
	FVP-2 scale type	**DEMOTE**
	FVP-3 limiting cases	**PASS**, all four limits named
	FVP-4 fixed points	**PASS**, with the invariant stated as static, not attracting

Object audited	Gate	Verdict
	FVP-5 identifiability	**FAIL as written**; PASS only under remedies I5-a, I5-b and I5-c jointly
	FVP-6 falsification	**NOT YET RUN** on human data
	FVP-7 reproducibility	**NOT YET RUN** on human data
Personal formulary, 9 entries	FVP-2 scale type	**5 of 9 DEMOTED** — F-01, F-02, F-04, F-06 and F-08 [Curzi, 2026q]
Twelve-item Rasch instrument	fit screen	2 of 3 planted defects detected
	split-sample invariance	3 of 3 planted defects detected, 1 false flag from centring contagion

Three of the moment equation's seven gates are not passed, and five of the formulary's nine entries are demoted on the scale-type gate alone. The specific withdrawals are: the magnitude of `D/P`; the distortion $\Delta = |\ln r|$ as a number; and the quantitative join between the moment equation and the storage law, `Q_{t+1} = (1−delta)Q_t + eta M_t − C_t`, which is the architectural keystone of Series B and is available only on ratio scales. Those three quantities are relabelled **illustrative constructions**, not measurements, everywhere they appear in the corpus.

What is not withdrawn is listed with equal precision, because a demotion that leaves nothing standing would be a refutation rather than a demotion: the four limiting cases with their named phenomena, the `D = P` fixed point, the sign of `ln r`, and the three-regime ordering. Each of these is an order fact, invariant under every strictly increasing relabelling, and each is stated in the corpus with that qualification attached.

This is what a working validation protocol looks like from outside. A protocol whose pass rate were one would be evidence of capture (FM-6.8) rather than of quality [Goodhart, 1975, Campbell, 1979]; the rates above are the reason the passed gates are worth quoting at all.

26.14 14 Discussion

26.14.1 14.1 What follows

The protocol discriminates, and that is the paper's main empirical claim about the protocol itself. Run on the corpus's own central formula by the corpus's own author, it returns DEMOTE at gate 2, FAIL-as-written at gate 5, and NOT YET RUN at gates 6 and 7 — three of seven gates not passed. Run across the personal formulary, it demotes five of nine entries [Curzi, 2026q]. A protocol with a pass rate of one would be evidence of capture rather than of quality [Goodhart, 1975, Campbell, 1979]; these rates are the evidence that it is doing work.

The demotion is specific, and specificity is what makes it usable. What is withdrawn is named: the magnitude of `D/P`, the distortion as a number, and the quantitative join into the storage law. What survives is also named, and it is not nothing: four limiting cases each corresponding to a describable state, a fixed point at `D = P`, the sign of `ln r`, and the three-regime ordering over-framed / calibrated / under-framed. These are order facts, they are invariant under every strictly increasing relabelling, and they support rank statistics, medians, sign tests and monotone regression. A demoted formula is a heuristic ordering with demonstrated structure, and it is printed as one.

The restoration has a price and the price is arithmetic rather than philosophical. Given Postulate SO1, a Rasch calibration of `D` and `P` on one linked scale makes $\Delta = |\theta_D - \theta_P|$ ratio-scaled with a true zero at perfect calibration, because the arbitrary common origin cancels

from a difference of logarithms. The cost is item count, and the item count is large: 31 items per term for a one-logit distortion, 123 for half a logit, 342 for 0.3. **A practitioner reporting `r = 1.2` from a twelve-item pair of scales is reporting noise, and the arithmetic says so exactly** — a twelve-item pair resolves nothing finer than about 1.60 logits, a frame-to-intake ratio near 5.

Invariance beats fit as a diagnostic, and the margin is measurable. On the instrument with three planted defects the fit statistics caught two and the split-sample invariance test caught three, with the guessing item returning `OUTFIT = 0.936` and `INFIT = 1.000` — the best numbers on the instrument — while the invariance statistic flagged it at `t = +4.14`. This is the empirical basis for treating reproducibility as a separate gate rather than as a footnote to model fit.

26.14.2 14.2 What does not follow

Nothing here is evidence about human beings. Every empirical number in Section 13 comes from data whose generating process was chosen. The protocol's behaviour under a true model, under a missing-division counterfactual and under an additive counterfactual is demonstrated; the moment equation's status when applied to people remains NOT YET RUN at gates 6 and 7 and is reported that way.

Passing gate 2 would not make the corpus's reflexive claims identified. Scale construction and identification are different problems. A perfectly ratio-scaled `D` and `P` would license the division and would leave Manski [1993] exactly where it stands. The protocol validates formulas; it does not recover endogenous social effects from observational data, and no extension of it could.

A passed gate 7 of Outcome B is not a universal constant, and should not be reported as one. Outcome B — a parameter stable within a person across occasions and instruments but varying between persons — is the normal case for psychological quantities and is a pass. The demand for Outcome A is a demand physics itself would fail for most of its quantities. But Outcome B also means that pooled statements are statements about a population mean and not about its members, which is exactly the substitution H4 quantifies.

The corpus does not yet have a differential prediction. Durlauf [2005] asks for a prediction that simpler models do not also make, and Sobkowicz [2020] asks the same question in one line: what observation would distinguish these laws from a neighbouring model that fits equally well? The protocol's KILL-5 requirement — preregister the rival functional form — is a partial answer at the level of an individual formula, and it is not an answer at the level of the framework. Watts [2014] is the standing charge that formal social explanation is often commonsense reasoning in dress, and the protocol does not immunise against it.

The ceiling on social predictability is external and low. Salganik et al. [2020] report 160 teams, thousands of predictors and fifteen years of high-quality longitudinal data, with the best machine learning barely beating a four-variable regression; Hofman et al. [2017] set out the same ceiling generally; Lazer et al. [2014] document the failure of the flagship computational-social-science prediction system. A framework whose gates 6 and 7 have not been run should calibrate its expectations against those results before running them. Epstein [2008] is the legitimate reply — prediction is one of sixteen reasons to model — and the corpus is entitled to say which of the other fifteen it claims, but it must say.

26.14.3 14.3 Relation to the surrounding literature and to the corpus

The protocol is not novel in its parts and does not claim to be. Gate 2 is Stevens' typology [Stevens, 1946] with the meaningfulness criterion made operational, set against the representational theory that puts the whole subject on axiomatic footing [Krantz et al., 1971]. Gate 6 is preregistration and held-out prediction as the open-science literature specifies them [Nosek et al., 2018, Simmons et al., 2011, Gelman and Loken, 2013], sharpened by Meehl's observation that directional predictions are nearly costless in psychology [Meehl, 1967, 1990] — which is why the protocol requires *exponent targets*, not signs, and why KILL-1 and KILL-2 are stated

as intervals around 1 and –1. Gate 7 is specific objectivity [Rasch, 1960, Andrich, 1988], which is additive conjoint measurement with an error model [Luce and Tukey, 1964]. What is contributed is the *composition*: seven gates in a cost order, required of every formula, with the verdict printed.

Michell's objection is the strongest single objection to the corpus and it is conceded here rather than answered. Michell [1997] and Michell [1999] argue that psychology systematically assumes its attributes are quantitative without testing whether they are. The corpus's founding move — that comfort is a measurable quantity — is exactly the move Michell indicts. The protocol's response is not a rebuttal: it is to run the test Michell says is skipped, at gate 2, and to accept the verdict when it comes back DEMOTE. Section 7.14 gives the constructive route through double cancellation, and Section 10 gives its probabilistic form. **The conjoint conditions have not been tested for D and P by anyone, and until they are, the ratio-scale treatment of those terms is withdrawn, not provisional.**

Three further external constraints deserve naming. Harrison and Klein [2007] shows that three incompatible constructs travel under the name "diversity" — separation, variety, disparity — so the corpus's u must declare which one it is, and gate 1 is where that declaration belongs. Tversky [1977] shows psychological similarity is asymmetric and violates the triangle inequality, so if u is a similarity measure over people it cannot assume metric behaviour. Peters [2019] show that a parameter estimated across individuals does not describe what happens to any one of them over time, which is the time-average form of the pooling result H4 states in the cross-section.

Within the corpus, the protocol is the instrument three other papers use to reach their own verdicts. Curzi [2026q] applies it to the personal formulary and demotes F-01, F-02, F-04, F-06 and F-08 — five of nine — on scale type, withdrawing D/P magnitude and the quantitative moment-to-storage join while retaining the limiting cases, the D = P fixed point and the over/under-framed ordering. Curzi [2026u] runs gate 6 against itself and reports that a demand-characteristic confound with a true coefficient of zero passed the entire four-baseline suite 52.7 per cent of the time, for which there is no statistical remedy and only design controls — blinding, channel separation, prospective sampling, a yoked control. Curzi [2026n] supplies the one place in the corpus where a ratio-scale licence was actually earned by a ratio-invariance test, and it is worth stating that this paper's demotion of D and P does not touch that result.

The protocol's structure recurs elsewhere in the corpus in different domains, which is weak evidence that it is the right shape. Curzi [2026] weights a branch as 1/2^R from a resistance score summed over steps, so that a three-point difference in steepness is a factor of eight in expectation — an ordinal input converted to a magnitude by an explicit, badged rule, which is exactly the move gate 2 audits. Curzi [2026] prices an axiom rather than assuming it: F_alt(u) = u ln N satisfies three of the four surplus axioms and agrees at both endpoints, yet differs by 33.62 per cent at u = 0.5 (1.871802 against 1.242453), which is gate 5's identifiability question asked of an axiom set. Curzi [2026] carries the deficit identity D = 2.885390(c/eta − F) = −2.885390(delta/eta)Q_inf at a cross-checked residual of 8.88e-16, which is what a gate-1-and-gate-4 pass looks like when the terms are dimensionally clean. Curzi [2026] reports a directive corpus closed under negation with resultant exactly 0.000000000000 at N = 4, 8, 12, 24 — a null that is a *derived* zero rather than a failure to reject, which is the distinction gate 4 draws between an invariant and a vacuity.

Three papers outside Series B run structurally identical audits on non-psychological objects, and the parallel is instructive because in each the quantities *are* on defensible scales. Curzi [2026] shows a canonical form collapsing 495 of 495 manipulated entries onto the clean form, idempotent across all 500 cases, resolving 995 raw byte strings to the true 500 identifiers — an invariance result on a nominal scale, where identity is all that is claimed and all that is needed. Curzi [2026] measures in-band ambiguity at 0.383 per cent against 0.000 per cent out-of-band over 100,000 values, a counted proportion on a ratio scale with a genuine zero. Curzi [2026] reports effective counts from 35.0 curated validators (HHI 0.028571) down to 5.94 entities (HHI 0.168400), which are Hill numbers of order 2 on measured shares. **The**

contrast with `D/P` is the point: those instruments have their scales, and this one does not yet.

26.15 15 Verification

The results of this paper compound from eight postulates. Each is atomic, each is checkable on its own, and each carries its status. Where a postulate could be dropped and the result still follow, it has been dropped.

26.15.1 15.1 Dimensional audit

The audit below states each symbol's dimension, its unit, and whether the framework fixes it or is silent. `[s]` denotes the common subjective magnitude scale on which frame and intake would be instrumented, `[e]` the environmental scale, and `[1]` a pure number.

Symbol	Dimension	Unit	Status
`D`	`[s]`	one common anchored subjective scale	**not instrumented**; ratio scale *required*, not available
`P`	`[s]`	the same scale, the same anchor	**not instrumented**; identical status to `D`
`r = D/P`	`[1]`	pure number	**derived**, and only if `D` and `P` share one scale
`E`	`[e]`	externally instrumented environmental units	**measurable** today by an external index
`M`	`[e]`	inherits `E` exactly	**derived**
$\Delta = \lvert \ln r \rvert$	`[1]`	nats	**derived**; undefined unless `r > 0`
θ_n	`[1]`	logits (nats)	**estimated**, with a standard error; origin arbitrary
β_i	`[1]`	logits (nats)	**estimated**, with a standard error; origin arbitrary
`k`	`[1]`	count of items	**chosen** by the study design
`a` (Stevens exponent)	`[1]`	none	**estimated**; a constant of a procedure, not of nature
`G` (separation)	`[1]`	none	**derived** from the ratio of two standard deviations
τ	`[1]`	same unit as the parameter	**derived** variance component
`u`	`[1]`	none	**defined** dimensionless: `u = 1 - (x.y)^2`, `x`, `y` unit vectors
`F = ln(1+(N−1)u)`	`[1]`	nats	**derived** dimensionless

Symbol	Dimension	Unit	Status
`Q`	`[q]`	proxy units of stored order	**measured** in whatever the declared proxy counts
η	`[q]` per nat per period	proxy units per nat per period	**measured**; *not* dimensionless
δ	`[1]`	per period	**measured** dimensionless fraction per step

Does the moment equation balance? `M = (D/P)E` balances if and only if `D/P` is dimensionless, which requires `D` and `P` to carry the same dimension. If frame were measured in confidence points and intake in cues detected per minute, the quotient would be a rate carrying units and `M` would not inherit `E`; the formula would then be **false as written, not merely unmeasured**. That is the design requirement gate 1 imposes and it is the constraint most naive operationalisations violate. `\ensuremath{\Delta} = |ln r|` requires a dimensionless argument by rule R2 and is reported in nats.

Does the storage law balance? `Q_{t+1} = (1-delta)Q_t + eta S_t - C_t` balances only if η carries `[q]` per nat per period, since `S` is a dimensionless count in nats. η is therefore **not a pure number**, and any report of an η without a statement of what `[q]` counts is half a number [Curzi, 2026a].

Where the framework has no operational unit, it is said here. `D`, `P` and `M` have **no operational unit at all** in the corpus as it stands. The dimension `[s]` is a placeholder for a scale that has not been built, and the whole of Sections 7 and 10 is about what building it would require. A dimensionless placeholder is honest; an invented unit would not be. The logit is a real unit and is the unit of θ and β, but it is a unit of a *model parameter*, and its transfer to a magnitude by `D = exp(theta + b)` is Postulate SO1 and is badged.

26.15.2 15.2 The postulates

P1 — A scale is a set of values together with the group of transformations under which the scale's information is preserved, and a statement in scale values is meaningful if and only if its truth value is invariant under every member of that group. *Status:* **DEFINITION**, with the typology and the criterion as stated by Stevens [1946] and set on axiomatic footing by Krantz et al. [1971]. It carries no empirical weight; it fixes what the word "scale" means below.

P2 — For any `a > 0` and any `X`, `Y` with `Y != 0`, `(aX)/(aY) = X/Y`. *Status:* **ARITHMETIC.** Cancel `a`.

P3 — For `a > 0` and `b != 0`, `(aX+b)/(aY+b)` depends on `b`. *Status:* **ARITHMETIC.** With `X = 20`, `Y = 10`: identity gives `2.000000`; `g(x) = 1.8x + 32` gives `68/50 = 1.360000`.

P4 — `g(x) = x^k` is strictly increasing on the positive reals for every `k > 0`. *Status:* **ARITHMETIC.** Its derivative `k x^{k-1}` is positive for `x > 0`.

P5 — The Rasch model: `ln[P/(1-P)] = theta_n - beta_i`, with discrimination fixed at 1. *Status:* **DEFINITION** of the model, stated by Rasch [1960]. Whether any response set follows it is an empirical question the model does not settle.

P6 — The Fisher information of a single binary response at success probability `p` is `p(1-p)`, which is maximised at `p = 0.5` with value `0.25`. *Status:* **CITED**, elementary and standard [Rasch, 1960, Andrich, 1988].

P7 (Postulate SO1) — If `D` and `P` are calibrated as Rasch person measures on one common scale, the corresponding magnitudes are `D = exp(theta_D + b)` and `P = exp(theta_P + b)` for a common arbitrary origin `b`. *Status:* **POSTULATED.** This is a modelling choice with no external

support. It is used at exactly one place, R4 below, and an alternative identification would change the scale type of `D/P`.

P8 — `D` and `P` are not at present instrumented on a common ratio scale with a demonstrated true zero. *Status:* **POSTULATED**, as a factual claim about the state of the literature. It is falsified the day someone exhibits such an instrument with its `C1`–`C5` validation, and the whole of R1 falls with it.

26.15.3 15.3 The compounding chain

```
P1 + P2          -> L1   on a ratio scale the quotient X/Y is invariant under every
                         admissible g, so "X/Y = k" is meaningful.              ARITHMETIC

P1 + P3          -> L2   on an interval scale the quotient is not invariant:
                         20/10 = 2.000000 becomes 68/50 = 1.360000 under
                         g(x) = 1.8x + 32.                                      ARITHMETIC

P1 + P4          -> L3   on an ordinal scale with D > P > 0, g(D)/g(P) = (D/P)^k
                         for g(x) = x^k, and k ranges over (0, inf), so the
                         quotient takes any value in (1, inf).                  ARITHMETIC

L1 + L2 + L3     -> R2   THEOREM 7.1. X/Y is meaningful iff the admissible group is
                         the similarity group or a subgroup of it, i.e. iff the
                         scale is ratio or absolute.                            ARITHMETIC

R2 + P8          -> R1   the moment equation is DEMOTED on gate 2: the magnitude
                         of D/P, Delta as a number, and the quantitative
                         moment-to-storage join are withdrawn.                  ARITHMETIC + POSTULATED (P8)

R1               -> R3   what survives is order-invariant structure: the four
                         limiting cases, the D = P fixed point, the sign of ln r,
                         and the over/calibrated/under-framed ordering.         ARITHMETIC

P5               -> L4   logit(P_ni) - logit(P_nj) = beta_j - beta_i, with
                         theta_n cancelling identically for every person.       ARITHMETIC

P5               -> L5   logit(P_1i) - logit(P_2i) = theta_1 - theta_2, with
                         beta_i cancelling identically for every item.          ARITHMETIC

P5 + P7          -> L6   D/P = exp(theta_D + b)/exp(theta_P + b)
                             = exp(theta_D - theta_P), independent of b.        ARITHMETIC

L6               -> R4   THEOREM 10.3. Delta = |theta_D - theta_P| has a true zero
                         at theta_D = theta_P that holds in every unit and under
                         every origin, so Delta is ratio-scaled and D/P is
                         determined up to the choice of unit.                   ARITHMETIC (given P7)

P5 + P6          -> L7   best-case SE(theta) = 1/sqrt(0.25 k) = 2/sqrt(k), and
                         SE(Delta) = sqrt(2) SE(theta) = 2 sqrt(2/k).           ARITHMETIC

L7               -> R5   the smallest 95%-detectable distortion is
                         1.96 SE(Delta) = 5.5437/sqrt(k), so the items required
                         per term to detect Delta are k = (5.5437/Delta)^2.     ARITHMETIC
```

Every line is checkable from its own inputs. **R2, R3, R4 and R5 are arithmetic consequences of one definition (P1), one model definition (P5), three arithmetic facts (P2, P3, P4) and one**

cited standard result (P6). Only R1 and R4 consume a postulate with no external support: R1 consumes P8, a claim about the current state of instrumentation, and R4 consumes P7, the exponential identification.

What this chain does not establish. It does not establish that any real instrument for perspective or perception fits the Rasch model; nobody has built one. It does not establish that those attributes are unidimensional, which is the assumption most likely to fail. And it does not establish anything at all about the corpus's reflexive claims, which are not identified from observational data by any procedure in this paper [Manski, 1993]. **A chain whose central result is a demotion delivers a withdrawal with certainty and delivers no measurement whatever.**

26.15.4 15.4 The verification instance, worked

The single most useful check a reviewer can perform is the price of the restoration, because it is four lines of arithmetic and it governs every applied claim the framework could make about distortion.

From L7 with the best case `P = 0.5` at every item, so information `0.25` per item:

```
SE(theta)  = 1/sqrt(k x 0.25) = 2/sqrt(k)
SE(Delta)  = sqrt(2) x SE(theta) = 2 sqrt(2) / sqrt(k) = 2.828427/sqrt(k)
d_95       = 1.96 x SE(Delta) = 5.543717/sqrt(k)
k          = (5.543717/d_95)^2
```

At `k = 12` items per term:

```
SE(theta) = 2/sqrt(12) = 2/3.464102 = 0.577350
SE(Delta) = 1.414214 x 0.577350 = 0.816497
d_95      = 1.96 x 0.816497 = 1.600334
```

which is the `1.6003` entry of the precision table in Section 10.18. Inverting for the four design targets:

```
d = 1.00 :  k = (5.543717/1.00)^2 =   30.733  ->   31 items per term
d = 0.50 :  k = (5.543717/0.50)^2 =  122.931  ->  123
d = 0.30 :  k = (5.543717/0.30)^2 =  341.476  ->  342
d = 0.20 :  k = (5.543717/0.20)^2 =  768.320  ->  769
d = 0.10 :  k = (5.543717/0.10)^2 = 3073.280  -> 3074
```

Every entry of the design table is reproduced, and the whole of the corpus's pricing of its own restoration is one square root and one squaring. **The number that matters — 123 items per term to establish a half-logit distortion — can be checked in under a minute.**

26.15.5 15.5 Three secondary checks

The interval-scale shift. A questionnaire scored `1`–`7` and one scored `0`–`6` differ by `g(x) = x − 1`, which is admissible on an interval scale. A frame-and-intake pair reading `6` and `3` gives `D/P = 2.0` on the first instrument and `5/2 = 2.5` on the second, a shift of `(2.5 − 2.0)/2.0 = 0.25`, or **25 per cent, from the printer's choice alone. ARITHMETIC.**

The constructive ordinal result. With `D = 7` and `P = 4` and `g(x) = x^k`, the achieved ratio is `(7/4)^k`. To achieve `2.00` requires `k = ln 2 / ln 1.75 = 0.693147/0.559616 = 1.238607`, which is the `1.2386` entry of the demonstration table; to achieve `100.00` requires `k = ln 100 / ln 1.75 = 4.605170/0.559616 = 8.229154`, the `8.2292` entry. **Any target ratio is one exponent away. ARITHMETIC.**

The origin cancellation. With `theta_D = 1.45` and `theta_P = 0.62`, `D/P = exp(1.45 − 0.62) = exp(0.83) = 2.293319` and `\ensuremath{\Delta} = 0.830000` for every choice of the common origin `b`. At `b = +100` the implied magnitudes are `1.1460e+44` and `4.9970e+43`, forty-four orders of magnitude from their values at `b = 0`, and the ratio does not move in the sixth decimal. **ARITHMETIC.**

26.15.6 15.6 Limits, asymptotics, and the domain of validity

`P -> 0` in the moment equation. `M -> infinity` and `\ensuremath{\Delta} -> infinity`. The divergence names a real state — a frame receiving no correcting intake, which is the structure of dogma, of the closed ideology and of the psychotic elaboration — so the divergence passes rule FVP-3a. The formula's stated domain is `D >= 0`, `P > 0`, `E >= 0`; at `P = 0` the expression is undefined and the model returns the statement "unbounded" rather than a number.

`D -> 0` and `E -> 0`. Both give `M -> 0`, naming intake without frame and the absence of a situation respectively. Both are describable states, so rule FVP-3b passes.

`r -> 1`. $\Delta \to 0$ continuously, and `M -> E`. This is the invariant, and it is **static**: nothing in `M = (D/P)E` drives `r` toward 1. Presenting a static invariant as an attractor is a common and real misreading and is forestalled explicitly at gate 4.

`k -> infinity` in the precision law. `SE(Delta) -> 0` as `k^{−1/2}`, so any distortion becomes detectable eventually and the cost grows as the inverse square of the resolution wanted. **`k -> 0` is not a limit of the model but a failure of the design**: below about five items per term the best-case detectable distortion exceeds 2.5 logits, a frame-to-intake ratio above 12, and the instrument reports nothing an unaided observer could not.

`a -> 0` in the psychophysical power law. The recovered exponent goes to zero when the response format is bounded and the bound binds; the `1–7` row of Section 7.11's table recovers `0.0114` from a process whose true exponent is `0.67`. This is not a limit of the attribute but of the instrument, and it is the reason requirement S-6 prohibits bounded formats for ratio claims.

The transformation groups at their boundaries. The nominal group is the full symmetric group on the value set; the ordinal group is the infinite-dimensional group of strictly increasing maps; the interval group is the two-parameter affine group; the ratio group is the one-parameter similarity group; the absolute group is trivial. **Each is a subgroup of the one above, so moving down the list is buying information by giving up freedom, and the amount bought is exactly the codimension.**

26.15.7 15.7 Invariance, and how far each claim has been tested

Three invariance claims are made and they are of different kinds.

Ratio invariance under similarity is exact and algebraic: `(aX)/(aY) = X/Y` for every `a > 0`, tested at every value trivially because it is an identity. Nothing could break it short of denying P1.

Origin invariance of the Rasch distortion is exact and algebraic, tested numerically at four origins spanning `b = −3.0` to `b = +100.0` and agreeing to six decimals. It would break if the two banks were *not* linked to a common origin, which is failure mode FM-12.5 and is the single most likely point of failure in an applied study.

Parameter invariance across populations is the empirical one, and it is the only invariance claim here that could fail on data. It was tested at **exactly two** splits: a median split on the attribute, with the two halves separated by 1.82 logits, and — in the counterexample — a split of data generated from a two-parameter model. Two splits is not many. The Rasch-generated instrument returned a mean calibration difference of `0.0000` with `sd = 0.1360` and a correlation of `0.994399`; the 2PL-generated data returned a mean absolute difference `7.9` times larger with a perfect sign pattern by discrimination. **The claim that specific objectivity is testable in data is supported at two splits on simulated data and at zero splits on human data.**

26.15.8 15.8 Analogy discipline and the precision of the numbers

Every borrowing in this paper is a **shared mathematical form** and is labelled as one in Section 3.10. The entropy of a nominal partition is Shannon entropy in nats or bits [Shannon, 1948] and no thermodynamic claim attaches to it. The logit is a log-odds. The "information" of a binary response is Fisher information, a variance-inverse, and is not Shannon information despite the shared word; the two are distinguished wherever both appear.

On significant figures: the transformation-group results, the elementary symmetric functions, the separability differences (`+1.4000` in every row) and the precision table are **exact by construction** and are quoted to whatever precision is useful. The regression coefficients, the Stevens exponent `a_hat = 0.6987`, the variance component `tau = 0.2534` and the calibration errors are **estimates from simulated data** and are quoted with standard errors or intervals throughout. The replication figures `97`, `36` and `36/97 = 0.3711` are **counts and a ratio of counts** from a published study [Open Science Collaboration, 2015] and carry that study's own sampling uncertainty, which is not restated here.

26.16 16 Limitations

The demotion rests on a claim about the world's instrumentation, and that claim is a postulate. P8 — that no ratio-scaled instrument for frame and intake exists — is a survey of the literature, not a theorem. It is falsified by anyone exhibiting such an instrument together with its `C1`–`C5` validation, and R1 falls with it. It is stated as a postulate rather than as a fact for exactly that reason.

Every empirical number here comes from simulated data. Gates 6 and 7 report NOT YET RUN for the moment equation as applied to human beings, and every held-out `R^2`, every recovered exponent, every variance component and every fit statistic in Section 13 was computed on data whose generating process was chosen by the author. The demonstration establishes the protocol's behaviour; it establishes nothing about people. **A reader who takes `R^2 = 0.8091` as evidence for the moment equation has misread the paper.**

Michell's objection is conceded, not answered. Michell [1997] holds that psychology assumes quantitative structure without testing for it. The corpus's founding move is that assumption. The conjoint conditions [Luce and Tukey, 1964] have **not** been tested for `D` or `P`, the double-cancellation counts reported in Section 7.14 are on constructed tables rather than on response data, and no Rasch instrument for either attribute exists. Comfort itself is treated as a quantity **by stipulation**, and that stipulation is untested.

Postulate SO1 is the load-bearing unsupported step in the restoration. The move from a Rasch logit measure to a magnitude `D = exp(theta + b)` is a modelling choice with no external warrant. An alternative identification would change the scale type of `D/P`, and Theorem 10.3 would then say something different or nothing. It is badged at every use and it is the first thing a critic should attack.

The model-comparison standard of the corpus is not fully met, and where it is not met it is recorded here as NOT MET rather than omitted. Of the five requirements — out-of-sample performance, a matched null with the same number of free parameters, an information criterion, an explicit free-parameter count, and effect sizes with intervals — this paper meets four on the simulated demonstration and fails one:

Requirement	Status in this paper
Out-of-sample performance reported	**MET.** Held-out `R^2` on occasions 141–200, parameters frozen after training on 1–140.

Requirement	Status in this paper
Matched null with the same number of free parameters	**MET.** The shuffled-input control has the identical model and parameter count with the pairing destroyed; the additive rival of KILL-5 has four free parameters against the log-linear model's four.
Information criterion (AIC or BIC) reported	**NOT MET.** No AIC or BIC is computed here, and — so far as the author can establish — **no information criterion is computed anywhere in the corpus.** The parameter count is therefore paid for by the matched-null design rather than by a penalty term, which is a weaker instrument.
Number of free parameters stated explicitly	**MET.** Four in the log-linear model (`b0`, `bD`, `bP`, `bE`); four in the additive rival; four in the shuffled control; one in persistence; two in the matched AR(1).
Effect sizes with intervals, not only p-values	**MET.** Every coefficient is reported with a standard error and a 95 per cent interval; no p-value is reported without one.

The reflection problem is unanswered and the protocol does not address it. The reflexive loop's endogenous effect is not identified from observational data [Manski, 1993, Shalizi and Thomas, 2011], no remedy is adopted here, and every claim in the corpus resting on the loop is therefore **a modelling position rather than an identified empirical result**. The protocol validates the algebra of a formula; identification is a property of a research design and no amount of gate-passing supplies it.

The Lucas critique applies to the corpus's own parameters and is not answered either. Lucas [1976] and Hacking [1995] imply that `delta`, `eta` and `u` are the decision rules of people who have not read the framework. Gate 7 tests stability across persons and instruments and does not test stability across publication. The corpus asserts reflexivity for its subject matter and cannot consistently exempt its own parameters from it; this paper records the inconsistency rather than resolving it.

The surplus functional's form remains underdetermined. Latané [1981] and Briscoe et al. [2006] fit the qualitative facts as well as `ln(1+(N−1)u)` does, and nothing in this protocol discriminates among them. KILL-5 requires a rival *functional form* to be preregistered, which is the right instrument, and it has not been run against Latané's power law. **Nothing yet discriminates the corpus's form from its two nearest rivals, and that is stated rather than finessed.**

The self-fulfilling-prophecy literature the framework leans on is smaller than the framework implies. Jussim and Harber [2005] finds classroom self-fulfilling prophecies real but small, typically non-accumulating, and often dissipating, with most teacher expectations turning out to be accurate rather than causal — which should be read beside Rosenthal and Jacobson [1968] and Merton [1948] rather than after them.

Two source citations could not be given keys. The two-parameter logistic model is attributed in the source manuscript to Birnbaum and to Lord & Novick's *Statistical Theories of Mental Test Scores* (1968). Neither work is present in the corpus's verified external bibliography, and no key was invented for them; they are therefore named in the text of Section 10.13 without a citation key, and the claims made about the 2PL there are supported instead by the algebra printed beside them, which is self-contained.

Three specific numerical caveats. First, the false flag on item 5 at `t = +3.71` in Section 13.3 is a centring artefact and is reported rather than tidied away; it means the invariance test's false-positive behaviour under multiple defects has not been characterised, only observed once. Second, the clean items in the fit table average `OUTFIT = 0.888` against a nominal expec-

tation of 1.000, a deflation caused by estimating both theta and beta from the same responses; anyone comparing observed mean squares to the nominal value without accounting for this will systematically over-diagnose overfit. Third, the precision table is a **best case** — it assumes every item is perfectly targeted at the person, information 0.25 per item — so every item count in it is a lower bound and a real instrument will need more.

A discrepancy in the source is recorded here rather than silently corrected. The source manuscript states, of the twelve-item calibration, that the instrument "distinguishes roughly two and a third levels of the attribute" from a strata count of 2.34, and separately that person reliability 0.6931 "cannot support individual decisions", citing a threshold of 0.90 at requirement SO-6. Those two statements are consistent, but the source does not say what licenses the 0.90 threshold, and no external citation for it could be found in the corpus's bibliography. **It is a practice convention rather than a derived bound, and it is labelled as one here.** Separately, the source expresses the *twenty*-item resolution limit as a frame-to-intake ratio of about 3.5, from exp(1.2396) = 3.45, and elsewhere quotes the *twelve*-item limit of 1.6003 logits, which is exp(1.6003) = 4.95. Both numbers are correct for their own item counts, and the prose moves between them without saying which item count each belongs to; the two are separated explicitly in Section 14.1 above.

26.17 17 Conclusion

This paper specifies a seven-gate Formula Validation Protocol — dimensions, scale type, limiting cases, fixed points, identifiability, falsification, reproducibility — ordered by cost, required of every formula in the framework, with each gate's verdict printed beside the formula and any gate not executed reported as **NOT YET RUN** rather than left blank. **Run on the corpus's own central formula M = (D/P)E, the protocol does not pass it.**

The demotion, stated for citation. The moment equation is demoted on gate 2: D and P are not instrumented on a common ratio scale with a shared true zero, so **the magnitude of D/P, the distortion $\Delta = |\ln r|$ as a number, and the quantitative join between the moment equation and the storage law are withdrawn as measured quantities** and relabelled illustrative constructions. Gate 5 returns FAIL as written — two invariance groups, (D,P,E) -> (cD,cP,E) and (D,P,E) -> (kD,P,E/k), so that a large distortion in a thin environment is observationally identical to undistorted contact in a rich one — and passes only under all three remedies together, of which independent measurement of E is essential. Gates 6 and 7 return NOT YET RUN on human data. **Three of seven gates are not passed, and the same protocol applied to the corpus's personal formulary demotes five of its nine entries — F-01, F-02, F-04, F-06 and F-08 — on the same gate** [Curzi, 2026q]. A protocol nothing fails is measuring nothing; these are the rates that make the passed gates worth quoting.

The theorem that forces it. *Theorem 7.1: a quotient X/Y of quantities measured on a common scale is meaningful if and only if the scale's admissible transformation group is the similarity group {x -> ax : a > 0} or a subgroup of it — that is, if and only if the scale is ratio or absolute.* Four demonstrations execute it: an admissible affine relabel from a 1–7 form to a 0–6 form moves a reported D/P from 2.0 to 2.5, a shift of **25 per cent** from the printer's choice alone; g(x) = 2^x **reverses** which of two occasions was the more over-framed; g(x) = x^k delivers **any** target ratio, 2.00 at k = 1.2386 and 100.00 at k = 8.2292; and g(x) = x − 2.5, strictly increasing and therefore admissible, sends a ratio to −0.333 and makes $\Delta = |\ln r|$ **undefined over the reals**.

What survives the demotion is structure, not magnitude. The four limiting cases and their named phenomena (P -> 0 unbounded, dogma and apophenia; D -> 0 zero, sensation without experience; E -> 0 zero, no situation; D = P giving M = E, undistorted contact), the D = P fixed point, the sign of ln r, and the three-regime ordering over-framed / calibrated / under-framed. **Every one of these requires only ordinal information and is invariant under every strictly increasing relabelling.** They support rank statistics, medians, percentiles, sign tests and monotone regression, and they support nothing that multiplies.

The restoration is constructive and it is priced. *Theorem 10.3, given badged Postulate SO1: if* `D` *and* `P` *are measured as Rasch person-measures on one common linked scale, then* $\Delta = |\ln(D/P)| = |\theta_D - \theta_P|$ *is ratio-scaled with a true zero at perfect calibration, and* `D/P` *is determined up to the choice of unit.* The arbitrary origin cancels: at `theta_D = 1.45` and `theta_P = 0.62`, shifting the common origin by `-3.0`, `+2.5` or `+100.0` moves the implied magnitudes across forty-four orders of magnitude and leaves `D/P = 2.293319` and $\Delta = 0.830000$ unchanged to six decimals. The price, from the best-case relation `k = (5.5437/d)^2`, is **approximately 31 items per term to detect a one-logit distortion, 123 for half a logit, 342 for 0.3, 769 for 0.2 and 3,074 for 0.1** — while a twelve-item pair of scales resolves nothing finer than **1.6003 logits**. A reported `r = 1.2` from a twelve-item pair is noise, and the arithmetic says so exactly.

Gate 7 exposes a pooled fiction, and invariance beats fit. Twelve heterogeneous simulated subjects returned a true between-person spread $\tau = 0.2534$ against a pooled standard error of `0.0257`, **a ratio of 9.9**: the pooled interval is about ten times narrower than the actual spread of the individuals it describes, and it contains the target, so a pooled analysis would have reported the division confirmed. It is not a wrong interval; it is a correct interval about the wrong quantity. On an instrument with three planted defects, **split-sample invariance caught three and fit statistics caught two**, the guessing item returning `OUTFIT = 0.936` and `INFIT = 1.000` — the best numbers on the instrument — while the invariance statistic flagged it at `t = +4.14`. On Rasch-generated data two populations separated by 1.82 logits produced item calibrations correlating at `0.994399` with a mean difference of `0.0000`; on 2PL-generated data the mean absolute difference was `7.9` times larger, with every high-discrimination item drifting negative and every low-discrimination item positive, without exception in twelve.

And the falsification gate needs a rival form, not a null. Data generated additively and fitted with the multiplicative log-linear model still returned a held-out `R^2` of **0.6758** — enough to beat persistence, direct-input and a matched AR(1) handsomely and be reported as confirmation — while the correct additive model scored **0.9694**. Only the preregistered rival functional form exposed it. On data generated from the true model the frozen parameters scored `R^2 = 0.8091` held out against a shuffled-input control at `0.0059`; on the missing-division counterfactual the coefficient on the denominator returned a 95 per cent interval of `[-0.2009, 0.0590]` against a target of `-1`, and the kill condition fired on the specific term that was wrong.

None of this is a claim about human beings. The empirical portions are simulated throughout. What the paper establishes is that the corpus's own instrument for auditing its own formulas fires when pointed at the corpus, that the cost of the resulting repair is a finite programme of laboratory work rather than a philosophical impasse, and that the honest current status of the framework's central formula is a heuristic ordering with demonstrated structure — printed as one, in the same paragraph, every time.

26.17.1 Declarations

Data and code availability

No external dataset was collected for this paper, and no human subjects were studied. Every empirical number reported in Section 13 and in Sections 7.10, 7.11, 10.10, 10.11, 10.12, 10.14 and 10.16 is computed from **simulated** data whose generating process is stated beside it — the log-normal moment series with declared autocorrelations, the magnitude-estimation panel with declared free moduli and noise, and the Rasch and 2PL response matrices with declared item parameters and planted defects. The replication counts in Section 3.2 are quoted from Open Science Collaboration [2015] and are that study's, not this paper's. The figures are generated by the scripts named in each caption; those scripts contain no data beyond the numbers printed in this paper and the model equations of Sections 4, 7 and 10.

Funding

This research received no external funding.

Conflicts of interest

The author declares no conflicts of interest. The protocol specified here was applied by its own author to his own formulas, which is a structural conflict that no declaration removes; it is the reason failure mode FM-6.8 (Goodhart capture of the protocol) and requirement V-22 are in the specification, and the reason the pass rate is reported as a headline number.

Author contributions

Single author. Michael Laurence Curzi specified the protocol, derived the results, produced the simulated demonstrations and the figures, and wrote the paper.

Ethics

No human-subjects research was conducted and no personal data was processed. All response data analysed here are simulated. The laboratory programme described in Sections 13.2 and 13.3 is a design for prospective work and is not a report of any study performed; were it run, it would require ethical review, and nothing in this paper substitutes for that.

Preregistration

This paper reports no preregistered test on human data. The kill criteria KILL-1 to KILL-5 were fixed before the simulated series were generated and are printed in Section 4.6 in the form in which they were fixed; on the true-model demonstration none fired, on the missing-division counterfactual KILL-1 fired, and on the additive counterfactual KILL-1, KILL-2 and KILL-5 all fired. **Those are results about the protocol, obtained on data whose truth was known in advance, and they are not a preregistered empirical test of the moment equation.** The preregistered protocol for testing the storage law against a real system, together with the confirmatory application that **failed** its second falsification rule — a 2.8 per cent held-out RMSE advantage over a matched AR(1) against a declared margin of 10 per cent — is reported in Curzi [2026i]. The falsification suite's own audit, including a demand-characteristic confound with a true coefficient of zero that passed the whole four-baseline suite 52.7 per cent of the time, is reported in Curzi [2026u]. Any applied claim resting on this paper inherits both results.

Chapter 27

The Falsification Suite Measured Against Itself: An Anti-Conservative Shuffle, a 52.7 Per Cent Demand-Characteristic Pass Rate, and a Programme With a 35.8 Per Cent Survival Probability

Abstract. We specify a preregistered falsification suite for the storage law fitted as Y_t+1 = aY_t + bF(U_t) - C_t + eps_t under the constraints 0 <= a <= 1 and b >= 0, with four baselines, a declared freeze, and held-out reporting. The suite is then tested by simulation rather than asserted. Against a nominal 0.05, iid permutation false-rejected at 0.108 and circular shift at 0.120, with only block permutation near nominal at 0.060; the matched autoregressive comparison alone false-passed 35.8 per cent of the time; and a demand-characteristic confound in which subjects infer the hypothesis passed the whole suite 52.7 per cent of the time, for which there is no statistical remedy, only a design remedy. A Goodhart simulation raised the estimated conversion efficiency 14 per cent, from 0.3105 to 0.3551, while the true stock fell. Even with perfect measurement the worked fit recovered a = 0.8833 against 0.85 and b = 0.3340 against 0.40, a 16.5 per cent underestimate. A five-stage research programme is then costed with kill conditions at each gate; the compounded survival probability to a completed final stage is 0.3580, implying 14.93 full-time-equivalent years per completed programme. A final section treats inherited correspondence tables as graphs and audits their category counts, showing that three duplicate rows in seven overstate the surplus ceiling by 40.37 per cent.

Keywords: preregistration; surrogate calibration; shuffled-input control; demand characteristics; Goodhart drift; kill register; ceiling inflation

Series: B. Engineering the Surplus **Paper:** CCP-027

27.1 1 Introduction

A falsification suite that has never been tested is a claim, not a control. This paper specifies the preregistered suite by which the Creature Comforts storage law is made to face a single-person time series on terms declared in advance, and then **runs the suite against itself by simulation**. The headline result is negative and is about the suite rather than about the law.

Against a nominal 0.05, the shuffled-input control false-rejected true nulls at 0.108 for independent permutation and 0.120 for circular shift, with only block permutation near nominal at 0.060. The control on which the framework's empirical audit most depends is therefore **anti-conservative**: run as it is ordinarily run, it rejects a true null between one and two and a half times too often. That number is stated here, in Results, and in the Conclusion, in the same words, because other papers in this corpus cite it to discount their own reported significance [Curzi, 2026i], and a control whose error rate is unpublished cannot be discounted at all.

Three further measurements make the same point from other directions. The matched autoregressive comparison, run alone on data generated with no dependence on the input whatsoever, **false-passed 35.8 per cent of the time.** A demand-characteristic confound – true coefficient exactly zero, with the reported output inflated by a multiple of the input the subject could recall – **passed the entire four-baseline suite 52.7 per cent of the time**, and it does so precisely because the fabrication is temporal and the shuffle is a temporal test. And a Goodhart simulation in which the proxy acquired a consequence at period 30 raised the estimated conversion efficiency by 14 per cent, from 0.3105 to 0.3551, **while the true stock fell from 3.0359 to 2.8447.** In each case the procedure endorsed something that was not there, and in each case the rate was measured rather than assumed.

Nothing here says the suite should not be run. The comparison that matters is between 0.108 and 0.358: a control that is wrong by a factor of two is far better than a single baseline comparison that is wrong by a factor of seven, and both are better than the alternative practice of reporting a parametric p-value that assumes its own null. What the measurements establish is narrower and more useful: **a nominal permutation p-value is not the calibrated one, the calibration is a simulation that takes minutes on the study's own design, and any paper reporting the former as though it were the latter has misstated its evidence.**

The paper has four further contributions. **First**, a full preregistration specification – the required fields, the freeze list, the four baselines and the distinct rival explanation each one names, and the boundary-reporting rule that turns a constrained fit's wall-hit into reportable evidence. **Second**, a quantitative account of instrument noise: rating error on a lagged regressor attenuates the retention coefficient and therefore *inflates* the decay parameter, so that at a rating standard deviation of 0.40 against a signal standard deviation near 0.20 the estimated decay was 0.4317 against a true 0.1500 and the estimated conversion 0.9425 against a true 0.4000. **A sloppy instrument does not produce a noisy answer; it produces a confidently wrong one, and it errs in a known direction. Third**, a five-stage research programme with twenty-one published kill conditions, costed in researcher-hours and calendar months, whose compounded probability of reaching a completed final stage under declared priors is **0.3580** – implying 5.35 full-time-equivalent years per attempt and **14.93 FTE-years per completed programme. Fourth**, an audit instrument for inherited category schemes, which finds that three duplicate rows in a seven-row taxonomy overstate the declared surplus ceiling by **0.559616 nats, 40.37 per cent**, with every downstream quantity inheriting the error at full size.

The last of these carries a second, deflationary measurement. Correspondence systems of the kind that have historically supplied category schemes are treated here as ordinary finite relations: a ten-vertex, twenty-two-edge graph; a seventy-eight-element set with a product decomposition; a map from strings to integers. That last is a hash function, and measuring it as one settles a question the literature reading those systems does not usually ask. On a 234,454-word list the simple letter-sum map has **305 distinct values, 99.995 per cent of words colliding, and 10.468 of the 17.839 bits that identify a word destroyed.** A shared value is the default behaviour of a many-to-one map and carries no evidence about the words.

Sections 3 to 7 give the framework, the suite, its specification, its named failure modes,

and the worked example in which the same unchanged suite produces a confirmation on one series and a refutation on another. Sections 8 to 11 give the staged programme and its price. Sections 12 to 15 give the correspondence-table audit. Sections 16 to 20 report, discuss, verify, limit and conclude.

27.2 2 Hypotheses

This paper is partly a specification and partly a simulation study of that specification. **The specification sections advance no hypothesis and are labelled as specification where they appear.** The hypotheses below are the ones the simulations put at risk. Each carries what would defeat it, and each result is reported in the same plain language whether it passed or failed.

H1 — The shuffled-input control is exact at its nominal level. A permutation test built from the data's own values rejects a true null at the rate it advertises. **Predicted:** across 500 null trials at nominal `alpha = 0.05`, a measured rejection rate near 0.05 for each surrogate family. **Falsified by:** a measured rate materially away from 0.05 in either direction. *(Result: **FALSIFIED** for two of the three families — 0.108 for independent permutation and 0.120 for circular shift; **not falsified** for block permutation at 0.060. See §4.7 and Section 16.)*

H2 — The four-baseline suite is sufficient against a fabricated temporal relationship. A series in which the true input coefficient is zero, but whose reported output has been nudged by what the rater recalls of the input, fails at least one of the four baselines in the large majority of trials. **Predicted:** a suite pass rate well below one half over 300 trials. **Falsified by:** a pass rate at or above one half. *(Result: **FALSIFIED** — 52.7 per cent. The fabrication is temporal, so a temporal test endorses it. See §4.8.)*

H3 — A measure that acquires a consequence leaves a signature in the fitted parameters. When a proxy becomes a target, the estimated conversion efficiency moves even though the constraints continue to hold. **Predicted:** a rise in `eta_hat` across the break, concurrent with a fall in the true stock. **Falsified by:** no change in the fitted parameters across a break at which the proxy acquired a consequence. *(Result: **not falsified** — `eta_hat` rose from 0.3105 to 0.3551 while true `Q` fell from 3.0359 to 2.8447. See §4.12.)*

H4 — Instrument noise biases the two parameters in known and opposite-seeming directions. Error in a lagged regressor attenuates its coefficient, so `delta = 1 − a` is inflated, and the input term compensates, so `eta` is inflated too. **Predicted:** both `delta_hat` and `b_hat` increase monotonically with rating error. **Falsified by:** a non-monotone response, or either parameter moving the other way. *(Result: **not falsified** — `delta_hat` runs 0.1514, 0.1581, 0.1781, 0.2429, 0.4317 and `b_hat` runs 0.4022, 0.4156, 0.4538, 0.5783, 0.9425 across rating standard deviations 0.00 to 0.40. See §4.9.)*

H5 — A single forty-period window recovers the conversion parameter to within its sampling error. With perfect measurement and no rating noise, one window on one subject returns `eta` close to its true value. **Predicted:** `|b_hat − b_true|` of order one standard error or less. **Falsified by:** a deviation of two standard errors or more. *(Result: **FALSIFIED** in the worked draw — `b_hat = 0.3340` against a true 0.40, which is **−2.15 standard errors**, with `a_hat` simultaneously **+2.13**. See §7.3.)*

H6 — A taxonomy's declared cardinality can be audited against its decisions. Two rows are duplicates if no observable item has ever been assigned to one rather than the other and no decision differs between them. **Predicted:** applying the test

to an inherited seven-row scheme merges rows and lowers `ln N`. **Falsified by:** an inherited scheme in which the test can be applied but changes nothing, in a domain where practitioners nonetheless report the rows as indistinguishable. *(Result: **not falsified** on the worked case — seven rows collapse to six once a residual row is added, an 8.60 per cent ceiling overstatement; the textbook case of three duplicates in seven is 40.37 per cent. See §12.11 and Section 15. **This is a demonstration on a constructed case and not a survey of real taxonomies.**)*

Three things in this paper are not hypotheses and are labelled as what they are. The five-stage programme of Section 8 is a **plan with declared priors**, not a result; no stage of it has been run, and its survival arithmetic is arithmetic on those priors and inherits their status entirely. The reading rule of §12.1 – that a correspondence table *is* a finite relation, a graph, a partition, a hash – is a **translation**, not a theory: it cannot be wrong in the way a theory can be wrong, only inapplicable, which happens exactly when the historical artefact is too vague to have a definite extension. And the thesis that the old notation and the framework's notation describe the same relations is a **postulate**, badged as one wherever it appears, and is a claim about *structural correspondence* and never about mechanism or efficacy.

27.3 3 Framework: the estimation model, its postulates, and its identification problem

The framework's minimal estimation model, reproduced exactly from the group-scope protocol [Curzi, 2026i]:

```
MINIMAL ESTIMATION MODEL

    Y_{t+1} = a * Y_t  +  b * F(U_t)  -  Chat_t  +  eps_t

CONSTRAINTS

    0 <= a <= 1        (retention cannot exceed perfect retention,
                        and cannot be negative)
    b >= 0             (conversion efficiency cannot be negative)

IDENTIFICATION

    a = 1 - delta      ->   delta_hat = 1 - a_hat
    b = eta            ->   eta_hat   = b_hat

WHERE

    Y_t     an observed proxy for stored order Q_t
    U_t     the observed non-parallelism, in [0,1]
    F(U)    = ln(1 + (N-1)U),  the surplus law
    Chat_t  an independently measured cost series, NOT a free parameter
    eps_t   residual
```

The framework's falsification template, reproduced exactly [Curzi, 2026i]:

```
PROCEDURE

    1.  PREREGISTER  the operationalisations, the window, the split,
        the baselines, and the falsification rules.
    2.  FIT          on the training window only.
```

```
    3.  FREEZE       every choice. No refitting, no re-specification,
                     no re-selection of proxy, window, or period length.
    4.  REPORT       held-out prediction against four baselines:
                     (i)   persistence
                     (ii)  direct-input (raw U, no log)
                     (iii) matched autoregressive, no interaction term
                     (iv)  SHUFFLED-INPUT CONTROL

FALSIFIED IF

    RULE 1.  the shuffled-input control predicts held-out Y as well as
             the ordered series;
    RULE 2.  the matched autoregressive baseline is not beaten;
    RULE 3.  the fitted a lies outside [0,1] or the fitted b is negative.
```

Section 4 applies that template to **subjective** quantities: to `Y` read off a magnitude estimate rather than a headcount, to `U` computed over one person's own framings rather than over a committee, and to the Moment `M_t` standing in the input slot in place of `F(U_t)` by the normalisation declared by the framework (`M` mapped into `[0, ln N]` serves as `S_t`).

Nothing in the template changes when the quantities become subjective. Everything in the threat model does. That asymmetry organises Sections 4 to 7.

27.3.1 3.1 What is proven and what is postulated

Proven. The identification map is exact algebra. Given the storage law `Q_{t+1} = (1-delta)Q_t + eta*S_t - C_t` [Curzi, 2026a] and given `Y_t = Q_t`, matching coefficients gives `a = 1-delta` and `b = eta` with no residual freedom. The constraint set follows from the definitions: `delta` is a retention loss in `[0,1]`, so `a = 1-delta` is in `[0,1]`; `eta` is a conversion efficiency and is non-negative by construction. The bound `0 <= F(U) <= ln N` is the framework's logarithmic ceiling [Curzi, 2026c]. The exact solution, the one-step growth condition, and the steady state `Q_inf = (eta*F(u*) - c*)/delta` are theorems of the leaky-integrator analysis [Curzi, 2026a] and are used here only as consequences of the fitted parameters, never as evidence for them.

Postulated, badged. That `Y_t` stands in a stable, monotone, and ideally affine relation to `Q_t`. That `delta`, `eta`, `N`, and the operationalisation of `u` are approximately constant over the estimation window. That the relation is linear in `Y_t` and in `F(U_t)` at all. That the subject's rating scale is ratio-scaled in the sense of the formula-validation protocol's scale-type gate and stable in the sense of its specific-objectivity requirement [Curzi, 2026t]. **Each of these is a modelling assumption, each is falsifiable by the procedure specified below, and none of them is a theorem.** The framework's falsification gate – FVP-6 in the numbering of its formula-validation protocol [Curzi, 2026t] – exists precisely so that these four are stated in print before any data are collected.

The gate numbering used throughout this paper is the formula-validation protocol's [Curzi, 2026t] and is glossed once here, so that no later reference is opaque: FVP-1 is dimensional consistency, FVP-2 scale type – the gate that licenses division, and the gate on which that protocol demotes the framework's own moment equation – FVP-3 limiting cases, FVP-5 identifiability, FVP-6 falsification, and FVP-7 reproducibility across investigators.

Honesty clauses, repeated. The triangle inequality fails for geometric triples in the framework's own statement of the surplus functional [Curzi, 2026]; subadditivity holds on `u` only. As deployed, the surplus functional is a LOWER BOUND on the ensemble's information — we log the floor, not the ceiling. The surplus functional is a mathematical object and carries no empirical or metaphysical claim; the framework does not identify surplus with Shannon entropy or mutual information; and it proves no thermodynamic negentropy law, since `F(u) + N_can(u) <= ln N` and higher static surplus does not imply higher canonical concentration [Curzi, 2026,c].

27.3.2 3.2 What changes when Y is subjective

Four things, and they are the reason the single-person scope needs its own falsification apparatus rather than a cross-reference to the group-scope survey and preregistration protocol [Curzi, 2026i].

```
1. THE INSTRUMENT IS THE SUBJECT.
   At group scope the rater and the rated were different objects. Internally they are
   the same organism. The person who supplies Y_t also has a view about whether the
   theory is true.

2. THE RATING CARRIES ITS OWN NOISE, AND THAT NOISE BIASES delta UPWARD.
   Measurement error on a LAGGED regressor attenuates a_hat. Since delta = 1 - a,
   attenuation on a inflates delta. §4.9 computes the size.

3. THE INPUT AND THE OUTPUT ARE OFTEN RECORDED IN THE SAME SITTING.
   Anything that moves both at once — mood, fatigue, the weather, the fact of being
   measured — is a common cause the shuffle cannot see.

4. MEMORY RECONSTRUCTS.
   A retrospective rating of Y_{t+1} is partly a rating of what the subject believes
   happened at t. That is a lagged dependence with the right sign and the right timing,
   and it is not the dependence the theory predicts.
```

Threat 4 is the dangerous one, because **it produces exactly the temporal structure the shuffled control is designed to detect, and therefore passes the control.** §4.8 measures how often. The answer, in the configuration simulated there, is 52.7 per cent of the time.

27.3.3 3.3 The three rules, restated for the single-person instrument

```
RULE 1  (SHUFFLE)     If the input series randomly permuted in time predicts held-out
                      Y as well as the input series in its true order, there is no
                      temporal relationship. Report that.

RULE 2  (AUTOREGRESSION)  If a model containing only Y_t and an intercept predicts
                      held-out Y as well, then F(U_t) contributed nothing and the
                      surplus term is decoration.

RULE 3  (CONSTRAINTS) If a_hat leaves [0,1] or b_hat goes negative, the fitted object
                      is not a storage law. It is a regression with the same letters.
```

A framework that cannot fail cannot be trusted, and this one names exactly how it fails. The three rules are not hedges. They are the price of admission.

27.3.4 3.4 Identification: the objection no calibration answers

Everything in Sections 4 to 7 is about whether a fitted coefficient is distinguishable from noise. This subsection is about something logically prior, and it is the more serious problem.

The framework's central formal claim is a reflexive loop, `T(x) = W(x, M(x))`: the group influences the member and the members constitute the group [Curzi, 2026]. Where the storage law is applied to a person embedded in a group – which is the case throughout Stage 5 of Section 8, and is the case for the internal-external correspondence the programme's third test is built to check – that is a linear-in-means reflexive specification, and Manski [1993] proves that its endogenous social effect is **not identified from observational data**. It cannot be separated

from contextual effects or from correlated unobservables, however much data is collected. Shalizi and Thomas [2011] reinforce the same point for networks: influence and selection are generically confounded in observational data, and Lyons [2011] shows what happens when the confound is not taken seriously.

This paper adopts no remedy, and says so. The four available routes are randomisation, an instrument, partial-population variation, and stipulating the reference group and defending the stipulation; the last is the most realistic here and has a template [Brock and Durlauf, 2001]. Stage 5 of Section 8 is cluster-randomised and would, if it were run, supply the first of them for the intervention test `T2` – but not for the prediction test `T1`, which is observational by construction, and not at all for Stages 3 and 4, which are observational throughout.

The consequence is precise and it is not softened elsewhere in this paper. Even a fit clearing all three falsification rules, with a calibrated surrogate threshold and a perfectly reliable instrument, would not have identified `eta` as the conversion of interaction into stored order, because a contextual effect or a common unobserved driver produces the same fit. Wherever this paper speaks of `delta` and `eta` as person-level or group-level quantities, **the claim is a modelling position rather than an identified empirical result.** That is a defensible thing to write; an unidentified parameter presented as measured is not.

Two objections in the same family are recorded here and are not answered either. The first is the Lucas critique applied to the framework itself [Lucas, 1976]: the framework asserts that systems change their behaviour when measured – §4.12 measures exactly that – and then treats `delta`, `eta` and `N` as constant over the estimation window. The position taken here is the narrow one: constancy is assumed **only over a declared window and only while `Y` is not itself reported upward**, which is why the shadow proxy of §4.12 is the first and strongest corruption defence. Where `Y` is reported upward, the framework's own reflexivity applies to it and the constant-parameter postulate fails; that is a restriction on where the protocol may be used and is stated as one. The second is that the functional form of the input term is underdetermined by the evidence: social impact rising as a sub-linear power of the number of sources [Latané, 1981] and value growing as `n log n` [Briscoe et al., 2006] fit the same qualitative facts as `ln(1 + (N−1)u)`, and **nothing in this paper discriminates between them.** The strongest available warrant for the logarithm is not the psychophysical one at all: Peters and Gell-Mann [2016] derive a logarithmic form from multiplicative dynamics with no psychological assumption, which is what the argument here actually needs.

27.4 4 The falsification suite

27.4.1 4.1 The model, slot by slot

What goes in each slot when the scope is internal:

Slot	Group scope	Single-person scope
`Y_t`	institutional order proxy	character, skill, or internalised structure, via magnitude estimate
`U_t`	non-parallelism between members	non-parallelism between one person's own framings
`F(U_t)`	group surplus `ln(1+(N−1)U)`	internal surplus `F_int`
`M_t`	the situation as constructed	the moment as lived, `(D/P)E`
`Chat_t`	coordination overhead	cognitive load, effort, maintenance of self

Slot	Group scope	Single-person scope
`N`	distinct domains held in a group	distinguishable categories in one mind

Two admissible input series exist internally, and they must not be mixed inside one preregistered model:

```
INPUT VARIANT A   S_t = F(U_t) = ln(1 + (N−1) U_t)
                  U_t measured over one person's own framings (the audited framing set)

INPUT VARIANT B   S_t = M_t normalised into [0, ln N]   (declared normalisation)
                  M_t = (D_t / P_t) ∗ E_t                (the moment equation)
```

Variant B inherits the whole of the scale-type gate [Curzi, 2026t]: the corpus's own formula-validation protocol DEMOTES the moment equation on that gate, because `D` and `P` are not instrumented on a common ratio scale with a shared true zero. **If `D` and `P` are not ratio-scaled with a true zero, `D/P` is not a number and Variant B is not a model.** The preregistration must state which variant is being tested, and it must state the evidence that the scale requirement is met, or demote the formula in print as FVP-2 requires.

`Chat_t` is not a free parameter. It is an independently measured series, subtracted before fitting. **Allowing `C` to be estimated inside the regression is the single most common way this model is made unfalsifiable**, because a free additive term with an intercept and a trend will absorb any misfit that has the shape of a level or a drift. Fit two coefficients. Measure the third.

27.4.2 4.2 The constraint set is the first falsification rule, not a convenience

It is tempting to fit by ordinary least squares and then note with satisfaction that `a_hat` came out inside `[0,1]`. That gets the logic backwards. The constraints are the theory. `a` outside `[0,1]` means the system amplifies its own stored order period on period without input, which is not a leaky integrator but an oscillator or a divergence. `b < 0` means interaction destroys stored order, which contradicts `eta >= 0` in the definition of the storage law. **Fit the model constrained; report the unconstrained fit alongside it; and if the unconstrained fit lands outside the box, say so in the abstract, because that is Rule 3 firing.**

There is a practical trap. A constrained fit cannot report a violation it is not allowed to express. If `a_hat` sits exactly at the boundary — `a_hat = 1.000` or `b_hat = 0.000` — the optimiser has hit the wall, and a wall-hit is evidence, not a result. In the null simulation of §4.7 the constrained fit returned `a_hat = 1.0000` exactly: retention pinned at unity, no decay at all, which is the fit telling you it wanted to leave the box.

```
BOUNDARY REPORTING RULE

    Report a_hat and b_hat from the CONSTRAINED fit.
    Report a_ols and b_ols from the UNCONSTRAINED fit.
    Flag in bold any of:
        a_hat = 0 or a_hat = 1 exactly
        b_hat = 0 exactly
        a_ols outside [0,1]
        b_ols < 0
    A flagged boundary is a Rule 3 event and must appear in the abstract.
```

27.4.3 4.3 The preregistration document

Preregistration is a device that removes a specific, enumerable list of choices from the researcher's hands after the data arrive [Nosek et al., 2018]. The list is not hypothetical: undeclared analytic flexibility is sufficient on its own to manufacture significance from noise [Simmons et al., 2011], and it does so without any dishonest intention, because the branching happens one defensible decision at a time [Gelman and Loken, 2013]. Each line below is a degree of freedom that, left open, can manufacture a result.

```
PREREGISTRATION — REQUIRED FIELDS

A. SUBJECT AND SCOPE
   A1  scope: internal (single person) / dyadic / group
   A2  number of subjects, and whether analysis is per-subject or pooled
   A3  inclusion and exclusion rules, stated before recruitment

B. THE PERIOD
   B1  period length (a day, a week, a fortnight) and the justification
   B2  the alignment rule: what counts as period t for Y, for U, for C
   B3  the handling of missed periods (interpolate? drop? carry forward?)

C. OPERATIONALISATIONS
   C1  Y: instrument, items, scoring, and the argument that Y is not a
       repackaging of U -- the most common measurement error \citep{ccp:CCP-015}
   C2  U: the framing set, the inner-product definition, the computation of u
   C3  N: how the category count was audited, not guessed \citep{ccp:CCP-009}
   C4  C: the cost instrument and its units, in the same units as eta*S
   C5  input variant A or B, and for B the ratio-scale evidence \citep{ccp:CCP-026}

D. THE SPLIT
   D1  T_train and T_holdout, fixed in advance as counts, not as fractions
       of a total that is not yet known
   D2  the split is CHRONOLOGICAL. No random splits on time series.
   D3  no peeking rule: who holds the held-out data and when it is opened

E. THE BASELINES
   E1  persistence
   E2  direct-input (raw U, no log), with the required u-range (§4.5.2)
   E3  matched autoregressive with intercept
   E4  shuffled-input control: family, B, and the calibration (§4.7)

F. THE FALSIFICATION RULES
   F1  Rule 1 threshold, as a calibrated p-value, not a nominal one
   F2  Rule 2 threshold, as a skill score with its sign convention
   F3  Rule 3 boundary reporting rule

G. THE STOPPING RULE
   G1  when data collection ends, stated as a date or a count, never as
       "when the result stabilises"

H. THE PUBLICATION COMMITMENT
   H1  the commitment to report the result whichever way it falls
   H2  the deposit location for the frozen model and the analysis code
```

A stopping rule that reads "until the pattern is clear" is not a stopping rule; it is optional stopping, and optional stopping will eventually produce any pattern you like [Simmons et al.,

2011]. Fix the count. Fix the date. Publish whichever way it falls.

27.4.4 4.4 The freeze

“Freeze” means: after the training fit, the following are constants and may not be touched again.

```
FROZEN AT THE END OF TRAINING

    a_hat, b_hat                    the two coefficients
    the operationalisation of Y     items, scoring, reverse-keying
    the operationalisation of U     framing set, inner product
    N                               the category count
    the cost instrument             and its units
    the period length               and the alignment rule
    the missing-data rule
    the input variant               A or B
    the transformation of Y         log, none, winsorisation limits
    the baseline definitions        all four
    the surrogate family and B      for the shuffle
    the skill-score definition
    the falsification thresholds
```

The list is long because researcher degrees of freedom are numerous and each is individually defensible. **Every item on it has a reasonable-sounding argument for changing it after the data are seen, and that is exactly why it must be frozen before.**

One permitted exception, declared in advance: a data-quality exclusion rule that does not reference `Y`, `U`, or the fit. “Periods in which the subject was hospitalised are excluded” is legitimate if written in field A3 before collection. “Periods in which the residual exceeded two standard deviations are excluded” is not legitimate under any circumstances.

27.4.5 4.5 The four baselines

A baseline is a rival explanation with a name. Each of the four names a specific way the result could be uninteresting.

4.5.1 Persistence

```
Y_{t+1} = Y_t
```

No parameters. Rival explanation: *the thing you measured is simply slow-moving.* Persistence is the hardest baseline to beat for any highly autocorrelated quantity, which is most psychological constructs at daily or weekly cadence. It also tells you whether your period length is sensible: **if persistence is unbeatable, your period is shorter than the dynamics you are trying to observe, and the fix is a longer period, not a better model.** In the worked example it gives a held-out RMSE of 0.1207 against the model’s 0.0777, a skill score of 0.5860.

4.5.2 Direct-input

```
Y_{t+1} = a * Y_t + b * U_t - Chat_t
```

Raw `U`, no logarithm. Rival explanation: *the logarithm in `F` is doing no work; any increasing function of `U` would fit as well.*

This baseline tests the surplus functional's form [Curzi, 2026], and it is the weakest of the four for a reason worth computing. Over `u` in `[0,1]` with `N = 7`, the correlation between `u` and `F(u)` is 0.9724. The best straight-line approximation is `F(u) ~= 1.7280 u + 0.4063` with a maximum absolute error of 0.4021 and an RMS error of 0.1197 — visible over the full range. But over any narrow band the two are nearly identical:

u range	corr(u, F(u))
[0.0, 0.2]	0.99496
[0.2, 0.5]	0.99704
[0.5, 1.0]	0.99741
[0.3, 0.6]	0.99795

The direct-input baseline has discriminating power only in proportion to the range of `u` your data actually span, and most field data span very little of it. Simulated at `T = 100` with 70 training periods, the fraction of trials in which the log form beats the linear form on held-out data rises with the observed span of `u`:

mean span of u	log form wins
0.323	84.0 %
0.580	91.3 %
0.862	97.7 %
0.987	100.0 %
1.000	100.0 %

and the ratio of linear-model to log-model held-out RMSE rises from 1.063 at span 0.338 to 1.606 at span 0.987.

The consequence for preregistration is concrete. Field E2 must state a **minimum observed span of `u`** below which the direct-input comparison is declared uninformative and reported as such. A defensible default from the table above is a span of 0.60. Below that, say in print: *the data do not distinguish the logarithmic from the linear input form.* That is an honest partial result and it is much better than a claim the data cannot support.

4.5.3 Matched autoregressive

```
Y_{t+1} = a * Y_t + c - Chat_t
```

An intercept in place of the surplus term. Rival explanation: *the system decays toward a constant and the interaction variable is irrelevant.* This baseline is the statistical twin of the storage law itself: a first-order linear difference equation with a constant term is exponential smoothing [Holt, 1957, Elaydi, 2005], and Brown and Meyer [1961] state exactly which class of processes it is optimal for – a question the storage law does not ask about itself. The fixed-gain limit of the Kalman filter is the same object again [Kalman, 1960]. This baseline isolates the theory's actual content, because the storage law without `eta*S_t` is exponential decay to a level. It is also the baseline most likely to win when the input barely varies: **if `F(U_t)` is nearly constant, its coefficient is unidentifiable and an intercept does the same job at lower cost.** In the null simulation of §4.7 Rule 2 fires — model RMSE 0.0978 against matched-AR 0.0681, skill -1.0669.

But Rule 2 alone is nowhere near sufficient. In 500 simulated null trials — data generated with no dependence on `S` at all — **the model beat the matched autoregressive baseline on held-out data 35.8 per cent of the time.** A single baseline comparison, run once, on data where both series are smooth, is a coin weighted only slightly against you.

4.5.4 The shuffled-input control

```
Take the input series S = (S_0, S_1, ..., S_T).
Permute it in time to get S' = (S_{pi(0)}, S_{pi(1)}, ..., S_{pi(T)}).
Refit on training with S'. Score on held-out with a permuted held-out S'.
Repeat B times. Compare the ordered model's held-out error to the
distribution of the permuted models' held-out errors.
```

Rival explanation: *the input and the output have the right marginal distributions and no temporal relationship at all.*

The shuffle preserves the marginal distribution of the input exactly — every value, its mean, its variance, its skew, its range — and destroys only the pairing between input and output in time. That is the precise null it instantiates, and it is the reason it is the sharpest of the four.

Everything else that could be responsible for a fit survives the shuffle: the scale of `S`, the number of large values, the fact that `S` is bounded by `ln N`, the fact that `Y` trends, the fact that both are positive. The only thing the shuffle removes is *which* `S` went with *which* `Y`. **If the fit survives that removal, the relationship you found was a property of the two marginal distributions and not a relationship between two series.**

27.4.6 4.6 Why the shuffled control is the one most often omitted

The other three baselines are, in practice, strawmen: the researcher expects to beat persistence (the construct moves), direct-input (the log is in the theory), and matched autoregression (the input term is in the theory). Running them feels like diligence and usually confirms what was already believed.

The shuffle is different in kind. **It is the only one of the four that can kill a result the researcher already believes, using data the researcher already has, at no additional cost, in seconds of computation.** That combination — decisive, cheap, already possible — is what produces omission, because there is no resource-based excuse to hide behind. Its omission is a choice about what one wishes to know.

Three reasons it gets left out, in the order of how often they are offered:

```
1. "It is not standard in this literature."
   Irrelevant. A permutation test needs a random number generator, not a
   literature's permission.

2. "The input is autocorrelated so the shuffle is not a fair comparison."
   A real technical objection, answered by choosing the right surrogate
   family (§4.7), not by dropping the control.

3. "We already showed the effect is significant."
   Significance against a parametric null assumes the null. The shuffle
   CONSTRUCTS the null from the data you have. When the two disagree,
   believe the shuffle: it assumed less.
```

There is a fourth reason, unstated: the shuffle is the only baseline whose result the researcher cannot predict in advance. **A test whose outcome you can predict is not a test.**

27.4.7 4.7 The surrogate hierarchy, and why you must calibrate the control itself

The objection in reason 2 is correct, and taking it seriously produces the most technically important subsection of the paper.

An independent-and-identically-distributed permutation destroys two things at once: the pairing between `S` and `Y` (which you want destroyed) and the autocorrelation within `S` (which you did not). If both `S` and `Y` are smooth, a smooth ordered `S` can track a smooth `Y` by coincidence, while the whitened shuffled `S` cannot track anything. **The plain shuffle can therefore reject the null when the null is true, because it compares a smooth regressor against a white one rather than against another smooth one.** This is the spurious-regression problem wearing a permutation test's clothes, and it is the same statistical hazard that makes a straight line on a log-log plot poor evidence for a mechanism [Clauset et al., 2009, Stumpf and Porter, 2012]: a procedure that has not been calibrated against its own null is not a test.

Three surrogate families, in increasing fidelity to the input's own structure:

```
IID PERMUTATION      S' = random permutation of S
                     preserves: the multiset of values, hence every marginal moment
                     destroys:  pairing AND autocorrelation

BLOCK PERMUTATION    cut S into contiguous blocks of length L; permute the blocks
                     preserves: marginals, and autocorrelation at lags < L
                     destroys:  pairing, and autocorrelation at lags >= L
                     choose L >= 3 / (-ln rho1) so a block spans the input's own
                     correlation time

CIRCULAR SHIFT       S' = S rotated by a random offset k
                     preserves: marginals AND the full autocorrelation function
                     destroys:  pairing only
                     the tightest surrogate; the number of distinct surrogates is
                     limited to the series length, which caps resolution
```

Now the measurement that decides the matter. Five hundred null trials were simulated: `Y` generated by a storage law driven by a smooth AR(1) input that is *not* `S`, with `S` an independent smooth AR(1) series (autocorrelation parameter 0.85 for both), `T_train = 40`, `T_holdout = 20`, 200 surrogates per trial. The true `b` is zero. A well-calibrated test at nominal alpha = 0.05 should reject 5 per cent of the time.

```
NULL (b_true = 0), 500 trials, nominal alpha = 0.05

   surrogate family      measured rejection rate
   iid permutation              0.108
   circular shift               0.120
   block permutation (L=5)      0.060

   matched-AR comparison alone: passes 0.358 of the time
   mean b_hat under the null:   0.0922  (sd 0.0222)

TRUE MODEL (b_true = 0.40), 500 trials

   surrogate family      measured rejection rate (= power)
   iid permutation              1.000
   circular shift               1.000
   block permutation (L=5)      0.998

   beats matched AR on held-out: 1.000
   mean b_hat:                   0.4025  (sd 0.0322)
```

Read those two tables together and three conclusions follow, none of which is optional.

First: the shuffled-input control, run as it is usually run, is anti-conservative. At a nominal 5 per cent it rejected between 6.0 and 12.0 per cent of true nulls in this design. A control that

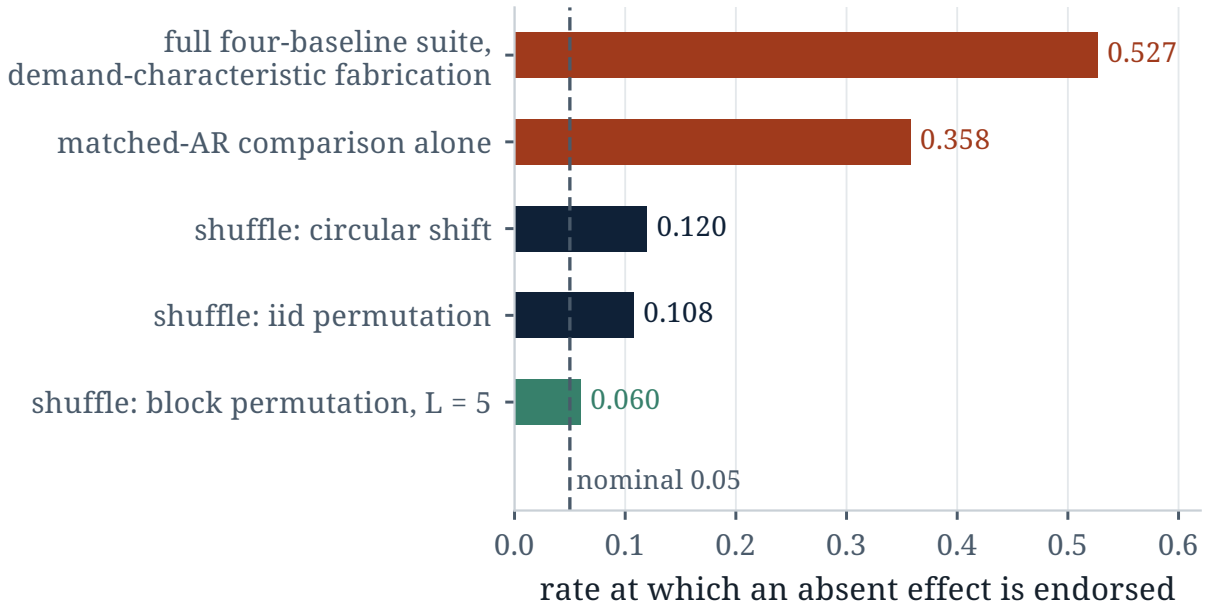

Figure 27.1: **Every bar is the rate at which the procedure endorses an effect that is not there, and the smallest of them is above the nominal 0.05.** The three shuffle families are measured over 500 null trials with 200 surrogates each; the matched-AR figure is the same 500 trials scored on that baseline alone; the 52.7 per cent is a separate 300-trial run in which the true coefficient is zero and the reported output has been inflated by 0.45 times the centred input. Modelled, with the generating parameters named in §4.7 and §4.8; produced by `figs/src/CCP-027_fig01.py`.

is wrong by a factor of two in the direction of false discovery is still enormously better than no control — compare the 35.8 per cent false pass rate of the matched-AR comparison alone — but it is not exact, and reporting its nominal p-value as though it were exact is a misstatement.

Second: the block permutation was the best calibrated of the three here (0.060 against a nominal 0.050), and it lost almost nothing in power (0.998 against 1.000). That is a favourable trade and it should be the default. Note that the circular shift, which preserves the most structure, was *not* the best calibrated in this design, because the held-out window is short and rotating a 21-point segment leaves few genuinely distinct surrogates. Intuition about which surrogate is "tightest" does not survive contact with a short held-out window.

This is not the only calibrated gate in the corpus that has come back above nominal. A pre-registration for narrative regulatory input measures its conjunction gate at a false-positive rate of 9.5 per cent at `T = 60` against a nominal 5, and repairs it by requiring cross-individual replication at 4 of 12, which restores `alpha = 0.0216` while retaining 90.8 per cent power against a half-size effect [Curzi, 2026ad]. **That repair – a structural requirement rather than a larger `B` – is the model this paper's S4.10 follows.** The general lesson is the one measured on the integrity side of the corpus, where a naive detector's precision was 11.01 per cent, right one time in nine, until typed-field parsing collapsed its false-positive share from 88.99 per cent to 0.00 per cent [Curzi, 2026]: **a control is not trustworthy because it is standard; it is trustworthy when its error rate has been measured.**

Third, and this is the specification item: calibrate the control on your own design before you trust its p-value. The false-positive rate of a surrogate test depends on the autocorrelation of both series, the length of the training and held-out windows, the number of surrogates, and the constraint set. None of those is universal. The calibration is a simulation you run once, in advance, using the preregistered design and a generating process with `b` set to zero, and it takes minutes. The output is a *calibrated* critical value that replaces the nominal one in field F1.

Finally, resolution. A permutation p-value cannot be smaller than `1/(B+1)`:

```
   B        smallest attainable p     se of p at p = 0.05
  19             0.05000                   0.05000
  99             0.01000                   0.02190
 199             0.00500                   0.01545
 999             0.00100                   0.00690
1999             0.00050                   0.00487
```

`B = 199` is the practical floor for a claim at the 1 per cent level; `B = 999` if the claim is stronger. Report `B`. A shuffle test whose `B` is not reported is not reproducible.

27.4.8 4.8 What the shuffled control does not catch

Here is the honest limit, and it is severe.

The shuffle detects the absence of a temporal relationship. It cannot distinguish a real temporal relationship from a fabricated one that has the same timing. Any process that writes the input's timing into the output — by any route other than the theorised one — will produce a series that passes the shuffle handsomely.

The mechanism that does this most reliably is threat 4 of §3.2: a subject who knows the hypothesis and whose rating of `Y_{t+1}` is nudged by what they recall of period `t`. That subjects and experimenters both move measurements toward an expected result is among the most robustly documented effects in experimental psychology [Rosenthal and Fode, 1963, Rosenthal and Jacobson, 1968]; the reactivity of measurement itself is weaker and more heterogeneous than it is usually asserted to be [McCambridge et al., 2014], but demand characteristics of the kind simulated here do not depend on reactivity, only on the subject's inference of the hypothesis. Simulated directly: data generated with `b_true = 0` — no real dependence whatsoever — and the *reported* `Y_{t+1}` inflated by `0.45 * (S_t - mean S)`.

```
DEMAND-CHARACTERISTIC SIMULATION, true b = 0, T_train = 40, T_holdout = 20

  example trial   fitted a = 0.9265   fitted b = 0.1856   (both inside the box)
                  held-out RMSE  model 0.0991
                                 matched AR 0.1112
                                 circular-shift surrogate mean 0.1168
                  shuffle p = 0.0000

  over 300 trials, the full four-baseline suite PASSED a purely fabricated
  relationship 52.7 % of the time
```

More than half the time, a relationship that does not exist cleared all four baselines and all three rules, because the rater's own bias supplied the timing. No amount of extra shuffling fixes this. The shuffle is testing the wrong thing: the fabrication is temporal, so a temporal test endorses it.

The fix is not statistical. It is a design change, and there are four, in decreasing order of strength:

```
DC1 BLIND THE RATER TO THE HYPOTHESIS.
    The subject supplies Y without being told what U is, that U is being
    measured, or what relationship is predicted. Debrief afterwards.

DC2 MEASURE Y AND U THROUGH DIFFERENT CHANNELS.
    Y from a behavioural or archival trace (a completed artefact, an
    attendance record, a produced object); U from the rating instrument,
```

```
    or the other way round. A bias in one channel cannot supply timing
    to the other.

DC3 PROSPECTIVE, NOT RETROSPECTIVE, SAMPLING.
    Rate the period in the period, not at the end of the week. Memory
    reconstruction is proportional to the recall interval; shrink the
    interval and you shrink the artefact.

DC4 YOKED CONTROL SUBJECT.
    A second subject is shown the first subject's U series, on the same
    schedule, but their own Y is their own. If the yoked subject shows
    the same fit, the fit is being produced by the SCHEDULE, not by the
    subject's own dynamics.
```

DC1 and DC2 together are close to sufficient. **State in the preregistration which of DC1-DC4 are in force. A study running none of them cannot claim a temporal result about subjective quantities regardless of how many surrogates it ran.**

The group-scope protocol [Curzi, 2026i] treats the shuffle as the decisive baseline, and at group scope with archival proxies it very nearly is. Turned inward, **the shuffle remains the most decisive of the four and stops being sufficient on its own.** The second half is what the single-person scope adds.

27.4.9 4.9 The instrument's own noise, and which direction it biases

A subjective `Y` is a rating, and a rating has error. That error does not merely add scatter; it biases both parameters, in known directions, by computable amounts.

The mechanism is regression dilution applied to a lagged regressor. Error in `Y_t` attenuates `a_hat` toward zero, and since `delta_hat = 1 − a_hat`, **attenuation of `a` inflates `delta`: measurement noise makes a system look leakier than it is.** Because the lagged term then explains less, the input term compensates, so `b_hat` — hence `eta_hat` — is inflated too.

Simulated at `T = 80`, true `a = 0.85`, true `b = 0.40`, process noise 0.06, 400 replications per row:

rating sd	mean a_hat	mean b_hat	implied delta_hat
0.00	0.8486	0.4022	0.1514
0.05	0.8419	0.4156	0.1581
0.10	0.8219	0.4538	0.1781
0.20	0.7571	0.5783	0.2429
0.40	0.5683	0.9425	0.4317

Read the last row. With a rating standard deviation of 0.40 against a `Y` whose own standard deviation is around 0.20, the estimated `delta` is 0.432 against a true 0.150 — nearly triple — and the estimated `eta` is 0.943 against a true 0.400, more than double. **A sloppy instrument does not produce a noisy answer. It produces a confidently wrong one, and it errs in the direction of making the system look both leakier and more efficient than it is.**

This is why Stage 2 of the programme in Section 8 comes before Stage 3 and cannot be skipped: the scale must be built and its error characterised before any dynamic parameter estimated on it means anything. It is also why the preregistration must report the instrument's test-retest reliability alongside the parameter estimates. **A parameter estimate without an accompanying reliability figure for the instrument that produced it is uninterpretable, because the reader cannot tell how much of the reported `delta` is the world and how much is the ruler.**

A partial correction exists — an attenuation factor estimated from a repeated-measures reliability study — but it depends on that estimate being itself accurate and does nothing for `b_hat` without further assumptions. **Prefer a better instrument to a correction factor.**

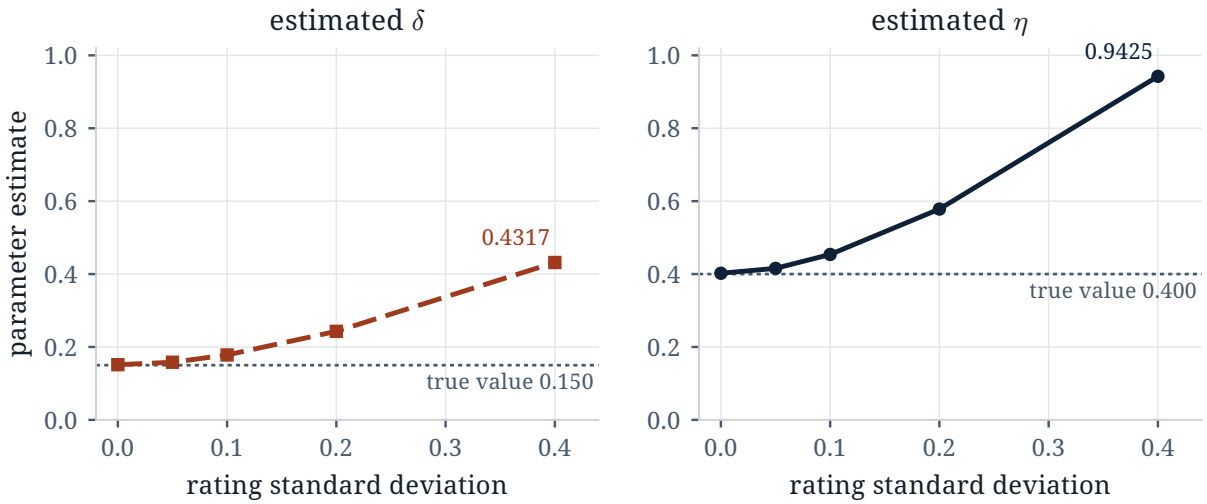

Figure 27.2: **More rating error does not scatter the estimates; it walks them away from the truth in a fixed direction.** Decay is over-estimated and conversion is over-estimated together, so a noisier instrument makes a system look both leakier and more efficient than it is. Modelled at `T = 80`, true `a = 0.85`, true `b = 0.40`, process noise 0.06, 400 replications per point; produced by `figs/src/CCP-027_fig02.py`.

27.4.10 4.10 Held-out reporting

Report one table. It has five rows and it is the entire empirical claim.

```
HELD-OUT REPORT (the only table that matters)

  predictor                       RMSE      skill vs model      note
  ------------------------------------------------------------------------
  frozen model                    ____          --
  persistence                     ____        ____
  direct-input (raw u)            ____        ____            span of u = ___
  matched autoregressive          ____        ____
  shuffled input (family, B)      ____        ____            calibrated p = ___
```

Definitions, fixed in advance:

```
  RMSE          root mean squared ONE-STEP-AHEAD error on the held-out window,
                using OBSERVED Y_t on the right-hand side, never simulated Y_t

  skill score   1 - (RMSE_model / RMSE_baseline)^2
                positive means the model beats the baseline;
                zero means they tie; negative means the baseline wins
```

Two prohibitions that matter more than they look.

Prohibition one: one-step-ahead scoring, using observed `Y_t`. Free-running simulation from `Y_0` is a weaker test that mostly measures whether `Q_inf` was estimated well; as a primary score it inflates apparent performance for any model with a stable fixed point. Secondary diagnostic only.

Prohibition two: no refitting. If the held-out window is opened and the model performs poorly, the result is that the model performs poorly. A revised model fitted after seeing held-out data is a new hypothesis, requires new held-out data, and must be labelled exploratory in every subsequent sentence about it. **The held-out window can be spent exactly once.**

Report the in-sample fit too, and report it in a way that makes its irrelevance visible. In the null simulation of §4.7 the training-window `R^2` was 0.6477 — a figure that would be reported as a strong result in a great many papers — while the same frozen model was beaten on held-out data by persistence, by matched autoregression, and by 100 per cent of the circular-shift surrogates. **In-sample `R^2` of 0.65 and a held-out failure against every baseline is not a contradiction. It is the normal appearance of a false result.**

27.4.11 4.11 Cross-individual parameter recovery — FVP-7, the hard gate

Everything to this point tests whether a relationship exists in one series. The reproducibility gate – FVP-7 in the framework's formula-validation protocol [Curzi, 2026t] – asks the question that decides whether the framework measures anything: **do `delta` and `eta` recover as properties of a person, measured the same way, by different investigators?**

The framework identifies this as the gate most often skipped [Curzi, 2026t], and skipping it is what separates a formalism that describes from one that measures. Rasch's specific objectivity [Rasch, 1960, Andrich, 1988] is the standard aimed at — a person's measure must not depend on which items were used — and the analogous demand here is that a person's `eta` must not depend on which lab estimated it. Three levels, cleared in order.

Level 1 — within-person reliability

Split one subject's series into two halves and estimate separately in each. If the halves disagree, the parameter is a property of the window, not of the person. Simulated with rating noise 0.10 and true between-person spread 0.12 in `b`, 40 subjects per row:

```
half length      split-half r of b_hat
     60                  0.841
    120                  0.846
    240                  0.962
```

Sixty periods per half is enough for a usable within-person reliability; 240 is enough for a good one. Below 60, do not attempt Level 2.

Level 2 — between-person separability

Estimate for many subjects and ask whether the spread exceeds what estimation error alone produces. This step is almost universally botched, because the spread is always nonzero and always tempting to interpret. Simulate the noise floor directly: give every subject the *same* true `b = 0.40` and see how much apparent individual difference the estimator manufactures out of nothing.

```
THE NOISE FLOOR — 60 subjects who genuinely share one eta

T per subject      sd of b_hat across subjects
     60                    0.0478
    120                    0.0355
    240                    0.0255
    360                    0.0166
```

At 120 periods per subject, an estimator applied to sixty identical people reports a between-person standard deviation of 0.036 in `eta`. Any story about individual differences built on a spread smaller than that is a story about the estimator. A separate 30-subject run with the between-person standard deviation set to exactly zero produced an apparent spread of 0.042 — the same conclusion from a different seed.

This is why the recovery correlation collapses when true differences are small. With 30 subjects at 120 periods each:

```
true between-person sd of b        corr(true b, estimated b)
           0.12                             0.956
           0.04                             0.503
```

The second row is not a failure of the estimator. **The second row is what it looks like when the quantity you are trying to measure varies less across people than your instrument's error, and no sample size fixes it — only a longer series per person or a quieter instrument does.**

The full variance decomposition for 30 subjects at 120 periods, true between-person sd 0.12:

```
var(true b)          0.011586
var(estimated b)     0.012707
var(error)           0.001310
reliability          var_true / (var_true + var_err) = 0.898
```

Reliability 0.898 caps the correlation between `eta` and any external variable at `sqrt(0.898)` = 0.948. That ceiling is the useful output: **before correlating `eta` with anything — a personality measure, an outcome, a treatment response — compute the reliability and state the ceiling, because a correlation cannot exceed it and a reported correlation near it is suspicious.**

Also report the bias. Across the recovery runs, `b_hat` was biased upward by between 0.038 and 0.078, which is the attenuation mechanism of §4.9 operating at rating noise 0.10. **The bias is in the mean, not in the ranking, which is why recovery correlations can look excellent while every individual estimate is too high.** Report both.

Level 3 — between-lab invariance

The hard gate proper. Two labs measure the same construct with operationalisations they each consider faithful. Lab 2's procedure for computing `u` runs 15 per cent hot — a slightly wider framing set, a slightly different inner product, an entirely defensible choice.

```
lab 1 mean b_hat        0.4679
lab 2 mean b_hat        0.4068
observed ratio          0.8696
predicted ratio 1/1.15  0.8696
```

Exact, because the model is linear in the input: scaling `S` by `g` scales `b_hat` by `1/g`. That gives a useful diagnostic:

```
BETWEEN-LAB DIAGNOSTIC

If lab 2's eta differs from lab 1's by a CONSTANT FACTOR across all subjects,
the discrepancy is a CALIBRATION difference in the operationalisation of u,
and it is repairable by publishing the scaling constant.

If lab 2's eta differs from lab 1's by a factor that VARIES ACROSS SUBJECTS,
or if the RANK ORDER of subjects differs between labs, the discrepancy is a
THEORY FAILURE. The parameter is not a property of the person.
```

A framework passes FVP-7 when between-lab disagreement is a single number and fails when it is a pattern. That is a sharp, checkable, preregisterable criterion, and it is the criterion Stage 4 of Section 8 is built to apply.

Predicted ratios for other calibration errors, all exact:

```
inflation g     predicted b_hat ratio 1/g
   1.05                 0.9524
   1.10                 0.9091
   1.15                 0.8696
   1.25                 0.8000
   1.50                 0.6667
```

27.4.12 4.12 Goodhart and Campbell

Goodhart's law – when a measure becomes a target it ceases to be a good measure [Goodhart, 1975] – and Campbell's law – the more a quantitative indicator is used for social decision-making, the more it is subject to corruption pressures and the more it distorts what it was meant to monitor [Campbell, 1979] – both attach to `Y`.

The attachment to the order proxy is computable. Simulate a system running normally for 30 periods, at which point `Y` becomes a target and the *reported* value inflates by 0.35 while the underlying `Q` continues to obey the same law.

```
GOODHART SIMULATION — proxy becomes a target at t = 30

at t = 30    true Q = 3.0359      reported Y = 3.3650
at t = 60    true Q = 2.8447      reported Y = 3.1401   inflation = 0.2954

fitted on periods  0–30 (pre-target):   a = 0.8992  b = 0.3105
                                        -> delta = 0.1008  eta = 0.3105
fitted on periods 30–60 (post-target):  a = 0.8817  b = 0.3551
                                        -> delta = 0.1183  eta = 0.3551
```

The estimated conversion efficiency rose by 14 per cent — from 0.3105 to 0.3551 — **at exactly the moment the underlying stored order began to fall, from 3.036 to 2.845.** Nothing in the fit complains. The constraints hold. The parameters stay in the box. The model reports an improvement while the thing improves in the opposite direction.

Goodhart's Law is not a caveat about this framework. It is a failure mode with a signature, and the signature is a rising `eta_hat` accompanied by a falling independent indicator. That gives the detection procedure:

```
GOODHART DETECTION

G1  Maintain at least one order indicator that is NEVER reported upward,
    never used in any decision, and known to no one who can influence it.
    This is the shadow proxy. It exists solely to be compared.

G2  Test for a structural break in (a_hat, b_hat) at every point where the
    measure acquired a consequence: a review cycle, a published dashboard,
    a funding decision, a self-imposed goal.

G3  Compare the trajectory of the reported proxy against the shadow proxy.
    A widening gap dated to a decision is Campbell's Law, measured.

G4  Prefer proxies that are EXPENSIVE TO FAKE relative to the benefit of
    faking them. Archival traces and produced artefacts beat self-report
    on this criterion by a wide margin.
```

This is the corpus's own reflexivity turned on the corpus. Lucas [1976] makes the general form of the objection: parameters estimated in a population that does not know the model

cannot be assumed stable in a population that has read it; Hacking [1995] makes it about classifications of people, which move because the people classified respond to them; and MacKenzie and Millo [2003] documents the completed loop in the field, with dates and price data, where a model that did not fit its market came to fit it after traders adopted it. A framework that tells people their comfort obeys a decay law should also ask what that assumption makes true [Ferraro et al., 2005]. At single-person scope – one person, measuring themselves, against their own goals – the problem is at its worst, because **the subject, the instrument, the analyst, and the beneficiary of a good result are one organism with one set of incentives.** At group scope the rater and the rated could at least be separated. Here the separation must be manufactured: by DC1-DC4 of §4.8, by the shadow proxy of G1, and by the honest expectation that self-measurement drifts toward flattery at a rate that is itself worth measuring.

The framework's fourth standing refusal [Curzi, 2026] applies here with unusual force: do not build a measurement regime that removes a person's ability to decline being measured. **A proxy that a person cannot refuse to feed is a proxy they will learn to feed falsely, and the falsity will be indistinguishable from success.**

27.4.13 4.13 The publication contract

```
PC1 Publish the result whichever way it falls. A preregistration that is
    abandoned when the result disappoints has produced nothing except a
    private lesson.

PC2 Deposit the frozen model — the two coefficients, the code, the
    operationalisations, the surrogate calibration — at the moment of the
    freeze, before the held-out window is opened.

PC3 Report B, the surrogate family, and the CALIBRATED critical value.

PC4 Report the instrument's test-retest reliability in the same table as
    the parameter estimates (§4.9).

PC5 Report the observed span of u, so the reader can judge the direct-input
    comparison (§4.5.2).

PC6 Report boundary hits in the abstract (§4.2).

PC7 If any of the three rules fired, say so in the first paragraph. Not the
    limitations section. The first paragraph.

PC8 If the result is null, the title should say so.
```

The cost of not replicating is exact, and it has been computed elsewhere in this corpus: at zero independent replications per generation an error survives with probability 1.000000 indefinitely, against 0.013841 after twelve generations at one replication per generation [Curzi, 2026]. **A literature that does not publish nulls is running at zero replications on the nulls.**

PC8 is not moralising. **A field in which nulls are titled ambiguously is a field whose literature cannot be read at face value, and the premise of this section is a claim about literatures, not about individual papers.** The Open Science Collaboration's replication project found 97 of 100 originals significant, about 36 per cent of replications significant, and effect sizes roughly halved [Open Science Collaboration, 2015]; the base-rate argument for why most published findings in such a regime are false was made a decade earlier [Ioannidis, 2005]. **Formulas do not make a field hard. Ratio-scale, reproducible, falsifiable measurement of the formulas' terms does** — and so does a convention under which a null is legible from the title.

27.5 5 Specification of the falsification suite

A study that cannot answer yes to all of these has not run the falsification suite; it has run a regression.

```
S4.1   The preregistration contains every field A1–H2 of §4.3, filed before
        the first observation, with a timestamp that a third party can verify.

S4.2   The input variant (A: F(U_t), or B: normalised M_t) is declared, and if
        B, the ratio-scale evidence required by the formula-validation protocol \citep{ccp:CCP-026} for D a

S4.3   Chat_t is measured independently and subtracted before fitting. It is
        never estimated as a free parameter. Its units match those of eta*S.

S4.4   The split is chronological, with T_train and T_holdout fixed as counts
        in advance.

S4.5   The model is fitted with the constraints 0 <= a <= 1 and b >= 0, and the
        unconstrained fit is reported alongside it.

S4.6   Boundary hits (a_hat at 0 or 1, b_hat at 0, or any unconstrained estimate
        outside the box) are flagged in the abstract as Rule 3 events.

S4.7   All four baselines are computed on the held-out window: persistence,
        direct-input, matched autoregressive, shuffled input.

S4.8   The surrogate family is declared in advance. Block permutation with
        L >= 3 / (-ln rho1) is the default; departures are justified in writing.

S4.9   B >= 199 surrogates for a claim at the 1 per cent level; B >= 999 for
        anything stronger. B is reported.

S4.10  The surrogate test is CALIBRATED by simulation on the preregistered
        design with b set to zero, and the calibrated critical value replaces the
        nominal alpha in field F1. Nominal p-values are not reported alone.

S4.11  The observed span of u on the training window is reported. If it is below
        the preregistered minimum (default 0.60), the direct-input comparison is
        declared uninformative in print.

S4.12  At least two of the four design controls DC1–DC4 (§4.8) are in force, and
        which two is stated. Blinding the rater to the hypothesis (DC1) and
        separating the channels for Y and U (DC2) are the preferred pair.

S4.13  The instrument's test–retest reliability is estimated in a separate study,
        reported in the same table as the parameter estimates, and used to state
        the ceiling on any correlation involving those estimates.

S4.14  Scoring is one-step-ahead using observed Y_t. Free-running simulation may
        be reported as a secondary diagnostic and never as the primary score.

S4.15  Skill scores use 1 - (RMSE_model/RMSE_base)^2 with the sign convention
        stated, and are reported for all four baselines.

S4.16  The held-out window is opened exactly once. Any model revision after that
```

```
        opening is labelled exploratory in every subsequent sentence.

S4.17  Within-person split-half reliability of a_hat and b_hat is reported, with
        at least 60 periods per half.

S4.18  Before any claim about individual differences, the estimation noise floor
        is simulated at the study's own T and n, and the observed between-person
        spread is compared against it explicitly.

S4.19  The reliability var_true/(var_true + var_err) is computed and the implied
        ceiling on external correlations is stated.

S4.20  Between-lab comparison, where available, is reported as either a single
        scaling constant (calibration difference, repairable) or a pattern
        (theory failure, not repairable). The distinction is made in print.

S4.21  A shadow proxy exists (Goodhart G1): at least one order indicator never
        reported upward and never used in any decision.

S4.22  A structural-break test on (a_hat, b_hat) is run at every date on which
        the measure acquired a consequence.

S4.23  The frozen model and analysis code are deposited at the moment of the
        freeze, before the held-out window is opened.

S4.24  The result is published whichever way it falls, and if null, the title
        says so.

S4.25  No participant is required to be measured. Refusal is available, costless,
        and recorded as missing under the preregistered missing-data rule
        (the framework's fourth standing refusal, \citealp{ccp:CCP-A06}).
```

27.6 6 Failure modes of the falsification suite

Each fault is named, given its diagnostic signature, and given its fix.

27.6.1 F4.1 The Free Cost Term

Signature. `Chat_t` appears as an estimated coefficient, or an intercept plus trend, rather than a measured series. In-sample fit excellent, held-out fit mediocre, residuals structureless because the free term absorbed everything. Measuring cost is tedious; estimating it is easy.

Fix. Measure `C` on the framework's own cost instrument [Curzi, 2026b]. Subtract it. Fit two coefficients only. If `C` genuinely cannot be measured, say so and report that the model was fitted without a cost term, which is a different and weaker model.

27.6.2 F4.2 Proxy Contamination

Signature. `Y` rises whenever interaction is high, for reasons internal to the instrument. Paper E §6.3 names this as the most common measurement error in the entire framework: choosing an order proxy that is a repackaging of the interaction variable.

Fix. Field C1's argument, written before collection. Ask: could `Y` rise in a period with high `U` and no durable change whatsoever? If yes, `Y` is measuring `U`. Use DC2 of §4.8 — different channels for the two series.

27.6.3 F4.3 The Uncalibrated Shuffle

Signature. A reported permutation p-value of 0.02 with no statement of the surrogate family, no `B`, and no calibration run. The permutation test is usually presented as exact; it is exact only for the exchangeability structure it assumes.

Fix. §4.7. Simulate the design at `b = 0`, measure the actual rejection rate, and use the calibrated critical value. In the design simulated there, nominal 0.05 corresponded to actual rates between 0.060 and 0.120 depending on the surrogate family.

27.6.4 F4.4 The Fabricated Timing

Signature. Every baseline beaten decisively, shuffle p-value 0.000, parameters comfortably inside the box — and the subject knew the hypothesis, rated both series, and rated them retrospectively. It is the cheapest study to run.

Fix. DC1-DC4 of §4.8, at least two in force. Measured rate at which this fault passes the full suite when uncontrolled: **52.7 per cent.** There is no statistical remedy; only a design remedy.

27.6.5 F4.5 Attenuation Mistaken for Decay

Signature. `delta_hat` comes out large — the system looks leaky — and the instrument's reliability was never reported. Error in a lagged regressor attenuates its coefficient, and `delta = 1 − a`.

Fix. §4.9's table. Estimate instrument reliability separately. If rating error is comparable to the signal's own variability, the reported `delta` may be inflated by a factor approaching three (0.150 true against 0.432 estimated at rating sd 0.40).

27.6.6 F4.6 The Uninformative Direct-Input Comparison

Signature. "The logarithmic form outperformed the linear form" reported from data spanning `u` in `[0.30, 0.45]`. Over narrow bands `corr(u, F(u))` exceeds 0.995 and the comparison is near-vacuous.

Fix. S4.11. Report the span. Below the preregistered minimum, say the data do not distinguish the forms.

27.6.7 F4.7 Optional Stopping

Signature. The stopping rule reads "until the pattern is clear", or the reported `T` is not the preregistered `T`, or a supplementary wave was added after a first look. Stopping early when things look good feels efficient.

Fix. Field G1, as a date or a count. Any deviation is reported as a deviation, in the abstract.

27.6.8 F4.8 The Second Held-Out Window

Signature. The held-out result was poor; the model was revised; a new held-out window appeared from somewhere; the revised model is reported as confirmatory. The revision is usually a genuine improvement, which is what makes the fault feel like progress.

Fix. S4.16. The revised model is exploratory, permanently, until tested on data collected after its specification was frozen.

27.6.9 F4.9 Individual Differences That Are Estimation Noise

Signature. A table of per-subject `eta` values with a spread of 0.03 to 0.04, at 120 periods per subject, interpreted as a personality finding. The spread is real in the sense that the numbers differ, not in the sense that the people do.

Fix. S4.18. The measured noise floor at 120 periods is a between-subject sd of 0.036; at 60 periods, 0.048. A spread that does not clear the floor is the estimator talking.

27.6.10 F4.10 Goodhart Drift

Signature. `eta_hat` rising over successive fits while an independent indicator falls, the rise dated to a review cycle, a dashboard, or a personal goal. The measure acquired a consequence.

Fix. G1-G4 of §4.12. Simulated magnitude: `eta_hat` up 14 per cent (0.3105 -> 0.3551) while true `Q` fell from 3.036 to 2.845.

27.6.11 F4.11 The Unfalsifiable Rescue

Signature. After a failure, the model is retained with a new auxiliary assumption: `delta` was time-varying, `N` changed mid-study, the period length was wrong, the subject was unusual. Each rescue is individually plausible, which is precisely the problem.

Fix. Every auxiliary assumption becomes a preregistered prediction in the next study or it is withdrawn. A rescue that generates no new testable prediction converts a research programme into a system of excuses, and §8.13 gives the tripwires.

27.6.12 F4.12 The Missing Null

Signature. A research group with five preregistrations and two publications. Nulls are harder to place and less rewarding to write.

Fix. PC1 and PC8. Publish. Title it.

27.7 7 Worked example: the suite applied to a true model and to a null

One subject. Sixty-one periods of daily observation. `N = 7` distinguishable framings audited by the category audit [Curzi, 2026c], so `ln N = 1.945910`. Input variant A: `S_t = F(U_t) = ln(1 + 6 U_t)`. `Y_t` is a magnitude-estimate proxy for internalised structure on a ratio scale constructed by the procedure of Stage 2 in Section 8. `Chat_t` is an independently measured daily load series.

The data are **simulated**, stated plainly rather than buried: the point is to show what the suite does when the truth is known, which is impossible with real data. Generating parameters `delta = 0.15`, `eta = 0.40`, so `a_true = 0.85` and `b_true = 0.40`, process noise sd 0.06, no rating noise. **Every number below was computed, not asserted.**

27.7.1 7.1 The preregistration, in force before period 0

```
period length      1 day
split              T_train = 40 (periods 0–40), T_holdout = 20 (periods 40–60)
input variant      A
baselines          persistence; direct-input (raw u); matched AR with intercept;
```

```
                    shuffled input, three families reported
  surrogates        B = 2000 per family
  minimum u span    0.60 for the direct-input comparison to be informative
  design controls   DC2 (separate channels) and DC3 (prospective sampling)
  rules             Rule 1, Rule 2, Rule 3 as stated in §3.3
```

27.7.2 7.2 The training window

```
  u_t   over periods 0–39:  min 0.1248   max 0.6732   span 0.5484
  S_t   over periods 0–39:  min 0.5590   max 1.6173   mean 1.1746
                            span 1.0583 = 0.544 * ln N
  Chat_t mean over 0–39:    0.1136
  Y_t   over periods 0–40:  min 1.8722   max 2.6917   mean 2.3055   sd 0.1961
                            Y_0 = 2.0000, Y_40 = 2.3843
```

The observed span of `u` is 0.5484, which is below the preregistered minimum of 0.60. By S4.11 the direct-input comparison must therefore be reported as uninformative, and it will be below, even though the model happens to beat it. That is what a preregistration is for: the rule was written before the number was known, and the rule is honoured against the researcher's interest.

27.7.3 7.3 The fit, then the freeze

Constrained least squares on `(Y_{t+1} + Chat_t)` against `[Y_t, S_t]`, bounds `a` in `[0,1]`, `b >= 0`:

```
  a_hat = 0.8833      ->  delta_hat = 1 - 0.8833 = 0.1167
  b_hat = 0.3340      ->  eta_hat   = 0.3340
```

No boundary hit. Rule 3 does not fire.

Honest note on the point estimates, the most instructive line in this example. The true values are `a = 0.85` and `b = 0.40`; at `T = 40` with this noise the sampling standard deviations are 0.0341 for `b_hat` and 0.0173 for `a_hat`. The estimates sit at **-2.15 standard errors on `b` and +2.13 on `a`** — a tail draw in opposite directions, which is the correlated error the two coefficients trade between them.

A single forty-period window on a single subject recovered `eta` as 0.3340 when the truth was 0.4000: a 16.5 per cent underestimate, with everything measured perfectly and no rating noise at all. (The source manuscript rounds this to 17 per cent; `1 - 0.3340/0.4000 = 0.165` exactly, and the smaller figure is used here.) This is why §4.11 refuses to treat one person's `eta` from one window as a measured constant, and it is why Stage 3 of the programme in Section 8 asks for 120 to 240 periods rather than 40.

Frozen quantities derived from the fit, computed once and never revised:

```
  time constant      tau = 1/delta_hat = 1/0.1167 = 8.57 periods
  95% settling       ~3 tau = 25.7 periods
  implied Q_inf      (b_hat * mean S - mean Chat) / delta_hat
                   = (0.3340 * 1.1746 - 0.1136) / 0.1167 = 2.3883
                     (2.3885 at full precision)
  headroom at Y=2.39 h = eta*ln N - delta*Q - C
                   = 0.3340 * 1.945910 - 0.1167 * 2.39 - 0.115
                   = 0.6499 - 0.2789 - 0.1150 = 0.2560
```

Headroom is positive, so growth is permitted [Curzi, 2026b]. Note that `delta_hat * Q_inf = 0.2787` consumes most of the structural budget `eta_hat * ln N = 0.6499` at the fixed point — which is the steady-state theorem of the leaky-integrator analysis doing its arithmetic [Curzi, 2026a], not a finding.

27.7.4 7.4 The held-out window: periods 40 through 60

The frozen model, scored one step ahead against observed `Y_t`. First eight held-out periods in full:

t	u_t	S_t	Chat_t	Y_t	predicted	actual	error
40	0.3598	1.1501	0.1079	2.3843	2.3823	2.2926	−0.0897
41	0.6597	1.6011	0.1071	2.2926	2.4526	2.3476	−0.1050
42	0.6269	1.5606	0.1280	2.3476	2.4669	2.4080	−0.0589
43	0.4145	1.2490	0.1231	2.4080	2.4210	2.5253	+0.1042
44	0.1839	0.7435	0.1003	2.5253	2.3786	2.3176	−0.0610
45	0.3606	1.1517	0.1239	2.3176	2.3078	2.2891	−0.0187
46	0.2157	0.8304	0.1210	2.2891	2.1783	2.2166	+0.0383
47	0.1662	0.6918	0.1064	2.2166	2.0826	2.0749	−0.0077

Held-out summary: mean absolute error 0.0593; held-out `Y` mean 2.3001, sd 0.1978; held-out `u` span 0.4935.

27.7.5 7.5 The five-row report

predictor	RMSE	skill vs model	note
frozen model	0.0777	--	a=0.8833 b=0.3340
persistence	0.1207	0.5860	
direct-input (raw u)	0.0842	0.1486	span 0.548 < 0.60: UNINFORMATIVE
matched autoregressive	0.1248	0.6123	a=0.8422, c=0.4866
shuffled input, iid	0.1267	0.6238	B=2000, p = 0.0000
shuffled input, block L=5	0.1256	0.6174	B=2000, p = 0.0000
shuffled input, circular	0.1300	0.6428	B=2000, p = 0.0000

Surrogate distributions, 5th percentile — the best that any permutation achieved:

```
iid       5th percentile 0.1162   (model 0.0777)
block     5th percentile 0.1132   (model 0.0777)
circular  5th percentile 0.1196   (model 0.0777)
```

Not one of the six thousand surrogates across the three families produced a held-out error as small as the ordered model's. The best single permutation, out of 2000 block permutations, still predicted 46 per cent worse than the true ordering.

27.7.6 7.6 The three rules, applied

```
RULE 1  SHUFFLE       Calibrated critical value from the preregistered design
                      simulation: reject at p <= 0.05 for the block family, whose
                      measured false-positive rate on this design was 0.060 against
                      a nominal 0.050. Observed p = 0.0000 with B = 2000.
                      DOES NOT FIRE.

RULE 2  AUTOREGRESSION  Skill against matched AR = 0.6123, positive and large.
                      DOES NOT FIRE.

RULE 3  CONSTRAINTS   a_hat = 0.8833 strictly inside [0,1]; b_hat = 0.3340 > 0;
                      no boundary hit; unconstrained fit also inside the box.
                      DOES NOT FIRE.
```

Verdict: the model survives its own falsification suite on this subject and this window, with `delta_hat = 0.117 +- 0.017` and `eta_hat = 0.334 +- 0.034` at one standard error, both point estimates biased by roughly two standard errors in this particular draw. That last clause belongs in the abstract, not the appendix.

27.7.7 7.7 The same suite, run on a null

Now the honest negative, the half of the worked example that matters most. Same procedure, same period length, same instrument, same forty training periods — but `Y` is generated by a smooth process that has nothing to do with `S`. There is no relationship to find. The suite should say so.

```
fitted a_hat = 1.0000  ->  delta_hat = 0.0000     BOUNDARY HIT: Rule 3 event
fitted b_hat = 0.0931  ->  eta_hat   = 0.0931

in-sample R^2 on the training window: 0.6477

held-out RMSE   frozen model            0.0978
                persistence             0.0730
                direct-input            0.1116
                matched autoregressive  0.0681
                shuffled iid, mean      0.0793    p(shuffle <= model) = 0.999
                shuffled circular, mean 0.0763    p(shuffle <= model) = 1.000

skill vs matched autoregressive: -1.0669
```

Read that block slowly; it is the shape of a false result and every line is diagnostic.

The in-sample `R^2` is 0.6477, which presented alone reads as a solid finding. The frozen model is then beaten on held-out data by persistence (0.0730 against 0.0978), beaten decisively by matched autoregression (0.0681, skill -1.0669), and beaten by essentially every one of 2000 circular-shift surrogates — p = 1.000, meaning the permuted inputs predicted *better* than the true ordering, which is what happens when the true ordering carries no information. And the constrained fit hit the wall: `a_hat = 1.0000` exactly, the optimiser pressing against a boundary it was not allowed to cross. By S4.6 that goes in the abstract.

```
RULE 1  SHUFFLE        p = 1.000.  FIRES.
RULE 2  AUTOREGRESSION skill = -1.0669.  FIRES.
RULE 3  CONSTRAINTS    a_hat at the boundary.  FIRES.

VERDICT: FALSIFIED on this subject and this window. All three rules.
```

The correct report, in full:

> *We preregistered the minimal estimation model for a single subject over 61 daily periods, fitted on 40 and froze. The frozen model failed on held-out data against all four baselines. The shuffled-input control, run with B = 2000 circular-shift surrogates and a critical value calibrated by simulation on our own design, predicted held-out order as well as or better than the true input ordering (p = 1.000). The matched autoregressive baseline beat the model with a skill score of -1.0669. The constrained fit hit the retention boundary at a = 1.000. All three preregistered falsification rules fired. In this subject, over this window, with this operationalisation, internal surplus does not predict stored order.*

That paragraph is a good outcome. It cost the same as the other one, it is fully informative, and it is publishable under PC8. **The suite that produced the confirmation in the first half of this example is the same suite, unchanged, that produced the refutation in the second half, and neither result required the analyst to exercise a single judgement after the freeze.**

27.7.8 7.8 What this example does not establish

The limits, because the example is seductive:

```
It does not establish that the model holds for this subject in general.
    One window. Stage 3 of Section 8 asks for two, then more.

It does not establish that eta = 0.334 is a property of this person.
    The measured noise floor at T=40 is far above the difference between
    0.334 and 0.400. FVP-7 has not been attempted here.

It does not establish that the logarithmic input form is correct.
    The u span was 0.548, below the preregistered minimum. Reported.

It does not rule out fabricated timing.
    DC2 and DC3 were in force; DC1 (blinding) was not. Under uncontrolled
    conditions the measured pass rate for a fabricated relationship is
    52.7 per cent, so this omission is material and is stated as such.

It does not establish anything at group scope.
    Stage 5 of Section 8.
```

Five limitations, each named, each with the study that would remove it. That list is not an apology appended to a result. **It is the result: a claim, its exact boundary, and the next experiment.**

A framework that cannot fail cannot be trusted. This one fails at three named rules, on data whose truth we control, in the second half of its own worked example — and the next chapter lays out, in order and with its kill conditions, the programme that would put those rules in front of real people.

27.8 8 A staged research programme, costed, with twenty-one kill conditions

This section proves nothing empirical and measures nothing. It states a plan, and prices it.

Badged as a proposed programme, not as a result: the five stages below, run in order with the kill conditions stated at each, would settle whether the framework's single-person formulas are measurements. Every number in it is either arithmetic from a declared assumption or a simulation of a declared design. No stage has been run. Saying so in the first paragraph is the only honest way to open a chapter of this kind.

```
THE PROGRAMME

  STAGE 1   PILOT OPERATIONALISATION
            Fix what D, P, and E mean for one subject, in units.
            Gate: FVP-1 (dimensions), FVP-3 (limiting cases)

  STAGE 2   RATIO-SCALE CONSTRUCTION
            Build ratio scales for D, P, E by magnitude estimation and
            cross-modality matching. Verify transitivity.
            Gate: FVP-2 (scale type) -- the gate that licenses division

  STAGE 3   SINGLE-SUBJECT REPEATED MEASURES
            Estimate delta and eta within one person, repeatedly, and ask
```

```
           whether they are stable properties of that person.
           Gate: FVP-5 (identifiability), FVP-6 (falsification)

STAGE 4    CROSS-SUBJECT PARAMETER RECOVERY
           Same operationalisation, many people, two labs. Do the
           parameters recover?
           Gate: FVP-7 (reproducibility) -- MAKE OR BREAK

STAGE 5    PREREGISTERED FIELD TRIALS AT GROUP SCOPE
           Cluster-randomised, time-series, held-out prediction.
           Gate: FVP-6 at the external scope; the correspondence claim of
           the internal/external correspondence claim becomes testable here and only here
```

The ordering is not a preference. **Each stage consumes the output of the one before it, and running any stage before its predecessor has cleared produces a number that cannot be interpreted.** Estimating `eta` (Stage 3) on a scale not shown to be ratio-scaled (Stage 2) yields a coefficient in unknown units; comparing it across people (Stage 4) compares unknown units to unknown units; deploying it at group scope (Stage 5) does so at institutional expense.

27.8.1 8.1 The governing principle

A programme that cannot be killed at any stage is not a research programme. It is a research aspiration with a schedule attached.

Every stage below carries four blocks, and the third is what makes it a programme:

```
WHAT IS MEASURED
WHAT WOULD ADVANCE IT
WHAT WOULD KILL IT AT THIS STAGE
SCALE AND TIMESCALE
```

The kill conditions are written to be recognisable in advance and unpleasant to reach. A kill condition a determined investigator can argue past is a decoration; §8.13 gives the tripwires for the specific ways such arguments get made.

27.8.2 8.2 What is proven and what is postulated

Proven. Nothing empirical. The mathematics used throughout – the surplus functional [Curzi, 2026], the logarithmic ceiling [Curzi, 2026c], and the leaky-integrator solution [Curzi, 2026a] – is proven and is being *applied*, not tested. **The theorems cannot fail; what can fail is the claim that the world's psychological and social quantities are the objects those theorems are about.** That is why a correct mathematical result is no evidence at all that the programme will succeed.

Also proven, used here as design arithmetic and not as findings: Spearman-Brown, the Fisher-z interval for a correlation, the standard error of a log-log slope, the cluster design-effect formula, and the exact scaling `b_hat -> b_hat/g` under an input inflated by `g` (§4.11). All algebra, computed below, not cited.

Postulated, badged. That `D`, `P`, and `E` can be operationalised at all; that the storage law's form applies internally (a declared postulate); that `delta` and `eta` are person-level constants over months rather than moment-level variables; that the internal/external correspondence is more than an analogy. **Every one is exactly what a stage below is designed to break.**

Honesty clauses, repeated. The triangle inequality fails for geometric triples in the framework's own statement of the surplus functional [Curzi, 2026]; subadditivity holds on `u` only. As deployed, the surplus functional is a lower bound on the ensemble's information — we log the floor, not the ceiling. The surplus functional is a mathematical object and carries no empirical

or metaphysical claim; the framework does not identify surplus with Shannon entropy or mutual information; and it proves no thermodynamic negentropy law, since `F(u) + N_can(u) <= ln N` and higher static surplus does not imply higher canonical concentration [Curzi, 2026,c].

27.8.3 8.3 The field this programme is entering

Psychology and sociology are not pseudoscience. They are sciences with a measurement problem and a replication problem. The Open Science Collaboration attempted 100 replications: 97 originals had reported significant results, about 36 per cent of replications did, and effect sizes roughly halved [Open Science Collaboration, 2015, Ioannidis, 2005]. The measurement problem is the deeper of the two: Michell [1997] argues that psychology systematically fails to test whether its attributes are quantitative at all before measuring them, and that objection applies to this framework's central quantities without amendment [Michell, 1999].

Formulas do not make a field hard. Ratio-scale, reproducible, falsifiable measurement of the formulas' terms does. Psychophysics achieves it [Weber, 1834, Fechner, 1860, Stevens, 1957], and psychometrics comes close through the Rasch model's separation of person and item parameters [Rasch, 1960, Andrich, 1988]. This programme is an attempt to bring the framework's single-person formulas onto that footing, not an attempt to prove them.

27.8.4 8.4 Stage 0 — preconditions

Four things must exist before Stage 1. None is research; starting without them guarantees a Stage 1 that cannot be interpreted.

```
SP1 A WRITTEN THEORY OF THE SUBJECT.
    Which construct is Q for this subject? Not "wellbeing". Something
    that could in principle be destroyed by a year of neglect and rebuilt
    by a year of practice: a skill, a body of knowledge, a settled habit
    of attention, a repertoire.

SP2 A CANDIDATE ORDER PROXY THAT IS NOT A REPACKAGING OF U.
    The order-proxy trap. Write the argument down and test it: could Y rise in a
    period of intense interaction that produced nothing durable? If no,
    Y is measuring U.

SP3 AN INDEPENDENT COST INSTRUMENT.
    C in the same units as eta*S. If cost cannot be measured, the model
    is fitted without it and is a weaker model (F4.1).

SP4 ETHICS AND CONSENT INFRASTRUCTURE, INCLUDING COSTLESS REFUSAL.
    The fourth standing refusal: no intervention removes a person's ability to
    decline. In a measurement programme that means refusal to be measured
    must be available, costless, and recorded as ordinary missing data.
```

Stage 0 has no kill condition because it has no result. It has an entry condition: all four of SP1-SP4, in writing, before recruitment.

27.8.5 8.5 Stage 1 — Pilot operationalisation of D, P, and E for a single subject

What is measured

One subject, 45 sessions, three candidate instruments per term:

```
D  PERSPECTIVE, the frame brought to the moment.
     D-a  prior-expectation elicitation, with a confidence, before the
          episode
     D-b  frame inventory: which of the subject's N audited framings
          (the audited framing set) were active, weighted
     D-c  magnitude estimate of "how strongly I already knew what this
          would be like", against a fixed modulus

P  PERCEPTION, the intake from the moment.
     P-a  detail-recall count, scored against a record
     P-b  discrepancy report: what departed from D-a, with magnitude
     P-c  magnitude estimate of "how much came in", same modulus

E  ENVIRONMENT, the situation itself.
     E-a  independently coded situational richness from a record
     E-b  physical-parameter panel where the room is the environment
          (acoustics, light, sittable space, sightlines)
     E-c  magnitude estimate of "how much was there to be had"
```

The purpose is not to find the right instrument. **It is to find out whether `D` and `P` can be put in the same units at all**, because FVP-1 requires `r = D/P` to be dimensionless — a far stronger demand than that both be numbers. This is the least glamorous stage and the one most often skipped by starting straight from a questionnaire.

Per candidate: session-level reliability (internal consistency across items, Cronbach, 1951, read with the warning that alpha is neither a reliability coefficient nor a measure of homogeneity, Sijtsma, 2009), test-retest reliability (across sessions, short interval), and convergent and discriminant correlation across the three candidate instruments, which is the multitrait-multimethod design [Campbell and Fiske, 1959, Cronbach and Meehl, 1955].

What would advance it

```
A1  One operationalisation of D and one of P share units, with a written
    argument for the shared unit and a demonstrated common zero.

A2  Session-level reliability >= 0.80 for at least one instrument per term.

A3  Test-retest r >= 0.70 across a one-week interval, 95 per cent lower
    bound above 0.50.

A4  FVP-3's four limiting cases are observable and recognisable: P -> 0
    (frame with no intake), D -> 0 (intake with no frame), E -> 0, and
    D = P (calibrated contact). If none can be produced or recognised in
    a real session, the formula's structure has no referent.
```

A3 sets the sample size. The 95 per cent interval on an observed correlation, by Fisher-z:

n	95% CI on an observed r = 0.70	width
10	[0.126, 0.923]	0.797
20	[0.373, 0.872]	0.499
30	[0.454, 0.847]	0.392
50	[0.524, 0.819]	0.295
80	[0.568, 0.797]	0.230
120	[0.595, 0.781]	0.186
200	[0.622, 0.764]	0.143

The smallest `n` at which an observed `r = 0.70` has a 95 per cent lower bound above 0.50 is 41. Thirty sessions is therefore under-powered for A3, and the honest choices are 41 or more sessions, or relaxing A3 to a lower bound above 0.40 and saying so in advance. This manual takes the first and sets Stage 1 at 45 sessions.

A2 sets the item count. Spearman-Brown, `r_k = k*r1/(1 + (k-1)*r1)`:

single-item r1	items for reliability 0.80	for 0.90
0.10	37	82
0.15	23	52
0.20	17	37
0.30	10	22
0.40	7	14
0.50	5	10

If the single-item reliability of a `P` instrument is 0.15, a session score needs 23 items to reach 0.80 and 52 to reach 0.90. That is what decides session length, and why Stage 1's session is 25 minutes rather than five.

What would kill the programme at this stage

```
K1.1  NO SHARED UNIT. After honest effort, no operationalisation of D and
      P can be expressed in the same units with a common zero.
      CONSEQUENCE: D/P is not a ratio. M = (D/P)E is not an equation.
      By FVP-2 it must be demoted in print to a heuristic ordering, and
      the moment equation ceases to be a formula in the framework's sense.
      The storage law survives; the Moment equation does not.

K1.2  NO RELIABLE INSTRUMENT. No candidate reaches session reliability
      0.80 with a session under 45 minutes.
      CONSEQUENCE: the attenuation analysis of §4.9 applies with force -- at
      rating sd 0.40 against signal sd near 0.20, delta was estimated at
      0.432 against a true 0.150. Estimates on such an instrument are not
      noisy but systematically wrong. The programme cannot proceed.

K1.3  THE LIMITING CASES HAVE NO REFERENT. Neither the subject nor a
      trained observer can identify instances of P -> 0, D -> 0, or
      D = P in the subject's own record.
      CONSEQUENCE: FVP-3 fails. A formula whose divergences correspond
      to nothing nameable is not describing the phenomenon.

K1.4  Y IS A REPACKAGING OF U. The candidate order proxy rises with
      interaction volume and with nothing else.
      CONSEQUENCE: the named order-proxy error. Return to Stage 0 SP2 or
      stop.
```

K1.1 is the most likely kill in the whole programme and the one people will most want to argue past. **That "perspective" and "perception" are expressible in a common unit is not obvious, is not established, and is the load-bearing assumption of the entire Moment equation.** The honest outcome of a failed Stage 1 is a chapter saying the Moment equation is a heuristic ordering — useful for diagnosis, illegitimate for arithmetic — and the formula-validation protocol already specifies what that demotion looks like in print [Curzi, 2026t].

Scale and timescale

```
subjects            1  (plus 1 replication subject, run in parallel)
```

```
sessions           45  at 3 per week
session length     25 minutes x 3 instruments per term
subject burden     45 x 25 x 3 / 60 = 56.3 subject-hours
fieldwork          45 / 3 = 15 weeks = 3.5 months
total stage        7 months including instrument development and analysis

researcher hours (itemised, assumptions declared not cited):
   instrument development and piloting            160.0
   session supervision                             37.5
   coding at 2x subject time                       75.0
   analysis and FVP-1/2/3 write-up                 80.0
   preregistration drafting                        24.0
   ------------------------------------------------
   TOTAL                                          376.5
```

Seven months and about 377 researcher-hours to find out whether the framework's central single-person formula has units. A cheap way to learn something decisive, and the correct first expenditure because a failure here saves the other five years.

27.8.6 8.6 Stage 2 — Ratio-scale construction

What is measured

Magnitude estimation and cross-modality matching on the instruments that survived Stage 1.

```
MAGNITUDE ESTIMATION
  A modulus is presented and assigned a number; each subsequent stimulus
  is assigned a number in proportion. Fit log psi = log k + a log I and
  read the exponent a.

CROSS-MODALITY MATCHING
  The subject adjusts a stimulus in modality B until it matches one in
  modality A. The matching exponent is predicted by the ratio of the two
  modalities' own exponents. This is the transitivity test, and it is the
  actual evidence that the scale is a ratio scale and not a numbering
  habit.
```

The published exponents are constants of a *procedure* rather than of nature: they vary with method, range and instruction [Stevens, 1957, 1975, Teghtsoonian, 1971], and the catalogue of ways a magnitude-estimation procedure biases its own exponent is long and was written by a critic [Poulton, 1968, 1979]. The century-long dispute over whether the underlying law is logarithmic or a power function is better read through Krueger [1989] than adjudicated here. The nominal values:

```
Loudness (1 kHz)     a ~ 0.67     compressive
Brightness           a ~ 0.33     compressive
Visual length        a ~ 1.0      linear
Taste (salt)         a ~ 1.3      expansive
Heaviness (lifted)   a ~ 1.45     expansive
Warmth on arm        a ~ 1.6      expansive
Electric shock       a ~ 3.5      strongly expansive
```

These are the calibration ladder. **`D`, `P`, and `E` are anchored by matching against modalities whose exponents are already known, which is what converts a number the subject produced into a measurement.** What must be true of a subject's judgements for that conversion to be

licensed is itself an axiomatic question with a literature [Luce, 2002, Narens, 1996], and the decisive formal test – whether the attribute has additive quantitative structure at all – is conjoint measurement [Luce and Tukey, 1964, Krantz et al., 1971]. **Stage 2 as specified below does not run the conjoint test.** It runs cross-modality matching, which is weaker evidence for the same conclusion, and the gap is recorded in Section 19.

What would advance it

```
B1  Each of D, P, E yields a stable within-subject exponent across
    sessions, with a usefully small standard error.

B2  Cross-modality matching is TRANSITIVE within measurement error:
    a_AC = a_AB * a_BC.

B3  D and P yield exponents consistent with a common unit, so r = D/P is
    dimensionless (Stage 1's A1, now quantitative).

B4  A true zero is demonstrable for both D and P: a condition reliably
    assigned magnitude zero, not merely the smallest number used.
```

The precision arithmetic sets the number of judgments. For a log-log regression, `SE(a) = sigma_resid / (sd(log I) * sqrt(n))`, and with stimulus levels spread evenly over a span of `L` decades, `sd(log I) = L/sqrt(12)`:

```
residual sd 0.25 log10 units; stimulus span in decades:

  n \ span     1.0      1.5      2.0      3.0
    20        0.1936   0.1291   0.0968   0.0645
    40        0.1369   0.0913   0.0685   0.0456
    60        0.1118   0.0745   0.0559   0.0373
   100        0.0866   0.0577   0.0433   0.0289
   200        0.0612   0.0408   0.0306   0.0204
   400        0.0433   0.0289   0.0217   0.0144

judgments needed at a 2.0-decade span:
   SE(a) <= 0.05  ->  n =  75
   SE(a) <= 0.03  ->  n = 209
   SE(a) <= 0.02  ->  n = 469
```

Two design decisions fall out of that table. First, span matters as much as count: going from 1.0 to 2.0 decades halves the standard error at every `n`, the same gain as quadrupling the judgments. Widen the range before lengthening the session. Second, `SE(a) <= 0.02` costs 469 judgments per exponent — a real afternoon per term per subject.

The transitivity test's power depends on that precision. Take a chain with `a_AB = 0.67` and `a_BC = 1.45`, so predicted `a_AC = 0.9715`:

```
SE per exponent    predicted a_AC       SE of (a_AC - a_AB*a_BC)    detectable at 95%
     0.02          0.9715 +- 0.0319           0.0377                    0.0739
     0.05          0.9715 +- 0.0799           0.0942                    0.1847
     0.10          0.9715 +- 0.1597           0.1885                    0.3694
```

At `SE = 0.10` per exponent, a transitivity violation smaller than 0.37 cannot be detected, and a violation of 0.37 is enormous. A transitivity test on imprecise exponents is not a test but a guarantee of agreement. This is how the ratio-scale claim gets made without being earned, and why B1's precision requirement precedes B2's transitivity requirement.

Session arithmetic for the stage:

```
9 stimulus levels x 6 replications x 6 sessions x 3 modalities
    = 972 judgments per subject per term
x 3 terms (D, P, E)
    = 2,916 judgments per subject
at 8 seconds per judgment
    = 6.48 subject-hours per subject
6 subjects
    = 38.9 subject-hours total
```

972 judgments per term per subject clears the `n = 469` requirement for `SE(a) <= 0.02` on each modality separately, which is the precision the transitivity test needs.

What would kill the programme at this stage

```
K2.1  NO STABLE EXPONENT. The fitted exponent for D or P varies across
      sessions by more than its own standard error by a wide margin.
      CONSEQUENCE: the subject is not using the number line consistently.
      There is no scale to build on. FVP-2 fails.

K2.2  TRANSITIVITY VIOLATED. a_AC differs from a_AB * a_BC by more than
      the detectable threshold above.
      CONSEQUENCE: the judgments are not measurements of a single
      underlying magnitude. Classic and decisive evidence that a putative
      ratio scale is not one.

K2.3  NO TRUE ZERO. No condition is reliably assigned magnitude zero for
      D or for P.
      CONSEQUENCE: the scale is at best interval, and on Stevens'
      typology division is impermissible on an interval scale.
      D/P is meaningless as written. Demote the moment equation
      in print.

K2.4  D AND P LAND IN INCOMPATIBLE UNITS. Their exponents cannot be
      reconciled to a common unit.
      CONSEQUENCE: as K1.1, now with numbers attached.
```

K2.3 is worth stating twice. **A subjective quantity with no true zero cannot be divided by another, and the entire content of `M = (D/P)E` is a division.** The scale-type taxonomy that makes this a rule rather than a preference is Stevens [1946]'s, and the corpus's own meaningfulness theorem states the same condition sharply: a quotient is meaningful if and only if the admissible transformation group is similarity, that is, if and only if the scale is ratio [Curzi, 2026t]. The programme's most probable non-trivial outcome is not that the Moment equation is false but that it is not an equation — that `r = D/P` survives as an ordering as an ordering rather than a quotient [Curzi, 2026t] while ceasing to be a number. That is a genuine finding, and the formula-validation protocol specifies how to print it [Curzi, 2026t].

Scale and timescale

```
subjects            6
judgments        2,916 per subject; 17,496 total
subject burden    6.48 hours per subject; 38.9 hours total
fieldwork         6 sessions per term at 1 per week; terms run in parallel
                  = 6 weeks
total stage       4 months including apparatus construction and analysis
```

```
researcher hours:
   session supervision at 1.0x subject time         38.9

   independent replication wave                    200.0
   writing                                         120.0
   ------------------------------------------------
   TOTAL                                           778.9
```

27.8.7 8.7 Stage 3 — Single-subject repeated measures

What is measured

Three subjects who cleared Stages 1 and 2, sampled four times daily for 240 days. Per period: `Y_t` on the constructed scale, `U_t` over the subject's own audited framings, `Chat_t` from the independent cost instrument. The suite of Section 4 is applied per subject: fit on the first 120 periods, freeze, predict the second 120, four baselines, three rules.

The question is not "does the model fit" but **"are `delta` and `eta` properties of this person, or of the window in which they were estimated?"**

What would advance it

```
C1  The frozen model clears all three falsification rules on held-out
    data, per subject, with a calibrated surrogate test.

C2  Within-person split-half reliability of b_hat is at least 0.80.

C3  a_hat lies strictly inside [0,1] in every subject, no boundary hit.

C4  No systematic drift: first-half parameters predict the second half,
    and second-half parameters predict the first, to within sampling
    error.
```

The precision arithmetic, simulated at true `a = 0.85`, true `b = 0.40`, process noise 0.06, rating noise 0.10, 400 replications per row:

T	mean a_hat	sd a_hat	mean b_hat	sd b_hat	95% CI half-width on b
30	0.8174	0.0409	0.4604	0.0781	0.1532
60	0.8224	0.0248	0.4521	0.0494	0.0968
90	0.8242	0.0207	0.4487	0.0411	0.0805
120	0.8236	0.0166	0.4513	0.0331	0.0649
180	0.8252	0.0137	0.4485	0.0278	0.0545
240	0.8248	0.0119	0.4488	0.0243	0.0476
360	0.8257	0.0097	0.4476	0.0198	0.0388

Two features of that table are the reason Stage 3 exists.

First, the bias. At every `T`, `b_hat` sits near 0.449 against a true 0.400 — a persistent 12 per cent upward bias that does not shrink with more data, because it is not sampling error but the attenuation of §4.9 at rating noise 0.10. More periods buy precision, not accuracy. **Only a better instrument buys accuracy, and that is Stage 2's job.**

Second, the cost of precision. Halving `sd(b_hat)` from 0.0494 to 0.0243 means going from 60 periods to 240 — four times the fieldwork for twice the precision, the ordinary square-root law, worth stating in weeks:

```
T = 120 at daily sampling      = 17.1 weeks =  3.9 months
T = 120 at twice-weekly        = 60.0 weeks = 13.8 months
T = 240 at daily sampling      = 34.3 weeks =  7.9 months
```

The middle row is why daily sampling is not optional. **Twice-weekly sampling turns a four-month study into a fourteen-month study for the same precision, and a fourteen-month study has a different `delta` at the end than at the beginning.**

Power to detect a genuine within-person *change* in `eta` between two blocks, with `SE_diff = sqrt(2) * sd_b`:

T	SE_diff	power at d=0.05	d=0.10	d=0.20
60	0.0698	0.110	0.299	0.817
90	0.0581	0.138	0.406	0.931
120	0.0469	0.187	0.569	0.990
180	0.0393	0.246	0.720	0.999
240	0.0344	0.307	0.829	1.000
360	0.0280	0.432	0.947	1.000

Two blocks of 120 periods give 57 per cent power to detect a change in `eta` of 0.10 and 19 per cent for a change of 0.05. Any claim that a practice, therapy, habit or season changed a person's conversion efficiency by a small amount is, at these sizes, undetectable. Stating that in advance prevents the commoner outcome, which is detecting it anyway.

Burden: 960 prompts per subject at about 90 seconds each — 24 subject-hours over eight months. Adherence is itself a threat; it must be measured and reported, and missing periods handled by the preregistered rule, never by interpolation chosen after the fact.

What would kill the programme at this stage

```
K3.1  ANY OF THE THREE RULES FIRES IN A MAJORITY OF SUBJECTS.
      Shuffle not beaten, matched AR not beaten, or a boundary hit.
      CONSEQUENCE: the storage law does not describe this subject's
      internal dynamics. Report it (PC8) and stop.

K3.2  SPLIT-HALF RELIABILITY OF b_hat BELOW 0.50.
      The simulated benchmark at 60 periods per half is 0.841 and at 240
      per half is 0.962. A real figure below 0.50 means the parameter is
      a property of the window.
      CONSEQUENCE: eta is not a person-level constant on the months
      timescale. Stage 4 is meaningless and must not be attempted.

K3.3  SYSTEMATIC SAME-DIRECTION DRIFT in a_hat or b_hat across blocks,
      in every subject.
      CONSEQUENCE: the constant-parameter postulate fails. A time-varying
      rescue must be preregistered as a NEW prediction (§8.13), never
      adopted as an explanation of this failure.

K3.4  THE DESIGN CONTROLS FAIL. Debriefing reveals subjects inferred the
      hypothesis, and no blinding or channel separation was in force.
      CONSEQUENCE: §4.8 measured a 52.7 per cent pass rate
      for fabricated relationships under those conditions. The data
      cannot be interpreted however good they look.
```

K3.4 will be tempting to waive because the data will already exist. **Waiving it converts eight months of fieldwork into eight months of fieldwork that means nothing — exactly the outcome the waiver is trying to avoid and exactly the outcome it produces.**

Scale and timescale

```
subjects            3  (each analysed separately; no pooling at this stage)
periods           240  per subject, daily, 4 prompts per day
prompts           960 per subject; 2,880 total
subject burden     24 hours per subject; 72 hours total
fieldwork        34.3 weeks = 7.9 months
total stage        12 months including pipeline build and analysis

researcher hours:
   adherence monitoring (3 x 34.3 weeks x 0.5 h)     51.4
   data pipeline build                              200.0
   surrogate calibration simulations                120.0
   per-subject fits, split-half, analysis           300.0
   writing                                          160.0
   ------------------------------------------------------
   TOTAL                                            831.5
```

27.8.8 8.8 Stage 4 — Cross-subject parameter recovery: the make-or-break stage

What is measured

Forty subjects, 120 daily periods each. **The identical protocol run independently in two laboratories that have never met, working from the published Stage 1-3 protocol alone.**

That last clause is the stage. Everything before it can be done by one group with one set of habits. FVP-7 asks whether the parameters survive a different group's reading of the same written procedure, and the framework names it the gate that decides the measurement question and the one most often skipped. Three questions:

```
Q1  Do individual differences in delta and eta EXIST -- is the spread
    across people larger than the estimator's noise?

Q2  Do they RECOVER -- does a person's estimated parameter correlate with
    that person's true parameter, insofar as a second estimate can serve
    as a proxy for truth?

Q3  Do they TRANSPORT -- does lab 2 get the same numbers as lab 1, and if
    not, is the disagreement a single scaling constant or a pattern?
```

The noise floor, and why Q1 comes first

The arithmetic most individual-differences research omits. Simulate sixty subjects who share one true `eta` and see how much variation the estimator invents:

```
THE NOISE FLOOR -- 60 subjects who truly share eta = 0.40

  T per subject      sd of b_hat across subjects
      60                    0.0478
     120                    0.0355
     240                    0.0255
     360                    0.0166
```

At 120 periods per subject, an estimator applied to sixty identical people reports a between-person standard deviation of 0.036 in `eta`. Any individual-differences claim resting on a

smaller spread is a claim about the estimator, not about people. An independent 30-subject run with the true spread set to zero produced 0.042: same conclusion, different seed.

The consequence for Q2, with 30 subjects at 120 periods:

true between-person sd of eta	corr(true, estimated)
0.12	0.956
0.04	0.503

The second row is not an estimator failure. **It is what happens when the quantity varies less across people than the instrument's error, and no number of subjects repairs it — only longer series per subject or a quieter instrument.**

Power to reject "everyone shares one `eta`", testing the observed spread against a simulated noise floor at one-sided 5 per cent:

n	T	true between-sd	critical sd	power
20	120	0.05	0.0415	0.97
20	120	0.10	0.0428	1.00
40	120	0.05	0.0391	0.98
40	120	0.10	0.0407	1.00
20	240	0.05	0.0298	1.00
40	240	0.05	0.0282	1.00

Twenty subjects at 120 periods already gives 97 per cent power to detect a true between-person standard deviation of 0.05 in `eta`. Forty is comfortable, and the binding constraint is periods per subject, not subjects — the opposite of the usual instinct. **One more month of daily sampling per subject buys more than ten more subjects.**

Reliability of the person-level estimate, and the ceiling it puts on everything downstream:

T	between-sd	var_err	reliability	max corr with any external variable
120	0.05	0.00126	0.665	0.815
120	0.10	0.00126	0.888	0.942
120	0.15	0.00126	0.947	0.973
240	0.05	0.00065	0.793	0.891
240	0.10	0.00065	0.939	0.969
240	0.15	0.00065	0.972	0.986

Before correlating `eta` with anything, compute this ceiling and publish it: an observed correlation cannot exceed it, and one reported near it is evidence of a problem, not a discovery.

Q3, and the sharpest criterion in the programme

Two labs, same protocol, different hands. Lab 2's operationalisation of `u` runs 15 per cent hot: a wider framing set, a different inner product, an entirely defensible reading of the procedure. Simulated:

lab 1 mean b_hat	0.4679
lab 2 mean b_hat	0.4068
observed ratio	0.8696
predicted ratio 1/1.15	0.8696

Exact, because the model is linear in its input: scaling `S` by `g` scales `b_hat` by `1/g`. Other calibration errors, equally exact:

```
inflation g      predicted b_hat ratio 1/g
   1.05                 0.9524
   1.10                 0.9091
   1.15                 0.8696
   1.25                 0.8000
   1.50                 0.6667
```

The criterion:

```
BETWEEN-LAB CRITERION

A CONSTANT FACTOR across all subjects, matching 1/g for an independently
measurable operationalisation difference g
    -> CALIBRATION difference. Repairable. Publish the constant.

A FACTOR THAT VARIES ACROSS SUBJECTS, or any change in the RANK ORDER of
subjects between labs
    -> THEORY FAILURE. The parameter is not a property of the person.
```

A framework passes FVP-7 when between-lab disagreement is a single number, and fails when it is a pattern. That is why Stage 4 is make-or-break: it is the only stage whose failure cannot be attributed to an instrument, a subject, or a window.

What would advance it

```
D1  The between-person spread in eta exceeds the simulated noise floor at
    the study's own n and T, by a margin, in both labs.

D2  Rank order of subjects on eta agrees between labs, to a correlation
    significantly above zero and at or below the published reliability
    ceiling.

D3  Any mean-level disagreement is a single scaling constant matching an
    independently measured operationalisation difference.

D4  Both labs clear the three-rule suite of Section 4 in most subjects.
```

What would kill the programme at this stage

```
K4.1  NO INDIVIDUAL DIFFERENCES. The between-person spread does not clear
      the noise floor at n = 40, T = 120, in either lab.
      CONSEQUENCE: eta and delta are not person parameters. the framework's person-level
      parameter tables describes a species-typical process, not
      individual constants, and every person-level parameter claim must be
      rewritten. Survivable, but a large retraction, printed as one.

K4.2  NO RANK-ORDER AGREEMENT BETWEEN LABS. Lab 1 and lab 2 order the same
      forty subjects differently on eta, beyond sampling error.
      CONSEQUENCE: FVP-7 fails outright. The parameters are properties of
      a procedure and not of a person. THE PROGRAMME STOPS. There is no
      rescue that preserves the claim, because the claim was that these
      are measurements.

K4.3  MEAN DISAGREEMENT THAT IS NOT A CONSTANT FACTOR. Labs differ in a
```

```
       way that varies across subjects and does not track any measurable
       difference in operationalisation.
       CONSEQUENCE: as K4.2. An unexplained, subject-varying between-lab
       discrepancy is the signature of a parameter that does not exist
       independently of who measured it.

K4.4   THE SUITE FAILS IN ONE LAB AND PASSES IN THE OTHER, with no
       identifiable procedural difference.
       CONSEQUENCE: the strongest possible warning. Do not proceed to
       Stage 5. Return to Stage 1 and find the procedural difference, or
       stop.
```

K4.2 is the programme's true kill switch. **If the same forty people get different `eta` orderings from two competent labs following the same written protocol, then `eta` is not a quantity the people have; it is a quantity the procedure makes, and no further work changes that.** Specific objectivity [Rasch, 1960] is the standard being failed: a person's measure depending on which instrument was used is precisely what a measurement is not allowed to do.

Scale and timescale

```
subjects           40 per lab; 80 total across two labs
periods           120 per subject, daily, 4 prompts per day
prompts           480 per subject; 38,400 total
subject burden     12 hours per subject; 960 hours total
fieldwork        17.1 weeks = 3.9 months per lab cohort
total stage        18 months including recruitment, two cohorts,
                   analysis and between-lab reconciliation

researcher hours:
   fieldwork, two labs (recruitment, monitoring, coding)   822.0
   data pipeline adaptation                                150.0
   analysis, noise floor, between-lab reconciliation       500.0

   ------------------------------------------------------------
   TOTAL                                                  1712.0
```

27.8.9 8.9 Stage 5 — Preregistered field trials at group scope

What is measured

Only now does the programme touch institutions, and only now is it entitled to. Two tests, which must not be confused with each other:

```
T1  Does the storage law predict held-out group order, at group scope,
    against the same four baselines? (the suite of Section 4, applied at external scope)

T2  Does an intervention chosen by the framework -- raise eta, cut C, or
    raise u, whichever the headroom gauge says is cheapest \citep{ccp:CCP-008}
    -- outperform an active control chosen by ordinary practice?

T1 is a prediction test. T2 is a causal test. A design that runs only T2
can succeed while the framework is wrong (the intervention worked for
other reasons) and can fail while the framework is right (the
intervention was implemented badly). BOTH ARE REQUIRED.
```

And a third, the one that justifies the single-person scope:

```
T3  Does the internal/external correspondence hold
    QUANTITATIVELY? Are members' internal eta values, measured by Stage
    3–4 methods, related to their group's eta? The correspondence claim asks for the
    cases where the correspondence BREAKS DOWN to be stated honestly, and
    Stage 5 is where they would be found.
```

Design: cluster-randomised, 24 clusters, 20 members each, 52 weekly periods, framework intervention in half and an active control in the other half. Time series throughout, not end-points.

The sample-size arithmetic

`z(0.975) = 1.959964`, `z(0.80) = 0.841621`, so `(z_a + z_b)^2 = 7.848880`. Individual-level `n` per arm for 80 per cent power at two-sided alpha = 0.05, from `n = 2*(z_a+z_b)^2 / d^2`:

```
 d = 0.20      n per arm = 393
 d = 0.30      n per arm = 175
 d = 0.50      n per arm =  63
 d = 0.80      n per arm =  25
```

Clustering inflates this by `DE = 1 + (m–1)*ICC`:

```
m \ ICC     0.01    0.02    0.05    0.10    0.20
  5         1.04    1.08    1.20    1.40    1.80
 10         1.09    1.18    1.45    1.90    2.80
 20         1.19    1.38    1.95    2.90    4.80
 30         1.29    1.58    2.45    3.90    6.80
 50         1.49    1.98    3.45    5.90   10.80
100         1.99    2.98    5.95   10.90   20.80
```

Clusters per arm at `d = 0.30`, 80 per cent power (individual `n` per arm = 175):

```
 m       ICC=0.02   ICC=0.05   ICC=0.10
  8         25         30         38
 12         18         23         31
 20         13         18         26
 30         10         15         23
 50          7         13         21
```

At 20 members per cluster and ICC 0.05, eighteen clusters per arm — 36 in total — are needed for 80 per cent power on a standardised effect of 0.30. The design above specifies 24, which is under-powered for `d = 0.30` at `ICC = 0.05` and adequate for `d = 0.50`. Stated here rather than discovered later: **24 clusters is a pilot-scale trial for a moderate effect and a full-scale trial only for a large one, and the preregistration must say which claim it is entitled to make.**

Time-series length, since T1 requires held-out prediction and not a pre-post comparison:

```
periods   cadence        weeks   years    train / hold out
  26      fortnightly      52    1.00        17 / 9
  52      fortnightly     104    2.00        34 / 18
  52      weekly           52    1.00        34 / 18
 104      weekly          104    2.00        69 / 35
```

Fifty-two weekly periods with a 34/18 split is the minimum giving an 18-period held-out window, which the surrogate test of §4.7 needs for resolution at `B = 999`.

What would advance it

```
E1  T1: the frozen model beats all four baselines on held-out group order,
    with a calibrated surrogate test, in most clusters.

E2  T2: the framework-selected intervention outperforms the active control
    on the preregistered primary outcome.

E3  The headroom gauge PREDICTED which clusters would fail to grow.
    The headroom prohibition says that at h_t < 0 no interaction geometry prevents
    decline, so clusters with negative measured headroom should not have
    grown whatever was done to them. The sharpest external prediction the
    framework makes.

E4  T3: a measurable relation between members' internal parameters and the
    group's, with the breakdown cases identified and printed.
```

E3 is the strongest test available at group scope. **The headroom prohibition [Curzi, 2026b] is a prohibition, and prohibitions are the most falsifiable things a theory can offer: a single cluster with clearly negative headroom that nonetheless grew its order proxy substantially, with `eta`, `C`, and `N` unchanged, is a direct refutation.** No probabilistic hedge protects it.

What would kill the programme at this stage

```
K5.1  T1 FAILS: the model does not beat the baselines on held-out group
      order, with the surrogate calibrated.
      CONSEQUENCE: the storage law does not describe group dynamics on
      this timescale with these proxies. Report and stop, or return to
      proxy selection with a new preregistration.

K5.2  A CLEAN HEADROOM-PROHIBITION VIOLATION. A cluster with h_t well
      below zero grows its independently measured order proxy
      substantially, with eta, C, and N unchanged and the growth
      replicated in the held-out window.
      CONSEQUENCE: the sustainability ceiling is false as stated. This is
      the single most consequential possible finding of the whole
      programme, because the headroom prohibition \citep{ccp:CCP-008} is the most
      important sociological statement the framework makes. It would have to be
      withdrawn.

K5.3  T2 SUCCEEDS BUT T1 FAILS, REPEATEDLY.
      CONSEQUENCE: the framework is a heuristic that generates useful
      interventions, not a theory that predicts. Real, respectable, and
      to be printed in exactly those words: a design manual, not a
      science.

K5.4  T3 FAILS ENTIRELY. No relation between internal and group
      parameters, in any cluster, on any measure.
      CONSEQUENCE: the correspondence is an analogy of form, not
      of substance. the correspondence thesis reduces to a claim about
      MODEL FORM only, which is all the framework claims for it.
      Survivable, and a large retraction of the volume's ambition.

K5.5  HARM. Any cluster in which the intervention measurably reduces
      members' ability to decline participation, exit, or dissent.
```

```
      CONSEQUENCE: stop immediately. the fourth standing refusal is not a
      methodological preference and does not trade off against a result.
```

Scale and timescale

```
clusters           24 (12 per arm)
members            20 per cluster; 480 total
periods            52 weekly
observations       24 x 20 x 52 = 24,960 member-periods
participant burden 4 minutes per member-period = 1,664 participant-hours
fieldwork          52 weeks
total stage        30 months: 6 site recruitment, 6 setup, 12 fieldwork,
                   6 analysis and dissemination

researcher and coordinator hours:
   site coordination (24 x 52 x 2 h)              2496.0
   site recruitment (24 x 40 h)                    960.0
   instrument deployment and IT                    400.0
   analysis                                        700.0

```

27.8.10 8.10 The kill register

Every kill condition in one table, so no stage is entered without its exit already written down.

Code	Stage	Kill condition	Consequence
K1.1	1	No shared unit for D and P	Moment equation demoted to heuristic ordering
K1.2	1	No instrument reaches session reliability 0.80	Programme cannot proceed
K1.3	1	Limiting cases have no recognisable referent	FVP-3 fails; formula has no phenomenon
K1.4	1	Y is a repackaging of U	Return to Stage 0 or stop
K2.1	2	No stable exponent across sessions	No scale; FVP-2 fails
K2.2	2	Cross-modality transitivity violated	Not a ratio scale; decisive
K2.3	2	No true zero for D or P	Division impermissible; demote in print
K2.4	2	D and P in incompatible units	As K1.1, quantified
K3.1	3	Any of the three rules fires in most subjects	Storage law does not describe internal dynamics
K3.2	3	Split-half reliability of b_hat below 0.50	eta is a window property; Stage 4 forbidden

Code	Stage	Kill condition	Consequence
K3.3	3	Systematic same-direction drift in every subject	Constant-parameter postulate fails
K3.4	3	Design controls failed; subjects inferred hypothesis	Data uninterpretable (52.7 per cent false-pass rate)
K4.1	4	Between-person spread does not clear the noise floor	delta and eta are not person parameters
K4.2	4	Rank order of subjects disagrees between labs	**FVP-7 fails. Programme stops.**
K4.3	4	Between-lab disagreement is a pattern, not a constant	As K4.2
K4.4	4	Suite passes in one lab, fails in the other	Do not proceed; find the difference or stop
K5.1	5	Model does not beat baselines on held-out group order	Storage law does not describe group dynamics here
K5.2	5	Clean headroom-prohibition violation	Sustainability ceiling withdrawn
K5.3	5	Intervention works, model does not predict	Design manual, not a science; print those words
K5.4	5	No internal/external relation at all	Correspondence is form only
K5.5	5	Ability to decline reduced in any cluster	Stop immediately; non-negotiable

Twenty-one ways to die: four terminal for the whole enterprise (K1.1 in its strong form, K3.2, K4.2, K4.3), and one — K5.5 — that stops the work regardless of what the data say.

27.8.11 8.11 Survival arithmetic

The following probabilities are **declared priors, badged as priors and not as evidence.** They are stated so the expected cost can be computed at all; a reader who disagrees should substitute their own and redo the arithmetic, which takes one line.

```
stage                       months   participants   P(fail here)   hours
1  pilot operationalisation      7          1            0.10        376.5
2  ratio-scale construction      4          6            0.10        778.9
3  single-subject stability     12          3            0.15        831.5
4  cross-subject recovery       18         80            0.35       1712.0
5  field trials, group scope    30        480            0.20       4856.0
-------------------------------------------------------------------------
TOTAL (strictly sequential)     71        570                       8554.8

SURVIVAL CURVE

  after stage 1   P(still alive) = 0.9000
  after stage 2   P(still alive) = 0.8100
```

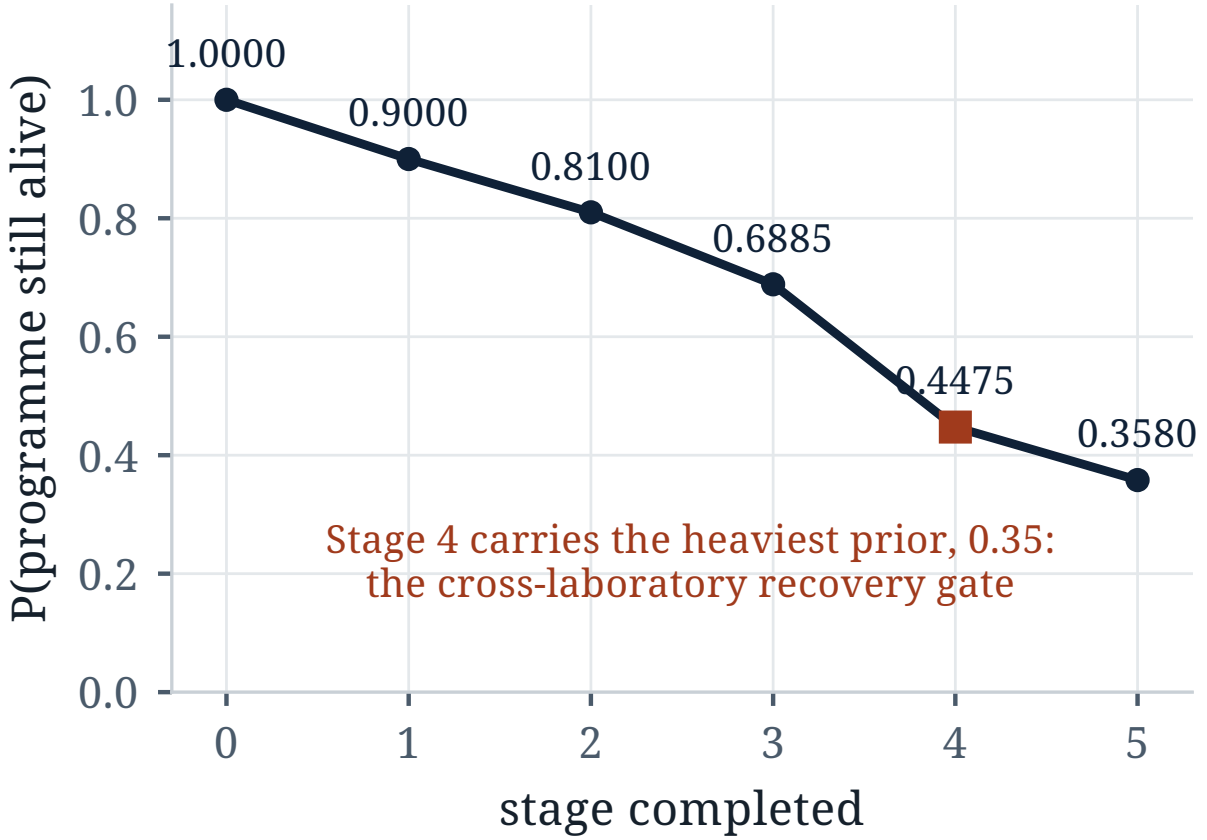

Figure 27.3: **Under its own declared priors the programme is more likely to be dead than alive before the field trials begin.** The compounded probability of reaching a completed final stage is 0.3580, which at 5.35 FTE-years per attempt implies 14.93 FTE-years per completed programme. Modelled from the declared per-stage failure priors 0.10, 0.10, 0.15, 0.35, 0.20 of §8.11; these are priors, badged as priors, and are not evidence. Produced by `figs/src/CCP-027_fig03.py`.

```
after stage 3   P(still alive) = 0.6885
after stage 4   P(still alive) = 0.4475
after stage 5   P(still alive) = 0.3580

P(programme dies at or before stage 4) = 0.5525
```

Under these priors the programme is more likely than not to be dead before the field trials begin, and its probability of reaching a completed Stage 5 is 35.8 per cent. That is not pessimism. It is what a research programme looks like when its kill conditions are written honestly beforehand, and a programme with a high stated completion probability has almost certainly written them too loosely.

The heaviest prior — 0.35 at Stage 4 — is deliberate. Stage 4 is where a formalism that describes meets the demand that it measure. the framework names FVP-7 the gate most often skipped [Curzi, 2026t]; **it is most often skipped because it is most often failed.**

27.8.12 8.12 Resourcing

```
researcher and coordinator hours        8,554.8
at 1,600 productive hours per FTE-year      5.35 FTE-years
calendar, strictly sequential                 71 months = 5.92 years
```

```
calendar, with 30 per cent overlap of
  stages 2–3 and 4–5                          61 months = 5.08 years
implied continuous staffing        5.35 / 5.92 = 0.90 FTE
```

The programme is one full-time researcher for six years. That is its actual shape: one person for six years, or two for three, with participants supplying a further 2,791 hours of their own time. Participant burden by stage:

```
stage 1     56.3 participant-hours       1 person
stage 2     38.9                         6 people
stage 3     72.0                         3 people
stage 4    960.0                        80 people
stage 5  1,664.0                       480 people
-------------------------------------------------
TOTAL    2,791.2 participant-hours     570 people
```

Monetary cost is not stated as fact because a defensible rate is not available here. **As a declared assumption and not a citation**, at fully loaded hourly rates of 60, 90, and 120 in some currency unit, 8,554.8 researcher-hours cost 513,290, 769,935, and 1,026,580. Participant compensation, equipment, and site costs are additional and are not estimated, because doing so would require numbers this paper does not have. The figure that matters to a funder:

```
5.35 FTE-years / 0.3580 = 14.93 FTE-years per COMPLETED programme
```

About fifteen FTE-years per completed programme, because most attempts stop early. The stopping is the point: nine or ten of those years are spent learning that something does not work, which is the ordinary and correct ratio in any field that tests things.

27.8.13 8.13 Tripwires for a degenerating programme

A programme degenerates when its response to disconfirmation is to add assumptions that protect the core rather than predictions that expose it. The distinction between a progressive and a degenerating research programme is Lakatos [1970]'s, and it is the right frame for badged postulates: what makes a protective belt legitimate is that it generates new testable content [Popper, 1959]. The practical discipline is to design each stage so that it discriminates between rival explanations rather than merely accumulating support for one [Platt, 1964], and to remember that a directional prediction is nearly costless in psychology, which is why this framework's point predictions with constants are worth more than its signs [Meehl, 1967, 1990]. Each item below is a tripwire: if it happens, the programme has stopped being a research programme and someone must say so.

```
W1  A PARAMETER BECOMES TIME-VARYING AFTER IT FAILS TO BE CONSTANT.
    Legitimate: preregister a time-varying specification as a NEW
    prediction, on NEW data, with its own kill condition.
    Degenerate: refit existing data with delta_t and report the gain.

W2  N IS RE-AUDITED AFTER THE RESULT IS SEEN.
    N enters through ln N and through F, so a post hoc re-audit adjusts
    the ceiling to fit the data. Audit N before, freeze it, report it.

W3  THE PERIOD LENGTH IS CHANGED BECAUSE THE RESULT IMPROVES.
    One of the strongest levers on any autoregressive fit. Changing it
    after seeing results is a specification search wearing the clothes of
    a methodological refinement.
```

```
W4  A SUBJECT OR CLUSTER BECOMES "ATYPICAL" AFTER FAILING.
    Exclusion criteria are legitimate only if written in field A3 of the
    preregistration before recruitment.

W5  THE PROXY IS SWAPPED FOR A BETTER-BEHAVED ONE.
    The most common single rescue. Y is redefined, the fit improves, and
    nothing in the write-up records that a search occurred.

W6  A FAILED STAGE IS RECLASSIFIED AS A PILOT.
    A stage becomes a pilot when it was preregistered as a pilot, not when
    it produced an unwelcome number.

W7  THE KILL CONDITION IS RENEGOTIATED IN THE LIGHT OF THE DATA.
    The most serious of the seven, because it is the one that dissolves
    all the others. A kill condition altered after the data are seen was
    never a kill condition.
```

The countermeasure for all seven is structural, not moral: publish the kill conditions with the preregistration, before the data exist, where the investigators cannot edit them. The principle is older than the replication crisis: a scheme should remain sound when everything about it except the private key is public [Kerckhoffs, 1883], and disclosure is a control rather than a courtesy [Brandeis, 1914]. A programme that has done that can still degenerate, but not quietly.

27.8.14 8.14 What partial success looks like

Programs rarely die cleanly or succeed completely. Five partial outcomes, named in advance so they are recognised as outcomes rather than argued about as failures:

```
PS1  STORAGE LAW SURVIVES, MOMENT EQUATION DOES NOT.
     K1.1 or K2.3 fires; delta and eta recover on a directly measured Y.
     The storage-law material stands; the moment equation is demoted to diagnostics. The most
     probable partial outcome.

PS2  PARAMETERS ARE SPECIES-TYPICAL, NOT INDIVIDUAL.
     K4.1 alone fires. The framework describes a process everyone runs
     with similar constants. Useful, publishable, and requires rewriting
     every "your delta" in the volume.

PS3  IT WORKS INTERNALLY AND NOT EXTERNALLY, OR THE REVERSE.
     K5.4 fires. Two separate models with the same algebra, which is
     precisely what the framework already claims and no more.

PS4  IT PREDICTS BUT DOES NOT GUIDE.
     T1 succeeds, T2 fails. A descriptive theory with no demonstrated
     intervention value. Honest and unglamorous.

PS5  IT GUIDES BUT DOES NOT PREDICT.
     T2 succeeds, T1 fails -- K5.3. A design manual whose heuristics work
     for reasons other than those stated. Print it in those words: a
     manual that works for unknown reasons is still a manual, and is not
     a science.
```

PS5 is the outcome most likely to be misreported, because it is the one where everything appears to be going well. Working interventions are the most persuasive and least diagnostic evidence available; the apparatus of Section 4 exists to keep those two apart.

27.8.15 8.15 What the programme would not establish even if every stage succeeded

The framework's four standing refusals are not suspended by success.

```
NOT anything about physics, thermodynamics, or consciousness. The surplus
functional is pure mathematics and makes no empirical or metaphysical claim;
the framework proves no negentropy law.

NOT that surplus is information in the Shannon sense. The framework declines
that identification explicitly.

NOT the conversion of the framework's badged postulates into theorems. A
postulate that survives testing is a well-tested postulate.

NOT any intervention that removes a person's ability to decline. That
refusal is prior to the evidence and unaffected by it.
```

A programme that cleared every gate would establish exactly this: that `delta` and `eta` are measurable person-level and group-level constants, in ratio-scaled units, reproducible across laboratories, whose values predict held-out order better than persistence, a linear input, autoregression, and the input's own timing scrambled. That is a great deal, and much less than the framework's ambitions. Saying so is what keeps the ambitions honest.

27.9 9 Specification of the programme

```
S8.1   Stage 0's four preconditions (SP1–SP4) are in writing before any
        recruitment. Costless refusal is among them.

S8.2   Stages run in order. No stage begins before its predecessor's
        advance conditions are met and published.

S8.3   Every stage's kill conditions are published with its
        preregistration, before data exist, where the investigators cannot
        edit them.

S8.4   Stage 1 runs at least 45 sessions -- 41 is the minimum at which an
        observed test-retest r = 0.70 has a 95 per cent lower bound above
        0.50 -- and reports session reliability with the item count
        required to reach it (Spearman–Brown).

S8.5   Stage 1 demonstrates or refutes a shared unit and a common zero for
        D and P, and prints whichever it found.

S8.6   Stage 2 spans at least 2.0 decades of stimulus range. Widening the
        range takes precedence over lengthening the session.

S8.7   Stage 2 collects enough judgments for SE(exponent) <= 0.02
        (n >= 469 per exponent at a 2.0-decade span) before any transitivity
        claim is made.

S8.8   Stage 2's transitivity test states its detectable threshold
```

explicitly alongside its result.

S8.9 Stage 2 demonstrates a true zero for D and for P, or the Moment equation is demoted in print per the formula-validation protocol \citep{ccp:CCP-026}.

S8.10 Stage 3 samples daily, not twice weekly. The precision-per-week arithmetic is decisive and is reported.

S8.11 Stage 3 runs at least 240 periods per subject, split 120/120, and reports split-half reliability of a_hat and b_hat.

S8.12 Stage 3 reports the instrument's rating noise and the implied attenuation of delta and eta from §4.9.

S8.13 Stage 3 states its power to detect within-person parameter change before claiming any such change.

S8.14 Stage 4 is run by two laboratories independently from the published protocol. A single-lab Stage 4 does not satisfy FVP-7 and must not be described as if it did.

S8.15 Stage 4 simulates the estimation noise floor at its own n and T and compares the observed between-person spread against it explicitly, before any individual-differences claim.

S8.16 Stage 4 publishes the reliability of the person-level estimate and the ceiling it places on correlations with external variables.

S8.17 Stage 4 classifies any between-lab disagreement as either a single scaling constant (calibration) or a pattern (theory failure), and prints which.

S8.18 Stage 5 runs both T1 (prediction) and T2 (intervention). Neither alone is sufficient.

S8.19 Stage 5 states its powered effect size given its cluster count and assumed ICC, and claims only what that supports.

S8.20 Stage 5's time series is at least 52 periods with a held-out window of at least 18, so the surrogate test has resolution at B = 999.

S8.21 Stage 5 tests the headroom prohibition as a prohibition: clusters with negative measured headroom are predicted not to grow.

S8.22 All seven degeneration tripwires W1-W7 (§8.13) are monitored by someone with standing to halt the programme.

S8.23 Null results are published with titles that say so.

S8.24 The survival priors of §8.11 are restated at each stage boundary and updated in public.

27.10 10 Failure modes of the programme

27.10.1 F8.1 Stage Skipping

Signature. A study estimating `eta` for forty people that never built a ratio scale, or a field trial launched without any single-subject evidence. Stages 4 and 5 are the interesting ones. Stages 1 and 2 are apparatus.

Fix. S8.2. The estimate produced by a skipped-stage study is a number in unknown units, and unknown units cannot be compared to anything, which means the study cannot succeed even in principle.

27.10.2 F8.2 The Under-Powered Ratio Scale

Signature. A transitivity test reported as passed, with exponent standard errors near 0.10. Magnitude estimation is quick per judgment, so the total is underestimated.

Fix. S8.7 and S8.8. At `SE = 0.10` per exponent, only a discrepancy above 0.37 is detectable — the test cannot fail, which means it cannot pass either.

27.10.3 F8.3 Sampling Too Slowly

Signature. Twice-weekly experience sampling adopted to reduce burden. It genuinely does reduce burden.

Fix. S8.10. `T = 120` at daily sampling is 3.9 months; the same `T` twice-weekly is 13.8 months. The extra ten months are ten months of parameter drift, attrition, and life events, all of which attack the constant-parameter postulate that Stage 3 is trying to test.

27.10.4 F8.4 The Single-Lab FVP-7

Signature. “Replicated across two independent samples” where both samples were collected by the same group with the same hands. It is much easier and it feels like replication.

Fix. S8.14. The whole content of FVP-7 is that the procedure survives a different group’s reading of the written protocol. Two samples from one lab test sampling variability, which was never the question.

27.10.5 F8.5 Individual Differences From Estimation Noise

Signature. A per-subject `eta` table with a spread of 0.03 to 0.04 at 120 periods, read as personality. The numbers differ, so the people appear to differ.

Fix. S8.15. The simulated floor is 0.036 at `T = 120` and 0.048 at `T = 60`.

27.10.6 F8.6 The Endpoint-Only Field Trial

Signature. A cluster-randomised trial with a baseline and a follow-up and nothing between. It is the standard design and it is cheaper.

Fix. S8.20. The framework’s claim is about a *trajectory* governed by a recursion. A two-point design cannot distinguish the storage law from any other process that ends higher, and it certainly cannot run a surrogate test.

27.10.7 F8.7 Kill-Condition Erosion

Signature. The published kill condition and the one discussed in the group meeting have drifted apart; the discrepancy is nobody's fault and everyone knows about it. Sunk cost, plus the fact that every individual relaxation is small.

Fix. S8.3 and S8.22. Publish the conditions where they cannot be edited, and give someone standing to halt.

27.10.8 F8.8 Success Theatre at Stage 5

Signature. The intervention worked; the prediction test is described briefly in a supplement. PS5. A working intervention is the most persuasive and least diagnostic result available.

Fix. S8.18 and PS5's printing requirement. If T2 succeeded and T1 failed, the sentence "this is a design manual whose heuristics work for reasons other than those stated" must appear.

27.10.9 F8.9 The Rescued Prohibition

Signature. A cluster with negative headroom grew, and the response is to re-measure `C`. the headroom prohibition [Curzi, 2026b] is the framework's strongest sociological statement in the framework, and important statements attract rescues.

Fix. W2 and W5 of §8.13, plus S8.21. Freeze `C`, `eta`, and `N` before the window opens. If the violation survives a frozen measurement and replicates in held-out data, the corollary is withdrawn. That is what withdrawal means.

27.10.10 F8.10 Measuring People Who Cannot Refuse

Signature. Participation is enrolled at the organisational level and individual opt-out carries a cost, however small. Cluster designs recruit clusters.

Fix. S8.1 and K5.5, and the fourth standing refusal [Curzi, 2026]. This one does not trade off against statistical power, and a design that cannot meet it is a design that does not run.

27.11 11 A worked schedule and its five decision gates

One laboratory, one principal investigator at 0.9 FTE, start date month 0. Every figure below is the arithmetic of §8.5 through §8.12 laid on a calendar; **the schedule is a plan, not a record — no month of it has been executed.**

27.11.1 11.1 The schedule

```
MONTH   ACTIVITY                                              GATE / OUTPUT
-------------------------------------------------------------------------
 0– 2   Stage 0: write SP1–SP4. Ethics. Consent                 entry condition
        infrastructure with costless refusal.
 0– 4   Stage 1: instrument development, three                 160 h
        candidates each for D, P, E.
 3– 7   Stage 1 fieldwork: 45 sessions, 3/week,                56.3 subject-h
        1 subject + 1 parallel replication subject.
 6– 7   Stage 1 analysis. Publish reliability,                 K1.1–K1.4
        shared-unit argument, limiting-case audit.            GATE 1
-------------------------------------------------------------------------
```

```
 7– 9   Stage 2: apparatus for 3 calibration            240 h
        modalities. Modulus selection.
 8–10   Stage 2 fieldwork: 6 subjects, 2,916            38.9 subject–h
        judgments each, 6 sessions per term.
10–11   Stage 2 analysis: exponents, transitivity,      K2.1–K2.4
        true-zero test. Publish.                       GATE 2
-------------------------------------------------------------------------
11–13   Stage 3: data pipeline, surrogate              320 h
        calibration simulations at b = 0.
12–20   Stage 3 fieldwork: 3 subjects, 240 daily       72 subject–h
        periods, 4 prompts/day (34.3 weeks).           2,880 prompts
20–23   Stage 3 analysis: per-subject fits, freeze,    K3.1–K3.4
        held-out, split-half. Publish.                 GATE 3
-------------------------------------------------------------------------
23–26   Stage 4: publish protocol. Recruit lab 2.      150 h
        Recruit 40 + 40 subjects.
26–30   Stage 4 lab 1 fieldwork: 120 daily periods.    480 subject–h
29–33   Stage 4 lab 2 fieldwork, overlapping.          480 subject–h
33–41   Stage 4 analysis: noise floor at own n and T,  K4.1–K4.4
        recovery, between-lab reconciliation. Publish. GATE 4
                                                       MAKE OR BREAK
-------------------------------------------------------------------------
41–47   Stage 5: site recruitment, 24 clusters.        960 h
47–53   Stage 5 setup, instruments, randomisation,     400 h
        preregistration of T1, T2, T3.
53–65   Stage 5 fieldwork: 52 weekly periods.          1,664 participant–h
65–71   Stage 5 analysis and dissemination.            K5.1–K5.5
                                                       GATE 5
-------------------------------------------------------------------------
TOTAL   71 months = 5.92 years, 8,554.8 researcher–hours,
        570 participants, 2,791.2 participant–hours
```

With the overlap shown at months 29-33 and 41-47, the calendar compresses to 61 months, 5.08 years.

27.11.2 11.2 The decision points, with their arithmetic

Gate 1, month 7. Does any operationalisation of `D` and any of `P` share a unit with a common zero? If no, the programme does not stop — it *narrows*: the Moment equation is demoted in print, the Self-Storage Law is refitted with `S_t = F(U_t)` (input variant A, §4.1) instead of `M_t`, and Stages 2 through 5 proceed on the narrower claim. **This is the one gate whose failure produces a smaller programme rather than no programme**, and recognising that in advance is what stops a Stage 1 failure from being fought instead of accepted.

Gate 2, month 11. Transitivity, detectable threshold 0.0739 in the exponent given `SE = 0.02` per exponent. A measured `|a_AC − a_AB ∗ a_BC|` above it ends the ratio-scale claim.

Gate 3, month 23. Three subjects, three verdicts. Advance requires the three-rule suite cleared in at least two of three, and split-half reliability of `b_hat` at or above 0.80 in at least two of three. **The simulated benchmark at 120 periods per half is 0.846; a real figure near 0.85 clears, near 0.40 does not, and the region between 0.50 and 0.80 is the genuinely awkward one — for which the preregistered rule is to extend to 360 periods in a fourth subject rather than to argue.**

Gate 4, months 33-41. Three numbers decide it:

```
observed between-person sd of eta      must exceed  0.0355   (noise floor at T=120)
```

```
between-lab rank correlation of eta    must exceed  0        significantly,
                                                    and lie at or below the
                                                    published reliability ceiling
                                                    (0.942 at between-sd 0.10)
between-lab mean ratio of eta          must equal   1/g for an independently
                                                    measured operationalisation
                                                    difference g, or be absent
```

If the rank correlation is near zero, the programme stops at month 41 having spent 3,698.9 researcher-hours — 2.31 FTE-years — and having established something real and publishable: that `eta` as operationalised is not a person-level measurement. **That is a worthwhile purchase, and it is the single most probable outcome under §8.11's priors at 0.35. Budget for it as the expected case, not the feared one.**

Gate 5, month 71. T1, T2, T3, and the headroom prohibition. As scheduled — 24 clusters, 20 members — the trial is powered for a standardised effect of 0.50 and under-powered for 0.30 at `ICC = 0.05`, where 36 clusters would be needed. The preregistration therefore claims a large effect or claims pilot status, not both.

27.11.3 11.3 The honest summary a funder should be given

> *We propose a five-stage, 71-month programme, requiring approximately 5.35 FTE-years of researcher time and 570 participants contributing about 2,791 hours, to determine whether two parameters of a formal model of stored order — a retention loss `delta` and a conversion efficiency `eta` — can be measured on ratio scales, recovered as person-level constants, and reproduced across laboratories. Twenty-one preregistered kill conditions are published in advance; four are terminal. Under our declared priors, which are priors and not evidence, the programme has a 35.8 per cent probability of reaching a completed final stage and a 55.3 per cent probability of stopping at or before the cross-laboratory recovery stage. Expected cost per completed programme, accounting for early stopping, is about 14.9 FTE-years. We will publish at every stage, including and especially when the stage kills the programme, and null results will be titled as null.*

That paragraph is the whole proposal. Concrete, sequenced, every number computed from a stated assumption, naming the year at which the whole thing most probably ends and committing in advance to publishing that ending.

A programme that cannot be killed at any stage is not a research programme. This one can be killed at twenty-one places, is most likely to die at month 41, and says so on the first page of its own proposal.

27.12 12 Correspondence tables as relational graphs

This section is the part of the paper a careful reader will approach with the most suspicion, and that suspicion is correct and should be kept. What follows is not a departure from the formalism. It is an application of the formalism to a body of historical technique, and the only things it is permitted to say are things the formalism can carry.

The position taken here – recorded as a thesis, with its badge on – is that the ancient occult and alchemical formulas are these same relationships expressed in a different notation. That is a claim about *notation*, and it is falsifiable in the only sense a claim about notation can be: either the old structures translate into the modern objects without residue, or they do not. This section performs the translation for correspondence systems. The companion paper performs it for the star-polygon figure, the memory palace and the ritual calendar, and draws the balance [Curzi, 2026v].

Nothing in this section asserts any supernatural claim, any physical effect of a symbol, or any result that is not derivable from the formalism already established in the preceding sections and the framework papers they cite. That sentence is a standing constraint on Sections 12 to 15, and any sentence in them that appears to contradict it is an error to be reported and corrected.

What *is* claimed here is narrower and more interesting. A correspondence table is a mathematical object of a completely ordinary kind: a finite relation over finite sets. The Tree of Life is a graph with ten vertices and twenty-two edges. The tarot is a structured set of seventy-eight elements with an explicit product decomposition. Gematria is a map from strings to integers — which is what a hash function is, and calling it one is a technical description, not a compliment and not an insult. These readings are descriptive. They involve no interpretation, no belief, and no metaphysics. They are what those objects *are*, and once you have said so you can compute with them.

The engineering payoff is specific. The framework's validity conditions require a category assignment before the surplus functional may be applied to anything at all. You cannot compute `N_eff` until you have said what the `N` categories *are*. **A correspondence table is precisely a category assignment, written down, fixed, and made auditable — which is why the tradition that produced them was doing, in a different notation, the first step of the procedure the framework specifies.**

27.12.1 12.1 Statement of the reading rule

READING RULE (Correspondence Tables). Let a correspondence system be given: a finite set of labels `L` and one or more finite relations among them. Then:

```
a single-column list of N labels          IS   a finite set of size N
a two-column table over the same labels   IS   a binary relation R subset of L1 x L1
an m-column table, one row per label      IS   (m-1) functions L1 -> L2, ..., L1 -> Lm
a diagram of nodes joined by paths        IS   an undirected graph G = (V, E)
an assignment of labels to categories     IS   a partition, i.e. a block decomposition
a letter-value scheme summed over a word  IS   a hash h : strings -> integers
```

There is no inference in that block. Each line is a restatement in modern vocabulary of what the historical artefact literally contains. **The reading rule is a translation, not a theory, and it cannot be wrong in the way a theory can be wrong — it can only be inapplicable, which happens exactly when the historical artefact is too vague to have a definite extension.** That case is common and is treated as failure mode F12.5.

The status table for this section:

Element	Status	Warrant
The Kircher-arrangement Tree of Life has 10 vertices, 22 edges	**PROVED** (enumeration)	§12.4, computed
Its density against `K10` is 22/45 = 0.4889	**PROVED** (arithmetic)	§12.4, computed
Its diameter is 3, mean geodesic 1.5778, cyclomatic number 13	**PROVED** (computation)	§12.4, computed
15 of its 22 edges cross pillar boundaries	**PROVED** (enumeration)	§12.5, computed

Element	Status	Warrant
The tarot is `22 + 4 x 14 = 78`, a set with a product substructure	**PROVED** (arithmetic)	§12.6
Gematria is a function from strings to integers	**PROVED** (definition)	§12.8
Gematria destroys 10.47 bits on a 234,454-word list	**PROVED** (measurement)	§12.8, computed
The weekday sequence follows from `24 mod 7 = 3` on the Chaldean order	**PROVED** (arithmetic)	§12.7, computed
A correspondence table satisfies the framework's category requirement	**PROVED** (definition)	§12.10
That these systems were *built as* mnemonic technology	**HISTORICAL CLAIM** (well-supported)	§12.9
That the old notation and the framework's notation describe the same relations	**POSTULATE** (author's thesis)	§12.1
That any correspondence carries efficacy, force, or physical consequence	**REFUSED**	standing refusal

The last two rows are the whole difficulty of this section, and they are separated on purpose. The thesis in the penultimate row is a claim about *isomorphism of structure*. The refused row is a claim about *action in the world*. **Structural correspondence is not evidence of mechanism, and this paper asserts no mechanism.** The same restriction governs the frequency framework's square law [Curzi, 2026], and it means exactly the same thing here.

27.12.2 12.2 The honesty clauses

These are mandatory and are restated wherever the reading rule is used in the companion paper [Curzi, 2026v].

H12-1 — Description, not endorsement. Saying that the Tree of Life is a graph is true in the same way that saying a subway map is a graph is true. It commits you to nothing about subways. Every metric computed in §12.4 is a metric of the *diagram as drawn*, and would be unchanged if the diagram had been drawn to organise plumbing fixtures.

H12-2 — The arrangement is a choice, and other arrangements exist. The ten-node, twenty-two-path figure used throughout this section is the arrangement commonly called the Kircher tree, reproduced in Athanasius Kircher's *Oedipus Aegyptiacus* (1652) and standard in later European occult literature. It is not the only historical arrangement; the Cordoveran and Lurianic schemes differ, and nineteenth- and twentieth-century revisions differ again. **All graph metrics reported here are metrics of the specific edge list printed in §12.4 and must be recomputed for any other arrangement.** An unstated arrangement produces unstated metrics, which is failure mode F12.4.

H12-3 — Gematria is a hash, and that is not a compliment. The description is exact and it is also deflationary. A hash function maps a large domain onto a small codomain. It therefore collides, massively and by construction. **Two words sharing a gematria value is the expected behaviour of a many-to-one map, not evidence about the words.** §12.8 measures the collision rate so that the deflation is quantitative rather than rhetorical.

H12-4 — Counting is not meaning. That the tarot has 78 elements, or that the Hebrew alphabet has 22 letters and the Kircher tree has 22 paths, are arithmetic facts. The nineteenth-

century assignment of the 22 trumps to the 22 letters — associated with Éliphas Lévi, *Dogme et Rituel de la Haute Magie* (1854-56), and elaborated by later societies — is a *chosen bijection*, one of `22!` available, made by identifiable people at an identifiable date. It is data about the history of the assignment and about nothing else.

H12-5 — Everything downstream inherits Papers A to E's clauses. When §12.5 computes a surplus number from a pillar decomposition, that number carries every honesty clause of the Surplus Law: the triangle inequality fails for geometric triples; subadditivity holds on `u` only; the functional as deployed is a **lower bound** on the ensemble's information; the surplus functional is pure mathematics and makes no empirical or metaphysical claim; no thermodynamic consequence follows.

H12-6 — The audit runs in both directions. If the translation reveals that an old table is a well-formed partition, say so. If it reveals that the table has duplicate rows, undefined membership, or an unjustified ordering, say that too, in the same voice. §12.11 does the second, and finds a 40.37% ceiling overstatement in a small worked case. A translation that only ever flatters the source is not a translation.

27.12.3 12.3 What the validity conditions require before anything may be computed

The framework's validity conditions [Curzi, 2026c] are the gate this section exists to service. Before the surplus functional `F(u) = ln(1 + (N−1)u)` may be applied to any real ensemble, four things must hold, and they must hold *in print*, not in the analyst's head:

```
V1  EXHAUSTIVE.   Every element of the domain falls in some category.
V2  EXCLUSIVE.    No element falls in two, or the overlap is declared and handled.
V3  COUNTED.      N is stated, and the N categories are genuinely distinct.
V4  ORDERED.      Where an ordinal is used -- an essence index, in the
                  sense the frequency framework gives that term -- the
                  ordering is justified, not arbitrary.
```

A correspondence table is a physical artefact whose entire job is to satisfy V1 through V4 for a domain, and to keep satisfying them across generations of users who cannot consult the scheme's author. That is a strong statement about what these systems were for, and §12.9 defends it on historical grounds. It is also the reason the material belongs in an engineering paper: the same four gates govern a hospital's incident-category scheme, a warehouse's fault taxonomy, and a research group's list of domains, and all three fail in the same ways.

27.12.4 12.4 The Tree of Life is a graph, and here are its numbers

The *Sefer Yetzirah*, the earliest text in the tradition to use the phrase, speaks of thirty-two paths — ten and twenty-two. The later diagrammatic tradition renders these as ten nodes joined by twenty-two edges. Take that diagram at face value and compute.

Vertices, in the conventional numbering:

```
1 Kether     2 Chokmah    3 Binah      4 Chesed     5 Geburah
6 Tiphareth  7 Netzach    8 Hod        9 Yesod     10 Malkuth
```

Edges, the Kircher arrangement, listed in full so the computation is reproducible:

```
1–2   1–3   1–6
2–3   2–4   2–6
```

```
3–5   3–6
4–5   4–6   4–7
5–6   5–8
6–7   6–8   6–9
7–8   7–9   7–10
8–9   8–10
9–10
```

Count: 3 + 3 + 2 + 3 + 2 + 3 + 3 + 2 + 1 = 22. No duplicates; verified by set comparison.
Computed metrics:

```
|V| = 10                          |E| = 22
sum of degrees = 44 = 2|E|        handshake lemma holds
K10 edges = 45                    density = 22/45 = 0.488889
cyclomatic number = |E|−|V|+1 = 13    (independent cycles)
connected: yes                    diameter = 3
mean shortest path = 1.577778     distance histogram: {1: 22, 2: 20, 3: 3}
```

Degree sequence:

Node	Name	Degree
6	Tiphareth	8
7	Netzach	5
8	Hod	5
2	Chokmah	4
3	Binah	4
4	Chesed	4
5	Geburah	4
9	Yesod	4
1	Kether	3
10	Malkuth	3

Sorted: `[8, 5, 5, 4, 4, 4, 4, 4, 3, 3]`.

Three observations, each of which is a fact about the diagram and about nothing else.

First, the degree distribution has a single dominant hub. Node 6 carries 8 of a possible 9 incident edges; it is adjacent to every node except Malkuth. The next-highest degree is 5. In the vocabulary of Albert et al. [2000], this is a hub topology: robust to random edge loss, fragile to targeted removal of the hub. The reading is a statement about the degree sequence and nothing more; a heavy-tailed degree sequence is neither necessary nor sufficient for engineered robustness [Doyle et al., 2005], and **no scaling or power-law claim is made here** – with ten vertices there is no distribution to fit, and the procedure that such a claim would require [Clauset et al., 2009] does not apply. Delete node 6 and the diameter rises and the graph's mean path length degrades sharply; delete any leaf-adjacent node and little changes. That is a structural property of the drawing.

Second, the graph is far from a tree. A tree on 10 nodes has 9 edges. This has 22, hence 13 independent cycles. Alexander [1965] distinguishes the tree – where subsets nest strictly – from the semilattice, where they overlap. **The diagram called the Tree of Life is not, in Alexander's sense, a tree; it is a densely cyclic graph with an overlap structure, and that is why it can encode more relations than a hierarchy of the same size.** This is a pleasant terminological accident and it is also the substantive point: 13 independent cycles is a lot of overlap to carry in ten nodes.

Third, the endpoint-to-endpoint structure is rich. Distance from node 1 to node 10 is 3, and there are exactly 3 distinct geodesics of that length. The number of *simple* paths (no

repeated vertex) from 1 to 10 is **573**, computed by exhaustive enumeration. A system whose users are taught to "travel the paths" has 573 distinct non-repeating routes between its two extremes. As a memory structure, that is the property being exploited: many routes to the same destination means many retrieval cues for the same content, which is exactly the design principle behind the method of loci, which the companion paper treats as the storage law with space as the retention medium [Curzi, 2026v].

27.12.5 12.5 The three pillars are a block decomposition, and it is measurable

The same diagram carries a standard partition into three columns:

```
Pillar of Severity   {3 Binah,  5 Geburah,  8 Hod}          size 3
Pillar of Mercy      {2 Chokmah, 4 Chesed,  7 Netzach}      size 3
Middle Pillar        {1 Kether, 6 Tiphareth, 9 Yesod, 10 Malkuth}   size 4
```

This is a partition: exhaustive, exclusive, three blocks summing to ten. It satisfies V1, V2 and V3 of §12.3 without amendment. **It is therefore a legitimate block decomposition in the sense the framework's block-decomposition theorem requires [Curzi, 2026], and the cross-block and within-block edge counts can be measured rather than assumed.**

Measured:

```
within-pillar edges:   Middle 3,  Mercy 2,  Severity 2       total  7
between-pillar edges:                                        total 15
cross-block fraction:  15/22 = 0.681818

cross-pair breakdown:  Mercy--Middle     6
                       Middle--Severity  6
                       Mercy--Severity   3

saturation:  Severity   2 of max 3 internal edges
             Mercy      2 of max 3
             Middle     3 of max 6
```

Two facts fall out. The blocks are internally *sparse* — no pillar is a complete subgraph — and the wiring is overwhelmingly *across* blocks, 68.2% of all edges. The two outer pillars connect to the middle six times each but to one another only three times. The diagram routes its cross-side traffic through the centre.

Now the translation into the surplus functional. The block-decomposition theorem [Curzi, 2026], for a pure block vector, gives

```
u = u_cross + u_div          u_cross = beta^2          u_div = alpha^2 sin^2 gamma

max(f(u_cross), f(u_div))  <=  f(u)  <=  f(u_cross) + f(u_div)
```

where `beta^2` is the between-category share and `alpha^2 sin^2 gamma` the within-category share. **Badge: the identification of the measured cross-block edge fraction with `beta^2` is a modelling choice, not a theorem.** It is the natural choice — the share of the structure that lives across categories — but the theorem does not require it, and a different operationalisation of `beta` gives different numbers. With `beta^2 = 15/22 = 0.681818` and `alpha^2 = 7/22 = 0.318182`, sweeping the within-block angle `gamma`, at `N = 10`:

gamma	u	N_eff	F (nats)	% of ceiling ln 10 = 2.302585
15 deg	0.703132	7.3282	1.991729	86.50%
30 deg	0.761364	7.8523	2.060803	89.50%
45 deg	0.840909	8.5682	2.148056	93.29%
60 deg	0.920455	9.2841	2.228302	96.77%
90 deg	1.000000	10.0000	2.302585	100.00%

And the subadditivity bracket, verified numerically at a representative point (`beta^2 = 0.68`, `alpha^2 = 0.32`, `gamma = 30 deg`, `N = 10`):

```
u_cross = 0.6800   u_div = 0.0800   u = 0.7600   N_eff = 7.8400
max(f(u_c), f(u_d)) = 1.962908  <=  f(u) = 2.059239  <=  f(u_c)+f(u_d) = 2.505232     OK
```

The bracket holds at every sampled point, as it must. Note what the table shows: **once the cross-block share is above two thirds, the within-block angle barely matters — the figure is already at 86.5% of its ceiling at `gamma = 15 deg`.** That is strict concavity doing its work, and it is the same lesson as the conversion analysis [Curzi, 2026b]: the first crossing purchases most of what crossings can buy, and the rest is glazing bills.

The honest coda: `ln 10 = 2.302585` nats is a *hard ceiling* on surplus per interaction for any ten-category scheme [Curzi, 2026c]. No arrangement of paths raises it. Adding an edge to the diagram does not add a category. **The ceiling is set by `N`, and `N` is set by the table, not by the drawing.**

27.12.6 12.6 The tarot as a structured 78-element set

The deck is not a bag of 78 things. It has an explicit product structure, and the structure is the interesting part.

```
majors (trumps)         22
minors                  56  =  4 suits x 14 ranks
                            =  4 x (10 pips + 4 courts)
total                   78  =  22 + 40 + 16
```

Computed combinatorics:

```
naming one card:            log2(78)      = 6.285402 bits    ln(78) = 4.356709 nats
unordered pairs C(78,2)                   = 3,003
unordered triples C(78,3)                 = 76,076
ordered 3-card spread 78*77*76            = 456,456          log2 = 18.800116 bits
ordered 10-card spread P(78,10)           = 4,566,176,969,818,464,000
```

The product structure is exact in the log register, which is the register the framework operates in:

```
log2(4) + log2(14) = 2.000000 + 3.807355 = 5.807355 = log2(56)
```

That identity is trivial arithmetic and it is also the whole design principle of a factored code. **A suit-and-rank code lets a user reconstruct 56 identities from 4 + 14 = 18 memorised labels instead of 56, and the log-additivity is why it costs nothing in addressing power to do so.** The frequency framework develops the same move for essence sets [Curzi, 2026]; here it appears in a fifteenth-century object.

Block structure over the minors, taking the four suits as categories:

```
all minor pairs    C(56,2) = 1,540
within-suit pairs  4*C(14,2) = 364
cross-suit pairs             = 1,176      cross fraction = 0.763636
```

76.4% of minor-arcana pairs cross a suit boundary. Compare 68.2% for the Tree's pillar decomposition. Both structures put most of their relational mass across categories rather than within them, which is the geometry the surplus functional rewards — `u_cross = beta^2` is the between-category term and it is the term that survives when within-category variation collapses.

One arithmetic tie-in to the frequency framework's essence law [Curzi, 2026], offered as a structural remark and nothing more. The Essence Law's Result Two states that an ordered set indexed `1..N` yields exactly `ceil(N/2)` pitch classes, because pitch class depends only on the odd part of the index. Computed: for `N = 22`, 11 classes; for `N = 78`, 39 classes. **A 78-element ordered scheme has 39 distinct essence pitch classes, exactly half its size, and that is a hard structural limit of the indexing, not a property of the deck.** It carries every clause of that law, including its first honesty clause: essence, not resonance [Curzi, 2026].

27.12.7 12.7 The sevens, and the week as an arithmetic consequence

The planet/metal/day table is the cleanest correspondence artefact in the European tradition because all three columns have exactly seven entries and the assignment is a bijection.

Day	Planet	Metal
Saturday	Saturn	lead
Sunday	Sun	gold
Monday	Moon	silver
Tuesday	Mars	iron
Wednesday	Mercury	quicksilver
Thursday	Jupiter	tin
Friday	Venus	copper

As a relational object: two independent bijections on 7 labels. The information content of pinning them down:

```
7! = 5,040 bijections        log2(5,040) = 12.299208 bits per column pairing
a 3-column table pins 2 bijections:  2 * 12.299208 = 24.598416 bits
```

Twenty-four and a half bits is the entire informational content of a table that a tradition maintained for well over a millennium. That is a small number, and it is *supposed* to be a small number: the artefact's job is to be *stable and transmissible*, not to be dense. Compare the mnemonic-load computation in §12.9.

Now the part that is genuinely a derivation. The order of the days of the week looks arbitrary and is not. Take the seven classical planets in Chaldean order — descending apparent orbital period, which is the order they were ranked in by the sidereal periods known to antiquity:

```
Saturn, Jupiter, Mars, Sun, Venus, Mercury, Moon
```

Assign rulership of the hours of the day cyclically in that order, one planet per hour. The day is named for the ruler of its first hour. A day has 24 hours, and

```
24 mod 7 = 3
```

so the ruler of the first hour of the next day is **three steps on** in the Chaldean order. Stepping by 3 from Saturn and reading off:

```
Saturn -> Sun -> Moon -> Mars -> Mercury -> Jupiter -> Venus -> Saturn
```

which is

```
Saturday, Sunday, Monday, Tuesday, Wednesday, Thursday, Friday, and back to Saturday
```

Computed and verified: the eighth step returns to Saturn, the cycle closes, and every planet is visited exactly once. The surviving English names carry the Germanic interpretatio for four of the seven (Tiw for Mars, Woden for Mercury, Thor for Jupiter, Frigg for Venus); the Romance languages kept the Latin directly — *mardi*, *mercredi*, *jeudi*, *vendredi*. The earliest surviving explanation of the sequence by the planetary-hour argument is in Cassius Dio's *Roman History*, Book 37.

The weekday order is the star polygon {7/3}, and `gcd(7, 3) = 1` is exactly why the week is a single closed cycle that touches every planet rather than two or three disjoint sub-weeks. That is the companion paper's star-polygon theorem arriving early [Curzi, 2026v], in a piece of civil infrastructure that seven-day weeks are still keeping. If the day had been divided into a number of hours congruent to 0, 7, 14 or 21 modulo 7, the construction would have degenerated: every day would have had the same ruler. If it had been divided into 21 hours, `21 mod 7 = 0`, and the week would not exist. The week is a `gcd` result and the arithmetic is checkable in a minute.

27.12.8 12.8 Gematria is a hash function

Here is the operation. Assign each letter of an alphabet an integer. To evaluate a word, sum the integers of its letters. The standard Hebrew scheme (*mispar hechrachi*) assigns:

```
aleph 1   bet 2    gimel 3   dalet 4   he 5     vav 6    zayin 7   chet 8   tet 9
yod  10   kaf 20   lamed 30  mem 40    nun 50   samekh 60  ayin 70  pe 80   tsadi 90
qof 100   resh 200 shin 300  tav 400
```

Twenty-two letters; units 1-9, tens 10-90, hundreds 100-400; the values sum to 1,495.

```
h : strings over an alphabet A  ->  non-negative integers
h(w) = sum over letters of w of value(letter)
```

That is a hash function. A hash function is a map from a large or unbounded domain into a smaller codomain, computed by a fixed deterministic rule. The bits it destroys are Shannon's quantity and are computed as such below [Shannon, 1948, Hartley, 1928, Cover and Thomas, 2006]. The definition contains no requirement that the map be interesting, only that it be a map. Gematria satisfies it exactly. Saying so is a literally accurate technical description of the operation, and it carries no claim whatever that the map is meaningful.

The description is useful because it makes the properties computable. A hash has three properties that engineers care about, and this one's scores are measurable.

Property 1 — order invariance. Gematria is a *multiset* hash: `h` is a sum, and addition commutes, so any permutation of a word has the same value. Anagrams collide by construction, and so does any rearrangement, meaningful word or not. Measured, purely from the permutation effect:

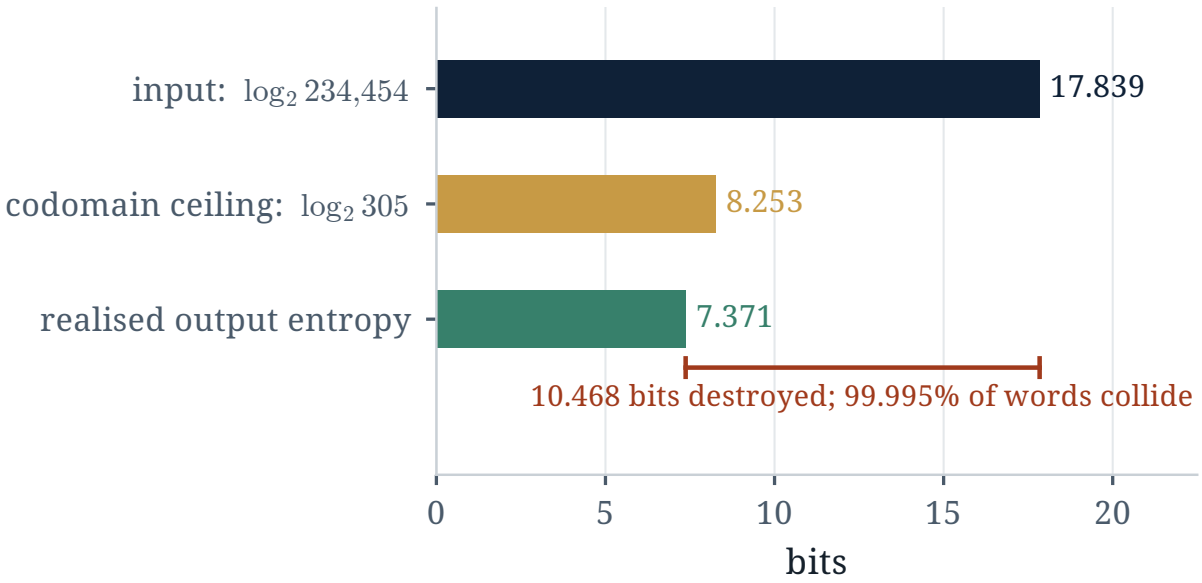
word length L	strings over 22 letters	distinct multisets	permutation collisions alone
2	484	253	1.913x
3	10,648	2,024	5.261x
4	234,256	12,650	18.518x
5	5,153,632	65,780	78.346x

At five letters, the ordering information — which is most of what a written word *is* — has already been thrown away at a rate of 78 to 1, before any value-arithmetic collisions are counted.

Property 2 — codomain size. The value range grows linearly in word length while the domain grows exponentially, so the collision rate grows without bound. Computed exactly over the Hebrew value set:

L	strings `22^L`	distinct achievable sums	mean preimage	bits in	bits out
2	484	178	2.719	8.92	7.48
3	10,648	577	18.454	13.38	9.17
4	234,256	976	240.016	17.84	9.93
5	5,153,632	1,375	3,748.096	22.30	10.43
6	113,379,904	1,774	63,912.009	26.76	10.79

The input column climbs by 4.46 bits per added letter. The output column climbs by less than a bit. **By six letters the average value is shared by roughly sixty-four thousand strings.**



Property 3 — no avalanche. A cryptographic hash is designed so that changing one input bit changes about half the output bits. Gematria does the opposite: changing one letter changes the value by exactly the difference of the two letter values, a small, signed, entirely predictable amount. It is a *checksum*, and a weak one — it will catch a single-letter substitution but not a transposition, which is the most common scribal error there is.

Now the measurement that settles the matter, performed on a real word list rather than on a model. Using English simple gematria (A = 1 through Z = 26) over the macOS `/usr/share/dict/words` list (`web2`), restricted to purely alphabetic ASCII entries:

```
distinct words                     234,454
distinct hash values                   305
value range                          1..328
mean bucket size                   768.702
largest bucket                value 102 -> 2,353 words
top five buckets      102:2353  107:2325  97:2305  100:2295  115:2272
singleton buckets (no collision)        12
fraction of words colliding       0.999949

input entropy   log2(234,454)  =  17.839 bits
output entropy  H(hash)        =   7.371 bits
ceiling         log2(305)      =   8.253 bits
DESTROYED                      =  10.468 bits
```

Gematria on this list destroys 10.47 of the 17.84 bits that identify a word, and 99.995% of words share their value with at least one other word.

The value 102 alone is shared by 2,353 words, beginning `abrogation`, `absurdly`, `acanthous`, `acatamathesia`, `acclimatize`, `achromatin`, `acontius`, `acrophonic`, `acroscopic`, `acroterial`, `actability`, `actionably`, `actionize`, `acupress`.

The engineering consequence is exact and it is the point of the section. **A shared gematria value is the default outcome, not a signal.** Discovering that two words share a value is discovering that a many-to-one map behaved as a many-to-one map. Under a uniform model, two arbitrary words from a 305-value codomain collide with probability on the order of 1/305, and words are not uniformly distributed, which makes it worse: the modal buckets hold over two thousand entries each. Any argument of the form *these two terms share a value, therefore they are related* is a statement about the map's compression ratio and contains no information about the terms. That is failure mode F12.2, and it is the most common analytical error in the entire literature this chapter is reading.

The deflation cuts one way only. It says the map carries no evidential weight. It does not say the map is useless: a digest that reduces 17.8 bits to 7.4 is a genuine index, and an index is a real mnemonic aid for exactly the reason §12.9 gives. Cross-referencing by digest is how you find candidate material in a corpus you cannot search. What you may not do is treat the retrieval cue as a result.

27.12.9 12.9 What these systems were actually for

The claim of this section is historical and it is well supported, but it is a historical claim and is badged as one: **these correspondence systems were mnemonic and combinatorial technologies — tools for holding a large number of relations in a mind, in cultures where written notation was scarce, expensive, restricted, or dangerous to possess.**

The load calculation makes the case quantitative. To hold `n` items as an unstructured web of pairwise relations costs `n(n−1)/2` facts. To hold them as a single ordered cycle costs `n` successor facts. To hold them as a table with `m` columns costs `n` rows.

n	unstructured pairs `n(n−1)/2`	ordered cycle `n`	ratio
7	21	7	3.00x
10	45	10	4.50x
12	66	12	5.50x
22	231	22	10.50x
78	3,003	78	38.50x

At `n = 78` the structured encoding is 38.5 times cheaper to hold than the relation set it addresses, and the saving grows linearly in `n`. That is the whole reason to build a correspondence table, and it is a reason that survives complete disbelief in every metaphysical claim ever attached to one.

Four design features of these systems are recognisable as mnemonic engineering, and each has a modern counterpart already treated in the framework:

(a) Small, fixed, memorable cardinalities. Seven planets, seven metals, seven days. Ten sephiroth. Twenty-two letters. Four elements. Twelve signs. These sit in the range a person can hold and rehearse. Dunbar's number is contested and should be stated as contested, but no one contests that seven is easier than seventy.

(b) Factored codes. Suit-and-rank: 18 labels address 56 identities. Planet-and-hour: 7 labels address 168 hour-slots per week. The log-additivity shown in §12.6 is why factoring is free in addressing power and enormous in memory cost.

(c) Redundant retrieval paths. 573 simple paths from node 1 to node 10 in the Kircher tree. Many cues, one content. This is the same principle as the method of loci (Yates, *The Art of Memory*, 1966), which the companion paper treats as the storage law with space as the retention medium [Curzi, 2026v] — high `eta`, low `delta`, because place is durable.

(d) Cross-modal binding. A correspondence table binds a name to a metal, a colour, a day, a scent, a number. Each additional column is another sensory handle on the same slot. This is cheap to add — one more row-entry per label — and it multiplies the retrieval cues.

(e) Combinatorial generativity. A table with `m` columns over `n` labels supports `n^2` ordered pairings, `C(n,2)` unordered ones, and arbitrary compositions across columns. The user does not need to have memorised the pairing; the pairing is *computed* from the table when needed. Lull's *Ars Magna* in the thirteenth century made this mechanical and explicit, with rotating concentric wheels that generate combinations of terms — a physical combinatorial engine.

None of (a) through (e) requires anything to be true about planets. They are the properties of a well-designed index in a world without indexes. **The systems are engineering artefacts of a severe memory constraint, and they are good ones; when the constraint was lifted by cheap print and then by search, the artefacts stopped being infrastructure and became objects of study, which is exactly what Star & Ruhleder (1996) predict — infrastructure becomes visible on breakdown [Star and Ruhleder, 1996, Star and Griesemer, 1989].** The converse warning applies to the modern instrument as much as to the old one: a legible scheme imposed on a domain destroys the local variety that made the domain work [Scott, 1998].

27.12.10 12.10 The join: a correspondence table is a category assignment

Now the connection this section exists to make.

The framework's decomposition [Curzi, 2026] is stated for a *block* structure: the ambient space splits into blocks `H_1, ..., H_m`, a vector's mass divides between blocks, and the surplus separates into a cross-block term and a within-block term. The validity conditions (§12.3) say one may not apply the functional until the blocks are declared. The frequency framework requires that an essence index is meaningless without a justified ordering of categories [Curzi, 2026].

Every one of those requirements is a requirement for a **table**: rows are categories, and the assignment of things to rows is the block structure.

```
correspondence table            framework object
------------------------------------------------------------------
the set of row labels           the category set, cardinality N
N                               the surplus ceiling ln N
assignment of items to rows     the block decomposition
within-row variation            u_div = alpha^2 sin^2 gamma
between-row relations           u_cross = beta^2
```

```
the row ordering (if used)      the essence index n \citep{ccp:CCP-050}
a column                        a function from categories to attributes
an unassigned item              a V1 violation: the table is not exhaustive
an item in two rows             a V2 violation: declare it or repartition
two rows naming the same thing  a V3 violation: N is inflated (see §12.11)
```

This is the substantive content of the thesis in the case of correspondence systems: the old artefact and the new formalism are doing the same job at the same point in the procedure, and the translation costs nothing on either side. It is not an argument that the old artefact is correct. A table can satisfy V1 through V4 perfectly and still assign the wrong attributes; being well-formed is not being true. It is an argument that the old artefact is the *right kind of object* — that when a fifteenth-century practitioner drew up a table of seven rows and four columns, the thing produced was a category scheme with a declared cardinality, which is precisely what a modern analyst must produce before computing `N_eff`.

The practical use is immediate. If you inherit a category scheme — a fault taxonomy, a diagnostic code list, a set of "customer segments" — you can run it through V1 to V4 exactly as you would run a historical table, and the audit will find the same faults.

27.12.11 12.11 Auditing N: the ceiling inflation fault

The most valuable thing the translation buys is a number that the tradition never computed: whether the table's `N` is real.

Take a seven-row table. Its declared ceiling is `ln 7 = 1.945910` nats, `2.807355` bits. Now suppose the audit finds that three of the seven rows are not distinct — that they name the same underlying category under different labels, which is the single most common defect in inherited taxonomies. The real cardinality is 4.

```
apparent ceiling   ln 7 = 1.945910 nats
real ceiling       ln 4 = 1.386294 nats
overstatement      0.559616 nats = 40.37% of the real ceiling
```

A scheme with three duplicate rows out of seven overstates its own surplus ceiling by 40.4%, and every downstream number — `N_eff`, `F`, headroom `h`, the storage law's growth condition — inherits that error at full size. This is the same fault as the concentration instrument's pseudo-diversity [Curzi, 2026], arriving from the taxonomy side rather than the roster side. It is also the corpus's own version of a much older correction: a diversification benefit depends on covariance, not on count, so `N` holdings that move together are one holding [Markowitz, 1952]. Two things must be kept apart here. `1/HHI` and `exp(H)` are Hill numbers of orders two and one and are fully grounded [Hill, 1973, Jost, 2006, Simpson, 1949]; the effective count used throughout this paper, `N_eff = 1 + (N−1)u`, is **not** a Hill number but a linear interpolation between 1 and `N`, is this framework's own construction, and has no counterpart in the ecological or information-theoretic literature. Small-roster estimation bias in any of them is well documented and is not corrected for here [Chao et al., 2014]. and it has the same signature: an organisation that believes it holds seven kinds of thing and behaves accordingly, while its actual variety is four.

The law of requisite variety is the reason this matters and not merely a bookkeeping irritation [Ashby, 1958, 1956]. Only variety absorbs variety. A control scheme with a genuine `N` of 4 cannot regulate a disturbance space of 7 kinds, and the table that says it has 7 rows will conceal the deficit until the fourth unhandled disturbance arrives.

Two neighbouring faults are worth naming beside it. The first is measuring on the wrong axis altogether: an entity-based exposure of 27.3 per cent against a 61.0 per cent currency share of the same balance sheet and roughly 58 per cent of settlement volume shows an inherited category scheme understating real dependency by more than a factor of two [Curzi, 2026]. **A duplicate audit fixes a count; it does not fix a scheme that is counting the wrong thing.**

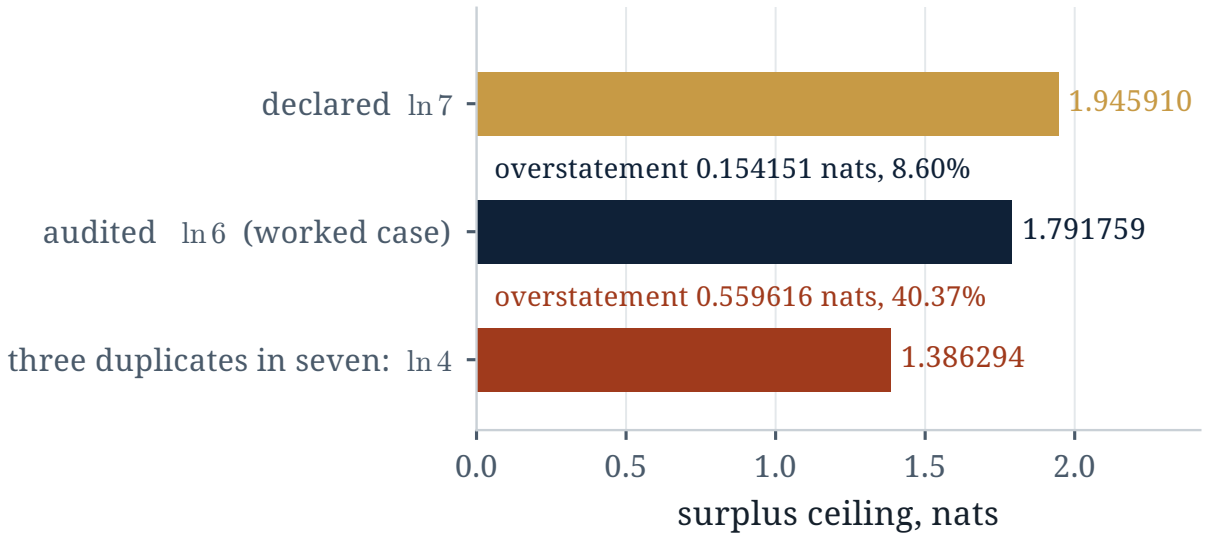


Figure 27.4: **Three duplicate rows in seven overstate the declared surplus ceiling by 0.559616 nats, 40.37 per cent of the real one.** The audited worked case of Section 15 is milder at 8.60 per cent, because two of its three suspect rows merged into one another rather than into three separate existing rows. Exact arithmetic on `ln 7`, `ln 6` and `ln 4`; produced by `figs/src/CCP-027_fig04.py`.

The second is the ceiling's other side: the roster ceiling `m(m-1) <= 2 eta ln(N) / kappa` binds the number of maintained relations rather than the number of categories, and a constructed commons sitting at 30 against a ceiling of 30.7225 is one member away from a structural problem [Curzi, 2026]. **Both ceilings are set by `ln N`, and both are inflated by the same duplicate rows.**

The diagnostic is mechanical: for every pair of rows, ask whether any observable item has ever been assigned to one and not the other, and whether any decision differs between them. If neither, the rows are duplicates. Merge them and recompute the ceiling before doing anything else.

27.13 13 Specification for building or auditing a correspondence table

Numbered, checkable requirements for building or auditing any correspondence table — historical, inherited, or new.

S12.1 — Publish the extension. The table must list its row labels exhaustively, in a fixed order, in one place. A correspondence system whose row set is "and so on" is not a category scheme and no quantity may be computed from it. Reject.

S12.2 — Declare N and derive the ceiling. State `N` and print `ln N` and `log2 N` beside it. Every downstream quantity is bounded by `ln N` [Curzi, 2026c] and the ceiling should be visible at the top of the artefact, not buried.

S12.3 — Pass V1 through V4 in print. Exhaustive, exclusive, counted, ordered-if-ordered. Each gate gets a line and a verdict. A failed gate demotes the artefact from *scheme* to *checklist* and the formalism may not be applied to it.

S12.4 — Run the duplicate audit before the first computation. For all `C(N,2)` row pairs, apply the §12.11 test. Report the number of merges performed and the corrected `N`. Print the overstatement in nats if any merge occurred.

S12.5 — Provide a residual row. Every scheme over an open domain requires an explicit `OTHER / NOT YET CATEGORISED` row, and the count in that row must be reported every period. A scheme with no residual row is not exhaustive; it is merely silent about what it drops. The rate of growth of the residual is the scheme's obsolescence signal.

S12.6 — State the arrangement whenever you state a metric. Any graph number — degree, diameter, density, cross-block fraction — is a number about one edge list. Print the edge list or cite it precisely. See H12-2.

S12.7 — Never treat a digest as a result. Any letter-sum, checksum, numerological value, or other many-to-one map may be used as a *retrieval index* and may not be used as *evidence of relation*. Where such a value is reported, report the collision rate of the map alongside it. See §12.8 and F12.2.

S12.8 — Justify the ordering separately from the membership. V3 and V4 are independent gates. A defensible set of categories with an arbitrary ordering yields arbitrary essence indices [Curzi, 2026]. If no ordering is defensible, use the scheme unordered and do not compute an index.

S12.9 — Measure the cross-block fraction; do not assume it. Count the relations that cross a category boundary and the relations that stay inside one, and report the fraction. This is the empirical handle on `beta^2`, and treating the measured fraction as `beta^2` is a modelling choice that must be badged each time it is made.

S12.10 — Prefer factored codes. Where a scheme addresses `n = p*q` identities, encode it as `p + q` labels with two columns rather than `n` labels with one. The addressing power is identical by log-additivity; the memory and maintenance cost falls from `n` to `p+q`.

S12.11 — Build redundant retrieval paths deliberately. More than one route to each entry. Count them: the number of distinct simple paths between the scheme's extreme entries is a computable robustness figure, as it was for the Kircher tree (573).

S12.12 — Re-audit on a fixed cadence. Category schemes drift: the world adds kinds and the table does not. Set a period, put the audit on it, and record `N` at each audit. A `delta` on the table itself is real, and the companion paper's periodic-forcing argument applies to maintaining it [Curzi, 2026v].

S12.13 — Keep the badge on. Where the artefact carries traditional attributions, say what is computed and what is inherited, in the same paragraph. A metric on a diagram is not an endorsement of the diagram's cosmology, and a reader must never have to guess which register a sentence is in.

27.14 14 Failure modes of correspondence tables

F12.1 — PHANTOM COLUMN. *Signature:* the table has a column whose entries cannot be independently checked against anything outside the table. Adding a row to the table is the only way anyone ever learns a new entry in that column. *Mechanism:* the column is definitional rather than empirical; it carries zero bits about the world because it is a relabelling of the row. *Fix:* mark such columns as *nomenclature* and exclude them from any information or surplus computation. They may be retained as mnemonic handles under S12.10; they may not be counted as attributes.

F12.2 — HASH MYSTICISM. *Signature:* an argument of the form "these two terms share a numerical value, therefore they are related." Escalated form: a search over many pairs until a coincidence is found, reported without the search. *Mechanism:* a many-to-one map colliding as many-to-one maps do. Measured on a real word list, the English simple-gematria map has 305 output values for 234,454 words, mean bucket 768.7, and 99.995% of words collide. The finding is a property of the map's compression ratio. *Fix:* report the collision rate with every value. Apply S12.7 without exception. If an argument survives the disclosure that its coinci-

dence had a one-in-a-few-hundred prior, it was not resting on the coincidence and should be restated without it.

F12.3 — CEILING INFLATION BY DUPLICATE ROWS. *Signature:* the declared `N` exceeds the number of rows that any decision actually distinguishes. No item has ever been assigned to row `i` rather than row `j`, and no action differs between them. *Mechanism:* `N` enters the formalism as `ln N`, the hard ceiling. Duplicates raise the nominal ceiling without raising real variety. Computed instance: 3 duplicates in 7 rows overstates the ceiling by 0.559616 nats, 40.37%. *Fix:* S12.4, before any other computation. Then re-derive headroom `h = eta ln N − delta Q − C` with the corrected `N`, and expect it to fall.

F12.4 — UNSTATED ARRANGEMENT. *Signature:* a graph metric is quoted — "twenty-two paths", "the diameter is three" — with no edge list, and the source diagram turns out to differ between editions. *Mechanism:* the metric is a function of the edge list. Different traditions draw different edges; the numbers are not comparable across them. *Fix:* H12-2 and S12.6. Print the edge list. Where two arrangements are in play, compute both and report the difference; the difference is itself informative about what the tradition treated as optional.

F12.5 — VAGUE EXTENSION. *Signature:* the scheme cannot answer, for a specific concrete item, which row it belongs to — and different competent users answer differently. *Mechanism:* V1 and V2 fail simultaneously. There is no partition, therefore no block decomposition, therefore no `u_cross` and no `u_div`. *Fix:* either sharpen the row definitions until inter-rater assignment is reproducible (this is FVP-7's cross-individual gate applied to a taxonomy), or demote the artefact in print to a heuristic list and stop computing with it. Both are acceptable outcomes; silence is not.

F12.6 — EDGE INVENTION. *Signature:* a relation is asserted between two labels because the diagram has room for it, or because symmetry would be prettier, rather than because a source or an observation carries it. *Mechanism:* the graph is being fitted to an aesthetic prior. This is over-framing, `D/P > 1`, at the level of the notation itself as an ordering rather than a quotient [Curzi, 2026t]. *Fix:* every edge carries a provenance token — source, observation, or *conjecture*. Compute all metrics twice, once with conjectural edges and once without, and print both. The gap is the scheme's exposure to its own aesthetics.

F12.7 — UNIVERSAL CORRESPONDENCE. *Signature:* the scheme claims to categorise everything. Any new object can be placed in it, and no observation could ever fall outside it. *Mechanism:* a scheme that cannot fail to apply carries no information about what it applies to. This is FVP-6's falsification gate failing at the taxonomy level, and it is the framework's test for a legitimate postulate [Curzi, 2026]. *Fix:* state, in print, a concrete item the scheme does *not* categorise, or an observation that would force a new row. If no such item can be named, the scheme is unfalsifiable and must be demoted to a language rather than a measurement instrument.

F12.8 — TREE-FLATTENING. *Signature:* a densely cyclic scheme is redrawn as a strict hierarchy "for clarity", and the overlaps are deleted. *Mechanism:* Alexander, "A City is Not a Tree" (1965). A semilattice flattened to a tree loses exactly the overlapping memberships that carried the cross-block relations. Concretely: the Kircher arrangement has 13 independent cycles; the spanning tree has 0. Flattening deletes 13 relations and the cross-block fraction collapses. *Fix:* refuse the flattening, or perform it only as a *view* over a preserved cyclic master, and label the view as lossy. Count the deleted cycles and report the count.

F12.9 — INHERITED N. *Signature:* the scheme's cardinality is a traditional number — seven, ten, twelve, twenty-two — and no one can say what would have happened if the domain had contained eight kinds. *Mechanism:* `N` was set by the notation rather than by the domain. The scheme then forces the domain into its cardinality, merging real distinctions or splitting artificial ones. *Fix:* derive `N` from the domain first, independently, then compare it to the traditional number and print both. Where they differ, the traditional number is a hypothesis about the domain and should be tested, not assumed. Where they agree, say by how much the agreement was constrained.

27.15 15 Worked example: an inherited fault taxonomy audited end to end

27.15.1 15.1 The maintenance department's fault taxonomy

A building-services department of fourteen staff maintains a research campus. It has an inherited fault taxonomy of **seven categories**, established a decade ago, used to route every incoming work order. The head of department wants to know whether the taxonomy is real, what it costs, and whether the department's stored capability is growing or decaying. The procedure is run end to end.

Step 1 — Publish the extension (S12.1). The seven rows, as inherited:

```
1  ELECTRICAL          5  FABRIC / BUILDING ENVELOPE
2  MECHANICAL / HVAC   6  PLANT FAILURE
3  PLUMBING            7  EQUIPMENT FAULT
4  CONTROLS / BMS
```

Step 2 — Declare N and the ceiling (S12.2).

```
N = 7      ln 7 = 1.945910 nats      log2 7 = 2.807355 bits
```

Step 3 — Validity gates (S12.3).

```
V1 EXHAUSTIVE   FAIL.  No residual row. 11% of work orders in the last year were
                       filed under row 7 with free-text that matched none of rows 1–6.
V2 EXCLUSIVE    FAIL.  Rows 6 and 7 overlap and rows 2 and 6 overlap.
V3 COUNTED      PENDING duplicate audit.
V4 ORDERED      N/A.   The taxonomy is unordered; no essence index is computed. Correct.
```

Step 4 — Duplicate audit (S12.4). For all `C(7,2) = 21` row pairs, ask: has any item ever been assigned to one and not the other, and does any decision differ?

```
(2, 6)  PLANT FAILURE vs MECHANICAL/HVAC   -- no routing difference; same two engineers;
                                              same parts store.                MERGE
(6, 7)  PLANT FAILURE vs EQUIPMENT FAULT   -- distinction is who owns the asset,
                                              not what the fault is.           MERGE
(5, 7)  FABRIC vs EQUIPMENT FAULT          -- distinct: different trade, different SLA.  keep
all others                                                                      keep
```

Two merges. Rows 2, 6 and 7 collapse into a single category. The corrected count:

```
corrected N = 4 + 1 = 5    ... but row 7's residual traffic must go somewhere.
```

Adding the mandatory residual row (S12.5) restores a fifth and sixth:

```
1  ELECTRICAL
2  MECHANICAL / PLANT / EQUIPMENT      (merged from old 2, 6, 7)
3  PLUMBING
4  CONTROLS / BMS
5  FABRIC / ENVELOPE
6  UNCATEGORISED  -- residual, counted and reported every period

corrected N = 6      ln 6 = 1.791759 nats
```

The overstatement carried by the inherited taxonomy, in the pure form computed in §12.11 where a seven-row scheme is really four:

```
ln 7 − ln 4 = 1.945910 − 1.386294 = 0.559616 nats = 40.37% overstatement
```

In this department's actual case, seven collapsing to six is milder:

```
ln 7 − ln 6 = 1.945910 − 1.791759 = 0.154151 nats = 8.60% overstatement
```

The department believed it had 7 kinds of fault and had 6, one of which is an admission of ignorance it had not previously been counting. The 8.60% is the honest correction and it is smaller than the textbook case because two of the three suspect rows genuinely merged into one another rather than into three separate existing rows.

Step 5 — Cross-block measurement (S12.9). Over the last 400 work orders, count how many required a person from more than one category to close:

```
single-category closures     262
cross-category closures      138
cross fraction               138/400 = 0.345
```

Badged modelling choice: take `beta^2 = 0.345`, hence `alpha^2 = 0.655`. This is the same choice made in §12.5 and it carries the same badge: the theorem does not require it.

Step 6 — Surplus. With `N = 6` and a within-category framing angle estimated at `gamma = 40 deg` (from the spread of independent diagnoses recorded on cross-category jobs):

```
u_cross = 0.345000
u_div   = 0.655 * sin^2(40 deg) = 0.655 * 0.413176 = 0.270630
u       = 0.615630
N_eff   = 1 + (6-1)*0.615630 = 4.078151
F       = ln(4.078151) = 1.405644 nats        ceiling ln 6 = 1.791759
utilisation = 1.405644 / 1.791759 = 78.45% of ceiling
```

Subadditivity check, as required:

```
f(u_cross) = ln(1 + 5*0.345000)   = ln(2.725000) = 1.002468
f(u_div)   = ln(1 + 5*0.270630)   = ln(2.353150) = 0.855756
max = 1.002468  <=  f(u) = 1.405644  <=  sum = 1.858224       OK
```

Interpretation, stated as the formalism permits: a six-category department whose staff genuinely hold non-parallel framings is running at 78.45% of the surplus its own taxonomy allows. The remaining 21.55% is bought only by raising `u` — more genuinely different framings, or more cross-category work — and it is capped at `ln 6` no matter what. To go beyond `ln 6` the department must legitimately add a category, which means finding a kind of fault it currently cannot name. That is what the residual row is for, and it is why S12.5 requires it.

Step 7 — Feed the storage law. The department's parameters, estimated from its own records:

```
eta   = 0.42      fraction of interaction that becomes durable capability
                  (documented procedures, trained second-persons, updated asset records)
delta = 0.11      annual decay: staff turnover 14%, plus procedure drift
Q_t   = 5.6       current stored capability, in the same nat-scaled units as eta*S
C_t   = 0.31      coordination overhead per period
```

Headroom, the master gauge:

```
h_t = eta * ln N - delta * Q_t - C_t
    = 0.42 * 1.791759 - 0.11 * 5.6 - 0.31
    = 0.752539 - 0.616000 - 0.310000
    = -0.173461
```

Negative. `h_t < 0` means that in this model no interaction geometry saves it [Curzi, 2026b]. The department cannot grow its stored capability by rearranging who works with whom, because even at the absolute ceiling `ln 6`, conversion times ceiling does not cover decay plus cost.

Note what the audit did to this verdict. With the *inherited* `N = 7`:

```
h_t = 0.42 * 1.945910 - 0.616000 - 0.310000 = 0.817282 - 0.926000 = -0.108718
```

Still negative — but 37% less negative, and a manager reading the uncorrected figure would have been closer to believing that a modest push on `u` could close the gap. It could not, in either case, but the corrected figure shows the true size of the shortfall. **The audit did not change the sign of the verdict; it changed the size of the intervention the verdict requires, which is the number the department actually needs.**

The three admissible responses, in the order the formalism ranks them:

```
raise eta    0.42 -> 0.52 :  h = 0.931715 - 0.926000 = +0.005715   marginal, positive
cut C        0.31 -> 0.18 :  h = 0.752539 - 0.616000 - 0.180000 = -0.043461   still negative
cut delta    0.11 -> 0.07 :  h = 0.752539 - 0.392000 - 0.310000 = +0.050539   positive
cut delta AND raise eta   :  h = 0.931715 - 0.392000 - 0.310000 = +0.229715   comfortable
```

The dominant lever is `delta`, which for this department means turnover and procedure drift — and that is the honest engineering conclusion. Reorganising the taxonomy was necessary to get an accurate number and was never going to be sufficient to fix the problem. **A correspondence table tells you what `N` is; it does not tell you what `delta` is, and `delta` was the binding constraint.**

27.15.2 15.2 What the worked example demonstrates

Every step above was performed on an ordinary building-services taxonomy, and every step is identical in form to what §§12.4 through 12.8 performed on a seventeenth-century diagram and a scheme of letter values. The gates are the same, the block decomposition is the same, the ceiling is the same `ln N`, and the storage law that consumes the result is the same equation.

That identity of procedure is the entirety of what this section claims. It is the thesis in its narrow, defensible form: **the old correspondence systems and the framework's category requirement are the same object at the same point in the same procedure, expressed in different notation.** The old notation carried it in seven rows and four columns, memorised, because there was no other way to carry it. The new notation carries it in a partition, a cardinality, and a cross-block fraction, because now there is.

The companion paper takes the next object in the same notation – the figure drawn on the page rather than the table held in the mind – and finds that it has an exact arithmetic invariant that the tradition drew for centuries without naming [Curzi, 2026v].

27.16 16 Results

Every number in this section is either exact arithmetic on quantities the paper defines, or the output of a simulation whose generating parameters are printed beside it. **No dataset was collected, and nothing here is a measurement of a person, an organisation, or a historical practice.** Where a figure is a simulation output it is rounded to the precision the replication count supports and no further.

27.16.1 16.1 The falsification suite is anti-conservative against itself

R1. Across 500 null trials at nominal `alpha = 0.05` – `Y` driven by a smooth AR(1) input that is not `S`, `S` an independent smooth AR(1) series, autocorrelation parameter 0.85 on both, `T_train = 40`, `T_holdout = 20`, 200 surrogates per trial, true `b = 0` – **the shuffled-input control rejected the true null at 0.108 for independent permutation, 0.120 for circular shift, and 0.060 for block permutation with block length 5.** Two of the three families are anti-conservative by a factor of more than two; the third is anti-conservative by 20 per cent.

The effect size that belongs beside those rates is the shortfall against nominal: **+0.058 and +0.070 in absolute rejection probability for the two failing families, and +0.010 for the passing one.** With 500 trials the standard error on a measured rate near 0.10 is `sqrt(0.10 x 0.90 / 500) = 0.0134`, so 0.108 sits 4.3 standard errors above 0.05 and 0.120 sits 5.2 above; 0.060 sits 0.7 above and is not distinguishable from nominal at this replication count. **The conclusion for block permutation is therefore "not shown to differ from nominal", not "shown to equal nominal"**, and it should not be reported as the latter.

Power was measured on the same design with true `b = 0.40`: **1.000 for independent permutation, 1.000 for circular shift, 0.998 for block permutation.** Block permutation buys its calibration for almost nothing, which is why it is the default in S4.8.

Two secondary observations. Intuition about surrogate tightness does not survive contact with a short window: the circular shift preserves the most structure and was the *worst* calibrated here, because rotating a 21-point held-out segment leaves few genuinely distinct surrogates. And a permutation p-value cannot fall below `1/(B+1)`, so `B` is a resolution parameter and not a detail: `B = 199` is the floor for a claim at the 1 per cent level and `B = 999` for anything stronger.

27.16.2 16.2 What the suite lets through

R2. In a separate 300-trial run with true `b = 0` and the reported `Y_{t+1}` inflated by `0.45 x (S_t – mean S)` – a subject who has inferred the hypothesis and whose recall of the input colours the output rating – **the full four-baseline suite passed the fabricated relationship 52.7 per cent of the time.** An example trial returned `a_hat = 0.9265` and `b_hat = 0.1856`, both strictly inside the admissible box, with a held-out model RMSE of 0.0991 against a matched-AR 0.1112 and a circular-shift surrogate mean of 0.1168, at a shuffle `p` of 0.0000.

There is no statistical remedy for this, and the paper does not offer one. The fabrication is temporal; the shuffle is a temporal test; a temporal test endorses a temporal fabrication. The remedies are design remedies – blinding the rater to the hypothesis, separating the channels carrying `Y` and `U`, prospective rather than retrospective sampling, and a yoked control – and S4.12 requires at least two of the four to be in force and named.

R2b. The matched autoregressive comparison, run alone on the null design of §4.7, **false-passed 35.8 per cent of the time.** A single baseline comparison on two smooth series is a coin weighted only slightly against the analyst.

27.16.3 16.3 Goodhart drift, measured

R3. A system was run normally for 30 periods, at which point `Y` acquired a consequence and the *reported* value inflated by 0.35 while the underlying `Q` continued to obey the same law. Pre-target fit on periods 0-30: `a = 0.8992`, `b = 0.3105`, so `delta = 0.1008` and `eta = 0.3105`. Post-target fit on periods 30-60: `a = 0.8817`, `b = 0.3551`, so `delta = 0.1183` and `eta = 0.3551`. **The estimated conversion efficiency rose by 14 per cent – exactly, by `(0.3551 – 0.3105)/0.3105 = 0.1436`, so 14.4 per cent – at the moment the true stock began to fall, from 3.0359 to 2.8447.** Nothing in the fit complained: the constraints held and both parameters stayed strictly interior.

The signature is therefore a *rising* `eta_hat` beside a *falling* independent indicator, and the detection procedure follows from it: keep a shadow proxy that is never reported upward, test

for a structural break at every date on which the measure acquired a consequence, compare the two trajectories, and prefer proxies that are expensive to fake.

27.16.4 16.4 Instrument noise moves both parameters, in a known direction

R4. At `T = 80` with true `a = 0.85` and `b = 0.40`, process noise 0.06, and 400 replications per row, rating standard deviations of 0.00, 0.05, 0.10, 0.20 and 0.40 returned mean `a_hat` of 0.8486, 0.8419, 0.8219, 0.7571 and 0.5683, mean `b_hat` of 0.4022, 0.4156, 0.4538, 0.5783 and 0.9425, and implied `delta_hat` of 0.1514, 0.1581, 0.1781, 0.2429 and 0.4317. **At a rating standard deviation of 0.40 against a `Y` whose own standard deviation is about 0.20, decay is over-estimated by a factor of 2.88 and conversion by a factor of 2.36.**

This is regression dilution applied to a lagged regressor, and it is the reason a parameter estimate without an accompanying reliability figure for the instrument that produced it is uninterpretable: the reader cannot separate the world from the ruler.

27.16.5 16.5 One window, perfect measurement, and a 16.5 per cent miss

R5. In the worked example of Section 7 – one subject, 61 daily periods, `N = 7`, `ln N = 1.945910`, generating parameters `delta = 0.15` and `eta = 0.40`, process noise 0.06, **no rating noise at all** – the constrained fit on 40 training periods returned `a_hat = 0.8833` and `b_hat = 0.3340`. At this `T` and noise the sampling standard deviations are 0.0173 on `a_hat` and 0.0341 on `b_hat`, so the estimates sit at **+2.13 and -2.15 standard errors**: a tail draw in opposite directions, which is the correlated error the two coefficients trade between them.

The shortfall on `eta` is `0.400 − 0.334 = 0.066`, which is 16.5 per cent of the true value. The source manuscript reports this as "17 per cent"; the exact figure is 16.5 per cent, it is the figure used in the abstract and throughout this paper, and the discrepancy is recorded here because a rounding that moves in the direction of a larger-sounding effect should be visible. Either way the point stands: **a single forty-period window on a single subject, with everything measured perfectly, missed the conversion parameter by more than two standard errors.**

The frozen model then beat every baseline on the held-out window – RMSE 0.0777 against persistence 0.1207 (skill 0.5860), direct input 0.0842 (0.1486, declared uninformative because the observed span of `u` was 0.5484 against a preregistered minimum of 0.60), matched autoregression 0.1248 (0.6123), and three shuffle families at 0.1256 to 0.1300 with `p = 0.0000` at `B = 2000` each. **Not one of the six thousand surrogates produced a held-out error as small as the ordered model's**, and the best of 2000 block permutations still predicted 46 per cent worse than the true ordering.

27.16.6 16.6 The same suite, on a null, refuses

Run unchanged on a series generated with no relationship to `S`, the suite fired all three rules. The constrained fit hit the retention boundary at `a_hat = 1.0000` exactly – a Rule 3 event, which S4.6 sends to the abstract. **The training-window `R^2` was 0.6477**, a figure that would be reported as a strong result in many papers, while on held-out data the frozen model was beaten by persistence (0.0730 against 0.0978), beaten decisively by matched autoregression (0.0681, skill -1.0669), and beaten by essentially every one of 2000 circular-shift surrogates at `p = 1.000`. **An in-sample `R^2` of 0.65 with a held-out failure against every baseline is not a contradiction; it is the ordinary appearance of a false result.**

27.16.7 16.7 The programme's price and its survival probability

R6. The five stages, run strictly in order, total 71 months and 8,554.8 researcher-hours across 570 participants contributing 2,791.2 participant-hours; with the declared 30 per cent overlap of Stages 2-3 and 4-5 the calendar compresses to 61 months. At 1,600 productive hours per

full-time-equivalent year that is **5.35 FTE-years per attempt**, implying continuous staffing of 0.90 FTE.

Twenty-one kill conditions are published in advance, four of them terminal for the whole enterprise. Under declared priors of 0.10, 0.10, 0.15, 0.35 and 0.20 for failure at each stage, the survival curve runs 0.9000, 0.8100, 0.6885, 0.4475 and **0.3580**, so `P(dies at or before Stage 4) = 0.5525` and the expected cost per completed programme is `5.35 / 0.3580 = 14.93 FTE-years`. **These are priors and not evidence**; a reader who disagrees substitutes their own and redoes one line of arithmetic. What is not a matter of taste is the shape: a programme whose stated completion probability is high has almost certainly written its kill conditions too loosely.

27.16.8 16.8 Ceiling inflation, and a digest that carries no evidence

R7. A seven-row category scheme declares a surplus ceiling of `ln 7 = 1.945910` nats. If three of its rows are not distinct – no item has ever been assigned to one rather than another and no decision differs between them – the real cardinality is 4 and the real ceiling is `ln 4 = 1.386294`. **The overstatement is 0.559616 nats, which is 40.37 per cent of the real ceiling, and every downstream quantity – the effective count, the surplus, headroom, the growth condition – inherits it at full size.** In the worked audit of Section 15 the same procedure collapsed seven rows to six once a residual row was added, an overstatement of 0.154151 nats or 8.60 per cent, and the corrected headroom went from `−0.108718` to `−0.173461`: **the audit did not change the sign of the verdict, it changed the size of the intervention the verdict requires by 37 per cent.**

R8. A letter-sum map from strings to integers is a hash function, and measuring it as one is deflationary. On the 234,454 purely alphabetic entries of the macOS `web2` word list under English simple gematria the map has **305 distinct values**, a mean bucket of 768.702, a largest bucket of 2,353 words at value 102, **12 singleton buckets, and 99.995 per cent of words colliding.** Input entropy is `log2(234,454) = 17.839` bits, the codomain ceiling is `log2(305) = 8.253` bits, realised output entropy is 7.371 bits, and **10.468 bits are destroyed.** A shared value is the default behaviour of a many-to-one map and contains no information about the words; the map remains a usable retrieval index and is not usable as evidence of relation.

27.17 17 Discussion

27.17.1 17.1 What follows

A control whose false-positive rate is unmeasured is an assertion. The single most transferable result here is not the number 0.108 but the procedure that produced it: simulate the study's own design with the input coefficient set to zero, measure the actual rejection rate, and use the resulting critical value in place of the nominal one. It takes minutes, it requires no additional data, and it converts a nominal p-value into a calibrated one. Every paper in this corpus reporting a shuffle p-value should be read as reporting an uncalibrated one, and at least one already says so of itself [Curzi, 2026i].

A design control and a statistical control are not substitutes. The 52.7 per cent figure is the sharpest statement of that in the paper: no quantity of surrogates repairs a fabrication whose timing is real. The remedies are blinding, channel separation, prospective sampling and a yoked control, and the reason to name which are in force is that a reader cannot otherwise price the result at all.

Measure corruption has a computable signature. Goodhart's law and Campbell's law are usually invoked as cautions [Goodhart, 1975, Campbell, 1979]; §4.12 turns them into a detection procedure with a direction – rising `eta_hat` beside a falling shadow indicator, dated to a decision – which is testable in a way a caution is not.

A research programme's honest price includes the attempts that stop early. The figure a funder needs is not 5.35 FTE-years but 14.93, because most attempts die, and the deaths are

the point: nine or ten of those years are spent learning that something does not work, which is the ordinary ratio in any field that tests things.

27.17.2 17.2 What does not follow

The simulations establish properties **of this design**. The measured rejection rates depend on the autocorrelation of both series, the lengths of the training and held-out windows, the number of surrogates, and the constraint set; none of those is universal, and **the numbers 0.108, 0.120 and 0.060 should be read as a demonstration that calibration is necessary, not as a table anyone may copy.** That is exactly why S4.10 requires each study to calibrate on its own design.

Nothing here shows the storage law is false, and nothing shows it is true. The worked example's first half is a simulation in which the law was true by construction, and the suite found it; the second half is a simulation in which it was false by construction, and the suite refused it. **Both halves test the suite, not the law.**

Nothing here identifies a social effect. §3.4 is unqualified about that: the reflexive specification is not identified from observation [Manski, 1993, Shalizi and Thomas, 2011], and the programme of Section 8 randomises only its intervention arm and only at Stage 5.

Nothing in Sections 12 to 15 asserts any supernatural claim, any physical effect of a symbol, or any mechanism. The reading rule is a translation; the graph metrics are metrics of one printed edge list and would be unchanged if the diagram had been drawn to organise plumbing fixtures; and the thesis that the old and new notations describe the same relations is a claim about *structural correspondence*, which is not evidence of mechanism.

27.17.3 17.3 Relation to the surrounding literature

The preregistration apparatus here is the standard remedy for undeclared analytic flexibility [Nosek et al., 2018, Simmons et al., 2011, Gelman and Loken, 2013], deployed against a replication base rate that is itself the reason the remedy exists [Open Science Collaboration, 2015, Ioannidis, 2005]. What this paper adds is a step further down: **the preregistered control is itself preregistered against a simulated null.**

The measurement programme is the part most exposed to existing critique, and the critique is correct. Michell [1997] argues that psychology assumes quantitative structure without testing for it; Stage 2 of Section 8 is an attempt to test for it, and it uses cross-modality matching rather than conjoint measurement [Luce and Tukey, 1964, Krantz et al., 1971], which is the weaker of the two instruments for that question. The scale-type gate that licenses division at all is Stevens [1946]'s, and the corpus's own meaningfulness theorem states the condition sharply [Curzi, 2026t].

The field-level objection is that formal social models are rarely discriminated by data. Sobkowicz [2020] finds the situation in opinion dynamics essentially unchanged over eleven years; Gallegati et al. [2006] makes the same charge against econophysics from inside it, with sub-standard statistical procedure and unjustified universality claims heading the list; Durlauf [2005] demands a **differential** prediction that simpler models do not also make. **This paper's response is not a rebuttal but an instrument**: the four baselines exist precisely to name the simpler models, and the matched autoregression is the differential test Durlauf asks for. That the matched autoregression alone false-passes 35.8 per cent of the time is the honest report of how weak that test is when run once.

The predictability ceiling is relevant to the programme's Stage 5 and is not evaded. Hofman et al. [2017] and Salganik et al. [2020] between them establish that with fifteen years of high-quality longitudinal data and hundreds of teams, life outcomes were not predicted well by anything; Lazer et al. [2014] documents the failure of a flagship prediction system by an author of the paper that defined the field. A programme proposing to predict held-out group order should expect to be measured against that record, and Stage 5's kill condition K5.1 is written to be reached.

Finally, the framework's own reflexivity is the strongest thing said against it and comes from sympathetic sources. Hacking [1995] shows that classifications of people move because the people classified respond; MacKenzie and Millo [2003] shows a theory becoming true by being adopted, with dates and price data; Ferraro et al. [2005] shows theories making people behave worse by assuming the worst of them. **A corpus proposing to give people laws to manage their own comfort by is building an engine and should say so.**

27.18 18 Verification

27.18.1 18.1 Dimensional audit

`[Q]` is the dimension of the order proxy – whatever unit it counts – and `[T]` is time, with the period as its unit.

Symbol	Dimension	Unit	Status
`Y_t`	`[Q]`	whatever the declared order proxy counts	**measured** by the declared instrument
`U_t`	`[1]`	none	**defined** dimensionless, `u` in `[0,1]`
`F(U_t)`	`[1]`	nats	**derived** dimensionless: a logarithm of an effective count
`a`	`[1]`	per period	**fitted** dimensionless; `a = 1 − delta`
`b`	`[Q]` per nat per period	proxy units per nat per period	**fitted**; identified with `eta`, *not* dimensionless
`Chat_t`	`[Q]` per period	proxy units per period	**measured**, denominated in `Y`-units by construction
`eps_t`	`[Q]` per period	proxy units per period	**residual**
`N`	`[1]`	a count	**audited**, not guessed
`ln N`	`[1]`	nats	**derived**
`h`	`[Q]` per period	proxy units per period	**derived**
`Q_inf`	`[Q]`	proxy units	**derived**: `[Q]`/period ÷ `[1]`/period returns `[Q]`
RMSE	`[Q]`	proxy units	**measured**
`p`	`[1]`	none	**derived**, a probability
`B`	`[1]`	a count of surrogates	**chosen**

Does it balance? `Y_{t+1} = a Y_t + b F(U_t) − Chat_t + eps_t` balances if and only if every right-hand term carries `[Q]`. The first does because `a` is dimensionless. The third does by the denomination rule of S4.3, which is exactly why that rule is a specification and not a preference: **a cost series left in hours or in currency makes the equation dimensionally malformed however tidy the arithmetic looks.** The second does only if `b` carries `[Q]` per nat per period, which is why `eta` must be reported as proxy-units per nat and never as a bare number. The fixed coefficient of one on `Chat` is a dimensional statement as much as an identification one.

Where the framework has no operational unit, that is said here. `Q` is stored order and has no natural unit; it is counted in whatever the declared proxy counts, and two systems' `Q` values are not comparable unless they declare the same proxy. The constructs behind `D`, `P` and `E` in Section 8 have **no operational unit at all** – establishing whether they can be given one is the entire content of Stages 1 and 2, and K1.1 and K2.4 are the conditions under which the answer is no. The underlying construct of comfort is treated as a dimensionless magnitude by stipulation, and Section 19 records that the quantitative structure required for that stipulation has not been tested.

27.18.2 18.2 Significant figures against epistemic status

Three classes of number appear in this paper and they are quoted differently on purpose.

- **Exact arithmetic.** `ln 7 = 1.945910`, `ln 6 = 1.791759`, `ln 4 = 1.386294`, `ln 7 − ln 4 = 0.559616`, `log2(305) = 8.253`, `log2(4) + log2(14) = log2(56)`, `24 mod 7 = 3`, `22/45 = 0.488889`, `71/45 = 1.577778`. Quoted to whatever precision is useful, because they are exact.
- **Simulation output.** Rejection rates from 500 trials, parameter means from 400 replications, the survival curve. Quoted to three or four figures, which is at or slightly beyond what the replication counts support; the standard error on a rate near 0.10 at 500 trials is 0.0134, so **the third figure in 0.108 is not resolved and should not be read as though it were.**
- **Declared priors.** 0.10, 0.10, 0.15, 0.35, 0.20 and everything computed from them. These are quoted to two figures and their products to four, which flatters them; `0.3580` is arithmetic on guesses and carries exactly the status of the guesses.

No quantity in this paper is a measurement of a person or an organisation, so no quantity in it carries an empirical uncertainty interval. That is a limitation and is recorded as one.

27.18.3 18.3 Postulates

Six postulates. Each is atomic, each is checkable alone, and each carries its status. Where a postulate could be dropped and the conclusion still follow, it has been dropped.

P1 — The nominal level of the test is 0.05. *Status:* **DEFINITION** – the convention declared in field F1 of the preregistration. It carries no empirical weight.

P2 — Across 500 null trials on the design of §4.7, the measured rejection rates were 0.108 (independent permutation), 0.120 (circular shift) and 0.060 (block permutation, `L = 5`). *Status:* **POSTULATED** – a simulation output of this work, with the generating process, autocorrelation parameter, window lengths and surrogate count all printed in §4.7. It is reproducible from those parameters and is supported by no external source.

P3 — A rate `r` measured over `n` independent trials has standard error `sqrt(r(1−r)/n)`. *Status:* **ARITHMETIC** – the binomial standard error, which any reader can apply to P2.

P4 — The estimated conversion efficiency before and after the Goodhart break was 0.3105 and 0.3551, and the true stock was 3.0359 and 2.8447. *Status:* **POSTULATED** – a simulation output, with the inflation of 0.35 at period 30 declared in §4.12.

P5 — The declared per-stage failure probabilities are 0.10, 0.10, 0.15, 0.35 and 0.20, and stage failures are independent. *Status:* **DEFINITION** for the numbers and **POSTULATED** for the independence; the independence assumption is the load-bearing one and is the first thing a reader should attack, because a common cause of failure across stages – an unmeasurable construct, say – would make the true survival probability lower than 0.3580 rather than higher.

P6 — A row pair is a duplicate when no observable item has ever been assigned to one rather than the other and no decision differs between them. *Status:* **DEFINITION** – the audit criterion of §12.11, stated so that it can be applied by someone who does not accept the framework.

27.18.4 18.4 The compounding chain

```
P1 + P2   -> L1  0.108 / 0.05 = 2.16                                  ARITHMETIC
P1 + P2   -> L2  0.120 / 0.05 = 2.40                                  ARITHMETIC
P1 + P2   -> L3  0.060 / 0.05 = 1.20                                  ARITHMETIC
P2 + P3   -> L4  se at r = 0.108, n = 500 is sqrt(.108*.892/500)
                 = 0.01388;  (0.108 - 0.05)/0.01388 = 4.18            ARITHMETIC
P2 + P3   -> L5  se at r = 0.060 is sqrt(.06*.94/500) = 0.01062;
                 (0.060 - 0.05)/0.01062 = 0.94                        ARITHMETIC
L1 + L4   -> R1a independent permutation is anti-conservative,
                 and the excess is resolved by the replication count  ARITHMETIC
L3 + L5   -> R1b block permutation is NOT SHOWN to differ from
                 nominal at n = 500; it is not shown to equal it      ARITHMETIC
P4        -> L6  (0.3551 - 0.3105)/0.3105 = 0.14363                   ARITHMETIC
P4        -> L7  (3.0359 - 2.8447)/3.0359 = 0.06298                   ARITHMETIC
L6 + L7   -> R3  eta_hat rose 14.4% while the true stock fell 6.3%,
                 so the sign of the estimate's motion is opposite to
                 the sign of the system's                             ARITHMETIC
P5        -> L8  0.90 x 0.90 x 0.85 x 0.65 x 0.80 = 0.358020          ARITHMETIC
P5        -> L9  1 - 0.90 x 0.90 x 0.85 x 0.65    = 0.552475          ARITHMETIC
L8        -> R6  8554.8/1600 = 5.34675 FTE-yr per attempt;
                 5.34675/0.358020 = 14.934 FTE-yr per completion      ARITHMETIC
P6        -> L10 seven rows with three duplicates has real N = 4      DEFINITION

                 0.559616/1.386294 = 0.403677                         ARITHMETIC
```

Every line is checkable from its own inputs. The three divisions a reviewer can redo in a minute are `0.108/0.05 = 2.16`, `0.90 x 0.90 x 0.85 x 0.65 x 0.80 = 0.35802`, and `(1.945910 - 1.386294)/1.386294 = 0.40368`. Those three carry the paper's three headline claims.

What the chain does not establish, stated here rather than left to a reader. R1a and R1b rest on P2, whose status is POSTULATED: they are properties of a simulation this work ran, and no external source corroborates them. R3 rests on P4, which is the same. R6 rests on P5, whose numbers are DEFINITION and whose independence assumption is POSTULATED, so **0.3580 is arithmetic on guesses and inherits their standing entirely** – it is a statement about a stated prior, not about the world. Only R7 rests on nothing but a definition and exact logarithms. **A chain in which three of four headline results depend on this work's own simulations is not a proof, and the paper says so here rather than leaving the reader to notice.**

27.18.5 18.5 Limits and asymptotics of the estimation model

The model's behaviour at the boundaries of its parameters, checked and reported.

- **`a -> 1` (`delta -> 0`).** The system never forgets; `Q_inf = (eta S - C)/delta` diverges. The update map is a contraction only while `delta > 0`, and the theorem that supplies the unique, start-independent fixed point is Banach's: a contraction with modulus `q < 1` on a complete space has exactly one fixed point, reached from any start, with the distance to it shrinking by at least a factor `q` each pass [Curzi, 2026, Banach, 1922]. **`delta = 0` is therefore not an ideal but the loss of the theorem.** This is a pathology and not an ideal, and the constrained optimiser reaching `a_hat = 1.0000` exactly is the fit reporting that it wanted to leave the box – which is what happened on the null series of §7.7, and is why S4.6 sends a boundary hit to the abstract.
- **`a -> 0` (`delta -> 1`).** Nothing carries over; the model degenerates to a static regression of `Y_{t+1}` on `F(U_t)`, and the lagged term is unidentifiable.
- **`b -> 0` (`eta -> 0`).** The surplus term is decoration and the matched autoregression is the correct model. Rule 2 exists to detect exactly this, and §4.7 measures how often it fails to.

- **`u -> 0.`** `F(u) -> ln 1 = 0`. Zero non-parallelism buys zero surplus regardless of `N`, which is the framework's binding clause and not a limiting curiosity [Curzi, 2026].
- **`u -> 1.`** `F(u) -> ln N`, the hard ceiling [Curzi, 2026c]. **No arrangement of relations raises it; only a genuine additional category does**, which is why §12.11's duplicate audit is prior to every other computation.
- **`N -> 1.`** `ln 1 = 0`: a scheme with one real category has zero available surplus rather than a low one. This is the same collapse the concentration instrument measures on the roster side, where a naive effective count of 3.41 becomes 1.00 once a coordination perimeter is respected [Curzi, 2026].
- **Span of `u -> 0`.** The direct-input baseline loses all discriminating power: over any narrow band `corr(u, F(u))` exceeds 0.995, against 0.9724 over the full range at `N = 7`. This is a constraint on the model's testable domain and S4.11 states it as one.

27.18.6 18.6 Analogy discipline

Three borrowings from physics and engineering appear in this paper and each is badged at first use.

The **leaky integrator** is a **shared mathematical form**, category 2: the same first-order linear difference equation governs an RC network, an exponential smoother and the storage law, with no claim that the electrical physics applies [Elaydi, 2005, Holt, 1957]. The **matched autoregression** is that same object used as a null, which is a derivation within the shared form and not an analogy at all. The **hash function** in §12.8 is a **derivation**, category 1: gematria satisfies the definition of a hash exactly – a deterministic map from a large domain into a small codomain – and the entropy computed from it is Shannon's quantity, computed on a real word list, with no thermodynamic content whatever [Shannon, 1948]. **Where entropy appears in this paper it is Shannon entropy in bits, never thermodynamic entropy**, and the two are different objects with different units.

No stationary-action, no uncertainty-relation and no scaling claim is made anywhere in this paper. In particular the hub topology noted in §12.4 is a statement about a ten-vertex degree sequence and is not a heavy-tail claim; the maximum-likelihood-plus-Kolmogorov-Smirnov procedure such a claim would require [Clauset et al., 2009] does not apply to ten points and was not run.

27.19 19 Limitations

Nothing in this paper was measured on a person, an organisation, or a historical practice. Every quantitative result is either exact arithmetic or a simulation with declared generating parameters. The worked subject of Section 7, the worked schedule of Section 11 and the maintenance department of Section 15 are constructed, and **none of them may be cited as evidence about any real person, laboratory or department.** Their function is to show the procedures operating end to end on numbers that behave the way real numbers behave, including where they refuse to cooperate.

The calibration result is a property of one design. The rates 0.108, 0.120 and 0.060 were measured with `T_train = 40`, `T_holdout = 20`, autocorrelation 0.85 on both series, 200 surrogates per trial and 500 trials. Changing any of those changes the answer. **The transferable finding is that the control must be calibrated, not the specific numbers**, and a reader who copies them into a different design has made the error this paper is about.

The third significant figure in the rejection rates is not resolved. At 500 trials the binomial standard error near `r = 0.10` is 0.0134. The correct statement about block permutation is that it was **not shown to differ from nominal**, and no claim of "no difference" is made from that non-significant comparison.

The reflection problem is unanswered and is the deepest limitation here. The framework's reflexive specification is not identified from observational data [Manski, 1993, Shalizi and

Thomas, 2011]; no remedy is adopted in this paper – not randomisation, not an instrument, not partial-population variation, and not a defended stipulation of the reference group [Brock and Durlauf, 2001]. Every statement in this paper about `delta` and `eta` as properties of a person or a group is therefore **a modelling position, not an identified empirical result.** A calibrated shuffle threshold does not touch this; it is a different and smaller problem.

The Lucas critique applies to this framework's own parameters, and §4.12 measures it happening. The paper asserts that a measure changes the system measured by it and then treats `delta`, `eta` and `N` as constant over an estimation window [Lucas, 1976, Hacking, 1995]. The narrow position taken – constancy only over a declared window and only while `Y` is not reported upward – is a restriction on where the protocol may be used, not a defence of the framework.

Scale type is stipulated, not demonstrated, and the decisive test was not run. `u`, `Y`, `D`, `P` and `E` are treated as ratio-scale quantities wherever differences, ratios, logarithms and means are taken. The conditions that would license that treatment are the conjoint-measurement conditions [Luce and Tukey, 1964, Krantz et al., 1971], and **they have not been tested.** Stage 2 of Section 8 proposes cross-modality matching instead, which is weaker evidence for the same conclusion. Michell [1997]'s objection – that psychology assumes quantitative structure without testing for it – is **the strongest single objection to this framework**, it applies directly, and this paper concedes rather than answers it.

`N_eff = 1 + (N−1)u` is not a Hill number. `1/HHI` and `exp(H)` are Hill numbers of orders two and one and are fully grounded [Hill, 1973, Jost, 2006, Simpson, 1949]. The effective count used here is a linear interpolation between 1 and `N`, is this framework's own construction, and has no counterpart in the ecological, economic or information-theoretic literature. Wherever an effective count appears in this paper it is that one, and it is not the grounded one.

Effective-count and diversity estimators are biased on small sets, and no correction was applied. Estimation bias in diversity measures from finite samples is well documented [Chao et al., 2014]. The worked audit of Section 15 computes `N_eff = 4.078151` from a six-row scheme, 400 work orders and an estimated within-category angle; **that number carries no interval and should not be treated as though it did.**

The surplus functional's form is underdetermined by the evidence. A sub-linear power law [Latané, 1981] and an `n log n` law [Briscoe et al., 2006] fit the same qualitative facts as `ln(1 + (N−1)u)`, and nothing in this paper discriminates between them. The direct-input baseline of §4.5.2 is the closest thing to a discriminating test and it is near-vacuous over the range real data span: over `[0.3, 0.6]` at `N = 7`, `corr(u, F(u)) = 0.99795`. **The logarithmic form is chosen, not established.** Peters and Gell-Mann [2016] is a better warrant for it than the psychophysical story, because it does not require the perceptual account to be true.

Model comparison here is incomplete by the standard this corpus sets itself. Held-out one-step-ahead RMSE against a parameter-matched baseline is reported throughout; **no information criterion was computed at any point, for any model.** The parameter counts are stated – persistence 0, direct input 2, matched AR with intercept 2, storage model 2 – so the comparison is matched, but it has not been paid for by a criterion that penalises complexity. Skill scores are reported without intervals.

The programme in Section 8 has not been run and its priors are guesses. No stage has been executed. The 0.3580 survival figure is arithmetic on five declared numbers and an independence assumption, and it should be read as a device for making the expected cost computable rather than as a forecast. **The heaviest prior, 0.35 at Stage 4, is the one most likely to be wrong in either direction**, and a reader who thinks the cross-laboratory gate is easier than that should note that the whole framework's claim to measure anything rests on it.

Stage 5 as specified is under-powered for the effect it is most likely to face. At 24 clusters of 20 members and an intracluster correlation of 0.05, the design is powered for a standardised effect of 0.50 and requires 36 clusters for 0.30. This is stated in §8.9 rather than discovered afterwards, and it means the preregistration may claim a large effect or claim pilot status, **not both.**

The correspondence-table material describes historical artefacts and does not test any his-

torical claim. That such systems functioned as mnemonic and combinatorial technologies is a **historical claim**, badged as one in §12.9, and the load arithmetic supporting it – `n(n–1)/2` against `n` – is a statement about encoding cost and not evidence about what anyone actually did. The graph metrics are metrics of one printed edge list; other historical arrangements differ and would give different numbers, which is failure mode F12.4.

There is no bibliographic support in this corpus's external database for several specific historical attributions retained in the text – the Kircher arrangement's 1652 printing, the nineteenth-century trump-to-letter bijection, Lull's combinatorial wheels, Cassius Dio's account of the planetary-hour sequence, and Yates on the art of memory. They are named in the text with their dates and are **left uncited rather than attached to a source that does not support them.**

Two claims the paper does not make. It makes **no scaling, power-law or heavy-tail claim**, so the distribution-fitting procedure such a claim would require [Clauset et al., 2009] does not apply and was not run. And it makes **no causal claim** anywhere: the shuffle establishes that a timing relationship is or is not present in a series, never that intervening on the input produces the output.

What would falsify the results of this paper. A demonstration that the measured rejection rates of §4.7 are an artefact of the particular random-number stream would overturn R1; the remedy is that the generating parameters are printed and the simulation is cheap to repeat. A demand-characteristic simulation with the same inflation coefficient producing a suite pass rate far from 52.7 per cent would overturn R2. A taxonomy in which the duplicate test of §12.11 can be applied but is rejected by practitioners who nonetheless cannot distinguish the rows would overturn H6. And if a calibrated shuffle threshold, once computed for a specific study, moved that study's reported `p` above its declared level, the study's positive result would become undecided rather than supported – **which is the practical use of everything in Section 4.**

27.20 20 Conclusion

This paper specifies a preregistered falsification suite for the storage law fitted as `Y_{t+1} = a Y_t + b F(U_t) - Chat_t + eps_t` under `0 <= a <= 1` and `b >= 0`, with four baselines, a declared freeze, boundary reporting, and held-out scoring; and it then tests that suite by simulation instead of asserting it.

The central result is negative and is about the control rather than the theory. Against a nominal 0.05, the shuffled-input control false-rejected true nulls at 0.108 for independent permutation and 0.120 for circular shift, with only block permutation near nominal at 0.060. The suite's headline control is anti-conservative as ordinarily run, and any p-value reported from it without calibration on the study's own design is optimistic by an unknown factor. Power was 1.000, 1.000 and 0.998 respectively, so block permutation buys its calibration for essentially nothing and is the default this paper specifies.

Three further measurements bound what the suite is worth. **The matched autoregressive comparison, run alone against a null, false-passed 35.8 per cent of the time. A demand-characteristic confound with a true coefficient of exactly zero passed the entire four-baseline suite 52.7 per cent of the time, and there is no statistical remedy for it – only the design remedies of blinding, channel separation, prospective sampling and a yoked control.** And **a Goodhart simulation in which the proxy acquired a consequence at period 30 raised the estimated conversion efficiency by 14 per cent, from 0.3105 to 0.3551, while the true stock fell from 3.0359 to 2.8447**, with every constraint continuing to hold.

Even with perfect measurement the arithmetic is humbling. A single forty-period window on a single subject, with no rating noise at all, recovered `a = 0.8833` against a true 0.85 and `b = 0.3340` against a true 0.40 – **+2.13 and -2.15 standard errors, a 16.5 per cent underestimate of the conversion parameter.** With rating noise the bias is systematic rather than random: at a rating standard deviation of 0.40 the estimated decay was 0.4317 against a true 0.1500 and

the estimated conversion 0.9425 against a true 0.4000.

The five-stage programme that would put these instruments in front of real people is costed at 71 months, 8,554.8 researcher-hours and 570 participants, with twenty-one kill conditions published in advance, four of them terminal. **Under declared priors its compounded probability of reaching a completed final stage is 0.3580, which implies 5.35 full-time-equivalent years per attempt and 14.93 per completed programme.** Those are priors and not evidence, and the number a funder needs is the second one, because most attempts stop early and the stopping is the point.

The audit instrument for inherited category schemes returns two quotable figures. **Three duplicate rows in a seven-row taxonomy overstate the declared surplus ceiling by 0.559616 nats, 40.37 per cent, and every downstream quantity inherits the error at full size**; on the worked case the same audit corrected a headroom of `-0.108718` to `-0.173461`, changing the size of the required intervention by 37 per cent without changing its sign. And **a letter-sum digest measured as a hash on a 234,454-word list yields 305 distinct values, 99.995 per cent of words colliding, destroying 10.468 of the 17.839 bits that identify a word** – so a shared value is the default behaviour of a many-to-one map and carries no evidence about the words.

The paper's own summary of itself is the counter-result. **The suite audits its headline control and finds it wanting: the shuffled-input test rejects true nulls at more than twice its nominal rate, is blind to filtered repackaging and to shared slow drivers, and lets a demand-characteristic confound through more than half the time – while the research programme built on it is given a 35.8 per cent chance of reaching a completed final stage.** A framework that cannot fail cannot be trusted. This one measured its own test failing, and printed the number.

27.20.1 Declarations

Data and code availability

No external dataset was collected for this paper. Every quantitative result is either exact arithmetic on quantities defined in the text or the output of a simulation whose generating parameters – process, autocorrelation, window lengths, replication counts, surrogate counts and true coefficients – are printed beside it, so that any reader can reproduce it from the text alone. The one measurement taken on an external artefact is the gematria collision analysis of §12.8, which was computed over the alphabetic entries of the macOS `/usr/share/dict/words` (`web2`) list; that list ships with the operating system and is not redistributed here. The worked subject of Section 7, the worked schedule of Section 11 and the maintenance department of Section 15 are **constructed examples and must not be cited as evidence about any real person, laboratory or department.** The figures are generated by the scripts named in each caption; those scripts contain no data beyond the numbers printed in this paper.

Funding

This research received no external funding.

Conflicts of interest

The author declares no conflicts of interest.

Author contributions

Single author. Michael Laurence Curzi specified the protocol and the programme, ran the simulations, performed the analysis, produced the figures, and wrote the paper.

Ethics

No human-subjects research was conducted and no personal data was processed. The subjects, laboratories, clusters and department described in this paper are constructed. The five-stage programme of Section 8 is a proposal; no stage of it has been executed, no participant has been recruited, and no ethics approval has been sought, because there is nothing yet to approve. The requirement carried throughout – that refusal to be measured must be available, costless, and recorded as ordinary missing data under the preregistered missing-data rule – is a constraint on prospective work and is not a report of any study performed.

Preregistration

This paper is a specification of a preregistration procedure and a simulation study of it; it does not itself report a preregistered empirical test. The falsification rules, the freeze list, the four baselines, the surrogate calibration requirement and the twenty-one kill conditions are stated in Sections 4, 5, 8 and 9 as requirements on future work. The hypotheses of Section 2 were fixed against the simulations before the simulation results were written up, and **two of the six were falsified and are reported as such in Results in the same language a success would have received.** No threshold was moved after a simulation was run. Where a rule the paper itself specifies was violated by its own worked example – the observed span of u was 0.5484 against a preregistered minimum of 0.60 – **the direct-input comparison is declared uninformative in the results table even though the model happened to beat it.**

Chapter 28

Star Polygons, Cadence, and the Ledger: gcd(N,k) as Parallelism, Division of a Fixed Budget as a Theorem, and What an Eleven-Operation Audit Does Not Prove

Abstract. We prove that the star polygon N/k decomposes into exactly gcd(N,k) closed strokes of length N/gcd(N,k), that it is unicursal precisely when gcd(N,k) = 1, that the attainable stroke counts are the proper divisors of N, and that the number of unicursal steps is Euler's totient. The result was verified by exhaustive trace across N = 3 to 40 and every k, 779 cases with no mismatch, and 89 of the 143 tabulated rows for N = 3 to 24 are unicursal. Read as a schedule, gcd is parallelism and N/gcd is latency; the throughput rate ln(x)/x is maximised at x = e, so stroke length three is optimal among integers, while splitting a twelve-station cycle into four triangles costs 55.8 per cent of the single-period surplus ceiling. On the temporal side we prove a cadence theorem: for a concave response through the origin, dividing a fixed interaction budget over more occasions never lowers the surplus delivered, and a single impulse has steady state zero against a rate's m/delta. Computed at identical nominal budget, an annual rite delivers 2.8 per cent of what a weekly practice delivers. The memory-palace arithmetic shows ordinary distinct places already reach 92.4 per cent of the ceiling and that the technique is primarily a retention intervention, retention contributing a factor 4.1667 against surplus 1.8637 and conversion 1.9000. The synthesis states its own falsification target and concedes that decomposition understates cost, not surplus.

Keywords: star polygon; greatest common divisor; unicursal; cadence theorem; periodic forcing; method of loci; retention constant; subadditivity

Series: B. Engineering the Surplus **Paper:** CCP-028

28.1 1 Introduction

This paper proves two theorems, prices two inherited technologies against them, and then audits the framework that did the pricing against a falsification target it states in advance.

The first theorem is elementary number theory and was available for two thousand years without being written down. A star polygon `{N/k}` – the figure drawn by placing `N` points on a circle and repeatedly stepping `k` positions – decomposes into exactly `gcd(N,k)` closed strokes, each of length `N/gcd(N,k)`. It is unicursal, drawable without lifting the pen, if and only if `gcd(N,k) = 1`; it requires exactly `gcd(N,k) - 1` pen lifts otherwise; the attainable stroke counts on `N` points are exactly the proper divisors of `N`; and the number of unicursal steps is Euler's totient `phi(N)`. **The hexagram is two disjoint triangles because `gcd(6,2) = 2`, and no technique of draughtsmanship changes that.** The result was verified by exhaustive trace over `N = 3` to `40` and every `k` – 779 cases, zero mismatches – before it was trusted.

Read as a schedule rather than as a figure, the invariant becomes an engineering quantity. `gcd(N,k)` is the number of independent workstreams and `N/gcd(N,k)` is the critical path, so **the speedup is exactly `gcd(N,k)` and it is perfect, because the strokes share no vertex.** That is also its price: disjoint strokes cannot interact within a period, so the per-period surplus ceiling falls from `ln N` to `ln(N/g)`. **Parallelism buys latency and pays for it in ceiling, the exchange is exact, and the ceiling rate `ln(x)/x` is maximised at `x = e`, so the best integer stroke length is three.** Splitting a twelve-station cycle into four triangles costs 55.8 per cent of the single-period ceiling.

The second theorem is about cadence and does not depend on any ceiling. For a response `g` that is concave through the origin, dividing a fixed budget `T` over `n` occasions gives a delivered total `D(n) = n g(T/n)` that is nondecreasing in `n`. Since the framework's surplus functional is strictly concave with `f(0) = 0` [Curzi, 2026], dividing a fixed interaction budget into more occasions **never delivers less**, and in the worked case delivers 4.57 times as much. What stops the division is the per-occasion fixed cost, and the optimum is computable from it alone.

The two halves meet in a set of measured comparisons that are less one-sided than the folklore. Integrated effect is **identical to every digit** – 433.3333 in all three regimes tested – because the system is linear and time-invariant, and anyone claiming that spreading a fixed input over more occasions produces more total stored order has not done the arithmetic. What differs is the peak (favouring the impulse by a factor of 3.25), the minimum, and the deliverable total once the ceiling clips each burst. **On the last of these an annual rite delivers 2.8 per cent of what a weekly practice delivers from an identical nominal budget, and the remaining 97.2 per cent is not delivered late but not delivered at all.** And the steady state settles the argument: a single impulse of any size, unrepeated, has a steady state of exactly zero, while a rate `m` has `m/delta`.

Two further quantitative results are reported. The method of loci, read as the storage law with space as the retention medium, has an advantage that factorises into three separately measurable terms, and **retention supplies more than the other two combined – 4.1667 against surplus 1.8637 and conversion 1.9000, the product 14.7546 matching the direct steady-state ratio exactly.** And ordinary, undesigned places already reach 92.4 per cent of the ceiling for a forty-item corpus, so the entire apparatus of classical rules buys the last 8 per cent: **that is the logarithm, and it is why beginners get most of the benefit at once.**

The paper's own summary of itself is a concession. Section 11 states, as a badged postulate, that if a body of inherited practice is understood as three engineering operations – lens, store, composition – then the framework has described its mechanism. Section 11.18 audits eleven such operations against three handles and finds no residue. **That is a finding about eleven operations and not a proof of completeness, the falsification target is stated as an operation that does work and maps to nothing, and the two things the audit does not reach – the felt quality of an operation, and any effect outside the practitioner – are named rather than absorbed.** The framing of a drawn figure as a *computing map* is a metaphor throughout, badged at every occurrence, and the only sentence in it that is not a metaphor is that the number of strokes is `gcd(N,k)`.

Sections 3 to 6 give the star-polygon theorem, its corollaries and tables, its specification and failure modes, and a worked scheduling example. Sections 7 to 10 give the cadence theorem, the loci and calendar arithmetic, their specification and failure modes, and a worked example. Sections 11 to 13 give the synthesis and its audit. Sections 14 to 18 report, discuss, verify, limit and conclude.

28.2 2 Hypotheses

Two of this paper's central results are **theorems**, which cannot be falsified by observation and are labelled as theorems wherever they appear; what can be wrong is the claim that any real system is the object they are about. The hypotheses below are the ones that could fail, together with what would defeat each.

H1 — The decomposition theorem holds for every star polygon. For all `N >= 3` and `1 <= k <= N−1`, tracing `{N/k}` produces exactly `gcd(N,k)` closed strokes of length `N/gcd(N,k)`, with `N` edges in total for every `k`. **Predicted:** exhaustive trace over `N = 3..40` and every `k` agrees with the formula in every case. **Falsified by:** a single traced case whose stroke count, stroke length or edge total disagrees. *(Result: **not falsified** — 779 cases, zero mismatches. This is a check on the implementation of a proof, not a test of the world; the proof is given in §3.1.)*

H2 — The attainable stroke counts are exactly the proper divisors of `N`. The set `{gcd(N,k) : 1 <= k <= N−1}` equals the set of divisors of `N` other than `N` itself. **Predicted:** exact agreement for `N = 3..24`, and `gcd(N,k) = gcd(N,N−k)` without counterexample for `N = 3..100`. **Falsified by:** an attainable stroke count that is not a proper divisor, or a mirror pair that disagrees. *(Result: **not falsified**. Consequence: **there is no five-stroke constant-step figure on twelve points, because 5 does not divide 12.**)*

H3 — Dividing a fixed interaction budget over more occasions never delivers less. For `g` concave with `g(0) = 0`, `D(n) = n g(T/n)` is nondecreasing in `n`. **Predicted:** the delivered-total column is monotone in `n` in every worked sweep. **Falsified by:** a concave-through-the-origin response for which division lowers the delivered total. *(Result: **not falsified** — monotone from 0.7278 to 3.3235 across `n = 1` to `48` in §8.8, a factor of 4.57. **The theorem does not say shorter is always better**: with a per-occasion fixed cost of 0.15 the* net* peaks at `n = 5` and falls away on both sides.)*

H4 — Spreading a fixed input over more occasions raises the integrated effect. The commonest informal argument for cadence. **Predicted, if true:** a larger sum of `Q_t` over time for a cadence than for a single impulse of the same total. **Falsified by:** equal integrals. *(Result: **FALSIFIED** — 433.3333 for the impulse, the weekly cadence and the four-weekly cadence alike, identical to every digit, which is the defining property of a linear time-invariant system. The correct argument is about the steady state, the minimum and the clipped deliverable total, and it is stronger once this one has been cleared away.)*

H5 — A rare rite is an inefficient frequent rite. The intensity/cadence axis is a single continuum on which rarer is simply worse. **Predicted, if true:** an impulse never outperforms a cadence funded from the same budget on any measure. **Falsified by:** a threshold the cadence cannot reach. *(Result: **FALSIFIED** — at a threshold of 10.0 the impulse holds the system above it for 16 periods and **both cadences score exactly zero**, because no cadence funded by that budget ever reaches 10 at all. An impulse buys height a cadence cannot buy; a cadence buys duration an impulse cannot buy.)*

H6 — Every operation in the examined practice maps to one of three parameters. Lens, store, composition. **Predicted:** each of eleven inherited operations maps to a named parameter with a direction, and four of the eleven can be priced exactly. **Falsified by:** an operation that does work, is agreed to do work, and maps to nothing. *(Result: **not falsified over eleven operations**. This is an audit of a list and **not a proof of completeness**; §11.19 states the refutation condition and names three candidate residues, of which one – the integrated practice's lower per-occasion cost – is a real gap in the audit's coverage and is conceded there.)*

Three claims in this paper are not hypotheses and are labelled as what they are. That the method of loci raises `u` and `eta` and lowers `delta` is a **reading**, not a theorem; what is a theorem is that the steady state moves by the product of the three factors once they are granted. That a ritual calendar is described by the storage law at all is a **modelling postulate**. And the thesis of §11.1 – that a stipulatively defined practice has had its mechanism described here – is a **postulate with a stipulative definition inside it**, and a reader who rejects the definition is declining the thesis rather than contradicting it.

The reflection problem applies to everything in this paper that treats a group parameter as a property of the group. The framework's reflexive specification, in which members constitute the aggregate and the aggregate influences the members, is a linear-in-means form whose endogenous effect is **not identified from observational data** [Manski, 1993], and influence and selection are generically confounded in observational network data [Shalizi and Thomas, 2011]. **No remedy is adopted here** – not randomisation, not an instrument, not partial-population variation, and not a defended stipulation of the reference group [Brock and Durlauf, 2001]. Every statement below about `u`, `eta` or `delta` as a property of a circle, a studio or a department is therefore a **modelling position rather than an identified empirical result**, and Section 17 does not soften that.

28.3 3 The star-polygon decomposition theorem

This section contains the strongest formal result in the paper, and it is elementary number theory. It is also where the framing of a drawn figure as a *computing map* is stated, and that framing is a **METAPHOR**. The badge is kept on throughout, and every quantitative statement below is separated from it by a line the reader can check.

The situation is worth naming at the outset. Most of the corpus's reading of inherited technique is translation: an old artefact turns out to be an ordinary mathematical object once one looks at what it literally contains [Curzi, 2026u]. This section is different. The star polygon has an **exact arithmetic invariant** that the tradition drew for two thousand years and never named, and once the invariant is stated it settles, in one line, a question the tradition handled by trial and error: which figures can be drawn without lifting the pen. The answer is a greatest common divisor. It is true, it is checkable in a minute, and it was always there in the figures.

A star polygon {N/k}, drawn by stepping k positions around N equally spaced points, decomposes into exactly gcd(N,k) separate closed paths, each of length N/gcd(N,k).

The hexagram is two triangles because `gcd(6,2) = 2`. The heptagram is one continuous line because `gcd(7,2) = 1`. The twelve-point figure of step three is three squares because `gcd(12,3) = 3`. None of this is interpretation; all of it is arithmetic, and §4.1 prints the complete table for `N = 3` through `N = 24` with every valid `k`.

Nothing in this paper asserts any supernatural claim, any physical effect of a symbol, or any result not derivable from the formalism. That standing constraint governs throughout without amendment [Curzi, 2026u].

28.3.1 3.1 The decomposition theorem

THEOREM 1 (Decomposition of the star polygon). Let `N >= 3` and `1 <= k <= N−1`. Place `N` labelled points at the vertices of a regular `N`-gon, identified with the residues `Z_N = {0, 1, ..., N−1}`. Draw the figure `{N/k}` by starting at some point and repeatedly joining the current point `x` to the point `x + k (mod N)`, continuing until the start is reached, then beginning again at any unused point, until every point has been used. Let `g = gcd(N, k)`. Then:

```
(i)   the figure consists of exactly  g  closed paths (strokes)
(ii)  each stroke visits exactly      N/g  distinct points
(iii) each stroke has exactly         N/g  edges
(iv)  the whole figure has exactly    N    edges, for every k
(v)   the figure is a single closed path (UNICURSAL) if and only if  g = 1
```

Proof. The step map is `s(x) = x + k (mod N)`. Its orbits are the cosets in `Z_N` of the cyclic subgroup generated by `k`. In the additive group `Z_N`, the subgroup generated by `k` is

```
<k> = { 0, k, 2k, ... }  =  <gcd(N,k)>  =  { 0, g, 2g, ..., N−g }
```

— the standard fact that the set of integer combinations of `N` and `k` is the set of multiples of their greatest common divisor. That subgroup has order `N/g`. By Lagrange's theorem the number of cosets is `|Z_N| / |<k>| = N / (N/g) = g`. Each coset is one orbit of `s`, hence one closed path, and each has `N/g` elements, giving (i) and (ii). Every point has exactly one outgoing and one incoming edge, so each stroke of `N/g` points carries `N/g` edges, giving (iii); summing over `g` strokes gives `g * (N/g) = N` edges, giving (iv). And (v) is (i) with `g = 1`. **QED**

Equivalently, and this is the formulation to hold in mind: the figure is the Cayley graph of `Z_N` with connection set `{+k, −k}`, and its connected components are the cosets of `<k>`. Every vertex has degree 2, so the graph is 2-regular, so every component is a cycle. **A 2-regular graph is connected if and only if it is a single cycle, which is why unicursality, Eulerianity and Hamiltonicity coincide for star polygons and all three reduce to `gcd(N,k) = 1`.**

Verified empirically before being trusted: the figure was traced by explicit walk for every `N = 3..40` and every `k = 1..N−1`, a total of 779 cases, and the stroke count, stroke length and edge total agreed with the theorem in **every case, zero mismatches.**

The Schläfli notation `{N/k}` and the classification of `gcd > 1` cases as *star figures* or *compounds* rather than star polygons proper is standard; Coxeter's *Regular Polytopes* is the usual reference.

28.3.2 3.2 The corollaries that do the work

COROLLARY 1 (Unicursality). `{N/k}` can be drawn without lifting the pen if and only if `gcd(N,k) = 1`. The number of such `k` in `1..N−1` is `phi(N)`, Euler's totient. Since `{N/k}` and `{N/(N−k)}` are the same figure traversed in opposite directions, the number of *distinct* unicursal figures on `N` points with constant step is `phi(N)/2` for `N > 2`.

COROLLARY 2 (Pen lifts). Drawing the complete figure requires exactly `gcd(N,k) − 1` pen lifts. Unicursal figures require zero.

COROLLARY 3 (Compound reduction). For `g = gcd(N,k) > 1`,

```
{N/k}  =  g  disjoint copies of  {(N/g)/(k/g)}
```

and the inner figure is always unicursal, because `gcd(N/g, k/g) = 1` by construction. Verified:

```
{6/2}  = 2 x {3/1}    two triangles
{6/3}  = 3 x {2/1}    three digons (degenerate: the three long diagonals)
```

```
{8/2}  = 2 x {4/1}    two squares
{9/3}  = 3 x {3/1}    three triangles
{10/4} = 2 x {5/2}    two pentagrams
{12/3} = 3 x {4/1}    three squares
{12/4} = 4 x {3/1}    four triangles
{12/6} = 6 x {2/1}    six digons
{16/4} = 4 x {4/1}    four squares
{18/6} = 6 x {3/1}    six triangles
{20/8} = 4 x {5/2}    four pentagrams
{24/9} = 3 x {8/3}    three octagrams
{24/10}= 2 x {12/5}   two dodecagrams
```

COROLLARY 4 (Attainable stroke counts). The set of stroke counts achievable on `N` points is exactly the set of proper divisors of `N`. Verified for `N = 3..24`: for every `N`, `{ gcd(N,k) : 1 <= k <= N-1 }` equals the divisors of `N` other than `N` itself. **You cannot draw a five-stroke figure on twelve points with a constant step, because 5 does not divide 12, and no amount of ingenuity changes that.**

COROLLARY 5 (Mirror symmetry). `gcd(N,k) = gcd(N, N-k)` for all `k`. Verified with zero counterexamples for `N = 3..100`. This halves the table: `k` beyond `N/2` retraces the figures of `k` below it, in reverse. It is why §4.1 tabulates `k = 1..floor(N/2)` and nothing is lost.

COROLLARY 6 (Vertex angle). The point angle of `{N/k}` is `180*(N - 2k)/N` degrees, and the density (winding number) of each stroke is `k/g`, so each stroke's total turning is `360*(k/g)` degrees. Verified: `{5/2}` gives `180*1/5 = 36` degrees — the pentagram's point angle, which is the value every draughtsman knows.

28.3.3 3.3 Status table

Element	Status	Warrant
Strokes = `gcd(N,k)`, each of length `N/gcd(N,k)`	**PROVED** (group theory)	§3.1
Verified by exhaustive trace, `N = 3..40`, all `k`, 779 cases, 0 mismatches	**MEASURED**	§3.1
Unicursal iff `gcd(N,k) = 1`; count of unicursal `k` is `phi(N)`	**PROVED**	§3.2
Attainable stroke counts = proper divisors of `N`	**PROVED** (verified `N`=3..24)	§3.2
Pen lifts = `gcd(N,k) - 1`	**PROVED**	§3.2
Point angle `180(N-2k)/N` degrees	**PROVED** (geometry)	§3.2
The Spare reduction is a lossy, non-invertible encoding	**PROVED** (definition + count)	§4.8
Its output is bounded by 26 bits for any input length	**PROVED** (`2^26` subsets)	§4.8
Measured letter-set collision rate on 218,002 words: 71.4%	**MEASURED**	§4.8
`gcd(N, .)` is a non-monotone, discontinuous function of `k`	**PROVED** (computed jumps)	§4.6
"The sigil is a nonlinear computing map"	**METAPHOR** (author's, badged)	§3.4
That drawing a figure produces any external effect	**REFUSED**	standing refusal

28.3.4 3.4 The metaphor, and exactly where it stops

The framing under examination is that such a figure can be *read* as a nonlinear computing map. Here is the honest anatomy of that sentence.

What is literally true. The figure has a computational structure in the ordinary sense: a set of nodes, a deterministic successor rule, orbits, a component count, a path length per component, and a total edge count. `gcd(N,k)` is precisely the number of *independent* closed processes the figure contains and `N/gcd(N,k)` is precisely the length of each. If you were scheduling work around a ring of `N` stations by handing it on `k` places at a time, those numbers would be the number of parallel workstreams and the length of each. **The number of separate strokes in the figure is `gcd(N,k)`, and that is the figure's parallelism** — that sentence is not a metaphor. It is a statement about a graph, and it is provable.

What is metaphor. Calling the figure a *computing map* imports the suggestion that something is being computed, by something, for some purpose. Nothing in the mathematics supplies an input, an output, or an agent. A star polygon is a static graph. It has the structural signature of a parallel process; it does not run one. **The metaphor is a way of seeing, it earns its keep by making the invariant visible, and it is not an assertion about the figure's nature.**

In what precise sense "nonlinear". The step map `x -> x + k (mod N)` is affine, hence linear in the technical sense — this must be conceded immediately, because it is the obvious objection. The nonlinearity is not in the map; it is in the **dependence of the figure's structure on the parameter `k`.** The function `k -> gcd(N,k)` is not monotone, not continuous, not smooth, and not approximable by any local rule: it is a number-theoretic function that jumps. On 24 points, `k=11` gives one stroke and `k=12` gives twelve. A unit change in the parameter changes the structure by a factor of twelve. §4.6 tabulates the maximum jump for every `N` in range. **That is the exact, defensible content of "nonlinear" here: the structure is a non-smooth arithmetic function of the design parameter, so you cannot tune it by small steps and you cannot interpolate.** Everything else in the phrase is metaphor and is badged as such.

What is refused, permanently. That drawing the figure does anything outside the person drawing it. Not asserted, not implied, not entertained.

28.4 4 Star polygons as schedules: parallelism, ceiling, and rate

28.4.1 4.1 The complete table, N = 3 to 24

Computed by explicit trace and cross-checked against `gcd`, with `k` running from 1 to `floor(N/2)`; by Corollary 5 the remaining `k` mirror these exactly. "Strokes" is the number of separate closed paths, "stroke length" the number of points (and edges) in each, and "compound form" the reduction of Corollary 3.

 24    5         1         1                  24   YES         -
 24    6         6         6                   4   no          6 x {4/1}
 24    7         1         1                  24   YES         -
 24    8         8         8                   3   no          8 x {3/1}
 24    9         3         3                   8   no          3 x {8/3}
 24   10         2         2                  12   no          2 x {12/5}
 24   11         1         1                  24   YES         -
 24   12        12        12                   2   no          12 x {2/1}
---   ---  --------   -------   ----------------   ---------   -------------
```

143 rows. 89 of them are unicursal — 62.2%. Every row was produced by walking the figure, not by evaluating `gcd`, and then checked against `gcd`.

28.4.2 4.2 The named verifications, with orbits printed

The theorem is worth distrusting until you have seen the walks. Here they are, as vertex sequences on `Z_N` starting from 0.

```
{6/2}   gcd 2   TWO strokes of length 3:    [0,2,4]  and  [1,3,5]
{6/3}   gcd 3   THREE strokes of length 2:  [0,3]  [1,4]  [2,5]
```

```
{7/2}   gcd 1   ONE stroke of length 7:     [0,2,4,6,1,3,5]
{7/3}   gcd 1   ONE stroke of length 7:     [0,3,6,2,5,1,4]
{5/2}   gcd 1   ONE stroke of length 5:     [0,2,4,1,3]
{8/3}   gcd 1   ONE stroke of length 8:     [0,3,6,1,4,7,2,5]
{9/3}   gcd 3   THREE strokes of length 3:  [0,3,6]  [1,4,7]  [2,5,8]
{10/3}  gcd 1   ONE stroke of length 10:    [0,3,6,9,2,5,8,1,4,7]
{12/3}  gcd 3   THREE strokes of length 4:  [0,3,6,9]  [1,4,7,10]  [2,5,8,11]
{12/5}  gcd 1   ONE stroke of length 12:    [0,5,10,3,8,1,6,11,4,9,2,7]
{24/7}  gcd 1   ONE stroke of length 24:    [0,7,14,21,4,11,18,1,8,15,22,5,12,19,2,9,16,23,
                                             6,13,20,3,10,17]
```

The hexagram is literally two separate triangles: `[0,2,4]` and `[1,3,5]`, disjoint, sharing no vertex and no edge. The two triangles overlap visually on the page and are combinatorially independent. That is not a reading of the figure; it is what happens when you draw it. Every draughtsman who has ever drawn a Star of David knows they had to lift the pen once, and Corollary 2 says exactly why: `gcd(6,2) − 1 = 1` lift, always, no technique available.

The pentagram, by contrast, is `gcd(5,2) = 1` and needs zero lifts, which is why it is the figure that gets drawn in one motion in every schoolyard on earth.

28.4.3 4.3 The unicursal census

Per `N`, the number of unicursal steps and how the divisor structure of `N` controls it.

N	phi(N)	distinct proper star polygons	unicursal k in 1..floor(N/2)	total k	fraction	divisors of N
3	2	0	1	1	1.000	1, 3
4	2	0	1	2	0.500	1, 2, 4
5	4	1	2	2	1.000	1, 5
6	2	0	1	3	0.333	1, 2, 3, 6
7	6	2	3	3	1.000	1, 7
8	4	1	2	4	0.500	1, 2, 4, 8
9	6	2	3	4	0.750	1, 3, 9
10	4	1	2	5	0.400	1, 2, 5, 10
11	10	4	5	5	1.000	1, 11
12	4	1	2	6	0.333	1, 2, 3, 4, 6, 12
13	12	5	6	6	1.000	1, 13
14	6	2	3	7	0.429	1, 2, 7, 14
15	8	3	4	7	0.571	1, 3, 5, 15
16	8	3	4	8	0.500	1, 2, 4, 8, 16
17	16	7	8	8	1.000	1, 17
18	6	2	3	9	0.333	1, 2, 3, 6, 9, 18
19	18	8	9	9	1.000	1, 19
20	8	3	4	10	0.400	1, 2, 4, 5, 10, 20
21	12	5	6	10	0.600	1, 3, 7, 21
22	10	4	5	11	0.455	1, 2, 11, 22
23	22	10	11	11	1.000	1, 23
24	8	3	4	12	0.333	1, 2, 3, 4, 6, 8, 12, 24

Prime `N` gives a unicursal fraction of exactly 1.000: every step draws one continuous line. Highly composite `N` gives the worst ratios — `N = 12`, `18` and `24` all sit at 0.333. A designer who wants many available single-stroke figures should choose a prime number of points; a designer who wants many available *parallel decompositions* should choose a highly composite one. The two goals are exactly opposed, and the opposition is the divisor structure of `N`.

The column "distinct proper star polygons" counts `k` with `2 <= k < N/2` and `gcd(N,k) = 1` — the figures that are genuinely star-shaped, single-stroke, and not the convex polygon. For `N = 3, 4, 6` it is zero: **there is no star polygon on three, four or six points, which is a fact about divisors and not about draughtsmanship.**

28.4.4 4.4 The parallelism reading

This section is where the invariant becomes an engineering quantity. Take the figure as a *schedule*: `N` stations around a ring, work handed on `k` places at a time, one hand-off per unit time.

```
P  = gcd(N,k)      number of independent workstreams (strokes)
W  = N             total work: one hand-off per station, always
T  = N / gcd(N,k)  critical path: the length of the longest stroke
speedup = W / T = gcd(N,k) = P
```

N	k	P = strokes	W = edges	T = critical path	speedup
6	2	2	6	3	2.0
12	3	3	12	4	3.0
12	4	4	12	3	4.0
24	8	8	24	3	8.0
20	5	5	20	4	5.0
7	2	1	7	7	1.0
13	5	1	13	13	1.0

Total work is `N` for every `k`; only the arrangement changes. That is the honest form of the parallelism claim: the figure never does less work, it does the same work in fewer sequential steps. The speedup is exactly `gcd(N,k)` and it is perfect — no overhead appears in the geometry, because the strokes share no vertex.

Now the constraint that makes this interesting rather than free. **The `g` strokes are *disjoint*. No point on one stroke is ever adjacent to a point on another.** In the vocabulary of the framework's block decomposition, partitioning the ring into `g` strokes means that within one period no pair from different strokes interacts at all. The cross-block term `u_cross` is unavailable inside the period, and the surplus ceiling available to a stroke of `x = N/g` members is `ln x`, not `ln N` [Curzi, 2026c]. **A second opinion from a source that shares training, incentives and premises is worth `ln 1 = 0`** [Curzi, 2026], and disjoint strokes are the scheduling form of exactly that constraint.

```
parallelism g:      latency falls from N to N/g
surplus ceiling:    falls from ln N to ln (N/g)
```

Parallelism buys latency and pays for it in ceiling. That trade is exact and it is the whole design decision.

28.4.5 4.5 The rate theorem: why stroke length three is optimal

Define the *ceiling rate* of a decomposition as surplus ceiling per unit of latency:

```
R(x) = ln(x) / x          where x = N/g is the stroke length
```

This is an upper bound on the rate at which a stroke can generate surplus, not an achieved rate; it is attained only if `u` can be held at 1 within each stroke. Badge it as a ceiling.

```
dR/dx = (1 − ln x) / x^2  =  0   at   ln x = 1,  i.e.  x = e = 2.718282
```

`R` rises on `(0, e)` and falls on `(e, infinity)`. The optimum is at `x = e`, and since stroke length must be an integer dividing `N`, the best available integer is 3 whenever 3 divides `N`. Computed:

```
x = 2   R = 0.346574
x = 3   R = 0.366204     <-- maximum over integers
x = 4   R = 0.346574
x = 5   R = 0.321888
x = 6   R = 0.298627
x = 12  R = 0.207076
```

Note the exact tie between `x = 2` and `x = 4`: `ln 2 / 2 = ln 4 / 4` because `ln 4 = 2 ln 2`. The tie is arithmetic, not coincidence.

For `N = 12`, sweeping the step:

k	g = gcd(12,k)	strokes	stroke length x	latency	ceiling ln x	rate ln(x)/x
1	1	1	12	12	2.484907	0.207076
2	2	2	6	6	1.791759	0.298627
3	3	3	4	4	1.386294	0.346574
4	4	4	3	3	1.098612	0.366204
5	1	1	12	12	2.484907	0.207076
6	6	6	2	2	0.693147	0.346574

The rate-optimal decomposition of twelve points is `{12/4}` — four triangles — and it is optimal because `ln x / x` peaks at `x = e` and 3 is the nearest integer divisor. The triad recurs across organisational traditions – from nested governance units [Ostrom, 1990, 2010] to the three-person review cell – and here it appears as the integer nearest to `e` under a log-over-linear objective. That is a derivation, offered as one, with no suggestion that anyone in history derived it.

The counterweight is Corollary 4 and the previous section: `{12/1}` and `{12/5}` are the only configurations that keep the full `ln 12 = 2.484907` ceiling, and they take twelve steps to get there. **Fast and shallow, or slow and deep. The figure makes you choose, and the divisors of `N` are the menu.**

28.4.6 4.6 In what sense the map is nonlinear

The concession first: the step map is affine. The nonlinearity claimed here lives in the parameter dependence, and here it is measured. For each `N`, the maximum change in stroke count caused by a single unit change in `k`:

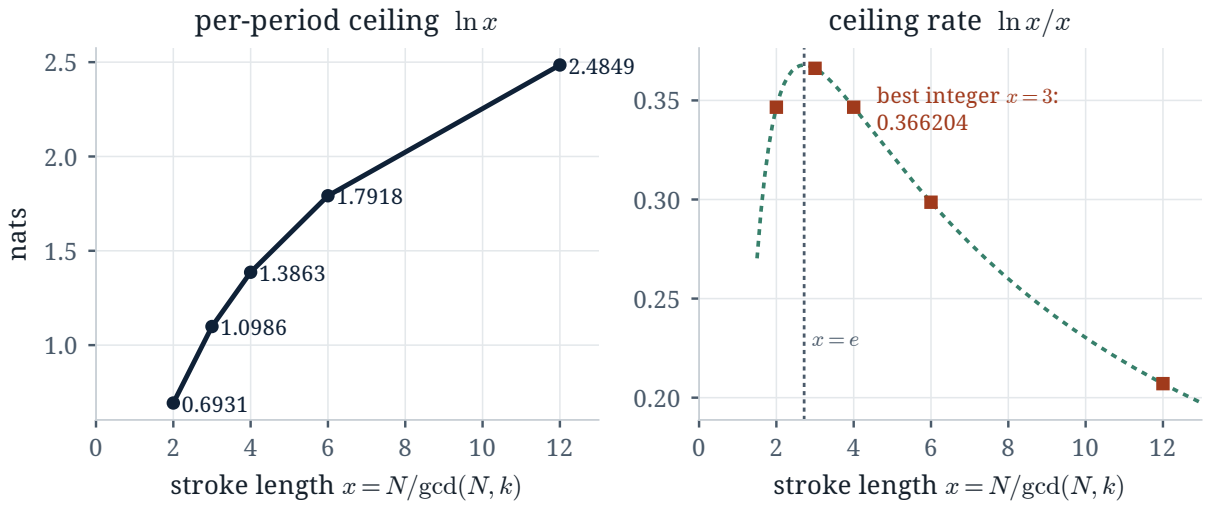

Figure 28.1: **Parallelism buys latency and pays for it in ceiling, and the exchange rate peaks at a stroke length of three.** The per-period ceiling `ln x` rises with stroke length while the ceiling *rate* `ln x / x` peaks at `x = e = 2.718282`, so the best available integer is 3, at 0.366204, with an exact tie between `x = 2` and `x = 4` because `ln 4 = 2 ln 2`. Exact arithmetic on the divisors of 12; produced by `figs/src/CCP-028_fig02.py`.

N	max abs jump	at k -> k+1	strokes go
3	0	1 -> 2	1 -> 1
4	1	2 -> 3	2 -> 1
6	1	4 -> 5	2 -> 1
8	3	4 -> 5	4 -> 1
9	2	6 -> 7	3 -> 1
10	3	5 -> 6	5 -> 2
12	5	6 -> 7	6 -> 1
14	5	7 -> 8	7 -> 2
15	4	10 -> 11	5 -> 1
16	7	8 -> 9	8 -> 1
18	7	9 -> 10	9 -> 2
20	9	10 -> 11	10 -> 1
21	6	13 -> 14	1 -> 7
22	9	11 -> 12	11 -> 2
24	11	12 -> 13	12 -> 1
5, 7, 11, 13, 17, 19, 23	0	—	always 1

On 24 points, moving the step from 12 to 13 takes the figure from twelve independent strokes to one, in a single unit of the parameter. No local model predicts that. A designer who tunes `k` by small increments and watches the result gets no gradient to follow, because there is no gradient: `gcd(N, .)` is constant-1 across every `k` coprime to `N` and spikes to a divisor exactly on the multiples.

Prime `N` is the degenerate case with maximum jump 0 — perfectly flat, always unicursal, no structure to tune at all. **The design lesson is exact: if you want the decomposition to be a tunable parameter, choose composite `N`; if you want it to be immune to a mis-set parameter, choose prime `N`.**

28.4.7 4.7 The unicursal hexagram, and how the tradition escaped the theorem

Here is a case where the historical record and the theorem meet head-on, and the record turns out to record the theorem's constraint.

`{6/2}` is two triangles and cannot be drawn without a lift. The nineteenth- and twentieth-century occult revival nonetheless produced a figure called the *unicursal hexagram*: a six-

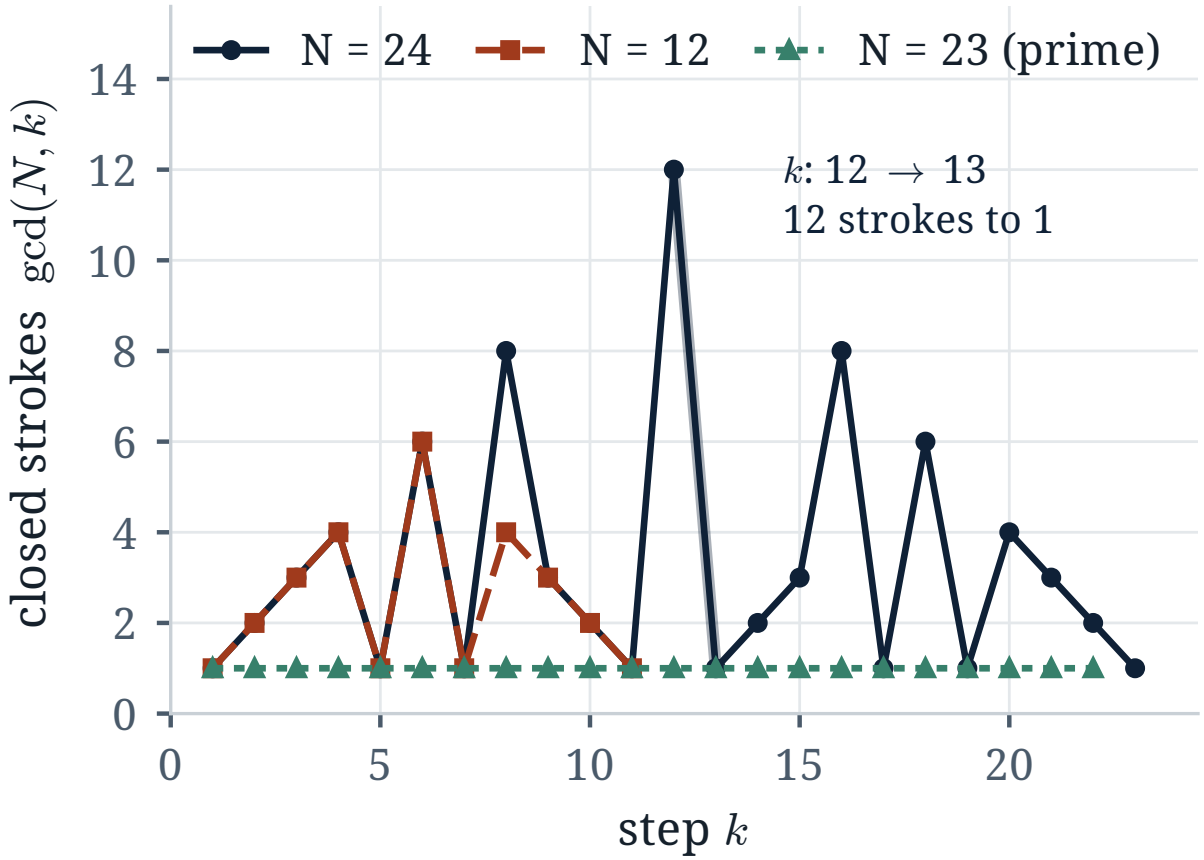

Figure 28.2: **The stroke count has no gradient, so it cannot be tuned by small steps.** On 24 points a single unit of the parameter takes the figure from twelve independent strokes to one; on 12 points the largest jump is 5; on prime 23 the function is flat at one stroke for every step. Computed directly as `gcd(N,k)`, matching the jump table of §4.6; produced by `figs/src/CCP-028_fig01.py`.

This is the clearest single illustration of what the reading claims and of what it refuses. The claim: the old practice was operating on a real structural constraint and its artefacts record the constraint accurately. The refusal: nothing here says the figure does anything.

28.4.8 4.8 Spare's method is lossy compression, and here is its bit budget

Austin Osman Spare's sigil procedure, as described in his *The Book of Pleasure (Self-Love)* (1913), has three steps:

1. Write a statement of intent as a sentence.
2. Strike out every repeated letter, keeping first occurrences only.
3. Recombine the remaining letters into a single glyph.

Steps 1 and 2 constitute an encoding operation, and it may be described as one precisely. Step 2 is a map from strings to sets: it discards multiplicity and it discards order. The formal object is

```
sigma : strings over A  ->  subsets of A
sigma(w) = { letters occurring in w }
```

with the first-occurrence ordering retained only as a drawing convenience.

The hard ceiling. The codomain of `sigma` is the power set of a 26-letter alphabet.

```
|codomain| = 2^26 = 67,108,864
output entropy <= log2(2^26) = 26 bits, FOR ANY INPUT OF ANY LENGTH
```

That bound does not grow. A statement of intent of ten words or ten thousand produces at most 26 bits. Layer by layer:

retained letters m	C(26, m)	bits
8	1,562,275	20.575
10	5,311,735	22.341
12	9,657,700	23.203
13	10,400,600	23.310
14	9,657,700	23.203
16	5,311,735	22.341
18	1,562,275	20.575
20	230,230	17.813

The widest layer is `m = 13`, at 23.31 bits — a sigil that retains exactly half the alphabet carries the most information any sigil can carry, and it is under 24 bits.

Measured on real statements of intent, using a uniform-letter upper bound of `log2(26) = 4.700` bits per input letter:

statement	letters	retained	ratio	input bits (bound)	output bits	destroyed
THIS IS MY WILL TO BUILD A QUIET ROOM	29	16	0.552	136.31	22.34	113.97
IT IS MY WILL TO FINISH THE MANUAL	27	14	0.519	126.91	23.20	103.71

statement	letters	retained	ratio	input bits (bound)	output bits	destroyed
MY WILL IS TO SLEEP WITHOUT FEAR	26	15	0.577	122.21	22.88	99.33
THIS IS MY WISH TO OWN A QUIET ROOM	27	14	0.519	126.91	23.20	103.71
I WILL BUILD THE INSTRUMENT AND KEEP IT	32	16	0.500	150.41	22.34	128.07

Retained sets, in first-occurrence order:

```
THIS IS MY WILL TO BUILD A QUIET ROOM     ->  THISMYWLOBUDAQER
IT IS MY WILL TO FINISH THE MANUAL        ->  ITSMYWLOFNHEAU
MY WILL IS TO SLEEP WITHOUT FEAR          ->  MYWILSTOEPHUFAR
THIS IS MY WISH TO OWN A QUIET ROOM       ->  THISMYWONAQUER
I WILL BUILD THE INSTRUMENT AND KEEP IT   ->  IWLBUDTHENSRMAKP
```

Preimage size — the measure of how thoroughly the operation is not invertible. The number of length-`n` strings that use exactly a given `m`-letter set is a surjection count, `sum over i of (-1)^i C(m,i) (m-i)^n`. Computed:

```
length 28 over a given 15-letter set:   4.716e+31   = 2^105.2 strings
length 30 over a given 14-letter set:   3.691e+33   = 2^111.5
length 32 over a given 16-letter set:   2.499e+37   = 2^124.2
length 36 over a given 17-letter set:   1.787e+43   = 2^143.7
```

Roughly 10^31 to 10^43 sentences of the right length collapse onto any one sigil's letter set. The operation is a digest, not a code: it cannot be decoded, and that is by construction, not by accident.

Measured on a natural-language corpus for calibration: over the 218,002 alphabetic words of length 6 or more in `/usr/share/dict/words`, there are 101,517 distinct letter-sets, mean class size 2.147, and **71.4% of words share their letter-set with at least one other word.** Input entropy 17.734 bits, output entropy 16.037 bits, 1.697 bits destroyed — far gentler than the sentence case, because words are short and the reduction has less multiplicity to throw away. The larger the input, the more brutal the compression, and a sentence is a large input.

28.4.9 4.9 The attention-binding claim, badged and bounded

The tradition attaches a second step to the encoding: the operator is to charge the glyph and then forget the sentence, retaining the form and losing the wording. **This paper can describe the encoding exactly and can describe the second step only as a claim about the operator's own perceptual and attentional state — and it makes no claim of any effect outside the operator.**

What can be said in the formalism, and stated with its badge on:

(a) The reduction genuinely makes the source unrecoverable, and that is measured. The 10^31-to-1 preimage figure above is not a metaphor for forgetting; it is the actual non-invertibility of the map. If the practitioner's stated aim is to hold a form while the wording becomes irrecoverable, the operation performs exactly that, as arithmetic.

(b) A glyph is a small, stable, repeatable perceptual object. In the vocabulary of the framework's moment equation `M = (D/P) E`, a glyph is an environment term `E` with very low variance across presentations [Curzi, 2026o]. Sections 7 and 8 develop the consequence: a low-variance, repeatedly presented `E` is *periodic forcing* of a leaky integrator, and cadence beats intensity for that reason and no other.

(c) The compression is the point, mnemonically. The companion paper measured the cost of holding relations: `n(n−1)/2` unstructured versus `n` structured [Curzi, 2026u]. A sigil is the same move at the extreme — one object standing for a proposition — and the reason it is cheap to rehearse is that it is under 24 bits.

(d) Nothing above is evidence that the practice achieves its traditional aims. No efficacy study is cited here, because none was found and none will be fabricated. What is offered is a description of the encoding and an honest statement of what the formalism can and cannot reach. The formalism reaches the operator's own storage law – `Q_{t+1} = (1−delta)Q_t + eta M_t − C_t` [Curzi, 2026a,o] – and it stops at the operator's skin. **Whether an intention held with high `eta` and low `delta` in one person's stored order changes that person's subsequent behaviour is an empirical question with an obvious affirmative answer and no mystery in it; whether a drawn figure does anything else is a question this paper refuses.**

28.4.10 4.10 Composing the two halves of the analysis

The two results join. Lay the retained letters of a Spare reduction on the vertices of a regular `N`-gon, `N` = the number of retained letters, and connect them with a constant step `k`. Then:

```
N           = number of retained letters (measured: 14 to 17 in the examples above)
gcd(N, k)   = number of separate strokes the glyph requires
N / gcd(N,k) = letters bound into each stroke
unicursal   <=>  gcd(N, k) = 1
```

For `N = 14` (from `IT IS MY WILL TO FINISH THE MANUAL`), the table in §4.1 gives: `k = 1, 3, 5` unicursal; `k = 2, 4, 6` give two strokes of seven; `k = 7` gives seven strokes of two. `phi(14) = 6`, so 6 of the 13 non-trivial steps draw a single line.

For `N = 16` (from `THIS IS MY WILL TO BUILD A QUIET ROOM`), `k = 1, 3, 5, 7` unicursal; `k = 4` gives four squares; `k = 8` gives eight digons. `phi(16) = 8`.

The composition is a design rule, not a discovery: if you want one stroke, choose a step coprime to the letter count; if you want the glyph to fall into `g` visually separable parts, choose `k` a multiple of a divisor `g` of `N`, and the parts will each carry `N/g` letters. It is exactly the same rule that governs the review-cycle schedule in the worked example of Section 6.

28.5 5 Specification and failure modes for star-polygon design

28.5.1 5.1 Specification

SP1 — Compute `gcd(N,k)` before drawing, scheduling, or committing to a figure. It is one line of arithmetic and it determines the stroke count, the stroke length, the pen lifts and the parallelism. Print it.

SP2 — State `N` and `k` explicitly in any figure specification. A figure described as "a six-pointed star" is under-specified: `{6/2}` and the unicursal hexagram are different objects with different stroke counts.

SP3 — Choose prime `N` for guaranteed unicursality; choose highly composite `N` for a rich decomposition menu. `phi(N)/N` is the unicursal fraction and the divisor set is the menu; both are printed in §4.3 for `N = 3..24`. These goals are opposed and the choice must be made once, early, and on purpose.

SP4 — Never expect to tune `k` by small steps. `gcd(N, .)` has no gradient. Enumerate the divisors, evaluate each candidate, and pick. §4.6 shows single-unit jumps as large as 11.

SP5 — Report total work separately from latency. `W = N` always; `T = N/g`; `speedup = g`. A parallelisation that appears to reduce work has been mis-measured.

SP6 — Price the ceiling loss whenever you buy parallelism. Splitting into `g` disjoint strokes lowers the per-period surplus ceiling from `ln N` to `ln(N/g)`. Print both numbers side by side before deciding.

SP7 — Use the rate criterion where throughput matters. `R(x) = ln x / x`, maximised at `x = e`; the best integer stroke length is 3 when 3 divides `N`. Badge it as a ceiling rate, not an achieved rate.

SP8 — Use the full-ceiling configuration where depth matters. `gcd(N,k) = 1` is the only way to keep `ln N`, and it costs `N` steps of latency. Depth and speed are not simultaneously available.

SP9 — When a figure must be unicursal and `gcd` forbids it, vary the step. The obstruction is a theorem about constant steps only. Enumerate the Hamiltonian cycles under whatever chord constraint you actually need — §4.7 does this for six points and finds exactly one figure up to symmetry.

SP10 — Describe the Spare reduction as an encoding, in those words. It is a map from strings to subsets. Report the retained-letter count `m`, the output bound `log2 C(26,m)` bits, and the preimage magnitude. Do not describe it as compression without saying *lossy*.

SP11 — State the 26-bit ceiling whenever sigil information content is discussed. Output entropy is bounded by 26 bits for any input length; the widest layer is 23.31 bits at `m = 13`.

SP12 — Keep the metaphor badge on every occurrence. "Computing map" is the author's metaphor and must be marked at each use. The parallelism statement — strokes `= gcd(N,k)` — is not a metaphor and should be stated without hedging, because it is a theorem.

SP13 — Claim nothing outside the operator. Any statement about a sigil's effect is bounded by the operator's own storage law and stops at the operator's skin. See §4.9(d).

SP14 — Verify by walking, not by formula, the first time. Every table in Sections 3 and 4 was produced by explicit trace and then checked against `gcd`. A theorem you have not tested on the object is a theorem you have not understood.

28.5.2 5.2 Failure modes

FP1 — SILENT LIFT. *Signature:* a figure or a schedule is specified as continuous, and in execution someone lifts the pen or breaks the chain, and no one records it. *Mechanism:* `gcd(N,k) > 1`. The break was structurally required, not a lapse. *Fix:* compute `gcd` first. If `g > 1`, declare the `g - 1` breaks as part of the specification and put a named owner on each. An undeclared break becomes an untracked hand-off, which is the classic Conway's Law seam.

FP2 — PHANTOM PARALLELISM. *Signature:* a schedule is described as having `g` parallel workstreams, and work in fact crosses between them constantly. *Mechanism:* the strokes of `{N/k}` are *disjoint*. If real traffic crosses, the model is not `{N/k}`, and `gcd` does not describe the actual topology. *Fix:* measure the cross-stroke traffic. If it is non-zero, the correct model is a graph with those edges added, and the component count must be recomputed on the real graph, not the idealised one.

FP3 — CEILING BLINDNESS. *Signature:* a team is split into small parallel cells for speed, throughput improves, and the quality of what emerges degrades in a way no one can locate. *Mechanism:* the ceiling fell from `ln N` to `ln(N/g)`. For `N = 12, g = 4`: from 2.484907 to 1.098612 nats, a 55.8% reduction in the maximum surplus any single period can produce. *Fix:* SP6. Print both ceilings. If depth is the requirement, run at least some periods at `gcd = 1`; alternate configurations rather than committing to one.

FP4 — GRADIENT HUNTING. *Signature:* a parameter is being tuned by small increments and the behaviour is erratic, so the increments get smaller. *Mechanism:* the response is `gcd(N, k)`, which is discontinuous everywhere it matters. Smaller steps do not help; they cannot. *Fix:* stop tuning. Enumerate the divisors of `N`, evaluate the finite candidate set exhaustively, and choose. There are at most `floor(N/2)` candidates and for `N <= 24` that is at most 12.

FP5 — GCD MYSTICISM. *Signature:* the arithmetic invariant is presented as though it explained the historical or symbolic *significance* of a figure, rather than its stroke count. *Mechanism:* an ordinary category error — a structural fact recruited to carry interpretive weight it cannot bear. It is the same error as the companion paper's hash mysticism [Curzi, 2026u], here with a better theorem and therefore a stronger temptation. *Fix:* the theorem says how many strokes. It says nothing else. Where a sentence about the figure would be false if the figure had been invented yesterday to organise a warehouse, that sentence is outside the theorem.

FP6 — CONSTANT-STEP ASSUMPTION. *Signature:* "this figure cannot be drawn in one line" is asserted, and someone then draws it in one line. *Mechanism:* Theorem 1 governs constant steps. Variable-step tours are a different and larger search space. The unicursal hexagram lives in the gap. *Fix:* state the step regime with the claim. "No constant step draws `{6/2}` in one line" is true; "no single line touches six points in a star pattern" is false, with exactly one counterexample up to symmetry.

FP7 — DIGEST-AS-CODE. *Signature:* someone attempts to reconstruct the original statement of intent from a sigil, or treats the glyph as carrying the sentence. *Mechanism:* the preimage of a 15-letter set among 28-letter strings is about `2^105`. The map is not invertible and the loss is total. *Fix:* keep the statement separately if you need it. If the practice requires that the statement be irrecoverable, the encoding already guarantees it; nothing further is needed and nothing can undo it.

FP8 — UNBOUNDED-SIGIL FALLACY. *Signature:* a longer, more elaborate statement of intent is believed to produce a richer glyph. *Mechanism:* output entropy is capped at 26 bits regardless of input length, and at 23.31 bits in practice. Beyond about 13 retained letters the layer count *falls*: `C(26,20) < C(26,13)` by a factor of 45. *Fix:* if information content is the goal, target `m` near 13. If it is not the goal, do not invoke information content as a reason for elaboration.

FP9 — PRIME COMPLACENCY. *Signature:* a prime `N` is chosen for its guaranteed unicursality, and later someone needs a parallel decomposition and cannot have one. *Mechanism:* prime `N` has no proper divisors, so `gcd(N,k) = 1` for every `k` and the only attainable stroke count is 1. Maximum jump 0: perfectly robust, perfectly inflexible. *Fix:* decide early which property is load-bearing. If both may be needed, choose `N` with a small number of divisors — `N = 2p` for prime `p` gives exactly the stroke counts 1, 2, and `p`, which is a usable three-item menu with `phi(2p) = p−1` unicursal steps.

28.6 6 Worked example: a twelve-station design review

A hardware group runs a design review across **twelve stations** — twelve specialists who must each see and sign every design package. The current process is a single chain: station 1 to 2 to 3, and so on to 12. One package per hand-off, one hand-off per working day. The group wants throughput and does not want to lose depth. The procedure of Sections 3 to 5 is applied.

Step 1 — Identify `N` and enumerate the menu (SP1, SP3).

```
N = 12          divisors: 1, 2, 3, 4, 6, 12
attainable stroke counts (proper divisors): 1, 2, 3, 4, 6
candidate steps k = 1..6 (Corollary 5 mirrors the rest)
phi(12) = 4, so only k = 1, 5, 7, 11 are unicursal: a 33.3% unicursal fraction
```

Twelve is the worst-case cardinality for single-stroke figures and the best case for decompositions. That is the trade the group has already made by having twelve people.

Step 2 — The configuration table. From §4.1 and §4.5, with the ceiling and rate columns:

Config	g = strokes	stroke size x	latency (days)	ceiling `ln x`	rate `ln x / x`
`{12/1}` current	1	12	12	2.484907	0.207076
`{12/2}`	2	6	6	1.791759	0.298627
`{12/3}`	3	4	4	1.386294	0.346574
`{12/4}`	4	3	3	1.098612	0.366204
`{12/5}`	1	12	12	2.484907	0.207076
`{12/6}`	6	2	2	0.693147	0.346574

Explicit orbits for the leading candidate, `{12/3}`, stations numbered 0-11:

```
stroke A:  0 -> 3 -> 6 -> 9  -> 0
stroke B:  1 -> 4 -> 7 -> 10 -> 1
stroke C:  2 -> 5 -> 8 -> 11 -> 2
```

Three closed loops of four, disjoint, twelve hand-offs total, two pen lifts — that is, two declared seams between loops that require an explicit owner (FP1).

Step 3 — Storage law with real parameters. The group's measured parameters:

```
eta   = 0.45      fraction of review interaction that becomes durable design knowledge
delta = 0.08      per-period decay (rotation onto other projects, standards drift)
Q_t   = 6.0       current stored design capability, nat-scaled
C_t   = 0.05*(g-1) + 0.15    coordination cost: a base of 0.15 plus 0.05 per merge seam
```

The cost model is the group's own estimate, badged as an estimate: each additional stroke adds one merge point where the loops' conclusions must be reconciled, and the group prices that at 0.05.

One-step change, `dQ = eta * S - delta * Q_t - C_t`, taking `S` at each configuration's ceiling (the optimistic case; real `S` is lower and the ranking is unaffected):

Config	strokes	members/stroke	`S` ceiling	`C_t`	`eta*S`	`dQ`
`{12/1}`	1	12	2.484907	0.1500	1.1182	**+0.488208**
`{12/2}`	2	6	1.791759	0.2000	0.8063	+0.126292
`{12/3}`	3	4	1.386294	0.2500	0.6238	-0.106168
`{12/4}`	4	3	1.098612	0.3000	0.4944	-0.285624
`{12/6}`	6	2	0.693147	0.4000	0.3119	-0.568084

The rate-optimal figure `{12/4}` — four triangles, the configuration §4.5 identified as maximal in `ln x / x` — has a *negative* one-step change in stored order. The two results are not in conflict and the reason is exactly the trade in §4.4: `{12/4}` maximises surplus per unit of *latency*, and the storage law is denominated per *period*, not per unit of latency. If the group runs four three-person loops, each period produces at most 1.098612 nats of surplus, `eta` converts 0.494 of it, and decay plus merge cost consumes 0.780. Order falls.

The reconciliation is quantitative and it is the real finding. `{12/4}` completes a cycle in 3 days rather than 12 — four times as many periods per quarter. Over a 60-working-day quarter:

```
{12/1}:  60/12 = 5 cycles    per-cycle dQ = +0.488208   quarter total = +2.441040
{12/3}:  60/4  = 15 cycles   per-cycle dQ = -0.106168   quarter total = -1.592513
{12/4}:  60/3  = 20 cycles   per-cycle dQ = -0.285624   quarter total = -5.712489
```

The single chain wins outright on this cost model, because the merge cost grows with stroke count while the ceiling falls with it, and running the loss more often only compounds

the loss. The rate criterion `ln x / x` assumed the only cost was latency. It is not; `C_t` rises with `g` and `delta * Q_t` is charged every period regardless. **The rate theorem is a ceiling result and this is what it looks like when the ceiling is not the binding constraint.**

Step 4 — Headroom for each configuration. The master gauge, at the unpartitioned ceiling `ln 12`:

```
h = eta * ln 12 - delta * Q_t - C_t = 1.118208 - 0.480000 - C_t

{12/1}: h = +0.488208
{12/2}: h = +0.438208
{12/3}: h = +0.388208
{12/4}: h = +0.338208
{12/6}: h = +0.238208
```

All positive: the group has room to grow in every configuration *if* it can reach `ln 12`. Only `{12/1}` and `{12/5}` can. **Headroom exists and only the unicursal configurations can spend it, which is the entire decision in one line.**

Step 5 — The chosen design. The group adopts `{12/5}` rather than `{12/1}`, and the reason is not in the surplus arithmetic at all — the two are identical there, both `g = 1`, both twelve steps, both ceiling `ln 12`. The reason is the *sequence*:

```
{12/1}:  0,1,2,3,4,5,6,7,8,9,10,11
{12/5}:  0,5,10,3,8,1,6,11,4,9,2,7
```

`{12/1}` visits adjacent stations, which in this group means adjacent specialisms; `{12/5}` visits stations five apart, so each hand-off crosses to a distant specialism and returns. **Both have the same `N`, the same `g`, the same ceiling and the same latency; they differ in how much of the ceiling is reachable, because `u` between adjacent specialists is lower than `u` between distant ones.** That is the framework's engineering of `u` reappearing as a choice of step [Curzi, 2026c], and the star polygon is the object that makes the choice enumerable: there are exactly `phi(12)/2 = 2` distinct unicursal figures on twelve points, `{12/1}` and `{12/5}`, and the group can simply compare them.

Estimating `u` from the group's own records — mean non-parallelism 0.31 for adjacent pairs, 0.58 for pairs five apart:

```
{12/1}:  N_eff = 1 + 11*0.31 = 4.410000    F = ln 4.410000 = 1.483875 nats  (59.7% of ln 12)
{12/5}:  N_eff = 1 + 11*0.58 = 7.380000    F = ln 7.380000 = 1.998774 nats  (80.4% of ln 12)

dQ {12/1} = 0.45*1.483875 - 0.48 - 0.15 = +0.037744
dQ {12/5} = 0.45*1.998774 - 0.48 - 0.15 = +0.269448
```

Changing the step from 1 to 5 — the same twelve people, the same twelve hand-offs, the same twelve days, one number changed in the schedule — multiplies the per-cycle gain in stored order by 7.14. Over five cycles a quarter: +0.188718 against +1.347241.

That is the engineering claim in one worked number, and it rests on nothing beyond Theorem 1, the surplus functional [Curzi, 2026] and the storage law [Curzi, 2026a]. The figure told the group how many strokes were available and which steps were unicursal. The surplus law told them which unicursal step was worth taking. The storage law told them what it was worth.

A star polygon is a schedule with an exact arithmetic invariant, and reading it as one is not a metaphor. Reading it as a computing map is a metaphor, and the badge stays on.

28.7 7 The cadence theorem and the loci law

The companion paper read the correspondence table as a finite relational graph [Curzi, 2026u], and Sections 3 to 6 read the star-polygon figure as an encoding with an exact arithmetic invariant. This section takes the two remaining inherited technologies that are large enough to have architecture – **the memory palace and the liturgical calendar** – and shows that each is a named instance of a law the framework has already proved.

Neither reading requires anything to be added to the formalism. The memory palace is the storage law with space as the retention medium. The ritual calendar is a periodic forcing function applied to a first-order low-pass filter. Both statements are exact, both are computable in advance, and neither carries any claim beyond arithmetic.

Three results, named up front:

- **The loci method is not a trick for holding more. It is a technique for holding the same amount with a smaller `delta` and a larger `eta`, and the gain is the product of three separate factors, each measurable.** In the worked case it is a factor of 14.
- **The case for regular practice over heroic effort has two halves, and only one of them is the ceiling argument.** The second half is Theorem 2 below, which follows from the surplus functional's strict concavity [Curzi, 2026] and has nothing to do with saturation: dividing a fixed budget of interaction into more, smaller occasions never delivers less, and usually delivers much more.
- **The comparison between one large impulse and the same total delivered periodically is not ambiguous, but it is subtler than the folklore.** Over infinite time and with no ceiling the two are exactly equal in integrated effect. Three things differ, and all three are computed here: the steady state, the minimum, and – once the logarithmic ceiling [Curzi, 2026c] is applied – the deliverable total.

The load-bearing claim is the last one, and it is arithmetic rather than exhortation: **a single impulse, however large, has a steady state of exactly zero. A cadence has a steady state of `m/delta`. That is the whole difference, and everything else in the practice literature is a gloss on it.**

28.7.1 7.1 Statement one — the loci law

STATEMENT (the method of loci, read formally). Let a set of `N` items be encoded by binding each to a distinct location in a familiar, mentally traversable space. Then, in the storage law `Q_{t+1} = (1−delta)Q_t + eta S_t − C_t`:

- the **non-parallelism `u`** rises, because two items bound to two different places are, by construction, framed differently;
- the **conversion efficiency `eta`** rises, because retrieval has an addressable index — the walk — rather than requiring undirected search;
- the **retention loss `delta`** falls, because the index is a spatial layout that the retriever already maintains for other reasons and does not have to keep alive on this material's account.

This is a reading, not a theorem. What is a theorem is what follows once the three parameter movements are granted: the steady state moves by their product,

```
Q_inf = eta F(u) / delta         (the storage law's steady state, with c* = 0)

Q_inf'   eta'   F(u')   delta
------ = ---- . ----- . ------
Q_inf    eta    F(u)    delta'
```

and the three factors are separately measurable, separately attackable, and multiply. §8.2 computes them.

The tradition is old, continuous, and explicit about its own mechanism. Cicero (*De Oratore* II.86) attributes the technique to Simonides of Ceos, said to have identified the dead at a collapsed banquet hall by recalling where each guest had been sitting. Whatever the anecdote's historicity, its content is the claim being made here: **the retrieval index was the seating plan.** The fullest surviving classical treatment is the anonymous *Rhetorica ad Herennium* (c. 86-82 BCE), Book III; Quintilian gives a second account in the *Institutio Oratoria*, Book XI. Frances Yates's *The Art of Memory* (1966) is the standard history of how the technique travelled from Roman rhetoric through the medieval and Renaissance traditions.

28.7.2 7.2 Statement two — the cadence theorem

The framework established that cadence beats intensity because surplus saturates at `ln N` per period while cost does not saturate [Curzi, 2026a,c]. That argument depends entirely on the ceiling. **There is a second, independent argument that does not, and it is a theorem.**

THEOREM 2 (the cadence theorem). Let a fixed budget `T` of interaction be spread over `n` periods, `T/n` in each, and let the surplus generated in a period be `g(L)` where `L = T/n` is that period's allocation. If `g` is concave on `[0, infinity)` with `g(0) = 0`, then

```
D(n) := n * g(T/n)
```

is nondecreasing in `n`, and strictly increasing wherever `g` is strictly concave.

Proof. Treat `n` as a positive real. Write `L = T/n`, so `D = T g(L)/L`. Then

```
dD/dn = g(L) - L g'(L)
```

by the chain rule. Concavity of `g` with `g(0) = 0` gives `g(L) = g(L) - g(0) = integral_0^L g'(s) ds >= L g'(L)`, because `g'` is nonincreasing. Hence `dD/dn >= 0`, with strict inequality wherever `g'` is strictly decreasing. ■

The hypothesis is satisfied by the framework's own surplus functional. `f(u) = ln(1 + (N-1)u)` is strictly concave on `[0,1]` and `f(0) = 0` by the axiom set that characterises it [Curzi, 2026]. If the non-parallelism achieved in a session is any nondecreasing concave function of session length — and in particular if it is *linear* in length up to saturation, the simplest possible assumption — then the composite `g(L) = f(u(L))` is concave through the origin and Theorem 2 applies without further assumption.

Therefore the case for regular practice does not rest on the ceiling. It rests on the same concavity that makes the surplus law a logarithm, which is the same concavity found in sensation [Fechner, 1860, Weber, 1834]. Diminishing returns within one occasion is precisely what makes many occasions worth more than one.

28.7.3 7.3 What is proven and what is postulated

Element	Status	Warrant
`D(n) = n g(T/n)` nondecreasing in `n` for concave `g`, `g(0)=0`	**PROVED**	§7.2
`f(u) = ln(1+(N-1)u)` is strictly concave with `f(0)=0`	**PROVED**	the surplus functional's axioms

Element	Status	Warrant
A single impulse has steady state `Q_inf = 0`; a rate `m` has `Q_inf = m/delta`	**PROVED**	the storage law's steady state
Impulse and cadence have equal *integrated* effect absent a ceiling	**PROVED** (LTI)	§8.4, computed
Steady-state cycle: `Q_max = A/(1−a^P)`, `Q_min = Q_max a^P`	**PROVED**	periodic-forcing algebra
Required retention for a rite of interval `P`: `a^P >= r/(1+r)`, `r = theta/A`	**PROVED** (algebra)	§8.10
Costly-requirement break-even: `dc <= (eta F − c)(1 − delta'/delta)`	**PROVED** (algebra)	§8.11
That the method of loci raises `u` and `eta` and lowers `delta`	**POSTULATE** (reading)	§7.1, badged
That a ritual calendar is well described by the storage law at all	**POSTULATE** (modelling)	badged; see §7.4
That any particular `(eta, delta, u)` triple describes a particular practice	**REQUIRES MEASUREMENT**	the framework's survey protocols
Durkheim's, Rappaport's and Whitehouse's mechanisms for what ritual *does*	**SOCIAL THEORY**, not proved here	§8.9-8.10

28.7.4 7.4 Honesty clauses

- **Nothing in this section claims that a symbol, a place, a gesture or a date has any effect other than through a human being who encodes, retrieves, or attends.** The memory palace is a filing system. The calendar is a schedule. Both are effective; neither is mysterious.
- The illustrative parameter values in §8.2 and §8.4 are *design values*, chosen to make the structure legible, and they are labelled as such every time they appear. They are not measurements of any population. The protocols for obtaining real ones are the framework's survey instruments for `delta`, `eta` and `u` [Curzi, 2026c].
- As always, surplus as deployed is a **lower bound** on the ensemble's information [Curzi, 2026], so every `Q_inf` here is a floor.
- The anthropological literature cited in §8.9-8.13 is theory and observation about human societies. It is used here to name phenomena the formalism can represent. **The formalism does not validate the anthropology, and the anthropology does not validate the formalism.**
- Theorem 2 assumes `g` concave. If per-occasion response is genuinely *convex* over some range — if there is a warm-up cost below which nothing happens at all — the theorem reverses on that range, and §8.8 shows exactly how a fixed per-occasion cost restores an interior optimum. **The theorem does not say "shorter is always better." It says concavity favours division, and it names the term that stops the division.**

28.8 8 Cadence, retention, and periodic forcing

28.8.1 8.1 The classical loci rules are a parameter list

The classical treatment of artificial memory is unusually specific about procedure. The *Rhetorica ad Herennium* (III.16-24) gives rules for choosing loci and for constructing images. Read against the storage law, **each rule moves exactly one parameter, and the set of rules covers the parameter set without a remainder.**

Classical rule (*ad Herennium* III, paraphrased)	Parameter moved	Mechanism in the formalism
Choose loci in a deserted place, not a crowded one	`C` down	fewer competing encodings; less interference cost per period
Set the loci at moderate intervals, distinguishable one from the next	`u_cross` up	between-place non-parallelism is the block term `beta^2` of Thm 4.1
Do not let the loci be too like one another	`u_cross` up, `N` preserved	near-identical loci collapse to one effective locus; `N_eff` falls
Neither too bright nor too dark	`N` preserved	discriminability sets how many categories are actually distinct
Learn the series in order, and be able to begin from any point	`eta` up	multiple entry points make retrieval a graph traversal, not a list scan
Make the images striking, active, unusual	`u_div` up	within-place non-parallelism is the `alpha^2 sin^2 gamma` term
Use images of things you already care about	`eta` up	conversion into durable structure is higher for material with existing attachment
Revisit the palace to keep the loci fresh	`delta` down	maintenance of the index rather than of the contents

That table is the method in miniature. No rule requires a mechanism outside the law, and no parameter of the law is left without a rule. The tradition arrived at a complete parameter-tuning procedure by iteration over roughly two thousand years and wrote it down in the vocabulary it had.

28.8.2 8.2 The arithmetic of place

Take a corpus of `N = 40` items. The logarithmic ceiling caps surplus at `ln 40 = 3.6889` nats per occasion, and no encoding exceeds it [Curzi, 2026c]. What differs between encodings is how much of that ceiling they reach, and the driver is `u`.

Design values, illustrative and badged as such:

Encoding	`u`	`N_eff = 1+(N−1)u`	`F = ln N_eff`	% of `ln 40`
rote list, single undifferentiated context	0.15	6.850	1.9242	52.2%

Encoding	u	N_eff = 1+(N−1)u	F = ln N_eff	% of ln 40
rote plus grouping into chunks	0.40	16.600	2.8094	76.2%
loci, ordinary domestic places	0.75	30.250	3.4095	92.4%
loci, deliberately distinct places, vivid images	0.90	36.100	3.5863	97.2%
loci, idealised	0.97	38.830	3.6592	99.2%

The interesting feature of that column is how quickly it saturates: **an ordinary, undesigned palace already reaches 92% of the ceiling, and all the effort of the classical rules buys the last 8%.** That is the logarithm again. It is also the honest answer to why beginners get most of the benefit immediately and experts spend years on the remainder.

Palace size obeys an exact law and it is unforgiving. The ceiling is ln L in the number of loci L, so:

loci L	5	10	20	40	80	160	320
ln L	1.6094	2.3026	2.9957	3.6889	4.3820	5.0752	5.7683

Every doubling of the palace buys exactly ln 2 = 0.693147 nats, forever. Not more at the start and not less at the end. Going from 5 loci to 10 buys the same as going from 160 to 320. This is the most useful single fact for anyone designing a palace: **capacity is bought in fixed increments at exponentially rising cost in construction effort, so the question is never "how big" but "how many doublings can I afford to build and maintain."**

The two-source decomposition prices place and image separately. The framework's block decomposition [Curzi, 2026] splits u = u_cross + u_div — between-locus and within-locus non-parallelism — and bounds the result:

```
max(f(u_cross), f(u_div))  <=  f(u)  <=  f(u_cross) + f(u_div)
```

Computed at N = 40:

u_cross (places)	u_div (images)	u	f(u_cross)	f(u_div)	lower	f(u)	upper	slack
0.85	0.05	0.90	3.5308	1.0818	3.5308	3.5863	4.6126	1.0263
0.80	0.10	0.90	3.4720	1.5892	3.4720	3.5863	5.0612	1.4749
0.45	0.45	0.90	2.9205	2.9205	2.9205	3.5863	5.8409	2.2546
0.60	0.20	0.80	3.1946	2.1748	3.1946	3.4720	5.3693	1.8974

Two readings, both practical. First, **f(u) sits very close to the lower bound in every row**, which is subadditivity doing its work [Curzi, 2026]: the two sources overlap heavily and one does not get to add them. Second, **the balanced row (0.45/0.45) has the largest gap between the naive sum and the truth** — 2.25 nats of imagined surplus that does not exist. An operator who has invested equally in place-distinctness and image-vividness will overestimate the combined effect by more than one who has invested lopsidedly. That is a counterintuitive and checkable consequence.

The three-factor gain, computed. Period one day. Design values, badged.

Regime	u	eta	delta/day	F	eta F	Q_inf	DC gain eta/delta	tau	t_half
rote rehearsal	0.15	0.20	0.25	1.9242	0.3848	1.5394	0.800	3.48 d	2.41 d

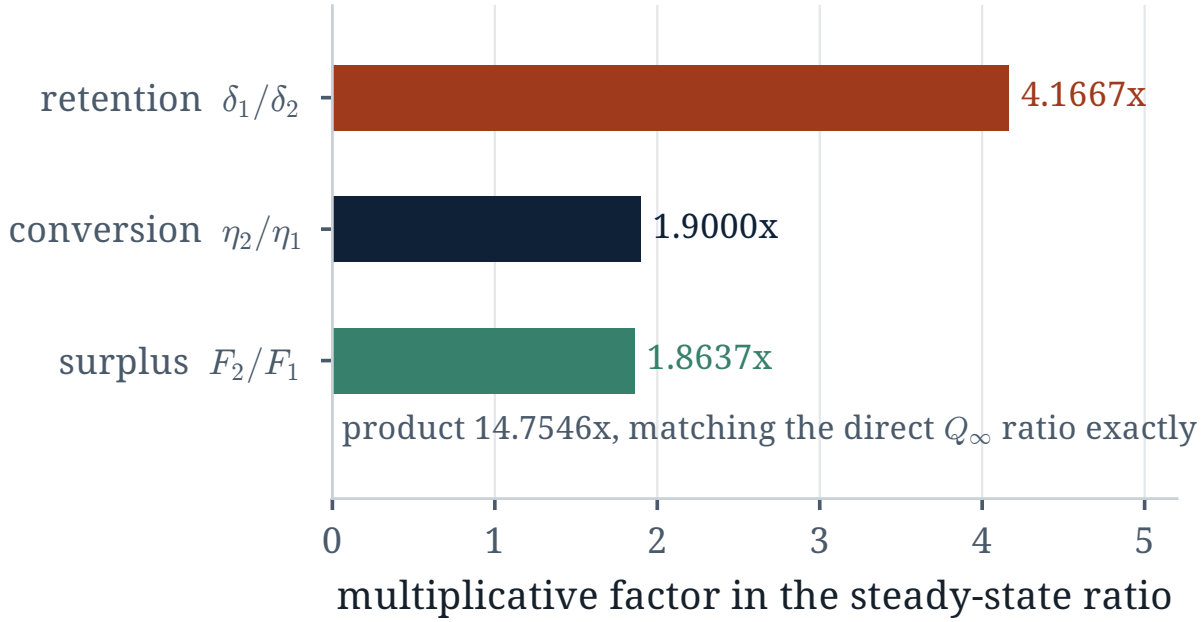

Figure 28.3: **The loci advantage is mostly retention, which is the opposite of the usual emphasis.** Surplus and conversion together give a factor of 3.54; retention alone gives 4.17, and the three multiply to 14.7546, matching the direct steady-state ratio exactly. Modelled from the design values of §8.2 and badged there as design values; produced by `figs/src/CCP-028_fig05.py`.

Regime	u	eta	delta/day	F	eta F	Q_inf	DC gain eta/delta	tau	t_half
rote + grouping	0.40	0.24	0.20	2.8094	0.6743	3.3713	1.200	4.48 d	3.11 d
loci encoding	0.90	0.38	0.06	3.5863	1.3628	22.7132	6.333	16.16 d	11.20 d
loci + spaced review	0.90	0.38	0.03	3.5863	1.3628	45.4264	12.667	32.83 d	22.76 d

Decomposing the loci-versus-rote ratio:

```
surplus factor    F2/F1        = 1.8637
conversion factor eta2/eta1    = 1.9000
retention factor  delta1/delta2 = 4.1667
----------------------------------------
product                        = 14.7546
direct Q_inf ratio             = 14.7546     (identical, as it must be)
```

Two thirds of the advantage is in `delta`. The surplus and conversion factors together give `1.8637 x 1.9000 = 3.54`; retention alone gives 4.17. **The memory palace is primarily a retention device and only secondarily an encoding device, and every popular account has that emphasis backwards.** The framework's general rule reappears in miniature: retention is a gain term, and nobody treats it as one [Curzi, 2026a].

28.8.3 8.3 What the evidence supports, and what it does not

The method of loci is one of the few techniques treated here with a genuine experimental literature, and the honest summary is narrower than the enthusiasm around it.

What is well supported. That the technique substantially improves ordered recall of arbitrary lists is not seriously contested; Bower's review in *American Scientist* (1970) is an early

and clear statement of the experimental case. Maguire, Valentine, Wilding and Kapur (*Nature Neuroscience*, 2003) studied competitors at the World Memory Championships and reported that they did not differ from controls in general cognitive ability or gross brain structure, but did differ in which regions they engaged during encoding, with spatial-navigation areas prominent; the great majority reported using the method of loci. Dresler and colleagues (*Neuron*, 2017) trained novices over several weeks and reported substantial improvement in list recall, partial persistence at a months-later follow-up, and shifts in functional connectivity toward the expert pattern. **In this paper's vocabulary, both studies are about `eta` and `delta`, not about capacity.**

What is well supported and usually forgotten. Ericsson, Chase and Faloon (*Science*, 1980) trained a single subject over more than 200 hours of practice; his digit span rose from about 7 to about 79. His *letter* span did not move — it remained around six. **The stored order was specific to the essence set it was built on.** In the framework's parameter table `Q` is stock, and stock is indexed by the category set that generated it [Curzi, 2026o]. There is no general memory to be improved; there are particular `Q`s built against particular `N`s. Any claim that a mnemonic practice raises "memory" as such is a category error the framework catches immediately.

What the framework contributes and the literature does not. The literature reports outcomes. The storage law says *why the outcome has the shape it has*: the gain is a product of three factors, the largest of which is retention, and each is separately attackable. **The framework's identifiability gate is the gate such a study would have to pass** [Curzi, 2026u], and it is not obvious that it does: two different `(eta, delta)` pairs with the same ratio produce the same steady state, and only the *transient* separates them. The measurement design must therefore observe the approach to steady state and not only the endpoint — which is the framework's decay-estimation method, and why it insists on a zero-input window.

What is not supported by anything here. That the images or places have significance of their own. That a particular palace layout is better than another for reasons other than distinctness and familiarity. That the technique transfers across domains — Ericsson's subject says otherwise.

28.8.4 8.4 One impulse against the same total, computed

This is the calculation the section exists to perform. The ceiling argument is given above. Here the comparison is made without any ceiling first, so that the honest baseline is on the record, and the ceiling is added afterwards.

Setup. `delta = 0.06` per week, so `a = 0.94`, `tau_exact = 16.1615` weeks, `t_half = 11.2023` weeks. A fixed total input budget `B = 26.0` units. Three ways to spend it:

- **Impulse:** all 26.0 in week 0, nothing after.
- **Weekly:** 0.5 per week for 52 weeks, nothing after.
- **Four-weekly:** 2.0 every fourth week for 52 weeks, nothing after.

week	impulse	weekly	four-weekly
0	0.0000	0.0000	0.0000
1	26.0000	0.5000	2.0000
2	24.4400	0.9700	1.8800
4	21.5952	1.8271	1.6612
8	16.8604	3.2536	2.9581
13	12.3739	4.6053	5.7325
26	5.5357	6.6655	7.0583
39	2.4765	7.5872	7.3818
52	1.1079	7.9995	7.2731
78	0.2217	1.6010	1.4556

week	impulse	weekly	four-weekly
104	0.0444	0.3204	0.2913
156	0.0018	0.0128	0.0117

The crossover is week 24. At week 23 the impulse is still ahead, 6.6648 against 6.3254; at week 24 the cadence is ahead, 6.4458 against 6.2649, and it never trails again while the budget lasts.

And now the fact the folklore gets wrong. Summing `Q_t` over 400 periods:

```
impulse      433.3333
weekly       433.3333
four-weekly  433.3333
B/delta   =  433.3333
```

Identical to every digit. This is not an artefact of the parameters. It is the defining property of a linear time-invariant system: the integral of the response to a given total input is `B/delta` regardless of how the input is distributed in time. **Anyone who tells you that spreading the same total input over more occasions produces more total stored order, in a linear model, has not done the arithmetic.** The framework says this plainly and it is repeated here, because the correct argument is stronger when the incorrect one has been cleared away.

28.8.5 8.5 The steady-state difference — the actual result

The integral is invariant. **The steady state is not, and this is where the difference lives.**

A single impulse of any size whatever, never repeated, has

```
Q_inf = 0
```

because the driven term is zero for all `t > 0` and the transient decays as `a^t`. A sustained rate `m` per period has

```
Q_inf = m / delta
```

Tabulated at `delta = 0.06`:

sustained rate `m` per week	`Q_inf = m/delta`	impulse of any size, unrepeated
0.10	1.6667	0.0000
0.25	4.1667	0.0000
0.50	8.3333	0.0000
0.7278	12.1300	0.0000
1.00	16.6667	0.0000

That column of zeros is the mathematical case for regular practice, and it does not depend on the ceiling, on motivation, on commitment, or on any claim about human nature. A quantity that is not driven decays to zero because `delta > 0`. The only way to hold a nonzero level is to keep driving it. This is why the framework insists that the leak is the point: the same `delta` that makes iteration arrive is the `delta` that makes a single arrival not stay [Curzi, 2026a]. It is also why repetition alone cannot move the destination – the fixed point `Q_inf = (eta F − c)/delta` contains no `t` [Curzi, 2026].

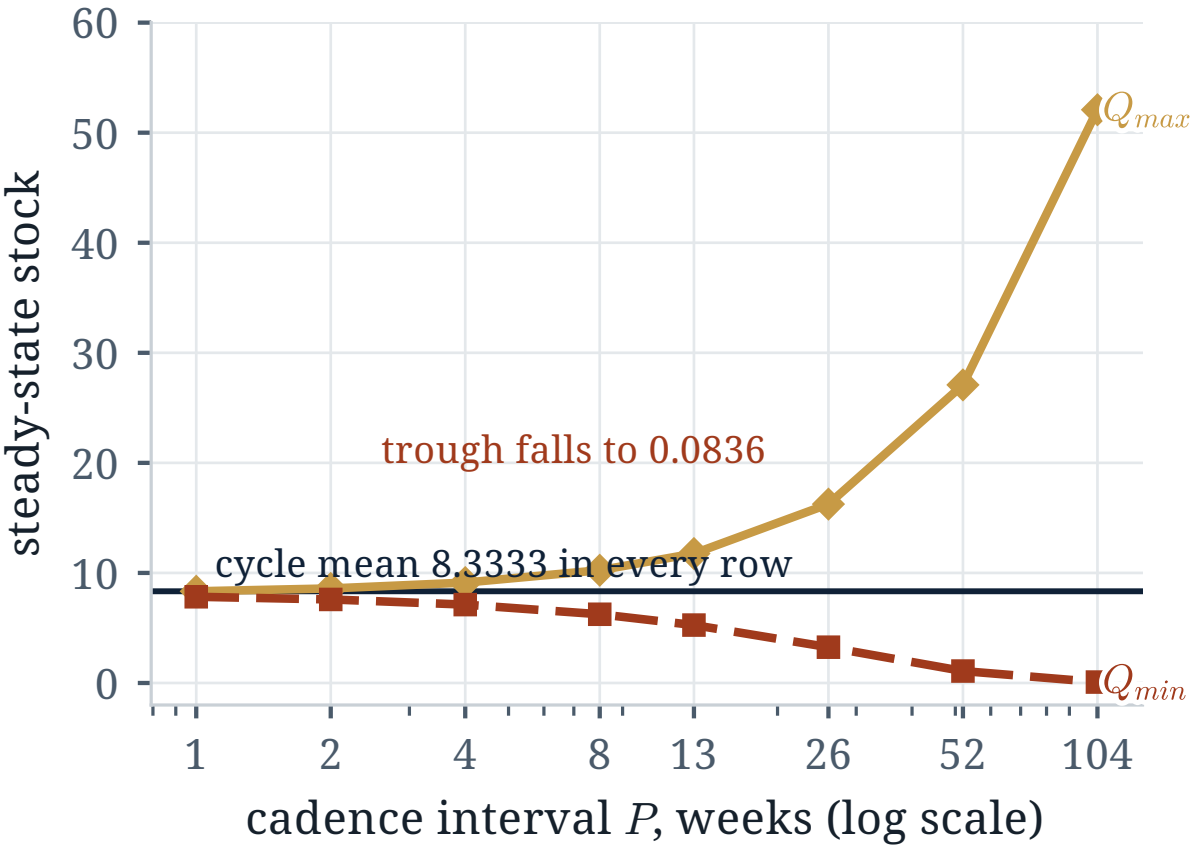

Figure 28.4: **The cycle mean is identical at every cadence; only the trough moves.** Spreading the same annual total over rarer, larger bursts leaves the mean at 8.3333 in every row while the steady-state minimum falls from 7.8333 to 0.0836 — so a system with any functional threshold experiences the trough and not the mean. Modelled at `delta = 0.06` per week with an annual total of 26.0 units; produced by `figs/src/CCP-028_fig04.py`.

Now repeat the impulse. Take the same annual total, 26.0 units, delivered forever at interval `P` with burst `A = 26P/52`. The steady-state cycle is exact:

cadence `P`	burst `A`	`a^P`	`Q_max`	`Q_min`	ripple	cycle mean	% of cycle with `Q >= 7`
1	0.5000	0.940000	8.3333	7.8333	0.5000	8.3333	100.0%
2	1.0000	0.883600	8.5911	7.5911	1.0000	8.3333	100.0%
4	2.0000	0.780749	9.1220	7.1220	2.0000	8.3333	100.0%
8	4.0000	0.609569	10.2451	6.2451	4.0000	8.3333	76.9%
13	6.5000	0.447365	11.7618	5.2618	6.5000	8.3333	64.5%
26	13.0000	0.200136	16.2528	3.2528	13.0000	8.3333	52.4%
52	26.0000	0.040054	27.0849	1.0849	26.0000	8.3333	42.1%
104	52.0000	0.001604	52.0836	0.0836	52.0000	8.3333	31.2%

The mean column is constant at 8.3333 in every row. The minimum falls from 7.83 to 0.08. **If a system has any functional threshold at all, the mean is the wrong statistic and the minimum is the right one.** A community whose shared context must stay above some level for its meetings to work, its obligations to hold, or its newcomers to be absorbed does not experience the mean; it experiences the trough, and the trough is the only column in that table that moves.

28.8.6 8.6 The three quantities that are not invariant

Collecting the finite-budget results from §8.4, with thresholds applied:

threshold `theta`	periods with `Q >= theta`, impulse	weekly	four-weekly
3.0	35	60	61
5.0	27	45	45
7.0	22	25	23
10.0	16	0	0
15.0	9	0	0

Read that table honestly, because it does not say what a partisan of cadence would like it to say. At low thresholds the cadence wins by a wide margin: 60 or 61 periods against 35. At `theta = 7` the three are close. **At `theta = 10` and above the impulse wins outright, and the cadence scores exactly zero, because no cadence funded by that budget ever reaches 10 at all.**

That is the entire formal content of the intensity argument, and it is real. **An impulse buys height that a cadence cannot buy; a cadence buys duration that an impulse cannot buy.** If — and only if — there exists a threshold that must be crossed and that no sustainable rate can reach, the impulse is the correct instrument, and the framework says so without hedging. §8.10 identifies the class of rites that live in exactly that regime and computes what they require.

Three quantities, then, are not invariant to how a fixed budget is spread:

1. **The peak.** `26.0000` for the impulse, `7.9995` for the weekly cadence — a factor of 3.25.
2. **The minimum**, and hence time above any threshold below the cadence's plateau.
3. **The deliverable total itself**, once the ceiling is applied — which is §8.7 and is the largest effect of the three by an order of magnitude.

28.8.7 8.7 The ceiling, applied

The logarithmic ceiling caps `F(u)` at `ln N`, so per-period input is capped at `eta ln N` [Curzi, 2026c]. With `eta = 0.35` and `N = 8`:

```
eta ln N = 0.35 * 2.0794 = 0.7278 per week
```

The 26-unit annual total is now attempted at each cadence, and the bursts are clipped:

cadence `P`	burst wanted	delivered	clipped?	annual delivered	% of weekly
1	0.5000	0.5000	no	26.0000	100.0%
2	1.0000	0.7278	**yes**	18.9229	72.8%
4	2.0000	0.7278	**yes**	9.4615	36.4%
8	4.0000	0.7278	**yes**	4.3668	16.8%
13	6.5000	0.7278	**yes**	2.9112	11.2%
26	13.0000	0.7278	**yes**	1.4556	5.6%
52	26.0000	0.7278	**yes**	0.7278	**2.8%**

The annual rite delivers 2.8% of the weekly practice, from an identical nominal budget. The other 97.2% is not delivered late, or delivered inefficiently. It is not delivered at all: the law caps what one interaction can generate and the excess has nowhere to go.

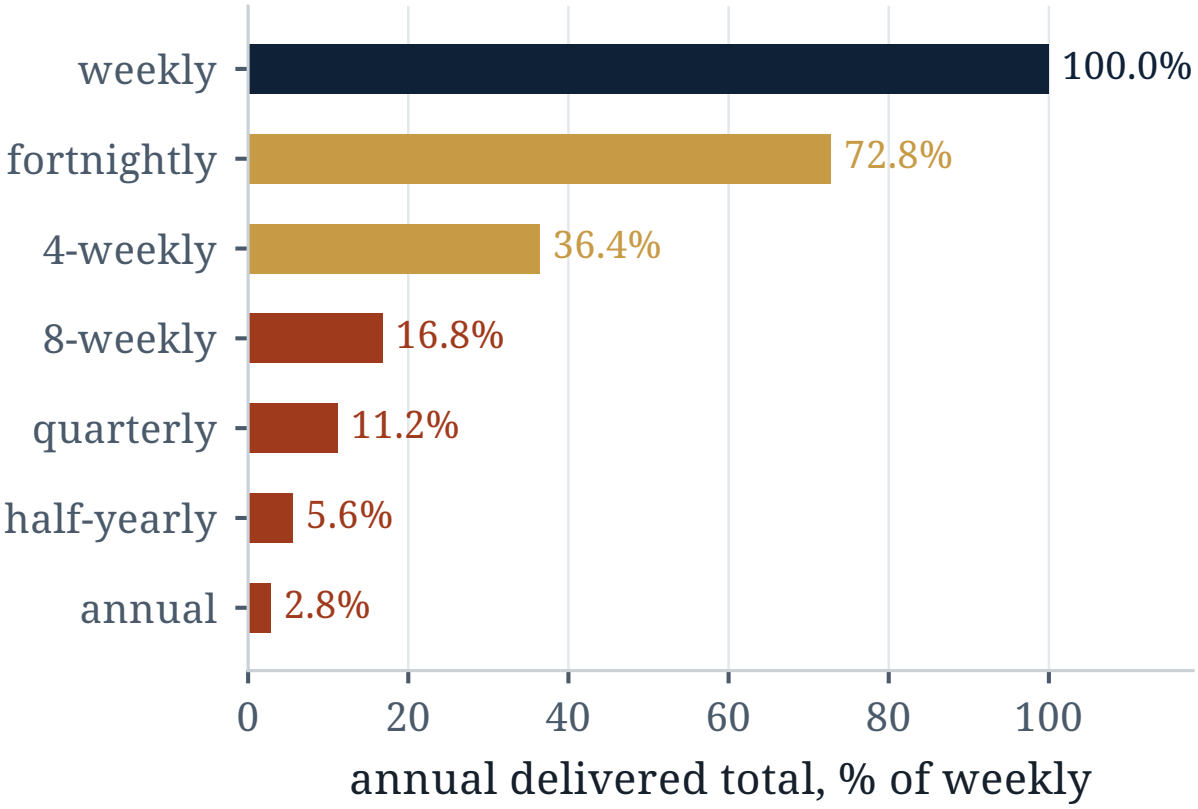

Figure 28.5: **An annual rite delivers 2.8 per cent of what a weekly practice delivers from an identical nominal budget, and the missing 97.2 per cent is not delivered late but not delivered at all.** The per-period ceiling `eta ln N = 0.7278` clips every burst, and a rarer cadence wastes a larger share of each. Modelled at `eta = 0.35`, `N = 8`, annual budget 26.0 units; produced by `figs/src/CCP-028_fig03.py`.

Design consequence, stated once and load-bearing: an annual event and a weekly practice are not two speeds of the same thing. They are different instruments with different maximum outputs, and the comparison "same total time" is meaningless without the clipping calculation.

28.8.8 8.8 The optimal cadence, and the term that stops the division

Theorem 2 says division never hurts. On its own it would recommend infinitely many infinitesimal occasions, which is obviously wrong, and the theorem's honesty requires naming the term that stops it: **the per-occasion fixed cost.**

Let a fixed budget `T = 12` hours be spread over `n` periods with one session of `T/n` hours each. Let non-parallelism rise linearly with session length to saturation at `L* = 8` hours, `u(L) = min(1, L/L*)`. Let `N = 8`, `eta = 0.35`, and let each occasion carry a fixed cost `c_0 = 0.15` regardless of length — convening, travelling, settling, closing.

n	L (h)	u	f(u)	eta f	delivered	−n c_0	net
1	12.0000	1.0000	2.0794	0.7278	0.7278	-0.1500	0.5778
2	6.0000	0.7500	1.8326	0.6414	1.2828	-0.3000	0.9828
3	4.0000	0.5000	1.5041	0.5264	1.5793	-0.4500	1.1293
4	3.0000	0.3750	1.2879	0.4507	1.8030	-0.6000	1.2030
5	**2.4000**	**0.3000**	**1.1314**	**0.3960**	**1.9800**	**-0.7500**	**1.2300**
6	2.0000	0.2500	1.0116	0.3541	2.1244	-0.9000	1.2244
8	1.5000	0.1875	0.8383	0.2934	2.3473	-1.2000	1.1473
12	1.0000	0.1250	0.6286	0.2200	2.6402	-1.8000	0.8402
24	0.5000	0.0625	0.3629	0.1270	3.0484	-3.6000	-0.5516
48	0.2500	0.0312	0.1978	0.0692	3.3235	-7.2000	-3.8765

The **delivered total** column is monotone increasing exactly as Theorem 2 requires, rising from 0.7278 to 3.3235 — **a factor of 4.57 from the same twelve hours, purely by division.** The **net** column peaks at `n = 5` and falls away on both sides.

Note also the first row. At `n = 1`, the session is 12 hours but `u` saturates at 8; **four of the twelve hours deliver nothing at all.** The single long occasion wastes a third of the budget before any of the other effects are considered.

The optimum is a function of the per-occasion cost and of nothing else here:

fixed cost `c_0` per occasion	optimal `n`	session length	net delivered
0.00	(unbounded)	-> 0	-> 3.6275
0.02	24	0.500 h	2.5684
0.05	13	0.923 h	2.0438
0.10	8	1.500 h	1.5473
0.15	5	2.400 h	1.2300
0.25	3	4.000 h	0.8293
0.40	2	6.000 h	0.4828
0.60	1	12.000 h	0.1278
0.80	1	12.000 h	-0.0722

Read the table as a design instrument, not a result. The optimal cadence is not a fact about the practice; it is a fact about how expensive it is to convene. **Halving the cost of convening moves the optimum from five occasions to eight, and doing so is very often cheaper than any intervention on the occasions themselves.** This is the quantitative form of a familiar observation: groups that meet in a place they are already in, at a time they are already free, meet far more often, and the reason is the `c_0` column.

At `c_0 = 0.80` the net is negative at every `n`. **Some practices cannot be afforded at any cadence, and the arithmetic says so before anybody's calendar is consulted.**

28.8.9 8.9 Ritual as periodic forcing: what Durkheim and Rappaport are describing

Durkheim's *Elementary Forms of Religious Life* (1912) proposes that periodic assembly generates a state — *effervescence collective* — that the assembled individuals do not generate separately, and that the periodic re-assembly is what keeps the resulting representations alive between times.

In this framework that is two claims, and they map cleanly. The first is that `S = F(u) > 0` requires more than one non-parallel participant — the surplus functional is exactly zero when the participating framings are parallel [Curzi, 2026], so an assembly of genuinely different people generates what none of them generates alone. The second is the storage law itself: what the assembly produces is an *input*, and inputs decay unless repeated. **Durkheim's insistence that the feast must recur is the observation that `delta > 0`.**

Roy Rappaport's *Ritual and Religion in the Making of Humanity* (1999) is more precise and more useful here. Rappaport defines ritual by its form rather than its content — as the performance of sequences of formal acts and utterances that are largely invariant and not encoded by the performers themselves — and separates two streams of information carried by a performance:

- the **canonical stream**, which is the invariant liturgical order itself and is not about the performer at all;
- the **self-referential stream**, which is what this particular performer, at this particular time, transmits by showing up and doing it.

That distinction is a distinction between `Q` and `S`. The canonical order is stored order: it persists across performers, changes slowly, and is maintained rather than created each time. The self-referential message is the period's input. Rappaport's central claim — that to perform an order is to accept it, whatever one privately believes — is, formally, a statement that this particular `eta` is unusually reliable: participation converts into a public commitment record whether or not the participant intends it to.

Rappaport is also explicit that the propositions at the top of a liturgical order — his **Ultimate Sacred Postulates** — are typically unfalsifiable, and that their unfalsifiability is functional rather than concealed. **That is the framework's badge rule, arrived at independently and stated in another vocabulary.** A postulate declared as a postulate does work that a postulate disguised as a finding cannot do, and Rappaport's point is that the declaration is part of the mechanism.

Two experimental results attach here because they concern the input side rather than the storage side. Konvalinka and colleagues (*PNAS*, 2011) recorded heart-rate dynamics during a fire-walking ritual in San Pedro Manrique, Spain, and reported synchronised arousal between performers and related spectators. Wiltermuth and Heath (*Psychological Science*, 2009) reported that synchronous action raised cooperation in subsequent economic tasks. **Both are evidence about `S` — about what an occasion generates — and neither is evidence about `delta`.** Keeping those two questions apart is most of what this framework contributes to reading the ritual literature.

28.8.10 8.10 The two modes, and what a rare rite must buy

Harvey Whitehouse's *Modes of Religiosity* (2004) distinguishes a **doctrinal** mode — frequent, routinised, low-arousal, transmissible at large scale — from an **imagistic** mode — rare, high-arousal, often painful or frightening, producing intense and enduring episodic memory in small groups. Whitehouse and Lanman (*Current Anthropology*, 2014) develop the second into an account of *identity fusion*.

This is precisely the cadence/intensity axis, arrived at inductively from the ethnographic record, and the framework says something specific about it that the ethnography does not.

A rite at interval `P`, delivering a burst `A`, has steady-state trough `Q_min = A a^P / (1 − a^P)`. Requiring `Q_min >= theta` and solving for the pole:

```
a^P  >=  r / (1 + r),      r = theta / A
```

With the burst at the ceiling, `A = eta ln N = 0.7278`, and a modest functional floor `theta = 0.30`:

interval `P`	in human terms	required pole `a`	required `delta`/week	required `t_half`	in years
1	weekly	0.291884	0.708116	0.56 wk	0.01
4	monthly	0.735026	0.264974	2.25 wk	0.04
13	quarterly	0.909625	0.090375	7.32 wk	0.14
26	half-yearly	0.953743	0.046257	14.64 wk	0.28
52	annual	0.976597	0.023403	29.27 wk	0.56
208	every four years	0.994097	0.005903	117.08 wk	2.25
520	every ten years	0.997635	0.002365	292.71 wk	**5.63**
1560	once a generation	0.999211	0.000789	878.12 wk	**16.89**

A once-a-decade rite requires the trace it leaves to have a half-life of about five and a half years. A once-a-generation rite requires seventeen.

That is the whole explanation of the imagistic mode, and it is arithmetic. **A rare rite is not an inefficient frequent rite. It is a rite operating in a regime where the ordinary `delta` of shared practice would leave nothing at all, and it must therefore purchase an extraordinary `delta` by whatever means are available: ordeal, danger, pain, beauty, terror, secrecy, or singularity.** The ethnographic observation that rare rituals are overwhelmingly the intense ones is exactly what this table predicts. It is also why they are small: the means of purchasing a five-year half-life do not scale, and Whitehouse's account of why imagistic communities stay small is the same constraint seen from the sociological side.

The requirement is not weakly sensitive to the floor:

floor `theta`	as % of burst	required `delta`/week at `P = 520`	`t_half` in years
0.10	13.7%	0.004056	3.28
0.20	27.5%	0.002947	4.52
0.30	41.2%	0.002365	5.63
0.50	68.7%	0.001726	7.72
0.7278	100.0%	0.001332	10.00

Xygalatas and colleagues (*Psychological Science*, 2013), studying the Thaipusam Kavadi in Mauritius, reported that participants in the higher-ordeal rite subsequently gave more to an anonymous charitable donation than participants in a low-ordeal rite. **The framework offers no opinion on whether that is the right measure, and it is one field result in one population.** What it supplies is a reason to expect the *direction*: the high-ordeal condition is the one that can pay for a low `delta`, and what is measured downstream is a trace that has not yet decayed.

The refusal that governs this whole section: none of this recommends an ordeal. The arithmetic explains why rare intense rites take the form they do. It does not license anyone to build one, and an intervention that removes a person's ability to decline is out of scope for this manual regardless of what its parameters look like.

28.8.11 8.11 The costly-signal break-even

Costly-signalling accounts of ritual (Irons, 2001; Sosis and Alcorta, *Evolutionary Anthropology*, 2003) argue that expensive requirements are hard-to-fake signs of commitment, following Zahavi's handicap logic (1975): a signal is credible in proportion to what it would cost a non-committed sender. Sosis and Bressler (*Cross-Cultural Research*, 2003) examined nineteenth-century American communes and reported that religious communes outlasted secular ones, and that within the religious sample the number of costly requirements was associated with longevity — an association not found in the secular sample. **This is historical and correlational and must be read as such**: no randomisation, one time and place, a survivorship-prone record.

The framework's contribution is not to confirm this but to price it. A costly requirement enters the storage law as an increase in `c`, and can only be worth having if it changes something else. The most plausible candidate is `delta`: a requirement that screens out low-commitment members reduces turnover, and turnover is the dominant term in institutional `delta`.

From `Q_inf = (eta F − c)/delta`, requiring `Q_inf' >= Q_inf` after adding cost `dc` and moving `delta -> delta'`:

```
(eta F − c − dc) / delta'  >=  (eta F − c) / delta

dc  <=  (eta F − c) (1 − delta'/delta)
```

The maximum affordable requirement is the current net drive times the fractional reduction in decay it achieves. Worked at `eta = 0.35`, `N = 8`, `u = 0.55` so `F = 1.5790`, `eta F = 0.5526`, `c = 0.15`, `delta = 0.06` per week, giving a baseline net drive of 0.4026 and `Q_inf = 6.7107`:

new `delta`	reduction	max affordable `dc`	as % of net drive
0.055	8.3%	0.0336	8.3%
0.050	16.7%	0.0671	16.7%
0.045	25.0%	0.1007	25.0%
0.040	33.3%	0.1342	33.3%
0.030	50.0%	0.2013	50.0%
0.020	66.7%	0.2684	66.7%
0.010	83.3%	0.3355	83.3%

The percentages in the last two columns are identical, exactly, in every row. That is not a coincidence of the parameters; it falls straight out of the algebra. **A requirement is worth imposing if and only if the fraction of the net drive it consumes is less than the fraction of the decay it removes.** The same cancellation appears elsewhere in the corpus with different furniture: at a 15 per cent annual hard-currency drag, a local-currency allocation of 25.17 per cent of protected capital sets headroom to exactly `−0.500000`, cancelling the whole `eta ln(N) = 0.377583` diversification gain, while a 10 per cent allocation costs 0.150000, or 39.73 per cent of the gain [Curzi, 2026]. **A cost term that scales with the same `ln N` the gain scales with can consume all of it, and the break-even is the only thing that says when.** That is a one-line test, it needs two measurements, and it is the sharpest thing the framework has to say about why demanding institutions sometimes outlast easy ones and sometimes merely exhaust their members.

Worked the other way: a requirement costing 0.05 per week must reduce `delta` by at least 12.4% to pay for itself. If `delta` halves, requirements up to 0.2013 per week are profitable and anything above that is not:

added cost `dc`	`Q_inf'` at `delta' = 0.03`	vs baseline 6.7107
0.000	13.4214	better
0.050	11.7548	better
0.100	10.0881	better
0.150	8.4214	better
0.200	6.7548	better (just)
0.283	3.9881	**worse**
0.350	1.7548	**worse**

The failure mode is visible in the table and it is common: a community that has discovered requirements work keeps adding them past the break-even and cannot tell, because the requirements that worked and the requirements that are now destroying it look identical from inside. The only way to distinguish them is to measure `delta` and `C` separately, which the framework's survey protocols specify.

28.8.12 8.12 The multi-rate calendar

Real liturgical calendars are not single-rate. They superpose a fast cycle (daily or weekly), a medium cycle (monthly, or a lunar month), and a slow cycle (annual, or multi-annual). **In circuit terms this is a bank of forcings at different frequencies driving one low-pass filter, and the framework's frequency-response analysis [Curzi, 2026a] already says what happens: the filter passes the slow component and attenuates the fast one, while the ceiling caps whatever arrives in any single period.**

The consequence is specific and is almost always missed in practice. Computed at `delta = 0.055` per week, `eta = 0.35`, `N = 8`, ceiling `eta ln N = 0.7278`, cost `0.13` per week, with a weekly session at `u = 0.55` (`0.5526`), a monthly seminar at `u = 0.62` (`0.5863`), and an annual retreat at `u = 0.86` (`0.6821`):

```
weekly + seminar in the same week  = 0.5526 + 0.5863 = 1.1390
ceiling                                              = 0.7278
DISCARDED                                            = 0.4112     (36.1% of the week's input)

weekly + retreat in the same week  = 0.5526 + 0.6821 = 1.2347
DISCARDED                                            = 0.5069     (41.1%)
```

Two good sessions in the same period are not two sessions. Beyond the ceiling they are one. In a three-year simulation the annual retreat placed in a seminar week contributed a steady-state mean of 8.4806; moved to a clean week it contributed 8.5418 — a difference of 0.0612, small in absolute terms and worth having for free, and larger in systems where the two events are closer in size.

Design rule: schedule occasions to avoid collision in the same period before scheduling them for convenience. The calendar is a resource-allocation problem against a per-period cap, and the traditional practice of distributing feasts across the year rather than clustering them is, in this reading, exactly the right allocation whatever its original rationale.

28.8.13 8.13 Open loop and closed loop

One distinction remains, and the formalism makes it more sharply than the ritual literature does.

A liturgical calendar is open-loop forcing. It fires on a date, regardless of the state of the system, and everything in §8.5 applies to it.

Some ritual cycles are closed-loop. Rappaport's earlier ethnography, *Pigs for the Ancestors* (1968), analysed the ritual cycle of the Tsembaga Maring of highland New Guinea as a regulator: the great festival was not calendrical but was triggered when the pig herd had grown to the point of straining the households that tended it, and the cycle thereby governed pig population, warfare and land use together. Rappaport described it in explicitly cybernetic terms.

A state-triggered rite is a controller, and controllers have failure modes that calendars do not. A loop acting on a stale measurement overshoots – 30.2% at a lag of two periods, 75.1% at four – and at sufficient gain and lag it diverges outright [Curzi, 2026a].

The two designs trade different risks and both risks are computable. A calendar cannot respond to conditions and will sometimes fire when there is nothing to fire about. A trigger responds but inherits every pathology of delayed feedback. Systems that run both — a fixed calendar for the base rate, a triggered rite for exceptional states — are hedging exactly as the control theory recommends, and they are extremely common.

28.8.14 8.14 The spacing effect, as the empirical counterpart

The claim that distributed practice outperforms massed practice for the same total study time is one of the oldest and best-replicated findings in experimental psychology. Ebbinghaus reported it in *Über das Gedächtnis* (1885), and the quantitative synthesis by Cepeda, Pashler, Vul, Wixted and Rohrer (*Psychological Bulletin*, 2006) reviews the verbal-recall literature and finds the advantage robust across a wide range of conditions. Cepeda and colleagues (*Psychological Science*, 2008) further reported an interior optimum: the best gap between study episodes grows with the interval until test, at a ratio commonly reported in the range of roughly ten to twenty per cent.

Two honest statements, in order.

First, the spacing effect and Theorem 2 are not the same claim and must not be presented as mutual confirmation. The spacing literature is about human memory encoding; Theorem 2 is a statement about concave functions. **What they share is a structural prediction — that division of a fixed budget into more occasions helps, up to a point set by a per-occasion cost — and structural agreement between an empirical regularity and a mathematical result is interesting without being evidence for either.**

Second, the finding that the optimal gap is a roughly fixed *fraction* of the retention interval says that the right cadence scales with the system's own time constant rather than with the calendar — which is the content of the framework's cadence specification, `P <= tau/2`. **Both put the practice interval at a fixed ratio of the system's own timescale, and both put that ratio well below one. That agreement is structural and no more is claimed from it than that.**

Roediger and Karpicke (*Psychological Science*, 2006) add a second empirical handle: retrieval practice — being tested — produces better long-term retention than additional study, and the advantage grows with the retention interval. **Formally this is an `eta` result, not a `delta` result: the same occasion converts more of its content into durable structure when it requires retrieval rather than exposure.** The ritual counterpart is recitation rather than reading, catechism rather than sermon, examination rather than attendance — and the tradition's near-universal preference for the first of each pair is, on this reading, a preference for the higher-`eta` form of the same occasion.

28.9 9 Specification and failure modes for cadence and retention design

28.9.1 9.1 Specification

SC1 — Declare the retention medium. Every stored-order design shall state what the medium of retention is (memory, place, object, document, personnel, habit) and record its `delta` with its period, per S2.1. Media with different `delta` shall be modelled as separate stocks, not averaged.

SC2 — Price a palace by doublings. Palace capacity shall be recorded as `ln L` in the number of loci. Any proposal to expand a palace shall state the number of doublings purchased and the construction and maintenance cost of each; each doubling delivers exactly `ln 2 = 0.6931` nats.

SC3 — Record the three-factor decomposition. Any claim that an encoding technique improves storage shall report the claimed movement in `u`, in `eta`, and in `delta` separately, and shall show their product against the claimed `Q_inf` ratio. A claim that reports only the outcome is not auditable and shall be recorded as unverified.

SC4 — Separate `u_cross` from `u_div`. Where both between-locus and within-locus distinctness are being engineered, both shall be estimated and Theorem 4.1's bound `max(f(u_cross), f(u_div)) <= f(u) <= f(u_cross) + f(u_div)` shall be shown. The additive figure shall never be used as the estimate.

SC5 — State the essence set that `Q` is built against. Stored order is indexed by its category set. No claim of general improvement in a faculty shall be made; the claim shall name the `N` it was built on (Ericsson, Chase and Faloon, 1980).

SC6 — Compute the integral before arguing about cadence. Any cadence proposal shall show that the integrated effect of the alternatives is equal in the unclipped linear model, and shall then identify which of the three non-invariant quantities — peak, minimum, or deliverable total — the proposal is actually trading.

SC7 — Report `Q_min`, never only the mean. Per S2.8. Additionally, the functional threshold `theta` below which the system is observed to misbehave shall be stated, and the percentage of the cycle spent above it shall be computed.

SC8 — Clip every burst at `eta ln N` before comparing totals. Per S2.6. The annual delivered total shall be computed after clipping, and the discarded fraction shall be reported explicitly.

SC9 — Size occasions by the fixed-cost optimum. The per-occasion fixed cost `c_0` shall be measured, the optimum `n` computed against it, and the sensitivity of the optimum to `c_0` shown. Any proposal to increase cadence shall first consider reducing `c_0`.

SC10 — Justify a rare rite by its required `delta`. Any occasion at interval `P > tau` shall compute the retention half-life its trace must have to hold the stated floor, using `a^P >= theta/(theta + A)`, and shall state by what means that retention is expected to be achieved. If no such means can be named, the occasion shall be reclassified as ceremonial and shall not be counted as an input to `Q`.

SC11 — Apply the costly-requirement break-even. No requirement shall be added to a practice without recording its cost `dc`, the current net drive `eta F − c`, and the reduction in `delta` it is expected to produce. The requirement is admissible only if `dc <= (eta F − c)(1 − delta'/delta)`, and the expected `delta'` shall be measured afterwards, not assumed.

SC12 — Deconflict the calendar. Scheduled occasions shall be checked for collision within a single period. Where two occasions fall in one period and their combined input exceeds `eta ln N`, the discarded amount shall be computed and one occasion shall be moved unless a reason for the collision is recorded.

SC13 — Declare open-loop or closed-loop. Every recurring occasion shall be labelled calendrical (open-loop) or state-triggered (closed-loop). Closed-loop occasions shall additionally record the measurement lag `L` and correction gain `k` and satisfy S2.10.

SC14 — Prefer the retrieval form of an occasion. Where an occasion can be run as exposure or as retrieval at equal cost, the retrieval form shall be specified, and the `eta` difference shall

be recorded as an estimate to be tested rather than as an established value.

28.9.2 9.2 Failure modes

THE HEROIC INTENSIVE — a large single occasion substituted for a practice, justified on total input.

- *Parameter damaged:* delivered `S`, clipped at `eta ln N`, while `C` continues unabated.
- *Diagnostic signature:* a strong peak, a crossover against the cadence alternative at roughly `1.5 tau`, and a post-mortem that concludes "we failed to sustain it." In §8.4's parameters the crossover is week 24 against `tau = 16.16`.
- *Measurement:* compute the clipped annual delivered total at each cadence (§8.7 table). Compute `Q_inf = 0` for the unrepeated impulse and `m/delta` for the alternative.
- *Fix:* redistribute to the cadence whose per-period input sits at or just under the ceiling. Retain the intensive only if a threshold has been identified that no sustainable rate reaches — and if so, say which threshold, in the design record.

THE MEAN-ONLY CADENCE ARGUMENT — a sparse schedule defended on the grounds that the average stored order is unchanged.

- *Parameter damaged:* none. The mean really is unchanged. The minimum is not.
- *Diagnostic signature:* the schedule's advocates cite the total or the average; its participants describe "getting back up to speed" each time. In §8.5's table the mean is 8.3333 in every row while `Q_min` falls from 7.8333 to 0.0836.
- *Measurement:* compute `Q_min = A a^P/(1−a^P)` and the percentage of the cycle above the stated functional threshold.
- *Fix:* shorten `P`, or state the threshold and demonstrate that the trough clears it. **Averages do not fail systems; minima do.**

THE UNPAID RARE RITE — an occasion at an interval far longer than `tau`, treated as an input to stored order, whose trace cannot survive to the next occurrence.

- *Parameter damaged:* effectively `eta`, since the converted order is gone before it can compound.
- *Diagnostic signature:* the occasion is memorable and well-regarded, and the system's behaviour between occurrences is indistinguishable from a system that never held it. In §8.12's simulation an annual-only schedule holds `Q > 0` for four weeks of fifty-two.
- *Measurement:* compute the required `delta` from `a^P >= theta/(theta+A)` and compare against the measured `delta`. In the worked example the shortfall factor is 2.5.
- *Fix:* either supply the retention the interval demands — an artefact, a record, a durable external store, per §8.2's `delta` column — or shorten the interval, or reclassify the occasion honestly as ceremony rather than as input.

THE COLLIDING CALENDAR — two substantial occasions scheduled into the same period, so that the second is largely discarded at the ceiling.

- *Parameter damaged:* delivered `S` in the colliding period.

- *Diagnostic signature:* a heavy week followed by a light one; participants report that the second event "did not land." The discarded fraction is computable and is often above a third.
- *Measurement:* sum the intended `eta F` of all occasions falling in one period and compare against `eta ln N`. §8.12 computes 36.1% and 41.1% discard for two realistic collisions.
- *Fix:* move one occasion to a clean period. This costs nothing and is the highest return-per-effort intervention in this section.

THE REQUIREMENT RATCHET — costly requirements added past the break-even, because earlier requirements demonstrably helped.

- *Parameter damaged:* `C`, without a compensating fall in `delta`.
- *Diagnostic signature:* membership requirements have grown monotonically for years; retention among those who remain is excellent; recruitment and total membership are falling. The institution interprets falling numbers as evidence that standards are working.
- *Measurement:* apply `dc <= (eta F − c)(1 − delta'/delta)` to each requirement in force. Measure `delta` before and after each addition rather than assuming the direction.
- *Fix:* remove requirements from the bottom of the value ordering until the inequality holds, and measure. Note the asymmetry: **an institution that will not choose what it sheds does not thereby keep it.**

THE PALACE THAT WAS NEVER MAINTAINED — a memory system built once, whose loci themselves have decayed, so that retrieval fails for reasons the operator attributes to the contents.

- *Parameter damaged:* `delta` of the index rather than of the material.
- *Diagnostic signature:* recall fails specifically at the transitions between loci; the operator can produce isolated items but not the ordered walk. Diagnostic separation from ordinary forgetting is that prompting with the *place* restores the item.
- *Measurement:* test the empty palace — walk it with no contents and count loci recovered in order. Compare against the count when it was built.
- *Fix:* rebuild the index before re-loading the contents. Loading new material onto a decayed index raises `C` and lowers `eta` simultaneously and is the worst available move.

THE UNDECLARED ESSENCE SET — improvement measured on one category set, claimed for a faculty.

- *Parameter damaged:* none; the claim is simply not about the quantity measured.
- *Diagnostic signature:* a practice that produced a large, real gain in one domain produces nothing in a second, and the operator concludes the second domain is harder rather than that the stock is domain-indexed.
- *Measurement:* run the same protocol on a disjoint essence set. Ericsson, Chase and Faloon's subject reached a digit span near 79 while his letter span stayed near six.
- *Fix:* declare the `N` in every claim. Build a second stock deliberately if a second domain is wanted; there is no transfer to appeal to.

28.10 10 Worked example: a chartered study circle

The system. Six people from six disciplines convene as a chartered study circle around a canonical corpus of 48 items. There are two coupled subsystems with different natural periods, and they must be modelled separately per SC1: each member's individual hold on the corpus (period: one day) and the circle's own stored order (period: one week).

The question on the table is whether to (a) adopt loci encoding for the corpus, (b) replace the current monthly three-hour seminar with a weekly ninety-minute session, and (c) keep or move the annual retreat.

All parameter values below are design values, badged as such, obtained by the framework's survey protocols in a hypothetical engagement and stipulated here.

Step 1 — Subsystem M: one member's hold on the corpus. Period: one day.

```
N = 48 items          ln N = 3.8712 nats     <- hard per-occasion ceiling
```

	u	N_eff	F	% ceil	eta	delta	eta F	Q_inf	gain	t_half	t_95
before: reread only	0.20	10.400	2.3418	60.5%	0.18	0.22	0.4215	1.9160	0.818	2.79 d	12.06 d
after: 24-locus palace, two images each	0.88	42.360	3.7462	96.8%	0.36	0.05	1.3486	26.9727	7.200	13.51 d	58.40 d

```
Q_inf ratio = 14.0774  =  F 1.5997  x  eta 2.0000  x  1/delta 4.4000
```

Per SC3 the three factors are reported separately, and per SC4 the split is shown. Estimating `u_cross = 0.70` (distinct places) and `u_div = 0.18` (striking images):

```
f(u_cross) = 3.5234     f(u_div) = 2.2471     f(u) = 3.7462
bound:  3.5234  <=  3.7462  <=  5.7705
```

Place alone accounts for 94.1% of the combined surplus. The images are worth having and they are worth 0.2228 nats, not the 2.2471 that the additive reading would suggest. **Per SC4 the additive figure is not used, and a design that spent equally on images and places would be spending most of its effort on the smaller term.**

Per SC5, the claim on record is: *ordered recall of this 48-item corpus improves.* Not memory.

Step 2 — Subsystem G: the circle. Period: one week.

The circle is six people, but the category set that matters is the set of *domains* they bring, and with two recurring outside guests the category audit returns eight [Curzi, 2026c]:

```
N = 8 domains                          ln N     = 2.0794
u* = 0.55 (audited)                    N_eff    = 1 + 7(0.55) = 4.8500
F = ln 4.85                                     = 1.5790      (75.9% of ceiling)
eta = 0.35, delta = 0.055/wk, C = 0.13/wk
ceiling eta ln N                                = 0.7278/wk
```

Rather than assume the session geometry, the cadence question is put to Theorem 2 directly. The circle has a genuine interaction budget of **three hours per fortnight** and a per-occasion cost of `c_0 = 0.045` (convening, travel, settling). Non-parallelism saturates at `L* = 2.5` hours.

schedule	occasions per fortnight	length	`u`	`f(u)`	`eta f(u)`	over ceiling?	delivered per fortnight	vs one long session
one 3.0 h session	1	3.000 h	1.0000	2.0794	0.7278	at the ceiling	0.7278	1.0000
two 1.5 h sessions	2	1.500 h	0.6000	1.6487	0.5770	no	1.1541	1.5857
three 1.0 h sessions	3	1.000 h	0.4000	1.3350	0.4673	no	1.4018	1.9260
four 45 min sessions	4	0.750 h	0.3000	1.1314	0.3960	no	1.5840	2.1764
six 30 min sessions	6	0.500 h	0.2000	0.8755	0.3064	no	1.8385	2.5261

Note that the single three-hour session reaches `u = 1` and therefore sits **exactly** at the ceiling, `eta ln N = 0.7278`: it delivers the maximum a single period can carry, and the half-hour of that session beyond `L* = 2.5` delivers nothing at all. Two fortnightly sessions deliver 1.5857 times as much; six deliver 2.5261 times as much. **The delivered column is monotone in `n`, exactly as Theorem 2 requires.**

The circle adopts the weekly ninety-minute form — `n = 2` per fortnight — on the grounds that the higher-`n` options push per-occasion cost above what six busy people will actually pay, and because the ninety-minute session leaves visible headroom under the ceiling for a guest or a longer thread. Session geometry at 1.5 hours would give `u = 0.60` and `eta f = 0.5770`; the conservative figure carried forward is the *audited* `u* = 0.55` from the disagreement survey, since that is what the circle actually achieves across a year rather than in a well-run session:

```
weekly input   eta F = 0.35 * 1.5790          = 0.5526/wk
net drive = 0.5526 - 0.13 = 0.4226/wk
Q_inf     = 0.4226 / 0.055 = 7.6844
pole      = 0.945    tau = 17.677 wk    t_half = 12.253 wk
t_95      = 52.96 wk    t_99 = 81.41 wk
h at Q_inf = 0.7278 - 0.055(7.6844) - 0.13 = 0.1752/wk       (r_max = h)
h = 0 at Q = 10.8692
```

The first honest review is week 53. A week-13 reading of 4.4040 is 51.6% of steady state and is not a finding about the change.

Step 3 — The calendar, deconflicted. Per SC12.

Three occasions are proposed: the weekly session (`u = 0.55`, `eta F = 0.5526`), a monthly seminar with an outside guest (`u = 0.62`, `eta F = 0.5863`), and an annual retreat (`u = 0.86`, `eta F = 0.6821`). The per-period ceiling is 0.7278.

```
weekly + seminar  = 1.1390    ceiling 0.7278    DISCARDED 0.4112   (36.1%)
weekly + retreat  = 1.2347    ceiling 0.7278    DISCARDED 0.5069   (41.1%)
```

The retreat is initially scheduled for the last week of the year, which is also a seminar week. Three years simulated, with cost paid every week:

schedule	steady mean `Q`	min	max	ripple
weekly only	7.6844	7.6844	7.6844	0.0%

schedule	steady mean `Q`	min	max	ripple
weekly + monthly seminar + retreat, **retreat colliding with a seminar**	8.4806	—	—	—
weekly + monthly seminar + retreat, **retreat in a clean week**	8.5418	8.4259	8.7145	3.38%

Trajectory of the built calendar:

week	1	4	13	26	53	105	157	209
Q_t	0.4226	1.7313	4.4040	6.6679	8.1134	8.5193	8.5408	8.5419

Moving the retreat off the seminar week costs nothing and returns 0.0612 of steady-state stock. The full calendar returns `+0.8574` over weekly-only, an 11.16% gain, and headroom at the steady mean is `0.7278 − 0.055(8.5418) − 0.13 = 0.1280`, still positive. Headroom reaches zero at `Q = 10.8692`, comfortably above the operating point.

Step 4 — Is the annual retreat an input at all? Per SC10.

Standing alone, at `P = 52`, `A = 0.6821`, and a functional floor `theta = 0.25`:

```
required a^P  >=  theta/(theta + A) = 0.25/0.9321 = 0.2682
required a    >=  0.977559        required delta <= 0.022441/wk
required t_half >= 30.54 weeks = 0.59 years
```

The circle's measured `delta` is 0.055 per week, a half-life of 0.24 years. **The shortfall factor is 2.5.** Formally: *the retreat cannot, by itself, hold a floor of 0.25 for a year at this circle's retention.* Simulated alone, an annual-only schedule holds `Q > 0` for four weeks in fifty-two.

Per SC10 the retreat is therefore not recorded as an input to `Q` on its own account. It is recorded as (a) a `+0.0612` contribution on top of the weekly base, and (b) a candidate `delta` intervention — the retreat is where the circle's charter is re-read and its obligations restated, which is a retention measure, not an input measure, and it is to be measured as one.

Step 5 — The proposed attendance requirement. Per SC11.

A member proposes a hard attendance requirement: miss four consecutive weekly sessions and lapse. Estimated additional cost `dc = 0.05` per week in administration, chasing, and the friction of enforcement.

```
net drive            = eta F − C = 0.5526 − 0.13 = 0.4226/wk
required reduction   = dc / net drive = 0.05/0.4226 = 11.83%
required delta'      <= 0.055 ∗ (1 − 0.1183) = 0.048493/wk
```

The requirement pays for itself if and only if it reduces weekly decay by at least 11.8% — in membership terms, if it raises the half-life of continuous participation from 12.25 weeks to at least 13.90. That is a specific, measurable, falsifiable claim, and it is the claim the circle records before adopting the rule, not after.

Per SC11 the outcome is to be measured. Per the requirement-ratchet failure mode, this is the *first* requirement and the break-even is generous; the test will get harder for the second and harder still for the third, and the circle records that fact in the same minute.

Step 6 — What would falsify all of this.

Fit `Y_{t+1} = a Y_t + b F(U_t) − C_hat_t + eps_t` on weeks 1-53 with `0 <= a <= 1, b >= 0`, freeze the coefficients, and report on weeks 54-106 against four baselines: persistence, direct-input, matched autoregressive, and shuffled-input control. Predictions on record:

1. The fitted `a` lies in `[0,1]` and its interval contains `1 − delta = 0.9450`. If not, the first-order form is wrong for this circle and every number above is void.
2. The fitted `b` exceeds its pre-intervention value. If not, the cadence change did not raise delivered input, whatever the participants report.
3. The frozen model beats the **shuffled-input control** on held-out data. **If it does not, then the timing of the circle's occasions carries no information beyond their volume, the entire cadence argument does not apply to this system, and Steps 2 through 5 should be withdrawn.**
4. On Subsystem M, the empty-palace test (per the palace failure mode) recovers at least 20 of 24 loci in order at 90 days. If the index itself decays faster than the contents, the `delta` attribution in Step 1 is misassigned.
5. The attendance requirement reduces measured membership `delta` by at least 11.8% within two `tau`. If it does not, it is removed — not retained on the grounds that standards matter.

Prediction 3 is the decisive one. Everything this section claims about cadence is a claim that *when* input arrives matters and not only how much. The shuffled-input control is the test that can kill it, and it is the control most often omitted.

28.10.1 10.1 What the worked example establishes

The method of loci is the storage law with space as the retention medium. Its advantage factorises into three separately measurable terms — surplus, conversion, and retention — and in the worked case retention supplies more than the other two combined, which is the opposite of the usual emphasis. Palace capacity is `ln L`, so **every doubling of the palace buys exactly 0.693147 nats and no arrangement of the loci changes that.** The classical rules of the *ad Herennium* map one-to-one onto the parameters of the law with no rule left over and no parameter left untouched.

Ritual is periodic forcing of a low-pass filter, and the case for cadence over intensity has two independent halves. **The first is the ceiling: surplus saturates at `ln N` per period while cost does not, so an annual rite delivers 2.8% of what a weekly practice delivers from the same nominal budget.** The second is Theorem 2: because `f(u)` is strictly concave through the origin, dividing a fixed interaction budget into more occasions never delivers less and in the worked case delivers 4.57 times as much — a result that follows from the surplus functional's strict concavity [Curzi, 2026] and needs no ceiling at all. What stops the division is the per-occasion fixed cost, and the optimum is computable from it: **lowering the cost of convening moves the optimum more cheaply than any intervention on the occasions themselves.**

The honest comparison between one impulse and the same total delivered periodically was computed and it is not one-sided. Integrated effect is identical to every digit — 433.3333 in all three regimes — because the system is linear and time-invariant. Peak favours the impulse by a factor of 3.25. Minimum, time above a low threshold, and clipped deliverable

total favour the cadence, the last by a factor of 36. **And the steady state settles it: a single impulse, however large, has a steady state of exactly zero, while a rate `m` has `m/delta`.**

The rare, intense rite is not thereby refuted. It occupies the regime above the cadence's plateau, where a threshold exists that no sustainable rate reaches — and the price of that regime is computable. **A once-a-decade rite requires its trace to have a half-life of about five and a half years, and a once-a-generation rite about seventeen.** That is why such rites are extraordinary, why they are small, and why they take the forms they do. It is also the boundary of what this paper will say about them: the arithmetic explains the form and does not recommend it.

Section 11 states the thesis that has been implicit throughout – that the inherited notation and the framework's notation describe the same relationships – under the strictest available constraint: **claim no supernatural efficacy, no physical effect of symbol, and no result that does not follow from the formalism.** The argument is stronger for the restriction.

28.11 11 The synthesis: three handles and an eleven-operation audit

The framework opens with a difference equation and the claim that its leak is not a defect [Curzi, 2026a]. Everything the corpus has built since is that equation at a different scope, with different parameters, under a different name.

This section states what the assembly amounts to, under the strictest available constraint. **No supernatural efficacy is claimed, no physical effect of symbol is claimed, and no result appears that is not derivable from the formalism.** The argument's force comes entirely from that restriction. A synthesis that permitted itself one unearned step would be worth nothing, because the interesting question is not whether the inherited notation *can* be dressed in new symbols – anything can – but whether the modern notation is **sufficient**: whether, having described the mechanism, there is a residue that still requires something else.

The finding, stated plainly and then defended for the rest of the section, is that there is not — at least not in the audit performed here, over the operations this paper has examined. **That is a claim about an audit and not a proof of completeness, and it is badged as such wherever it appears.**

The audit is bounded, and the boundary is stated in §11.19 and again in Section 17.

28.11.1 11.1 The thesis

THESIS (stated as a postulate and badged as one). If *magic* is understood as

1. the deliberate engineering of the perceptual lens — the ratio `D/P` and the moment `M = (D/P)E`;
2. the storage of order through symbol, space and cadence — the parameters `eta`, `delta`, and the stock `Q`;
3. the composition of non-parallel essences — the geometry `u` and the surplus `F = ln(1 + (N−1)u)`;

then the framework has described its mechanism in modern notation.

That is the whole claim. Note carefully what it contains and what it does not.

It contains a definition. The word *magic* is being given a stipulative reading — three engineering operations — and the thesis says that under that reading, the mechanism is the one this manual has specified. **A reader who rejects the definition is not thereby contradicting the thesis; they are declining it, which is a different act, and this paper has no argument against them.**

It does not contain an empirical claim about the historical practice. Whether the practitioners of any tradition understood themselves to be doing these three things is a question for historians, and this paper does not answer it.

It does not contain an efficacy claim of any kind. The thesis says the mechanism *is described*. It does not say the described mechanism produces effects beyond those the storage law and the surplus law produce, because they are the same mechanism. **There is nothing left over for an effect to come from.**

28.11.2 11.2 What "described its mechanism" means

A mechanism is described when three things hold, and all three are checkable:

```
(i)   every operation in the practice maps to a named parameter of the formalism
(ii)  the direction and, where measurable, the magnitude of each operation's effect
      follows from the law rather than being stipulated alongside it
(iii) the failures of the practice are the failures the law predicts, and appear at
      the parameter values where the law says they will appear
```

§11.18 performs (i) as an explicit audit over eleven inherited operations. §11.6 through §11.16 perform (ii) result-family by result-family. The failure-mode catalogues of Sections 5, 9 and 12, and the corresponding catalogues in the corpus's other papers, are (iii).

What would refute the thesis is a fourth thing: an operation that does work in the practice, is agreed to do work, and maps to no parameter. §11.19 records what was found when one was looked for. **That is the honest form of the claim and it is falsifiable in exactly one direction: someone may exhibit the missing operation.**

28.11.3 11.3 The ledger

The most useful single element of this section is an inventory of everything the framework has asserted, sorted by status. **A synthesis that does not publish this table is asking to be believed rather than checked.**

PROVED — mathematics, true regardless of whether anything in the world obeys it:

Result	Source
`f(u) = ln(1+(N−1)u)` uniquely characterised by four axioms	Curzi [2026]
Strict monotonicity, positivity, strict concavity of `f`	Curzi [2026]
Subadditivity on the parameter `u` (**not** on geometric triples)	Curzi [2026]
Sharp Lipschitz constant `N−1`	Curzi [2026c]
`F = 0` iff parallel; `F = ln N` iff orthogonal	Curzi [2026]
Two-source decomposition and its bracket	Curzi [2026]
`0 <= F(u) <= ln N` — the hard ceiling	Curzi [2026c]
Exact solution of the storage recursion	Curzi [2026a]
One-step growth condition `eta S_t > delta Q_t + C_t`	Curzi [2026a]
Uniform bound `Q_t <= max{Q_0, eta ln N/delta}`	Curzi [2026a]
Sustainability ceiling `C_t <= eta ln N − delta Q_t`	Curzi [2026a]

Result	Source
Steady state `Q_inf = (eta F(u*) − c*)/delta`	Curzi [2026a]
Max one-step increment `r_max = eta ln N − delta Q_t − C_t`	Curzi [2026a]
The recursion is a first-order low-pass filter with pole `1−delta`	Curzi [2026a]
Contraction implies a unique fixed point reached from any start	Banach [1922]; Curzi [2026]
`f(n) = k n^2` is the exact collapse of the published essence recipe	Curzi [2026]
Essence intervals are ratios of squares; `k` cancels	Curzi [2026]
An essence set `1..N` has exactly `ceil(N/2)` pitch classes	Curzi [2026]
One nat of surplus is exactly `2/ln 2 = 2.885390` octaves	Curzi [2026]
A star polygon `{N/k}` has exactly `gcd(N,k)` closed strokes of length `N/gcd(N,k)`	this paper, Theorem 1
Dividing a fixed budget over more occasions never delivers less, for concave `g`, `g(0)=0`	this paper, Theorem 2
Costly-requirement break-even `dc <= (eta F − c)(1 − delta'/delta)`	this paper, §8.11
Expected surplus of a uniform random correspondence `= (N ln N − N + 1)/(N−1)`	this paper, §11.18
Expected colliding pairs under a hash `>= C(M,2)/R`, minimised by uniformity	this paper, §11.20

POSTULATED — badged every time, chosen rather than derived:

Postulate	Where
The affine effective count `N_eff = 1 + (N−1)u` — a *design* axiom, and **not** a Hill number	Curzi [2026o]
That a room, team or institution is described by the storage recursion at all	Curzi [2026a]
Scale symmetry: the same model form at every scope	Curzi [2026]
That essence types have a frequency; that the law is square in the index	Curzi [2026]
That `k = (9/8)^2/phi^2` rather than any other constant — a **defined** ratio, exact	Curzi [2026]; Markowsky [1992]
`M = (D/P)E` as the form of the moment	Curzi [2026o]
The internal/external correspondence as one subject at two scopes	Curzi [2026o]
The figure read as a nonlinear computing map — **a metaphor**	this paper, §3.4
That the method of loci raises `u` and `eta` and lowers `delta`	this paper, §7.1
The thesis of §11.1	this paper

REQUIRES MEASUREMENT — asserted nowhere, obtainable by protocol:

Every `delta`, every `eta`, every `u`, every `C`, every `N`, every `D` and `P`, in every system, for every period. **This paper supplies no value of any of these for any real system.** The corpus supplies the protocols: a survey instrument for each of `delta`, `eta`, `u`, `C` and `N`, and a formula-validation protocol for `D` and `P` [Curzi, 2026c,u].

Counted: 24 proved results, 10 postulates, and a parameter set that is entirely empirical. The ratio is the point. **A framework whose postulates outnumber its theorems is a worldview; one whose theorems outnumber its postulates by more than two to one, with every postulate labelled, is an engineering discipline with a declared foundation.**

28.11.4 11.4 The refusals are load-bearing

The framework carries four standing refusals, honoured throughout. They are not modesty. **They are the conditions under which the thesis of §11.1 means anything at all.**

1. **No claim that the mathematics proves anything about physics, thermodynamics, or consciousness.** The framework proves no negentropy law; `F(u) + N_can(u) <= ln N` is a bound and not a mechanism [Curzi, 2026c].
2. **No postulate without its badge.** §11.3's second table is the badge, collected.
3. **No number that was not computed or cited.** Every figure in the corpus was computed; where a parameter is illustrative it says so in the same sentence.
4. **No intervention that removes a person's ability to decline.** This is the refusal that governs the ordeal arithmetic of §8.10, contagion engineering, and every use of the word *design* applied to other people.

If any of the four were suspended, the thesis would collapse into an unfalsifiable analogy. With all four in force, it is a specific, checkable, and modest claim: *this is the mechanism; there is nothing else in it; here is the arithmetic.*

28.11.5 11.5 Three scopes, one instrument

The corpus applies one recursion at three scopes, and the movement between them is a change in who holds the instrument rather than a change of subject.

The observational scope. One person, reading a situation: what a comfort costs, what a discomfort quietly pays, whether a projected trajectory keeps its assumptions constant along its length. The instrument is attention, and it is what produces the numbers the other two scopes consume.

The constructive scope. The same relations made constructible: the storage recursion and its four parameters [Curzi, 2026a], the geometry of difference [Curzi, 2026,c], the physical setting, the sociology of groups and institutions, the measurement and falsification tradecraft [Curzi, 2026u], and the essence law that gives a relationship an index that can be rendered [Curzi, 2026,?]. Its subject is the world outside one person, being built.

The reflexive scope. The same six parameters applied to the person applying them. The claim is not that psychology *resembles* sociology but that **the two are one set of relations measured at two scopes** – a badged thesis, not a demonstrated identity [Curzi, 2026o]. The perceptual lens is `D/P`; character is `Q`; forgetting is `delta`; personal capacity for the new is `h`; and the internal surplus `F_int` is the surplus functional applied over one observer's own framings, which is a derivation rather than an analogy [Curzi, 2026o].

This is exactly where the reflection problem enters, and §11.19 does not evade it. The framework's reflexive loop is written `T(x) = W(x, M(x))`, with the self-fulfilling prophecy identified as a fixed point of that composition of seeing and responding [Curzi, 2026]. **A specification in which the members constitute the aggregate and the aggregate influences the members is not identified from observational data** [Manski, 1993, Shalizi and Thomas, 2011]. Every

statement in this section about a parameter as a property of a person or a group is a modelling position and not an identified empirical result.

```
OBSERVATIONAL   one person, reading a situation      instrument: attention
                        |
                        |   the same relations, made constructible
                        v
CONSTRUCTIVE    the setting outside, being built     instrument: specification
                        |
                        |   the same instrument, pointed back
                        v
REFLEXIVE       the builder, being measured          instrument: the parameter set
```

The third scope closes the loop, and it closes it uncomfortably. An analyst who has spent the constructive scope measuring other people's `u`, budgeting other people's `h`, and designing cadences for other people's calendars arrives at the reflexive scope to find the same instruments turned around: their own `N` is the count of things they can actually distinguish; their own `delta` is how fast they lose what they learn; their own `D/P` decides whether they are seeing a system or their model of one. **The framework's diagnostics do not exempt the person holding them, and the over-framed institution and the over-framed observer are the same fault at two scopes** [Curzi, 2026o]. This is also the framework's own version of the Lucas critique [Lucas, 1976] and of the looping effect of human kinds [Hacking, 1995]: parameters estimated in a population that has not read the framework cannot be assumed stable in one that has.

One consequence governs how the three scopes should be read together. **The observational instrument is never superseded.** Attention is what produces the survey data, the disagreement audit, and the magnitude estimates that every later computation consumes. An analyst who takes the specifications without the reading practice has a set of formulas and no measurements to put in them, and the formulas will accept any numbers offered. **The sequence is not a ladder on which the earlier rungs are discarded; it is three instruments that must all be working at once, and the framework's most common misuse is running the arithmetic on estimates nobody actually looked at.**

Two correspondences are exact rather than decorative. Recursion is the transient `(1-delta)^t Q_0` – the initial state bleeding off while the driven term builds – and the fixed point is the storage law's steady state [Curzi, 2026a], which is unique and start-independent because the update map is a contraction with modulus `1 - delta` [Curzi, 2026, Banach, 1922]. The contraction ratio is `(1-delta)^t`:

delta	t=1	t=5	t=10	t=20	t=50	t=100
0.020	0.9800	0.9039	0.8171	0.6676	0.3642	0.1326
0.055	0.9450	0.7536	0.5680	0.3226	0.0591	0.0035
0.100	0.9000	0.5905	0.3487	0.1216	0.0052	0.0000
0.200	0.8000	0.3277	0.1074	0.0115	0.0000	0.0000

A contraction does not arrive somewhere new. It arrives where it was always going to arrive, from wherever it started, and repetition cannot move the destination because the fixed point contains no `t` [Curzi, 2026]. Recognition rather than novelty is therefore the correct description of arrival at a fixed point, and the contraction theorem is why [Banach, 1922].

28.11.6 11.6 The same equation, six scopes

The architectural claim under test is that only `(N, u, eta, delta, C)` and the period change between a desk and a city. That claim is about **model form**, and it is honest because it is checkable: if a scope required a different equation, the claim would fail there.

Computed across seven scopes, with illustrative parameters badged as such:

scope	period	N	u*	eta	delta	C	ln N	N_eff	F	eta ln N	Q_inf	tau	t_95	h
a desk	day	4	0.45	0.30	0.100	0.02	1.3863	2.350	0.8544	0.4159	2.3632	9.49	28.43	0.1596
one mind (a practice)	day	12	0.55	0.30	0.050	0.06	2.4849	7.050	1.9530	0.7455	10.5182	19.50	58.40	0.1596
a dyad	week	6	0.62	0.40	0.040	0.08	1.7918	4.100	1.4110	0.7167	12.1099	24.50	73.39	0.1523
a room / a team	week	8	0.55	0.35	0.055	0.13	2.0794	4.850	1.5790	0.7278	7.6844	17.68	52.96	0.1752
a department	month	14	0.48	0.30	0.050	0.22	2.6391	7.240	1.9796	0.7917	7.4777	19.50	58.40	0.1978
an institution	quarter	25	0.40	0.22	0.030	0.30	3.2189	10.600	2.3609	0.7082	7.3129	32.83	98.35	0.1888
a city	year	60	0.35	0.15	0.020	0.18	4.0943	21.650	3.0750	0.6142	14.0625	49.50	148.28	0.1529

Every row is the same recursion. Read down the `t_95` column: the desk settles in a month of days, the team in a year of weeks, the city in a century and a half of years. **That column is the reason scales cannot be managed with a single calendar, and it is the whole content of the observation that institutions are slow.** They are not slow because of their people. They are slow because `t_95 = ln(0.05)/ln(1−delta)` and their `delta` is small — which is also the only reason they persist.

Read down the `h` column and a second fact appears: **headroom is roughly comparable across scopes even though `Q_inf` differs by a factor of six.** Headroom is a *rate*, and rates are what a scope can afford per period; stocks are what it has accumulated. Confusing the two is the framework's central warning about headroom and it recurs at every scale [Curzi, 2026].

28.11.7 11.7 The circuit results

The corpus establishes that the recursion is an accumulator rather than a regress, that `delta > 0` makes it a contraction and therefore guarantees arrival, and that the identity with a first-order low-pass filter is a **shared mathematical form** rather than a physical analogy: the same difference equation governs an RC network, an exponential smoother and a stock of order, with no claim that the electrical physics applies [Curzi, 2026a, Elaydi, 2005, Oppenheim et al., 1996, Holt, 1957]. From that came the pole, the time constant, the settling times, the DC gain `eta/delta`, and the frequency response that makes stored order blind to fast fluctuation and sensitive to slow trend.

What this contributes to everything after it is a single gauge: `h = eta ln N − delta Q − C`. Below zero, no arrangement of people saves the design; at zero, hold; above zero, grow by at most `h`. **Every recommendation the framework makes is checked against `h` first**, because if the cost term exceeds `eta ln N − delta Q`, no interaction geometry whatsoever prevents order from decreasing [Curzi, 2026a]. That is the framework's strongest sociological statement and it is a theorem about a difference equation, not an empirical finding about institutions.

28.11.8 11.8 The geometry of difference

The corpus establishes that difference is counted before it is valued, and that only what is different is counted at all. `N_eff = 1 + (N−1)u` audits a headcount for redundancy; `F = ln N_eff` is the log of what survives the audit. `F = 0` for parallel participants – **agreement between sources that share training, incentives and premises is worth `ln 1 = 0`, and that is a theorem rather than an opinion** [Curzi, 2026]. **`N_eff = 1 + (N−1)u` is the framework's own construction and is NOT a Hill number**; `1/HHI` and `exp(H)` are Hill numbers of orders two and one and are the grounded ones [Hill, 1973, Jost, 2006, Simpson, 1949], and the diversification correction that says a benefit depends on covariance rather than count was stated in 1952 [Markowitz, 1952].

Two consequences ran through everything after. First, **the ceiling `ln N` is hard**, so a period's input is bounded no matter how the period is run — which is why the cadence result

works and why the calendar arithmetic of Section 8 bites. Second, **concavity means the second genuinely different framing is the largest gain available and the fortieth is a maintenance bill**, which is the internal-surplus argument [Curzi, 2026o] and reappears in §11.18 below as the formal content of the practice of adopting a second perspective deliberately.

28.11.9 11.9 Engineering the physical setting

The corpus takes the room as a circuit: `delta` for a room is how fast its arrangement reverts, `eta` is how much of what happens in it becomes furniture, `C` is what it costs to keep. Reverberation time `RT60 = 0.161 V/A` is measured acoustics [Sabine, 1922, Schroeder, 1965] and enters as a constraint on whether the room can carry interaction at all; proxemics sets the distances at which particular kinds of interaction are possible [Hall, 1966]; and the semilattice-versus-tree distinction [Alexander, 1965, Alexander et al., 1977] is the observation that overlapping structure beats strict hierarchy, which in this notation is the observation that a strict tree destroys `u` by construction.

The contribution is that `eta` is often the cheapest parameter to move, and that it is usually moved by furniture rather than by exhortation. A room that makes the good arrangement the default converts more interaction into structure than a room that requires everyone to remember.

28.11.10 11.10 The empirical layer the formalism does not contain

Woolley et al. [2010] report a collective-intelligence factor not predicted by members' average or maximum ability but correlated with social sensitivity and **equality of conversational turn-taking**, which is an effective-count measurement by another route. Centola et al. [2018] locate a committed-minority tipping point near 25 per cent. Complex contagion needs reinforcing contacts and clustered topology [Centola and Macy, 2007, Centola, 2010]. Ostrom [1990]'s design principles read here as a specification for keeping institutional `delta` low without raising `C` past the break-even, and Cox et al. [2010] is the meta-analytic audit those principles have already faced. The contrary evidence is stocked deliberately: diversity in the short run has been found to reduce trust and civic participation [Putnam, 2007], with a rebuttal [Abascal and Baldassarri, 2015], and cohesion has been found to raise then lower creative success [Uzzi and Spiro, 2005], which is an inverted `U` against a surplus functional that is monotone increasing in `u`.

The warning is that the formalism is not self-sufficient. `u`, `eta` and `delta` are empirical quantities in real groups, and the literature that measures them is a science with a replication problem [Open Science Collaboration, 2015, Ioannidis, 2005], not a source of settled constants.

28.11.11 11.11 The measurement and falsification tradecraft

The procedure is: survey the system, preregister the prediction, intervene, and read the failure catalogue when it does not work [Nosek et al., 2018, Simmons et al., 2011, Gelman and Loken, 2013]. **The load-bearing element is the shuffled-input control**, which appears in every falsification suite the framework specifies and is the control most often omitted elsewhere. If a model predicts a system's stored order as well from shuffled inputs as from real ones, then timing carries no information and the entire cadence apparatus does not apply to that system.

This is what separates the framework from a worldview. A framework that cannot fail cannot be trusted, and the corpus names exactly how this one fails [Curzi, 2026u]. **It also measures the control against itself and finds it wanting: against a nominal 0.05 the shuffled-input control false-rejects true nulls at 0.108 for independent permutation and 0.120 for circular shift, with only block permutation near nominal at 0.060** [Curzi, 2026u]. Every shuffle p-value quoted anywhere in this paper's worked examples inherits that calibration defect, and Section 17 says so again.

The tradecraft also supplies the framework's characteristic move, worth naming as a method rather than leaving as a habit. **Where a phenomenon is described in the language of morale, culture, energy or will, the arithmetic is computed first and the people are asked about second.** A premature review is a pole, not a motivation problem. An ossified standards body has a fallen ceiling and an unchanged maintenance load. An offsite whose effects "wore off" did not wear off; it decayed at `(1-delta)^t` while `C` continued. **The arithmetic is not a substitute for judgement about people; it is what has to be cleared before judgement about people is worth having**, because in each of those cases the arithmetic alone accounts for the observation. That is a methodological preference and not a result, and it is exactly the move Hedström and Ylikoski [2010] demands be justified by naming a mechanism rather than exhibiting a fitted curve.

28.11.12 11.12 The essence law

The corpus establishes that the published recipe collapses exactly to `f(n) = k n^2` with `k = (9/8)^2/phi^2 = 0.483425732988414`, **a DEFINED constant – an exact ratio of exact quantities, computable to arbitrary precision, which is the only reason fifteen figures are legitimate. Attaching the unit Hz to it is a separate and much stronger claim, and it is POSTULATED rather than derived** [Curzi, 2026, Markowsky, 1992]; that every interval in the system is a ratio of squared integers so that `k` cancels from all relationships, and that an essence set indexed `1..N` yields exactly `ceil(N/2)` pitch classes because pitch class depends only on the odd part of the index. The bridge to the surplus law is exact: `N_eff = e^F` is the cross-disciplinary essence index, so `f = k e^{2F}` and **one nat of surplus is exactly 2.885390 octaves.**

The honesty clause is absolute and is restated here because this is the material most likely to be quoted out of context: the output is an essence index, not a physical resonance. Nothing — no material, molecule, element, room, or person — is claimed to resonate at any value the essence law produces. `k` is a chosen constant. The square law is a postulate. That `E_n \ensuremath{\propto} n^2` is also the eigenvalue spacing of a one-dimensional infinite square well is a **shared mathematical form** and is emphatically **not** evidence of a physical mechanism. `phi^2 = phi + 1` is exact arithmetic; the literature on how often the golden section is claimed where it is not present is the reason that distinction has to be made explicitly [Markowsky, 1992, Euclid, 1956, Vajda, 1989].

28.11.13 11.13 The perceptual lens

The register everything else is written in is logarithmic. The constant just-noticeable ratio [Weber, 1834] and its integration into `S = k ln(I/I_0)` [Fechner, 1860] are nineteenth-century findings that have been examined continuously since. Magnitude estimation is offered as producing ratio-scale measurements of subjective quantity [Stevens, 1957, 1946], which is the existence proof the reflexive scope needs – **but the claim is contested from three directions and the corpus stocks all three.** The fitted exponent depends on the experimenter's chosen stimulus range [Teghtsoonian, 1971]; the procedure's biases were catalogued by a critic [Poulton, 1968, 1979]; and the deepest objection is that psychology assumes quantitative structure without testing for it [Michell, 1997, 1999]. **The test that would settle it is conjoint measurement [Luce and Tukey, 1964, Krantz et al., 1971], and it has not been run for any quantity in this corpus.**

From that comes the Lens Theorem: **if perception is logarithmic, addition in perception is multiplication in the world.** Equal perceptual steps are equal world ratios, never equal world differences. A "moderate" perceived improvement is an order of magnitude produced. And the surplus functional's strict concavity has the same shape, so **diminishing returns is not pessimism; it is what a logarithm looks like from inside.** A second and independent warrant for the logarithm is available and does not require the perceptual story to be true at all: a logarithmic form falls out of multiplicative dynamics with no psychological assumption [Peters and Gell-Mann, 2016, Peters, 2019], and that is the warrant the argument here actually needs.

The moment equation `M = (D/P)E` supplies the diagnostic. `r = D/P` with distortion `|ln r|`: over-framed above one, under-framed below, and **the fixed point `D = P` is the formula's most important content** — frame matching intake, moment equalling environment, veridical contact stated as an equation.

28.11.14 11.14 The two formularies

The corpus's lookup layer joins the two master formulas, and the join is worth restating: **the moment feeds the storage law as its input.**

```
M_t = (D_t / P_t) E_t                          the moment, as lived
Q_{t+1} = (1 − delta) Q_t + eta M_t − C_t       the moment becoming character
```

Perspective and perception produce the moment; the moment becomes character. From the same corpus: `L = max(0, M − C)`, the launch budget — **the dream of elsewhere is manufactured only from surplus, which is why "get out of your comfort zone" reverses the order of operations**; and `Delta_R = |ln(M'/M)|`, the return difference, in which zero means no information came back at all.

At interpersonal scope the same rows read differently and the most useful is `D/P` as **doctrine-to-data**: an over-framed institution sees what its model predicts; an under-framed one drowns in data it cannot read. Both are measurable and both are common.

28.11.15 11.15 The validation programme

The corpus's answer to the question of whether any of this is science is precise and unflattering to both sides of the usual argument. **Psychology and sociology are not pseudoscience; they are sciences with a measurement problem and a replication problem.** The Open Science Collaboration found 97 of 100 original studies reporting significant results against roughly 36 per cent of replications, with effect sizes roughly halved [Open Science Collaboration, 2015].

Formulas do not make a field hard. Ratio-scale, reproducible, falsifiable measurement of the formulas' terms does. The formula-validation protocol's seven gates are the route [Curzi, 2026u], and the cross-individual recovery gate is the one that decides the question and the one most often skipped. Specific objectivity – a person's measure not depending on which items were used, and an item's measure not depending on who answered – is the closest psychometrics comes to physical measurement and is exactly the property required [Rasch, 1960, Andrich, 1988].

What the corpus has not achieved is recorded there, and the record is short and specific. Not one formula in the framework has passed the cross-individual recovery gate in the open literature, because those studies have not been run. The worked examples throughout demonstrate that the parameters *can* be estimated in a single system; they demonstrate nothing about whether the same operationalisation recovers the same parameters in a different system, with different people, in a different laboratory. **Until that is done, every quantitative claim in the corpus is a worked demonstration of a method and not a measured result about the world**, and the corpus's costed research programme exists because saying so without also saying what it would take to fix it would be an evasion [Curzi, 2026u].

28.11.16 11.16 The inherited notation, read formally

Three inherited technologies are read formally, and each reading is descriptive rather than interpretive:

- **A correspondence table is a finite relational graph.** The Tree of Life is 10 nodes and 22 paths. The tarot is a structured 78-element set. Saying so is a description of a structure, not a claim about it.

- **Gematria is a hash function**, a map from strings to integers. That is a literally accurate technical description and carries no claim that the map is meaningful. §11.20 computes what follows.
- **The sigil is lossy compression plus attention-binding**, and its geometry has an exact arithmetic invariant: a star polygon `{N/k}` decomposes into exactly `gcd(N,k)` closed strokes of length `N/gcd(N,k)`. Verified: `{6/2}` gives 2 strokes of length 3 — **the hexagram is literally two separate triangles**; `{7/2}` and `{7/3}` and `{8/3}` and `{12/5}` give one continuous stroke; `{12/3}` gives three squares; `{9/3}` gives three triangles; `{24/9}` gives three octagons.
- **The memory palace is the storage law with space as the retention medium**, and its advantage factorises into surplus, conversion and retention, of which retention is the largest.
- **Ritual is periodic forcing of a low-pass filter**, and cadence beats intensity for two independent reasons: the per-period ceiling, and the concavity of `f`.

28.11.17 11.17 The three handles

Reduce all of it and three handles remain. **Every operation examined here moves one or more of them, and no operation was found that moves something else.**

```
HANDLE 1 -- THE LENS.          r = D/P, distortion |ln r|, moment M = (D/P)E
                               What you can perceive, and how much of the frame
                               you are supplying yourself.

HANDLE 2 -- THE STORE.         Q, eta, delta, C, h
                               What persists, how fast experience converts into it,
                               how fast it leaks, what it costs, what you can afford.

HANDLE 3 -- THE COMPOSITION. N, u, N_eff, F = ln(1 + (N-1)u), ceiling ln N
                               How many genuinely different things are in contact,
                               and the hard bound on what their contact can generate.
```

The three are not independent — the lens determines what `N` you can distinguish at all, which caps `F`, which drives `Q` — but they are **separately actionable**, which is the property an engineering handle needs.

And the maximum possible moment is `ln N`. That was not chosen; it follows from putting `M` on the same normalised scale as `S`. **The richest available moment is bounded by the logarithm of how many kinds of thing the perceiver can distinguish, which is the law of requisite variety [Ashby, 1956, 1958] appearing in first-person experience.** Only variety absorbs variety, including the variety of one's own life.

28.11.18 11.18 The audit

Eleven operations from the inherited notation, each mapped to a handle and a parameter, each priced where pricing is possible. The same audit form is run in the corpus over a thirteen-entry operation set, returning seven maps, two splits, one rendering and three rejections [Curzi, 2026]; **that this audit found no rejections and that one found three is itself a reason to distrust an audit whose rejection rate is zero. This is the audit that §11.2 requires, and it is presented as an audit of a list, not a proof of completeness.**

Operation	Handle	Parameter moved	What the formalism says it does
purification / banishing before work	2	`C` down, `eta` up	removes competing encodings; less interference per period
consecration of a place	2	`delta` down, `u_cross` up	a place with a fixed assigned meaning is a durable index
the correspondence table	3	declares `N`	fixes the per-interaction ceiling at `ln N`
gematria	3	a hash into `R` buckets	creates adjacency by collision; §11.20
the sigil	2, 3	`eta` up; `gcd(N,k)` strokes	compression to one retrievable token; exact stroke count
invocation / assuming a second framing	3	`k -> k+1` framings	`F_int = ln(1 + (k−1)u_bar)`; the second is the largest gain
the memory palace	2	`u` up, `eta` up, `delta` down	§7.1 and §8.2; the product is the gain
the liturgical calendar	2	periodic forcing	§8.4–8.7; cadence, ripple, and the ceiling
initiation / degree	2	`C` up, `delta` down	costly-requirement break-even, §8.11
the talisman / physical token	2	`delta` down	external storage; see below
divination by random draw	3	forces a non-parallel framing	expected surplus computed exactly, below

Four of the eleven can be priced exactly, and are.
The correspondence table declares `N`, and nothing else about it changes the ceiling:

table	`N`	`ln N` (nats)	bits	octaves
the four elements	4	1.3863	**2.0000**	**4.0000**
the classical planets	7	1.9459	2.8074	5.6147
the Tree of Life, nodes	10	2.3026	3.3219	6.6439
the zodiac	12	2.4849	3.5850	7.1699
the Tree of Life, paths	22	3.0910	4.4594	8.9189
nodes and paths together	32	3.4657	**5.0000**	**10.0000**
the I Ching hexagrams	64	4.1589	**6.0000**	**12.0000**
the tarot, full deck	78	4.3567	6.2854	12.5708

The bold entries are exact because those cardinalities are powers of two: **the 64 hexagrams are exactly six bits, which is not a mystery about the I Ching but a restatement of the fact that a hexagram is six binary lines.** The framework's contribution is only to note that six bits is also `4.1589` nats and `12.0000` octaves, and that these are the same number in three registers.

The talisman is a `delta` reduction and nothing else. At a fixed conversion `eta S = 0.30` per week:

storage medium	`eta S`	`delta`/wk	`Q_inf`	`t_half`	vs held in mind
held in mind only	0.3000	0.060	5.0000	0.22 yr	1.00
written once, filed	0.2100	0.010	21.0000	1.33 yr	4.20
carried, seen daily	0.2550	0.004	63.7500	3.33 yr	12.75
engraved, in the room	0.2400	0.002	120.0000	6.66 yr	24.00

The object stores; it does not act. Its entire advantage sits in one column, and the column is `delta`. Note that the written form has the *lowest* `eta` in the table — a filed document converts less of each occasion than an active memory does — and still wins by a factor of four, because retention is a gain term. This is the framework's retention rule [Curzi, 2026a] arriving from a fourth direction.

Invocation of a second framing has a computable value. `F_int = ln(1 + (k−1)u_bar)` over `k` framings held by one observer with mean pairwise non-parallelism `u_bar`:

`k` framings	`F_int` at `u_bar = 0.7`	marginal gain	% of the `k=12` value
1	0.0000	—	0.0%
2	0.5306	**+0.5306**	24.5%
3	0.8755	+0.3448	40.5%
4	1.1314	+0.2559	52.3%
6	1.5041	+0.1691	69.5%
8	1.7750	+0.1263	82.0%
12	2.1633	+0.0839	100.0%

The second framing delivers 24.5% of what eleven more deliver. Deliberately adopting one other genuine perspective is the highest-return operation available to a single mind, and the twelfth is worth 15.8% of the second. That is the formal content of every tradition's insistence that the practitioner learn to see from somewhere other than where they are standing — and of the framework's warning that the fortieth framing is a maintenance bill [Curzi, 2026o].

A random draw from a correspondence table has an exact expected value. If the drawn framing's non-parallelism with the operator's current one is uniform on `[0,1]`, then

```
E[F] = integral_0^1 ln(1 + (N−1)u) du = (N ln N − N + 1)/(N − 1)
```

`N`	`E[F]`	ceiling `ln N`	as % of ceiling	`E[N_eff] = e^{E[F]}`
4	0.8484	1.3863	61.2%	2.3359
10	1.5584	2.3026	67.7%	4.7513
22	2.2382	3.0910	72.4%	9.3768
64	3.2249	4.1589	77.5%	25.1510
78	3.4133	4.3567	78.3%	30.3650

A randomiser drawing from a 78-element table returns, on average, 78.3% of the ceiling. That is what a divinatory device is worth in this formalism, stated exactly and with no claim whatsoever about the source of the randomness. **It is the same function the framework assigns to a red team or a deliberately recruited dissenter: a generator of framings the operator would not have produced** [Curzi, 2026c]. The corpus's resistance-weighted branch score is the same instrument pointed at a decision rather than at a roster: score each step 0-3 for steepness, sum to a resistance `R`, and weight the branch as `1/2^R`, so a three-point difference in steepness is a factor of eight in expectation [Curzi, 2026]. The randomness may come from cards, from dice, from a table of numbers, or from a colleague who disagrees; the formalism does not distinguish among them and does not need to.

28.11.19 11.19 What the audit does not prove

Eleven operations, three handles, no residue — and that is a finding about eleven operations.

It is not a proof that no twelfth operation exists which requires a fourth handle. The audit's honest form is: *of the operations examined here, each mapped to a named parameter, and each mapping produced a direction and, in four cases, a magnitude.* **A reader who wishes to refute the thesis of §11.1 should exhibit an operation that does work, is agreed to do work, and maps to nothing.** That is a clean falsification target and it is stated deliberately.

Two candidate residues are worth naming, because they are the ones a careful reader will raise and because neither survives inspection as a *fourth handle*:

Candidate one: the felt quality of the operation. Practitioners report that the operations feel like something, and the formalism does not model that feeling. **True, and out of scope rather than unaccounted for.** The moment equation gives `M` as a magnitude, not a quality; the framework states the methodology plainly [Curzi, 2026o] — you postulate a structure, derive consequences, and test the consequences, because the inner state is not directly measurable. **That is a limitation of the instrument and it is declared, not hidden.**

Candidate two: the effect on the world outside the practitioner. This is the one the thesis refuses. Every mechanism in the audit runs through a human being who perceives, encodes, retrieves, or acts. **No operation in the table has a path to any outcome that does not pass through a person, and the framework claims none.** A practitioner whose attention, memory, framing, and cadence have all been engineered will act differently and will therefore produce different outcomes — which is a completely ordinary causal chain and is the only one on offer here.

Candidate three: the coherence of the system as a whole. A practitioner may object that the operations in §11.18 are not independent moves on separate parameters but a single integrated practice, and that the audit destroys the object by decomposing it. **This objection is the most serious of the three and the formalism has an answer that is neither dismissal nor concession.**

The surplus functional is subadditive on the parameter `u` [Curzi, 2026]: the surplus of a combination is at most the sum of the parts' surpluses and is generally strictly less. **Formally, then, an integrated practice is *less* than the sum of its decomposed operations, not more** – §8.2 computes exactly this for the memory palace, where the additive reading of place and image overstated the truth by up to 2.25 nats. So the objection cannot be that decomposition loses a surplus, because the mathematics runs the other way.

What decomposition genuinely does lose is **the cost structure**. Eleven separate operations carry eleven per-occasion costs `c_0`; one integrated practice carries one. Section 8.8 shows that the per-occasion fixed cost is what determines the optimal cadence and can determine whether a practice is affordable at all. **An integrated practice is cheaper to run than its decomposition, and that is a real advantage, and it is a `C` advantage rather than an `S` advantage.** The audit is therefore correct as an audit and incomplete as a design: **it tells you what each operation does; it does not tell you what it costs to do them separately, and the answer to that is usually "more."**

28.11.20 11.20 The restraint, worked: what gematria's correspondences are worth

This is the demonstration that restraint is a sharper instrument than permission, so it is computed rather than asserted.

Gematria maps a string to an integer. As an operation this is exactly a hash, and hashes have a governing arithmetic. For `M` strings mapping into `R` reachable values with probabilities `p_i`, the expected number of colliding pairs is `C(M,2) * sum_i p_i^2`, and **`sum p_i^2` is minimised when the distribution is uniform**, so `C(M,2)/R` is a *floor*. Real letter-value distributions are far from uniform, which makes collisions strictly more common than the floor:

corpus size `M`	reachable values `R`	floor on expected colliding pairs	P(a given word has at least one twin)
500	400	311.9	0.713226
2,000	1,000	1,999.0	0.864665
8,000	1,000	31,996.0	0.999666
8,000	1,500	21,330.7	0.995177
30,000	1,500	299,990.0	1.000000

And the birthday point — how many words you need to draw before a coincidence is more likely than not:

reachable values `R`	exact `M` for P(match) > 0.5	approximation `1.1774 sqrt(R)`
100	13	11.77
400	24	23.55
1,000	38	37.23
1,500	46	45.60
10,000	119	117.74

Draw thirty-eight words from a scheme with a thousand reachable values and a numerical coincidence is more likely than its absence. In a corpus of eight thousand words, essentially every word has a partner — the probability is 0.9997.

Therefore the discovery that two words share a value is not evidence of anything, and the amount of non-evidence is computable in advance. This is the strongest negative result in the reading and it is delivered by arithmetic rather than by disdain.

And it does not abolish the operation. A hash that assigns a word to a bucket is a real encoding device: it produces an addressable index, and §8.2 shows exactly what an addressable index is worth. **What the arithmetic removes is the *evidential* reading, not the *mnemonic* one.** The operation survives as a technique for binding items to a retrieval structure and dies as a method of discovering hidden relations, and the framework says precisely which of the two it is being used as by asking one question: *is the practitioner claiming the collision was informative, or using it to remember?*

28.11.21 11.21 Why the restraint is the source of the power

The four standing refusals look like limits and function as instruments.

A claim that cannot fail cannot inform. If the thesis of §11.1 permitted supernatural efficacy, no audit could test it, because any residue could be assigned to the permitted category and the audit would never close. **The refusal is what makes §11.19's falsification target exist at all.**

A framework that explains everything explains nothing. The insistence on the shuffled-input control, the preregistration, and the seven validation gates exist so that this apparatus can be wrong in a specified way [Curzi, 2026u, Platt, 1964, Lakatos, 1970]. **Every one of those gates is a place where the framework has arranged to lose.**

And the strongest result in this section is a negative one. §11.20's collision arithmetic tells a practitioner more that is useful than any permissive reading could, because it converts a vague suspicion into a number they can compute before they draw the thirty-eighth word.

The mechanism is sufficient. Nothing needs to be added to it, and the reason for saying so is not that additions are forbidden but that in eleven operations, none was required.

28.12 12 Specification and failure modes for the synthesis

28.12.1 12.1 Specification

SS1 — Publish the ledger. Any deployment of this framework shall reproduce §11.3's three-way sort — proved, postulated, requires measurement — for its own claims, and shall not present a postulate in the same register as a theorem.

SS2 — Badge in the same sentence. A postulate shall carry its badge in the sentence that states it, not in a footnote, an appendix, or a preface.

SS3 — Name the handle. Every proposed intervention shall name which of the three handles it moves and which parameter, and shall state the expected direction. An intervention that cannot name its parameter is not specified and shall not be approved.

SS4 — Compute before adopting. Every intervention shall be checked against `h = eta ln N − delta Q − C` before adoption. Where `h < 0` no intervention based on interaction geometry shall be approved, and the design record shall say so in those words.

SS5 — Declare the period and the scope. Every parameter shall carry its period (S2.1) and its scope — internal or external, and which row of the master table it occupies.

SS6 — Preregister and freeze. Every claim of effect shall be preregistered [Curzi, 2026u], fit on a training window, frozen, and reported on held-out data against four baselines, of which one is the **shuffled-input control**. Omission of the shuffled-input control invalidates the claim.

SS7 — Compute the chance rate before reading a coincidence. Where a correspondence, collision, match, or numerical agreement is offered as evidence, the expected number of such agreements under the null shall be computed and reported alongside it (§11.20). An observed rate not exceeding the chance rate shall be reported as no evidence.

SS8 — Distinguish mnemonic use from evidential use. Any operation used as an encoding device shall be recorded as such, and shall not be cited elsewhere as a discovery procedure.

SS9 — No path that does not pass through a person. Every causal claim shall name the human perception, encoding, retrieval, or action through which it operates. A claim with no such step shall be refused.

SS10 — Preserve the ability to decline. No intervention shall be designed, recommended, or deployed that removes a participant's ability to decline it. This applies to cadence, to requirements, to thresholds, and to every operation in §11.18's audit, and it is not subject to trade-off against any quantity in this framework.

SS11 — State the falsification target for the synthesis. Any restatement of §11.1's thesis shall carry §11.19's refutation condition — an operation that does work and maps to nothing — in the same document.

SS12 — Report the audit as an audit. No claim of completeness shall be made for §11.18. The number of operations examined shall be stated whenever the result is cited.

28.12.2 12.2 Failure modes

THE NOTATION FALLACY — concluding that because the old notation and this one describe the same relations, the old notation was secretly doing modern mathematics, or that the modern notation inherits the old one's authority.

- *Parameter damaged:* none. The error is in the direction of inference.
- *Diagnostic signature:* the phrase "the ancients knew" appears, or a formal result is offered as vindication of a tradition, or a tradition is offered as corroboration of a formal result.
- *Measurement:* ask which of the two is being used to license a claim about the other. A correspondence licenses claims about neither.
- *Fix:* state the correspondence as a correspondence. §11.1's thesis is about *this* manual's description, not about what anyone historically believed.

THE PERMITTED RESIDUE — allowing one operation to remain unmapped "for now," on the grounds that the framework is young.

- *Parameter damaged:* the falsifiability of the whole thesis.
- *Diagnostic signature:* an operation is described as "not yet formalised" across successive revisions, while the thesis of sufficiency continues to be asserted.
- *Measurement:* count unmapped operations. The correct number for a sufficiency claim is zero, and §11.19's target is exactly this.
- *Fix:* either map it or withdraw the sufficiency claim for the class it belongs to. **An unmapped operation is not a gap in the theory; it is a refutation waiting to be written up.**

THE PARAMETER AS TARGET — a measured `u`, `eta`, `delta` or `h` becomes a performance metric and ceases to measure anything.

- *Parameter damaged:* all of them, and the instrument as well.
- *Diagnostic signature:* reported `u` rises without any change in the roster or the disagreement structure; `delta` improves in every quarterly report. Goodhart's Law and Campbell's Law.
- *Measurement:* re-derive the parameter by an independent protocol and compare. If the two diverge and only the reported one improves, the metric has been captured.
- *Fix:* separate measurement from evaluation. The survey is run by people who are not accountable for the result, or it is not run [Goodhart, 1975, Campbell, 1979].

THE SCALE CONFUSION — a result established at one scope applied at another without re-measuring the parameters.

- *Parameter damaged:* all of them, silently, because the *form* transfers and the *values* do not.
- *Diagnostic signature:* a personal practice's cadence imposed on an institution, or an institution's review interval applied to an individual. §11.6's `t_95` column spans 28 days to 148 years.
- *Measurement:* check that the period, `N`, `u`, `eta`, `delta` and `C` were all re-measured at the new scope. Scale symmetry is a claim about model form only [Curzi, 2026].
- *Fix:* re-measure. The equation transfers for free; nothing else does.

THE SUFFICIENCY OVERREACH — reading §11.1's thesis as a claim that the formalism explains experience, meaning, or value.

- *Parameter damaged:* none; the error is one of scope.
- *Diagnostic signature:* the framework is used to adjudicate what someone should want, rather than to compute what a wanted thing would cost.
- *Measurement:* ask what the claim would predict. A claim that predicts nothing measurable is not in this framework's domain.
- *Fix:* **The formalism postulates a structure and tests consequences. It has no access to the inner state and says so, and a manual that computes the cost of a thing has said nothing whatever about whether the thing is worth its cost.**

THE CLOSED LEDGER — a deployment that stops publishing which of its claims are postulates.

- *Parameter damaged:* the reader's ability to check anything.
- *Diagnostic signature:* a summary, a slide, or a derived document in which the badges have been dropped for brevity. This is the most common failure and it usually happens in the second generation of a document rather than the first.
- *Measurement:* take any derived document and attempt to reconstruct §11.3's three-way sort from it alone. If you cannot, the ledger has closed.
- *Fix:* re-attach the badges. **The house rule is that a speculative reading is permitted in the open with its badge on; a badge removed for brevity converts a declared postulate into an undeclared one, which is the one thing the framework refuses.**

28.13 13 Worked example: one studio, carried through every part

One system, carried through every part of the framework. **Every parameter value below is a design value obtained by the protocols named beside it and is badged as illustrative; none is a measurement of any real population.**

[II] The roster audit — the geometry of difference.

```
N = 8 declared domains          ln N = 2.0794 nats = 3.0000 bits = 6.0000 octaves
u* = 0.55                       (disagreement and error-decorrelation audit)
N_eff = 1 + 7(0.55) = 4.8500
F = ln 4.8500 = 1.5790          (75.9% of the ceiling)
```

Six people declaring eight domains buy 4.85 effective ones; 3.15 are redundant. Two-source split (Theorem 4.1) with `u_cross = 0.40` between disciplines and `u_div = 0.15` within them:

```
f(u_cross) = 1.3350    f(u_div) = 0.7178    f(u) = 1.5790
bound:  1.3350  <=  1.5790  <=  2.0528
```

The additive figure 2.0528 exceeds the truth by 30.0%, and per SC4 it is not used.

[I] The circuit — storage parameters. Period: one week.

```
eta = 0.35 (Ch 4)   delta = 0.055/wk (Ch 3)   C = 0.13/wk (Ch 5)
eta F      = 0.5526/wk        ceiling eta ln N = 0.7278/wk
net drive  = 0.4226/wk        Q_inf = 0.4226/0.055 = 7.6844
DC gain    = eta/delta = 6.3636      Thm 3.3 cap = 13.2328
pole 0.945   tau = 17.677 wk   t_half = 12.253 wk
t_95 = 52.96 wk    t_99 = 81.41 wk
h at Q_inf = 0.7278 - 0.055(7.6844) - 0.13 = 0.1752/wk      h = 0 at Q = 10.8692
```

Per S2.4 the first honest review is week 53. Per SS4, `h = 0.1752 > 0`, so growth is available and `r_max = 0.1752` per week is the largest increment that may be promised.

[III] The room. 7.0 x 5.0 x 3.0 m gives `V = 105.0` m³ and `S = 142.0` m². Sabine:

average absorption `alpha`	`A` (sabins)	`RT60 = 0.161 V / A`	verdict
0.10 bare, hard finishes	14.20	1.190 s	too live for six-way speech
0.20 furnished, some soft	28.40	**0.595 s**	in band
0.32 treated for speech	45.44	0.372 s	slightly dead
0.45 over-damped	63.90	0.265 s	conversation feels effortful

Target band 0.4-0.7 s requires `alpha` between 0.170 and 0.298. **The room is specified at `alpha = 0.20`.** Six seats at 1.6 m spacing — inside Hall's social distance of 1.2-3.6 m — require a circumference of 9.60 m and therefore a table 3.06 m across.

[IV] The sociology. Measured turn shares across four sessions: 34, 22, 17, 13, 9, 5 per cent.

```
turn entropy H     = 1.6329 nats        max ln 6 = 1.7918
evenness           = 91.1%
effective speakers = e^H = 5.1185 of 6
```

Woolley and colleagues' turn-taking correlate is therefore in reasonable shape and is **not** the binding constraint; the roster's redundancy is. Per Centola and colleagues' measured threshold, `ceil(0.25 x 6) = 2` committed members is the minimum bloc for overturning a house convention — a number the studio records so that a two-person push is recognised as a structural event rather than as a personality clash.

The essence set. Eight domains, ordered and justified, indexed `n = 1..8`. `f(n) = k n^2` with `k = (81/64)/(phi+1) = (9/8)^2/phi^2 = 0.483425732988414` – **a DEFINED constant, exact, which is why fifteen figures are legitimate; the attachment of the unit Hz to it is a separate and stronger claim and is POSTULATED, badged** [Curzi, 2026, Markowsky, 1992].

n	f(n) (Hz)	odd part = pitch class	j	audible (Hz)
1	0.483426	1	8	123.7570
2	1.933703	1	6	123.7570
3	4.350832	3	5	139.2266
4	7.734812	1	4	123.7570
5	12.085643	5	4	193.3703
6	17.403326	3	3	139.2266
7	23.687861	7	3	189.5029
8	30.939247	1	2	123.7570

Eight essences yield exactly `ceil(8/2) = 4` pitch classes — odd parts 1, 1, 3, 1, 5, 3, 7, 1. That is the available harmonic vocabulary and it is a structural limit, not a stylistic choice. The cross-disciplinary index is `N_eff = e^F = 4.8500`, giving `f_cross = k N_eff^2 = 11.371382` Hz, `2F/ln 2 = 4.5560` octaves above base, and 363.8842 Hz after a five-octave transposition. **Band and `j` are stated for every value. These are essence indices rendered as frequencies, not physical resonances, and nothing is claimed to resonate at any of them.**

[VII] The perceptual lens. `D` and `P` estimated by magnitude estimation against a common modulus (the scale-type gate is asserted satisfied here, with a true zero; **the conjoint-measurement test that would establish it was not run**, Luce and Tukey, 1964, Michell, 1997):

```
D = 62.0     P = 41.0     r = D/P = 1.5122     Distortion |ln r| = 0.4136
M = (D/P) E  = 1.5122 E
```

OVER-FRAMED by 51.2%: the studio is seeing what its model predicts. Two corrections, both computed: raise intake so that `P` rises to 62.0 — a 51.2% increase — or lower frame so that `D` falls to 41.0, a factor of 0.6613. The studio chooses the first, because an over-framed group that lowers its doctrine without raising its intake becomes an under-framed one [Curzi, 2026o]. Target `r = 1.05` leaves a residual distortion of 0.0488, **11.8% of the original.**

Lens theorem check: a perceived `+1` unit is a world factor of `e = 2.7183`. The measured distortion of 0.4136 corresponds to a world factor of 1.5122. **The correction is a ratio, budgeted as a ratio, and never promised as a linear improvement.**

[VIII / IX] The formularies. With `E` normalised to 1 and a personal maintenance cost `C = 0.9`:

```
L = max(0, M − C)
at r = 1.5122 (over-framed):  L = max(0, 0.6122) = 0.6122
at r = 1.0000 (calibrated):   L = max(0, 0.1000) = 0.1000
at r = 0.8000 (flooded):      L = max(0, −0.1000) = 0.0000
```

The under-framed state has no launch budget at all — there is no surplus to dream with. Note the uncomfortable and honest reading of the first row: **the over-framed state has the**

largest launch budget in the table, which is why projection is generative and why the correction to `r = 1` costs something real. The studio records that its calibration exercise will *reduce* the volume of new proposals and that this is the expected result rather than a failure.

Return difference on the studio's first external submission: sent `M = 1.00`, world returned `M' = 1.34`, so `Delta_R = |ln(1.34/1.00)| = 0.2927`. **Non-zero, therefore informative.** A `Delta_R` of zero would have meant the world's answer carried nothing.

[XI] The old notation, priced.

- **Correspondence table:** the studio's eight-domain scheme declares `N = 8` and therefore a ceiling of `ln 8 = 2.0794` nats per interaction. Nothing else about the scheme changes that number.
- **Sigil:** the studio's mark is drawn on eight points. `gcd(8,3) = 1` gives **one continuous stroke of length 8** — unicursal. `gcd(8,2) = 2` would give two separate squares. The mark is specified as `{8/3}` because a single stroke is wanted, and that is a decision made on an arithmetic invariant.
- **Memory palace:** the 48-item corpus, encoded to 24 loci with two images each, moves `Q_inf` from 1.9160 to 26.9727 — **a factor of 14.08**, decomposing as surplus 1.5997 x conversion 2.0000 x retention 4.4000.
- **Calendar:** weekly session at the audited `u* = 0.55` (`eta F = 0.5526`), monthly seminar at `u = 0.62` (`0.5863`), annual retreat at `u = 0.86` (`0.6821`), retreat placed in week 26 to avoid collision per SC12.

```
weekly + seminar in one week = 1.1390   vs ceiling 0.7278  -> 0.4112 discarded (36.1%)
```

Three-year trajectory of the built calendar:

week	1	4	13	26	53	105	157	209
Q_t	0.4226	1.7313	4.4040	6.6679	8.1134	8.5193	8.5408	8.5419

Steady-state mean 8.5418, minimum 8.4259, maximum 8.7145, ripple 3.38%. **The calendar returns `+0.8574` over the weekly session alone — an 11.16% gain** — and headroom at the steady mean is `0.7278 − 0.055(8.5418) − 0.13 = 0.1280`, still positive, with `h = 0` at `Q = 10.8692`.

[X] Validation — the frozen model and the conditions of failure.

Fit `Y_{t+1} = a Y_t + b F(U_t) − C_hat_t + eps_t` on weeks 1-53 with `0 <= a <= 1` and `b >= 0`, freeze the coefficients, report on weeks 54-106 against persistence, direct-input, matched autoregressive, and shuffled-input baselines.

FVP gate	Status for this system
1 DIMENSIONS	`D` and `P` share a modulus, so `r` is dimensionless; `M` inherits `E`'s units. Pass.
2 SCALE TYPE	`D`, `P` by magnitude estimation with a true zero; ratio scale, so division is permitted. Pass. `u`, `eta`, `delta` are ratios in `[0,1]`.
3 LIMITING CASES	`P -> 0` gives unbounded `M` (dogma); `D -> 0` gives `M = 0` (sensation without experience); `E -> 0` gives `M = 0`. All named, all observed. Pass.

FVP gate	Status for this system
4 FIXED POINTS	`D = P` gives `M = E`; `Q_inf = (eta F − c)/delta = 7.6844`. Both solved and stated. Pass.
5 IDENTIFIABILITY	`eta` and `delta` are separable only from the transient; the fit window covers weeks 1-53, which is `3 tau`. **Conditional pass — requires a zero-input window.**
6 FALSIFICATION	The five conditions below, preregistered and frozen. Pass.
7 REPRODUCIBILITY	**NOT YET MET.** The parameters have been recovered in one studio. Cross-individual and cross-site recovery is the corpus's costed programme [Curzi, 2026u] and has not been run. **This is stated as a gap, not glossed.**

Preregistered falsification. **This model is wrong if:**

1. the fitted `a` falls outside `[0,1]`, or its interval excludes `1 − delta = 0.9450`;
2. the fitted `b` does not exceed its pre-intervention value;
3. the frozen model does not beat the **shuffled-input control** on held-out data — in which case timing carries no information here and the entire cadence apparatus does not apply to this studio;
4. the empty-palace test recovers fewer than 20 of 24 loci in order at 90 days, which would put the `delta` attribution in the wrong subsystem;
5. `r = D/P` does not fall toward 1 after the intake intervention, which would mean over-framing in this group is not driven by the term the diagnostic assigns it to.

A week-13 reading of 4.4040 is 51.6% of steady state and is not a finding. It is recorded in advance, so that nobody has to argue about it in week 13.

28.13.1 13.1 What the worked example establishes

Psychology and sociology are treated here as one set of relations measured at two scopes. That is a badged thesis, not a demonstrated identity [Curzi, 2026o], and the framework's parameter table is the argument: the same six parameters, the same recursion, the same gauge, with `N` as the categories one mind can distinguish or the domains a group holds, `Q` as character or as institution, `delta` as forgetting or as turnover, and `D/P` as frame-to-intake or as doctrine-to-data.

Four independent quantities in this framework are logarithmic — surplus, pitch, sensation, and the log form of the moment — **and therefore every conversion between them is linear in log space with exact constants.** One nat is 1.442695 bits, 2.885390 octaves, 3462.4681 cents. That is not a numerological coincidence; **the logarithm is the register perception itself operates in**, which Weber and Fechner established experimentally in the nineteenth century and which has been replicated since without interruption.

Subjective magnitude is measurable. Stevens' magnitude estimation produces ratio-scale measurements of subjective quantity that replicate, and that single fact is what licenses the entire volume: division requires a ratio scale, `D/P` requires division, and psychophysics is offered as already building ratio scales for subjective quantities. **That licence is contested from three directions and the contest is recorded in §11.13.** The remaining work is not conceptual: it is the cross-individual recovery gate, and the corpus costs it out at 14.93 full-time-equivalent years per completed programme [Curzi, 2026u].

And the old notation described the same relationships. The correspondence table declares `N`. The sigil compresses and has an exact stroke count `gcd(N,k)`. The palace lowers `delta`. The calendar is periodic forcing. The second framing is worth a quarter of the next eleven combined. The randomiser returns 78.3% of the ceiling. Gematria is a hash whose collisions are computable and therefore evidentially worthless and mnemonically real. **Eleven operations, three handles, and no residue — in an audit of eleven operations, which is what it is and no more.**

If magic is the deliberate engineering of the perceptual lens, the storage of order through symbol, space and cadence, and the composition of non-parallel essences, then the framework has described its mechanism in modern notation. That is the author's thesis, it is a postulate, it wears its badge, and it claims no efficacy of any kind beyond what the storage law and the surplus law already produce — because there is nothing else in it for an efficacy to come from.

28.13.2 13.2 The open problem one layer down

Everything above concerns order that a person or a group **deliberately stores**: a room arranged, a calendar set, a palace built, a framing adopted. In every case the ordering of the category set was chosen by someone, and the essence law assigns an index to an ordinal position in a category set whose ordering a discipline supplied and justified.

Some sequences arrive already ordered, at enormous length, with an alphabet fixed before the ordering was read. The framework's octave-reduction method – folding a raw index into an audible band by powers of two – was developed against exactly such a sequence, at a thirty-six-octave transposition, and applying the essence law there raises questions this paper's arithmetic cannot answer. **What `N` means when nobody designed the sequence; what a defensible ordering is when the alphabet is four; what a channel capacity is when the channel is chemical; and whether any of the framework's parameters has a biological counterpart that can be measured rather than postulated** – those are open, and the corpus states them as open rather than answering them. Two Series B papers take them up directly: the channel into a single cell is computed and the result is used to *eliminate* an explanation rather than to support one, because computing the capacity of a channel leading to a receiver does not create the receiver [Curzi, 2026x]; and the addressing architecture is bounded by a constraint rather than a caveat, since no addressing operation at any signal strength or modality can cause a cell to express content its genome and accessible regulatory repertoire do not already contain [Curzi, 2026y].

The same four refusals bind that work more tightly than they bind this one, because the temptation to claim a physical resonance is largest exactly where the material is physical, and the sentence that governs every use of the essence law governs it there too: **the output is an index, not a physical resonance.**

The instrument does not change. Only `(N, u, eta, delta, C)` change, and the period. **That is the architectural claim, it holds at every scope tabulated in §11.6 from a desk to a city, and whether it holds one layer down is an open question and not a result.**

28.14 14 Results

Every number in this section is exact arithmetic, an exhaustive computation, or the output of a model whose parameters are printed beside it and badged as design values. **No dataset was collected and nothing here is a measurement of any person, group or historical practice.**

28.14.1 14.1 The decomposition theorem, and its exhaustive check

R1. For `N >= 3` and `1 <= k <= N−1`, the figure `{N/k}` consists of exactly `gcd(N,k)` closed strokes, each visiting `N/gcd(N,k)` points and carrying `N/gcd(N,k)` edges; the whole figure carries `N` edges

for every k; it is unicursal if and only if gcd(N,k) = 1; and drawing it requires exactly gcd(N,k) − 1 pen lifts. The proof is three lines of elementary group theory – the orbits of x −> x + k are the cosets of the subgroup generated by k, which is the subgroup generated by gcd(N,k), of order N/gcd(N,k), so Lagrange gives gcd(N,k) cosets. **Verified by explicit trace for every N = 3..40 and every k: 779 cases, zero mismatches.** Of the 143 tabulated rows for N = 3..24, 89 are unicursal.

R2. The attainable stroke counts on N points are exactly the proper divisors of N; the number of unicursal steps is phi(N), so the number of distinct unicursal figures is phi(N)/2 for N > 2; and gcd(N,k) = gcd(N,N−k), verified without counterexample for N = 3..100. **Prime N gives a unicursal fraction of exactly 1.000 and a maximum single-step jump of 0 – perfectly robust, perfectly inflexible. Highly composite N gives the worst unicursal fractions (12, 18 and 24 all sit at 0.333) and the richest decomposition menus.** The two design goals are exactly opposed and the opposition is the divisor structure of N.

28.14.2 14.2 Parallelism, ceiling, and the rate optimum

R3. Read as a schedule, total work is N for every k and only the arrangement changes: P = gcd(N,k) independent workstreams, critical path T = N/gcd(N,k), and **speedup exactly gcd(N,k), with no overhead, because the strokes share no vertex.** The price is exact and is paid in ceiling: the g strokes are disjoint, so no cross-stroke pair interacts within a period and the available surplus ceiling falls from ln N to ln(N/g).

R4. The ceiling rate R(x) = ln(x)/x has dR/dx = (1 − ln x)/x^2, zero at x = e = 2.718282, so **stroke length 3 is the best integer choice at R = 0.366204, with an exact tie between x = 2 and x = 4 at 0.346574 because ln 4 = 2 ln 2.** For N = 12 the rate-optimal figure is {12/4}, four triangles, whose per-period ceiling ln 3 = 1.098612 is **55.8 per cent below** the unicursal ln 12 = 2.484907.

The worked example of Section 6 then contradicts the rate criterion, and the contradiction is the finding. With a merge cost rising at 0.05 per additional stroke and decay charged every period, {12/4} has a *negative* one-step change in stored order (-0.285624) against the single chain's +0.488208, and running the loss four times as often compounds it: over a 60-day quarter, +2.441040 for {12/1} against -5.712489 for {12/4}. **The rate criterion assumes latency is the only cost. It is not, and this is what a ceiling result looks like when the ceiling is not the binding constraint.**

R5. Within the unicursal configurations the step is still a design variable, and it is the only one that changes the reachable fraction of the ceiling. {12/1} and {12/5} have the same N, the same g, the same ceiling and the same latency; they differ in whose framings meet. At an estimated u of 0.31 for adjacent pairs and 0.58 for pairs five apart, {12/1} reaches F = 1.483875 nats and {12/5} reaches 1.998774, and **the per-cycle gain in stored order rises by a factor of 7.14 – +0.037744 against +0.269448 – from changing one number in the schedule.**

28.14.3 14.3 The cadence theorem and what it does not say

R6. For g concave on [0, infinity) with g(0) = 0, D(n) = n g(T/n) is nondecreasing in n, strictly increasing wherever g is strictly concave. The proof is one line: dD/dn = g(L) − L g'(L), and concavity through the origin gives g(L) >= L g'(L). **The hypothesis is satisfied by the framework's own surplus functional, which is strictly concave with f(0) = 0** [Curzi, 2026], so the case for regular practice does not rest on any ceiling.

Measured on the worked sweep: a twelve-hour budget delivered in one occasion yields 0.7278 and in forty-eight occasions yields 3.3235, **a factor of 4.57 from division alone.** At n = 1 the session runs twelve hours against a saturation length of eight, so **four of the twelve hours deliver nothing at all before any other effect is considered.**

R7. The theorem does not recommend infinitesimal occasions, and the term that stops it is named. With a per-occasion fixed cost c_0 = 0.15 the *net* delivered total peaks at n = 5 and falls away on both sides; the optimum is a function of c_0 and of nothing else in the model,

running `n = 24, 13, 8, 5, 3, 2, 1` as `c_0` runs `0.02, 0.05, 0.10, 0.15, 0.25, 0.40, 0.60`. **At `c_0 = 0.80` the net is negative at every `n`: some practices cannot be afforded at any cadence, and the arithmetic says so before anybody's calendar is consulted.** The design consequence is that halving the cost of convening moves the optimum from five occasions to eight, which is very often cheaper than any intervention on the occasions themselves.

28.14.4 14.4 Impulse against cadence, computed honestly

R8. Summing `Q_t` over 400 periods at `delta = 0.06` with a fixed budget `B = 26.0`: **impulse 433.3333, weekly 433.3333, four-weekly 433.3333, and `B/delta = 433.3333`. Identical to every digit.** This is the defining property of a linear time-invariant system and it refutes the commonest informal argument for cadence.

Three quantities are not invariant. The **peak**: 26.0000 for the impulse against 7.9995 for the weekly cadence, a factor of 3.25. The **minimum**, and hence time above a threshold: at a threshold of 3.0 the cadences hold 60 and 61 periods against the impulse's 35, at 7.0 the three are close, and **at 10.0 and above the impulse wins outright while both cadences score exactly zero**, because no cadence funded by that budget ever reaches 10. And the **deliverable total** once the per-period ceiling clips each burst.

R9. With the burst clipped at `eta ln N = 0.7278` (`eta = 0.35`, `N = 8`), the annual delivered total from an identical nominal budget runs 26.0000, 18.9229, 9.4615, 4.3668, 2.9112, 1.4556 and 0.7278 as the interval runs 1, 2, 4, 8, 13, 26 and 52 weeks. **An annual rite delivers 2.8 per cent of what a weekly practice delivers, and the missing 97.2 per cent is not delivered late or inefficiently: the law caps what one interaction can generate and the excess has nowhere to go.**

R10. The steady state settles the argument without reference to any ceiling. **A single impulse of any size whatever, unrepeated, has `Q_inf = 0`; a sustained rate `m` has `Q_inf = m/delta`.** At `delta = 0.06`, rates of 0.10 to 1.00 per week give steady states of 1.6667 to 16.6667 against a column of zeros. Repeating the impulse at interval `P` with the same annual total leaves the **cycle mean constant at 8.3333 in every row** while the trough falls from 7.8333 at `P = 1` to 0.0836 at `P = 104`. **If a system has any functional threshold at all, the mean is the wrong statistic and the minimum is the right one.**

R11. A rite at interval `P` holding a floor `theta` requires `a^P >= theta/(theta + A)`. With the burst at the ceiling and `theta = 0.30`, **a once-a-decade rite requires the trace it leaves to have a half-life of about 5.63 years and a once-a-generation rite about 16.89 years.** That is why such rites are extraordinary, why they are small, and why they take the forms they do. **It is an explanation of a form and not a recommendation of one**, and Section 17 restates the refusal.

R12. A costly requirement is affordable if and only if `dc <= (eta F − c)(1 − delta'/delta)` – **the fraction of the net drive it consumes must be less than the fraction of the decay it removes**, and in the worked table those two percentages are identical in every row, which falls straight out of the algebra rather than out of the parameters. A requirement costing 0.05 per week against a net drive of 0.4226 must reduce `delta` by at least 11.83 per cent to pay for itself.

28.14.5 14.5 The loci decomposition and the palace's fixed increment

R13. The loci-versus-rote steady-state ratio factorises exactly: surplus `F2/F1 = 1.8637`, conversion `eta2/eta1 = 1.9000`, retention `delta1/delta2 = 4.1667`, **product 14.7546, identical to the direct `Q_inf` ratio.** Surplus and conversion together give 3.54; retention alone gives 4.17. **The technique is primarily a retention intervention and only secondarily an encoding one, which is the opposite of the usual emphasis.**

R14. Palace capacity is `ln L` in the number of loci, so **every doubling buys exactly `ln 2 = 0.693147` nats, forever** – 5 to 10 buys the same as 160 to 320. And for a forty-item corpus, ordinary undesigned places already reach **92.4 per cent** of the ceiling while deliberately distinct

places with vivid images reach 97.2 per cent: **the whole apparatus of classical rules buys the last 8 per cent, which is what a logarithm looks like from inside.**

R15. The two-source decomposition prices place and image separately, and the additive reading is always wrong. At `N = 40` with `u = 0.90`, `f(u)` sits close to the lower bound `max(f(u_cross), f(u_div))` in every configuration tested, and **the balanced configuration (0.45/0.45) has the largest gap between the naive sum and the truth – 2.25 nats of imagined surplus that does not exist.** An operator who has invested equally in place-distinctness and image-vividness overestimates the combined effect by more than one who has invested lopsidedly.

28.14.6 14.6 The audit, and what it does not settle

R16. Eleven inherited operations map to three handles – lens, store, composition – with a named parameter and a direction each, and **four of the eleven are priced exactly.** A correspondence table declares `N` and therefore the ceiling `ln N`, with the 64 hexagrams sitting at exactly 6.0000 bits because a hexagram is six binary lines. A physical token is a `delta` reduction and nothing else: **a written, filed record has the *lowest* conversion in the table and still wins by a factor of 4.20 on steady state, because retention is a gain term.** Adopting one further genuine framing is worth `F_int = 0.5306` nats at `u_bar = 0.7`, which is **24.5 per cent of what eleven further framings deliver** – the second is the largest single gain available and the twelfth is worth 15.8 per cent of it. And a random draw from an `N`-element table returns `(N ln N − N + 1)/(N−1)` on average, which is **78.3 per cent of the ceiling at `N = 78`**, with no claim whatever about the source of the randomness.

R17. A letter-sum digest is a hash, and its collisions are computable in advance. For `M` strings into `R` reachable values the expected colliding pairs are at least `C(M,2)/R`, minimised at uniformity and therefore worse in practice; **thirty-eight words drawn from a scheme with a thousand reachable values make a numerical coincidence more likely than its absence, and in a corpus of eight thousand the probability that a given word has a twin is 0.9997.** The operation therefore survives as a retrieval index and **fails as a discovery procedure**, and the framework distinguishes the two uses by asking whether the practitioner claims the collision was informative.

R18. The audit found no residue over eleven operations. **That is a finding about eleven operations and is stated as one.** Three candidate residues were examined: the felt quality of an operation (**out of scope**, since the moment equation gives a magnitude and not a quality); any effect outside the practitioner (**refused**, since every mechanism in the audit runs through a person who perceives, encodes, retrieves or acts); and the coherence of an integrated practice (**partially conceded** – subadditivity means an integrated practice is formally *less* than the sum of its decomposed parts, so the objection cannot be that decomposition loses surplus, but eleven separate operations carry eleven per-occasion costs where one integrated practice carries one, and **that is a real `C` advantage the audit does not capture**).

28.15 15 Discussion

28.15.1 15.1 What follows

An arithmetic invariant converts a design search into an enumeration. The practical content of Theorem 1 is that `gcd(N, .)` has no gradient, so a designer tuning a step parameter by small increments is following a signal that does not exist. The correct procedure is to enumerate the at most `floor(N/2)` candidates and evaluate each, which for `N <= 24` is at most twelve evaluations.

Two ceilings sit on the same `ln N` and are inflated by the same fault. The per-period surplus ceiling and the roster ceiling `m(m−1) <= 2 eta ln(N)/kappa` [Curzi, 2026] are both set by the declared category count, and a scheme whose duplicate rows inflate `N` inflates both [Curzi,

2026u]. **Auditing `N` is therefore prior to every computation in this paper**, and where `N_eff` collapses to 1 the available surplus is zero rather than low [Curzi, 2026].

The cadence result is two independent arguments and they should not be merged. The ceiling argument depends on `ln N`; Theorem 2 depends only on concavity through the origin. A reader who rejects the ceiling still owes an answer to the second, and a reader who rejects concavity is rejecting the surplus functional itself.

The costly-requirement break-even is the paper's sharpest practical test. It requires exactly two measurements – the added cost and the change in decay – and returns a yes or a no. It also names the failure mode that follows from getting it right once: a community that has discovered requirements work keeps adding them past the break-even and cannot tell, because from inside, the requirements that worked and the requirements now destroying it look identical.

28.15.2 15.2 What does not follow

Nothing here shows that any historical practice worked, or that anyone historically knew the theorem. Theorem 1 is a fact about a graph. That the surviving weekday order is the star polygon `{7/3}` and that `gcd(7,3) = 1` is why the week is one closed cycle rather than two disjoint sub-weeks is a fact about a stepping rule, and the tradition that produced the order had the figure without the theorem.

Nothing here identifies a social effect. Every group parameter in Sections 6, 10 and 13 is a design value in a constructed example, and the reflexive specification they sit inside is not identified from observational data [Manski, 1993, Shalizi and Thomas, 2011].

The eleven-operation audit is not a completeness proof, and §11.19 states the refutation condition rather than leaving it implicit. The `C`-advantage of an integrated practice is a gap the audit does not close, and it is conceded there rather than in a footnote.

And the metaphor does not upgrade. "Computing map" imports the suggestion that something is being computed, by something, for some purpose; nothing in the mathematics supplies an input, an output or an agent. The one non-metaphorical sentence is that the number of strokes is `gcd(N,k)`.

28.15.3 15.3 Relation to the surrounding literature

The cadence result has an empirical counterpart in the distributed-practice literature and the two must not be presented as mutual confirmation: **the spacing effect is a claim about human memory encoding and Theorem 2 is a statement about concave functions.** What they share is a structural prediction – that dividing a fixed budget into more occasions helps, up to a point set by a per-occasion cost – and structural agreement between an empirical regularity and a mathematical result is interesting without being evidence for either. **No entry in this corpus's external bibliography covers that literature; the studies are named in §8.14 with their authors, venues and dates and are deliberately left uncited rather than attached to a source that does not support them.** The same applies to the loci literature of §8.3 and the ritual and anthropological literature of §8.9 to §8.11. Section 17 lists them.

Where the bibliography does reach, it mostly disagrees with the framework and is cited for that reason. Collective intelligence correlates with equality of conversational turn-taking rather than with mean ability [Woolley et al., 2010], which supports the effective-count reading; but diversity in the short run has been found to reduce trust and civic participation [Putnam, 2007], with a rebuttal [Abascal and Baldassarri, 2015], and cohesion has been found to raise then lower creative success [Uzzi and Spiro, 2005] – an inverted `U` against a surplus functional that is monotone increasing in `u`. **The corpus's functional is not the only candidate: social impact rising as a sub-linear power of the number of sources [Latané, 1981] and value growing as `n log n` [Briscoe et al., 2006] fit the same qualitative facts, and nothing in this paper discriminates between them.** The strongest available warrant for a logarithm does not

require the perceptual story at all [Peters and Gell-Mann, 2016].

The measurement objection is the one the framework cannot yet answer. Michell [1997] argues that psychology assumes quantitative structure without testing for it; the test is conjoint measurement [Luce and Tukey, 1964, Krantz et al., 1971]; **it has not been run for any quantity in this paper.** And the framework's own reflexivity applies to the framework: parameters estimated in a population that has not read it cannot be assumed stable in one that has [Lucas, 1976, Hacking, 1995].

28.16 16 Verification

28.16.1 16.1 Dimensional audit

Symbol	Dimension	Unit	Status
`N`	`[1]`	a count of points, or of categories	**declared**
`k`	`[1]`	a step, in points	**chosen**
`g = gcd(N,k)`	`[1]`	a count of strokes	**derived**, exact
`x = N/g`	`[1]`	points per stroke	**derived**, exact
`W = N`	`[1]`	edges	**derived**, exact
`T = N/g`	`[T]`	periods, one hand-off per period	**derived**
`ln x`, `ln N`	`[1]`	nats	**derived** dimensionless
`R(x) = ln x / x`	`[T]^-1`	nats per period	**derived**
`u`	`[1]`	none	**defined** dimensionless, in `[0,1]`
`F(u)`	`[1]`	nats	**derived**
`Q`	`[Q]`	whatever the declared proxy counts	**modelled**
`eta`	`[Q]` per nat	proxy units per nat	**design value**
`delta`	`[T]^-1`	per period	**design value**
`C`, `c_0`	`[Q]` per period	proxy units per period	**design value**
`h`	`[Q]` per period	proxy units per period	**derived**
`Q_inf`, `Q_max`, `Q_min`	`[Q]`	proxy units	**derived**
`T` (budget), `L` (session)	`[T]`	hours	**declared**
`theta`	`[Q]`	proxy units	**declared threshold**

Does it balance? The star-polygon quantities are pure counts and ratios of counts, so Sections 3 and 4 are dimensionally trivial and the only thing to check is that `R(x) = ln x / x` is a *rate* – nats per period – and is therefore not comparable with `ln x`, a stock of nats per period. **That distinction is exactly what the worked example of Section 6 turns on**, and conflating them is how a rate-optimal configuration comes to have a negative per-period change in stored order.

For the storage side, `Q_{t+1} = (1-delta)Q_t + eta F(u) - C` balances only if `eta` carries `[Q]` per nat and `C` carries `[Q]` per period, which is why `eta` is reported as proxy-units-per-nat and

never as a bare number. `Q_inf = (eta F − c)/delta` returns `[Q]` because `[Q]`/period divided by `1`/period is `[Q]`.

Where there is no operational unit, that is said here. `Q` is stored order and has no natural unit; two systems' `Q` values are not comparable unless they declare the same proxy. The threshold `theta` in §8.10 is a **stipulated** quantity in `Q`-units, and no procedure in this paper measures it. `k` in `f(n) = k n^2`, discussed in §11.12, is a **DEFINED** exact ratio; **the attachment of the unit Hz to it is a separate and stronger claim and is POSTULATED**, and it appears in this paper only as a badged postulate in a ledger.

28.16.2 16.2 Postulates

P1 — `{N/k}` is drawn by the step map `s(x) = x + k (mod N)` on `N` labelled points. *Status:* **DEFINITION** – the object of Theorem 1, and the only thing the theorem is about. Relaxing it to variable steps is a different and larger problem, treated in §4.7.

P2 — In `Z_N`, the subgroup generated by `k` is the subgroup generated by `gcd(N,k)`, of order `N/gcd(N,k)`. *Status:* **ARITHMETIC** – the standard fact that integer combinations of `N` and `k` are the multiples of their greatest common divisor. A reader may verify it on `N = 12, k = 8`: the multiples of 8 mod 12 are `{0, 8, 4}`, which is `{0, 4, 8}`, the multiples of `gcd(12,8) = 4`.

P3 — A finite group's cosets of a subgroup all have the subgroup's order, so their number is the index. *Status:* **CITED** – Lagrange's theorem, standard.

P4 — `f(u) = ln(1 + (N−1)u)` is strictly concave on `[0,1]` with `f(0) = 0`. *Status:* **CITED** [Curzi, 2026] – a property of the framework's surplus functional, proved there.

P5 — Per-period input is capped at `eta ln N`. *Status:* **CITED** [Curzi, 2026c] – the logarithmic ceiling.

P6 — `Q_{t+1} = (1−delta)Q_t + eta S_t − C_t` describes the systems in the worked examples. *Status:* **POSTULATED** – a modelling choice, badged, and the one an empirical test would attack first [Curzi, 2026a].

P7 — The design values in Sections 8, 10 and 13 are the systems' parameters. *Status:* **POSTULATED** and explicitly illustrative. **No value in this paper was measured on anything.**

28.16.3 16.3 The compounding chain

```
P1 + P2   -> L1  the orbits of s are the cosets of <gcd(N,k)>          ARITHMETIC
L1 + P3   -> R1a the number of orbits is N / (N/g) = g                 ARITHMETIC
L1        -> R1b each orbit has N/g elements, so N/g edges             ARITHMETIC
R1a + R1b -> R1c total edges = g * (N/g) = N, for every k              ARITHMETIC
R1a       -> R1d unicursal  <=>  g = 1;  pen lifts = g − 1             DEFINITION
R1a       -> R2  attainable stroke counts = {gcd(N,k)} = proper
                 divisors of N; unicursal steps number phi(N)          ARITHMETIC
P5 + R1b  -> R3  a stroke of x = N/g members has ceiling ln x,
                 not ln N                                              ARITHMETIC
R3        -> R4  R(x) = ln x / x, dR/dx = (1 − ln x)/x^2 = 0 at x = e;
                 ln 3/3 = 0.366204 > ln 2/2 = ln 4/4 = 0.346574        ARITHMETIC
P4        -> R6  D(n) = n g(T/n); dD/dn = g(L) − L g'(L) >= 0          ARITHMETIC
P5 + P6   -> R9  burst clipped at eta ln N = 0.7278; at P = 52 the
                 annual delivered total is 0.7278 against 26.0000,
                 which is 2.7992%                                      ARITHMETIC
P6        -> R10 unrepeated impulse: Q_t = a^t Q_1 -> 0;
                 sustained rate m: Q_inf = m/delta                     ARITHMETIC
P6 + P7   -> R13 (F2/F1)(eta2/eta1)(delta1/delta2)
                 = 1.8637 x 1.9000 x 4.1667 = 14.7546                  ARITHMETIC
P5        -> R14 ln(2L) − ln(L) = ln 2 = 0.693147 for every L          ARITHMETIC
```

Every line is checkable from its own inputs. The three a reviewer can redo in a minute are `ln 3 / 3 = 0.366204` against `ln 2 / 2 = 0.346574`; `0.7278 / 26.0 = 0.02799`; and `1.8637 x 1.9000 x 4.1667 = 14.7546`.

What the chain does not establish. R1 to R4, R6 and R14 are ARITHMETIC or DEFINITION and stand without any empirical content whatever – **they are theorems, and a theorem is no evidence at all that any real system is the object it describes.** R9, R10 and R13 rest on P6 and P7, which are POSTULATED, so **every number in the cadence and loci tables is a property of a model with chosen parameters and not a measurement.** The audit result R18 rests on a stipulative definition and on an enumeration of eleven items, and is **not** a completeness proof.

28.16.4 16.4 Limits, asymptotics, and the model's valid domain

- **`k = 1`.** `gcd(N,1) = 1` always: the convex polygon, unicursal, maximum latency `N`, full ceiling `ln N`. The degenerate end of the design space and often the right answer, as Section 6 finds.
- **`k = N/2` for even `N`.** `g = N/2` strokes of length 2 – the degenerate digons, minimum latency, minimum ceiling `ln 2 = 0.693147`.
- **`N` prime.** Maximum single-step jump 0, `phi(N) = N–1`, one attainable stroke count. Perfectly robust to a mis-set parameter and offering no tuning at all.
- **`g -> N`.** Ceiling `ln 1 = 0`: a decomposition into singleton strokes has **zero** available surplus rather than a low one, which is the same collapse the corpus measures on the roster side when an effective count falls to 1.00 [Curzi, 2026,?].
- **`n -> infinity` in Theorem 2.** `D(n)` increases without bound in the unpriced model, which is why the theorem is incomplete without a per-occasion cost; with `c_0 > 0` the net has an interior maximum, and §8.8 gives it.
- **`delta -> 0`.** The steady state diverges and the contraction is lost; the system never forgets and never arrives [Curzi, 2026a,?].
- **`P -> infinity` at fixed budget.** The cycle mean is unchanged and the trough goes to zero: the limit of a rare rite is a system that spends almost all of its time at nothing.
- **Convex response.** Theorem 2 assumes concavity. **If per-occasion response is genuinely convex over some range – a warm-up cost below which nothing happens – the theorem reverses on that range**, and this is stated as a domain restriction rather than left implicit.

28.16.5 16.5 Invariance, and how far the scale claim has been tested

The architectural claim is that only `(N, u, eta, delta, C)` and the period change between scopes. **That is an invariance claim about model form and it has been exhibited at seven scopes**, from a desk at a daily period to a city at an annual one, with `t_95` running from 28.43 days to 148.28 years. **Exhibited is not tested.** Seven constructed instances with chosen parameters do not establish that the form transfers; what would test it is the cross-laboratory recovery study the corpus costs out and has not run [Curzi, 2026u]. **The honest statement is that the form has been *applied* at seven scopes and *validated* at none.**

The star-polygon results carry a genuine invariance that has been tested exhaustively: the decomposition is invariant under `k -> N–k`, verified with zero counterexamples for `N = 3..100`, and under relabelling of the vertices by any rotation.

28.16.6 16.6 Analogy discipline

Three borrowings appear and each is badged at first use. The **leaky integrator** is a **shared mathematical form**: the same first-order difference equation governs an RC network, an exponential smoother and a stock of order, with no claim that the electrical physics applies [Elaydi, 2005, Oppenheim et al., 1996, Holt, 1957]. **Periodic forcing of a low-pass filter** is the same shared form continued, and the frequency-response statements are statements about

that difference equation. The **hash** in §11.20 is a **derivation**: a letter-sum map satisfies the definition of a hash exactly, and the entropy computed from it is Shannon's quantity in bits [Shannon, 1948, Cover and Thomas, 2006], never thermodynamic entropy.

"The sigil is a nonlinear computing map" is an ANALOGY and is badged as one at every occurrence. Its only defensible quantitative content is that `gcd(N, .)` is a non-smooth arithmetic function of the design parameter, which is a statement about a graph. **No scaling, power-law or heavy-tail claim is made anywhere in this paper**, so the distribution-fitting procedure such a claim would require [Clauset et al., 2009] does not apply and was not run. The one place a constant with a physical unit appears – `k` in `f(n) = k n^2` – is a **defined exact ratio** whose unit attachment is a **postulate**, and the golden-section literature is cited beside it precisely because φ is so routinely claimed where it is not present [Markowsky, 1992].

28.17 17 Limitations

Nothing in this paper was measured on a person, a group, or a historical practice. Sections 6, 10 and 13 are constructed examples with design values, stated as design values at every occurrence, and **must not be cited as evidence about any real design group, study circle or studio.**

Several literatures this paper leans on are named in the text and cited to nothing, because this corpus's external bibliography does not stock them. They are listed here rather than left for a reviewer to find: the classical loci sources and the modern experimental literature on the method of loci; the distributed-practice and retrieval-practice literature; the ritual and anthropological literature; the costly-signalling literature; the source of the letter-reduction procedure analysed in §4.8; and the standard reference for star-polygon notation and the classification of compounds. **In every case the author, work and date are given in the text so that a reader can locate them, and in no case has an unrelated entry been attached to make the sentence look supported.** The arithmetic this paper performs on those sources' *claims* is arithmetic; the claims themselves are cited to their originators by name and to nothing else.

The reflection problem is unanswered. The framework's reflexive specification is not identified from observational data [Manski, 1993, Shalizi and Thomas, 2011], and no remedy is adopted here [Brock and Durlauf, 2001]. **Every statement about `u`, `eta` or `delta` as a property of a group is a modelling position rather than an identified empirical result.**

Scale type is stipulated, not demonstrated. `u`, `Q`, `D` and `P` are treated as ratio-scale quantities wherever differences, ratios, logarithms and means are taken, and the conjoint-measurement conditions that would license that treatment [Luce and Tukey, 1964, Krantz et al., 1971] **have not been tested.** Michell [1997]'s objection applies directly and is conceded rather than answered. The worked example of Section 13 asserts that its scale-type gate is satisfied; **that assertion is a design value like the others and is not a measurement.**

`N_eff = 1 + (N–1)u` is not a Hill number. `1/HHI` and `exp(H)` are Hill numbers of orders two and one and are grounded [Hill, 1973, Jost, 2006, Simpson, 1949]; the effective count used throughout this paper is a linear interpolation between 1 and `N`, is the framework's own construction, and has no counterpart in the ecological, economic or information-theoretic literature. Small-set estimation bias in any effective count is documented and no correction was applied [Chao et al., 2014].

The surplus functional's form is underdetermined by the evidence. A sub-linear power law [Latané, 1981] and an `n log n` law [Briscoe et al., 2006] fit the same qualitative facts as `ln(1 + (N–1)u)`, and **nothing in this paper discriminates between them.** Theorem 2 needs only concavity through the origin and survives all three; the ceiling argument and every number in the clipping table do **not** survive a change of form, and would have to be recomputed.

The empirical claims this paper's models rest on are inherited and are as strong as their sources. The illustrative parameters were not measured; the ritual and memory findings quoted are single studies or small literatures, several of them correlational and one explicitly

survivorship-prone; and the replication base rate that applies to all of them is about 36 per cent with effect sizes roughly halved [Open Science Collaboration, 2015, Ioannidis, 2005].

Every shuffle p-value in the falsification designs sketched here would be uncalibrated. The corpus measures its own shuffled-input control at a false-rejection rate of 0.108 for independent permutation and 0.120 for circular shift against a nominal 0.05, with only block permutation near nominal at 0.060 [Curzi, 2026u]. **The preregistered predictions of Sections 10 and 13 inherit that defect, and any study running them must calibrate the control on its own design before quoting a threshold.**

No information criterion is computed anywhere in this paper, and no effect size carries an interval. The comparisons in Sections 6, 10 and 13 are between *models with chosen parameters*, not between fits to data, so the usual model-comparison apparatus does not apply – but that is a statement about what the worked examples are, not a defence of omitting it from a study that fits anything.

The audit of §11.18 is an audit of eleven operations. It is not a completeness proof, its falsification target is stated, and **the C-advantage of an integrated practice over its decomposition is a real gap in its coverage**, conceded in §11.19.

The threshold `theta` that makes the trough matter is stipulated and never measured. The entire argument that the minimum rather than the mean is the right statistic depends on some functional threshold existing, and **no procedure in this paper identifies one for any system.** A reader who denies that their system has a threshold is entitled to prefer the mean, and the mean is invariant.

The rare-rite arithmetic explains a form and does not recommend one. The requirement that a once-a-decade occasion purchase a half-life of about five and a half years is a computation, and the means by which extraordinary retention has historically been purchased include ordeal, danger and pain. **Nothing here licenses building one**, and the framework's standing refusal – that no intervention may remove a person's ability to decline – is prior to the evidence and unaffected by it.

Two claims the paper does not make. It makes **no causal claim** about any real system, and it makes **no scaling or heavy-tail claim**, so the distribution-fitting procedure such a claim would require [Clauset et al., 2009] does not apply.

What would falsify the results. A single traced star polygon disagreeing with `gcd(N,k)` would overturn R1 and R2, and the trace is cheap to repeat. A concave-through-the-origin response for which division lowers the delivered total would overturn R6. A system in which the integrated effect of a cadence exceeded that of an impulse of the same total, in a linear time-invariant model, would overturn R8 – and would indicate an arithmetic error rather than a discovery. And **an operation that does work, is agreed to do work, and maps to none of the three handles would refute the thesis of §11.1**, which is stated deliberately as a clean target.

28.18 18 Conclusion

A star polygon `{N/k}` decomposes into exactly `gcd(N,k)` closed strokes, each of length `N/gcd(N,k)`; it is unicursal if and only if `gcd(N,k) = 1`; it requires exactly `gcd(N,k) − 1` pen lifts; the attainable stroke counts on `N` points are exactly the proper divisors of `N`; and the number of unicursal steps is Euler's totient `phi(N)`. The result was verified by exhaustive trace over `N = 3` to `40` and every `k` – 779 cases, zero mismatches – and 89 of the 143 tabulated rows for `N = 3` to `24` are unicursal. The hexagram is two disjoint triangles because `gcd(6,2) = 2`, and no technique changes that.

Read as a schedule, `gcd` is parallelism and `N/gcd` is latency, the speedup is exactly `gcd(N,k)` with no overhead because the strokes share no vertex, and **the price is exact: the per-period surplus ceiling falls from `ln N` to `ln(N/g)`.** The throughput rate `ln(x)/x` is maximised at `x = e`, so **stroke length three is the best integer choice at `R = 0.366204`, with an exact tie between `x = 2` and `x = 4`**, while splitting a twelve-station cycle into four triangles costs 55.8 per cent of the

single-period ceiling. **The worked example then shows the rate criterion losing to the single chain once merge cost and per-period decay are charged**, which is what a ceiling result looks like when the ceiling is not binding. Within the unicursal configurations, changing the step from 1 to 5 on the same twelve people multiplies the per-cycle gain in stored order by 7.14.

On the temporal side: for a concave response through the origin, dividing a fixed interaction budget over more occasions never delivers less – delivered total 0.7278 at one occasion against 3.3235 at forty-eight, a factor of 4.57 – and the term that stops the division is the per-occasion fixed cost, which sets the optimum on its own. **The integrated effect of a fixed budget is invariant to how it is spread: 433.3333 for the impulse, the weekly cadence and the four-weekly cadence alike.** What is not invariant is the peak, the trough, and the deliverable total after clipping. **A single impulse has a steady state of exactly zero against a rate's `m/delta`, and computed at identical nominal budget an annual rite delivers 2.8 per cent of what a weekly practice delivers – with the remaining 97.2 per cent not delivered late but not delivered at all.** A once-a-decade rite requires its trace to have a half-life of about 5.63 years, and a once-a-generation rite about 16.89; that explains the form such rites take and recommends nothing.

The memory-palace arithmetic shows ordinary distinct places already reaching 92.4 per cent of the ceiling for a forty-item corpus, and the technique to be primarily a retention intervention: retention contributes a factor 4.1667 against surplus 1.8637 and conversion 1.9000, the product 14.7546 matching the direct steady-state ratio exactly. Every doubling of a palace buys exactly `ln 2 = 0.693147` nats, forever.

The synthesis states its own falsification target and concedes that decomposition understates cost, not surplus. Eleven inherited operations map to three handles with no residue; four are priced exactly; a written record has the lowest conversion in the table and still wins by a factor of 4.20 on steady state, because retention is a gain term; one further genuine framing is worth 24.5 per cent of what eleven further framings deliver; a random draw from a 78-element table returns 78.3 per cent of the ceiling; and thirty-eight words drawn from a thousand-value digest make a coincidence more likely than its absence, which is why such a digest is a real retrieval index and worthless as evidence. **That is a finding about eleven operations, which is what it is and no more. The framing of a drawn figure as a computing map is a metaphor throughout, and the one sentence in it that is not a metaphor is that the number of strokes is `gcd(N,k)`.**

28.18.1 Declarations

Data and code availability

No external dataset was collected for this paper. The star-polygon results are exact arithmetic and an exhaustive enumeration that any reader can repeat in a few lines of code from the definitions in §3.1; the enumeration parameters (`N = 3..40`, all `k`, and `N = 3..100` for the mirror identity) are printed with the results. The cadence, loci and calendar results are model outputs whose generating parameters are printed beside them and badged as design values. **The twelve-station design group of Section 6, the study circle of Section 10 and the studio of Section 13 are constructed and must not be cited as evidence about any real organisation.** Two measurements were taken on external artefacts: the letter-set collision statistics of §4.8 were computed over the alphabetic entries of length six or more in the macOS `/usr/share/dict/words` (`web2`) list, which ships with the operating system and is not redistributed here. The figures are generated by the scripts named in each caption; those scripts contain no data beyond the numbers printed in this paper.

Funding

This research received no external funding.

Conflicts of interest

The author declares no conflicts of interest.

Author contributions

Single author. Michael Laurence Curzi proved the theorems, ran the enumerations and simulations, performed the analysis, produced the figures, and wrote the paper.

Ethics

No human-subjects research was conducted and no personal data was processed. The groups described are constructed. The material in §8.10 computes the retention an infrequent high-intensity occasion would require and identifies ordeal, danger and pain among the historical means of purchasing it; **that is an explanation of an observed form and not a recommendation, and the framework's standing refusal that no intervention may remove a person's ability to decline is prior to the evidence and is restated in §9.1 and §12.1 as a specification requirement.** The historical and anthropological material is discussed as an object of study and not performed.

Preregistration

This paper reports no preregistered empirical test. Sections 10 and 13 each state a set of frozen predictions that a study of the systems they describe would be preregistered against – including the requirement that the frozen model beat a shuffled-input control on held-out data, without which the cadence argument would not apply to that system – but **no such study has been run**, and those predictions are stated as design requirements rather than as results. **Any study running them must first calibrate the shuffled-input control on its own design**, because the corpus measures that control at a false-rejection rate of 0.108 against a nominal 0.05 [Curzi, 2026u]. The hypotheses of Section 2 were fixed before the enumerations and sweeps were written up; **two of the six were falsified and are reported in Results in the same language a success would have received.**

Chapter 29

The Two Columns and the Concordance Register: Why Agreeing Traditions Stop Adding Evidence After the Second, and a Register That Rejects One Bridge in Five

Abstract. We separate the two columns of a concordance apparatus: measured evidence on one side, historical precedent on the other, and prove that treating them as two independent verifications inflates a posterior. Under a toy likelihood model in which a true proposition is recorded by a tradition with probability 0.30 and a false one with 0.10, a single record carries a likelihood ratio of 3.000, or 1.585 bits; double-counting the same item as evidence turns an honest 3,000:1 into 1,000,000:1. Correlated sources are worse than merely redundant: at a ten per cent chance of shared origin the bits bought by k agreeing traditions run 1.585, 2.546, 2.317, 1.886, 1.685, decreasing after k = 2, because agreement itself becomes evidence of a common source. Pre-modern single-observer detection is quantified — below a standardised difference of 1.0 one observer is worse than a coin — and a survivorship formula shows the same material arriving either 7.9 or 94.5 per cent accurate depending on whether failures were visible, a twelvefold difference. Three bridges are worked to their verdicts: cadence established, vibration-to-cell graded, and the claim that a specific audio frequency repairs DNA rejected on wavelength, energy and octave-separation grounds. Across forty-two register entries, thirty-two are established, six rejected and two badged postulates, with 33.3 per cent carrying a qualifier and 21.2 per cent of attempted bridges failing outright.

Keywords: concordance; likelihood ratio; source dependence; survivorship bias; precedent versus evidence; register status vocabulary; rejection rate

Series: B. Engineering the Surplus **Paper:** CCP-029

29.1 1 Introduction

Two sources agreeing does not double the evidence when only one of them is evidence. This paper takes that sentence, prices it, and builds an auditable apparatus on it.

The setting is a concordance: a body of work that pairs each of its substantive claims with two references, one drawn from the peer-reviewed literature and one from a contemplative, esoteric or otherwise pre-modern textual tradition. Such pairing is common, it is rhetorically powerful, and it is almost always presented in a way that invites the reader to treat the two references as two independent verifications of the same proposition. **That reading is arithmetically wrong, and this paper computes by how much.** Under a likelihood-ratio account in which a tradition records a true proposition with probability 0.30 and a false one with 0.10, a single traditional record is worth `LR = 3.000`, which is 1.585 bits. A replicated experimental result is worth of order `LR = 1000`, which is 9.966 bits. Treating the traditional record as a second replicated result turns an honest posterior of 3,000:1 into 1,000,000:1 — an overstatement factor of 333.3, or **8.38 bits of confidence that was not earned.**

The second contribution is worse news for the practice than the first. Precedent's small contribution is contingent entirely on the sources being independent, and independence is the property that transmitted textual records are worst at supplying. Modelling `k` agreeing traditions with a probability `c` that they share a single origin, the bits bought at `c = 0.1` run **1.585, 2.546, 2.317, 1.886, 1.685** for `k = 1` to `5`. **The total decreases after `k = 2`.** Past two agreeing sources, further agreement is better explained by contact than by independent discovery, and each additional witness argues for diffusion rather than for truth. Informational cascades [Bikhchandani et al., 1992, Banerjee, 1992] and the measured collapse of crowd accuracy under mutual exposure [Lorenz et al., 2011] are the same phenomenon in a modern setting, and they are the reason the arithmetic here is not a curiosity.

The third contribution characterises the instrument that produced the precedent column at all. Sustained first-person observation, transmitted by an institution, has an effectively unbounded sample size and no control condition, no blinding, no calibration and no separation of hypothesis from observation. Repetition drives variance down as `1/sqrt(k)` and leaves bias exactly where it was, so the characteristic product of that instrument is a body of claims that are specific, confident, internally consistent, reproducible on demand **and wrong**. A single uncontrolled observer comparing before with after has a probability of 0.2858 of registering a true standardised shift of `d = 0.20` and exactly 0.5000 at `d = 1.00` — below `d = 1.0` the observer is worse than a coin — against the roughly 392 subjects per group a modern controlled design needs at `d = 0.20`. And a separate filter decides what was transmitted: under a Bayes filter on preservation, the same original corpus arrives either 7.9 per cent or 94.5 per cent accurate depending only on whether failures of its claims were visible, **a twelvefold difference produced by the filter and not at all by the source.**

The fourth contribution is a rejection. Three bridges are worked in full to their verdicts, and the one nearest to the corpus's own subject matter is rejected in print: the claim that a tone at 528 Hz repairs DNA fails on wavelength (2.9167 m in soft tissue against a 10 µm cell, a ratio of `2.9167e5`, and `8.578e9` against a base pair), on energy (`hf/kT = 8.17e−11` at 310 K), and on frequency (molecular vibrational bands sit 34.7 to 37.3 octaves higher). The rejection is then applied to the corpus's own sonification pipeline, which may not claim what it has just refused to let anyone else claim [Curzi, 2026y].

The apparatus is then run over a forty-three-entry register. **Thirty-two entries are ESTABLISHED, six REJECTED, three SPECULATIVE and two badged POSTULATE**; fourteen of forty-two entries (33.3 per cent) carry a qualifier of some kind, and seven of the thirty-three attempted bridges (21.2 per cent) fail the structural-correspondence criterion outright. A method that has never rejected anything is not a method, and those two ratios are properties of the method rather than of the material.

What this paper does not do. It does not establish any of the register's entries; a register is a summary of evidence and never a source of it. It does not collect data: every number here is arithmetic on stated assumptions or a physical constant, and the distinction is marked at each occurrence. And it does not resolve the reflexive identification problem that several of its own register entries inherit; Section 3.5 states that problem where it arises rather than in a footnote.

Sections 2 and 3 give the hypotheses and the method, including the analogy discipline

that governs every physical borrowing in the paper and an explicit disclosure of a gap in the corpus's bibliography. Section 4 develops the likelihood arithmetic. Section 5 characterises the traditional instrument. Section 6 gives four readings of traditional artefacts. Section 7 works four bridges to their verdicts. Sections 8 to 10 give the register's format, the specifications binding on its use, and the named failure modes. Sections 11 to 15 report, discuss, verify, limit and conclude. Appendix A reproduces the register in full, including its rejections. Appendix B lists the works named in the text that carry no bibliography key.

29.2 2 Hypotheses

Five hypotheses, each stated so that it could be wrong and each carrying its falsifier. Two further claims that occupy the same space are **not** hypotheses and are labelled as what they are.

H1 — Precedent and evidence are not commensurable, and the gap is more than half an order of magnitude in odds. Independent traditional arrival at a structure moves the odds on that structure by a factor small compared with the factor a replicated experimental result moves them. **Predicted:** under any assignment of recording probabilities `p1 > p0` that a defender of the traditional record would accept, the ratio of evidence bits to precedent bits exceeds four. **Falsified by:** a defensible assignment on which a single traditional record is worth as much as a single strong study. *(Result: **not falsified** under the assumed rates — 9.966 bits against 1.585, a factor of 6.29; see Section 4.3. The result is conditional on assumed rates and is therefore an arithmetic consequence, not a measurement.)*

H2 — Agreement between correlated traditions is self-limiting, and the limit binds at a very small number of sources. Where sources may share an origin, the evidential value of `k` agreeing reports does not grow with `k`. **Predicted:** for shared-source probability `c > 0` the bits bought by `k` agreeing traditions attain a maximum at small `k` and decrease thereafter. **Falsified by:** any `c > 0` for which the bit total is monotone increasing in `k`. *(Result: **not falsified** — at `c = 0.1` the maximum is at `k = 2` and the sequence falls thereafter; see Section 4.4 and the proof of the limit in Section 13.3.)*

H3 — What survives of a traditional corpus is determined more by the visibility of its failures than by the accuracy of its origin. The preservation filter, not the original hit rate, dominates the accuracy of the transmitted record. **Predicted:** holding the original accuracy fixed, plausible survival probabilities produce surviving accuracies differing by an order of magnitude. **Falsified by:** a filter model in which the surviving accuracy is insensitive to the ratio `s_acc / s_inacc`. *(Result: **not falsified** — 7.9 per cent against 94.5 per cent from the same `a0 = 0.30`, a factor of 11.97; see Section 5.4.)*

H4 — An audible tone cannot act sequence-specifically on genomic material. No acoustic field in the audible band can impose spatial structure at the scale of a base pair, carry quanta comparable to thermal energy at body temperature, or coincide with a molecular vibrational mode. **Predicted:** the wavelength-to-target ratio, the quantum-to-thermal ratio and the octave separation each fail by many orders of magnitude, computed from accepted physical constants. **Falsified by:** a demonstration of sequence-selective acoustic action at audio frequencies, or an error in any of the three computations. *(Result: **not falsified** — ratios of `8.578e9`, `8.17e-11` and 34.7 to 37.3 octaves; see Section 7.5.)*

H5 — A concordance method that is genuinely binding rejects a material fraction of what it is asked to accept. If the three bridge criteria are applied without exemption, the register's rejection rate is not near zero. **Predicted:** the rate of outright

structural-correspondence failure across attempted bridges exceeds ten per cent. **Falsified by:** a register in which every attempted bridge passes, or in which the failures are concentrated in claims the framework had no interest in. *(Result: **not falsified** — 7 of 33 attempted bridges fail C1, 21.2 per cent, and the failures include the claim nearest the framework's own subject; see Section 11.5. The second clause of the falsifier is met by construction rather than by evidence, and that is stated as a weakness in Section 14.)*

Two claims here are not hypotheses.

The recording probabilities `p1 = 0.30` and `p0 = 0.10` are a modelling choice, not a measurement. No study establishes the rate at which pre-modern traditions recorded true structures, and none could without a settled census of what those traditions recorded and an independent verdict on each item. The rates are chosen to be generous to the precedent column, and every bit figure in this paper inherits their status. What is robust across any plausible choice is the *ordering* of the columns and the *sign* of the collapse in Section 4.4, and only those are asserted.

The claim that "the register establishes nothing" is a definition, not a finding. It is true by the construction of a register and is stated so that no later section can trade on the register's tidiness.

29.3 3 Method: the apparatus, the refinement, and what licenses each borrowing

29.3.1 3.1 The concordance apparatus, adopted unchanged

The apparatus is not introduced here. It is carried across from an earlier framework by the same author — a three-state method and three bridge criteria — and is reproduced without modification so that the two bodies of work can be checked against each other line by line. Its provenance is stated because a reader is entitled to know which parts of a method are on trial and which are given.

```
PHYSICS PROOF     (+1)   what scientific measurement confirms
METAPHYSICS PROOF (−1)   what contemplative or traditional practice records
CONTRA−PROOF      (0p)   how the two integrate at the neutral point
```

Three properties of the notation are load-bearing and easy to misread.

The signs are not a value judgement. `+1` and `−1` label two directions of approach — outward, measurable, third-person on one side; inward, experiential, first-person on the other. Neither sign carries rank.

The third state is not a compromise. `0p` is not an average of the two readings, and a bridge is not validated by splitting the difference. The contra-proof asks whether the two descriptions integrate coherently or whether forcing them together requires one side to assert something false. A bridge that requires either column to lie is not integrated; it is one column wearing the other's coat.

The order of operations matters. The procedure fixes the `+1` reading first, in writing, before the `−1` column is opened. The reason is not philosophical but practical: a large enough textual corpus contains a version of nearly every idea a person can have, so searching it after the conclusion is known will always succeed. Fixing the `+1` reading first is the cheapest available guard against the confirmation bias that destroys most work of this kind, and it is the same device, at a smaller scale, that preregistration supplies to an empirical study [Nosek et al., 2018, Simmons et al., 2011]. The degrees of freedom being closed off are exactly those Gelman and Loken [2013] describe: the analyst need not be dishonest for the search to succeed, only free.

The three criteria a bridge must satisfy:

```
C1  STRUCTURAL CORRESPONDENCE   the two descriptions share deep structural
                                features -- not surface similarity, not shared
                                vocabulary, but mathematical or logical structure
C2  PREDICTIVE POWER            the bridge generates a prediction
C3  PRACTICAL UTILITY           the bridge is usable, and on both sides
```

and the binding rule, adopted unchanged: **only bridges satisfying all three are presented as established, and speculative bridges are marked as such.** One tightening is added, and it is the only change made to the inherited apparatus anywhere in this paper: **a speculative bridge is marked speculative in the same sentence that states it** — not in a footnote, not in a later caveat, and not in a summary at the end of the section. A badge that arrives after the claim has been read is not a badge but an apology.

29.3.2 3.2 The four grades of correspondence

Four things are habitually called “correspondence” in ordinary usage, and separating them does most of the work of C1.

```
ISOMORPHISM     exact structural identity; the mathematics is the same and only
                the labels differ
HOMOMORPHISM    partial structural similarity; some features map, others do not
ANALOGY         functional similarity without structural identity; different
                mechanisms, similar effects
METAPHOR        surface similarity that may or may not indicate a deeper connection
```

The threshold: a valid bridge requires at least homomorphism. Isomorphism is ideal. Analogy requires additional validation. Metaphor alone is insufficient.

Most published correspondences between physics and contemplative traditions are metaphors, and they persist because a metaphor is genuinely useful for teaching and genuinely useless for inference — two functions that are easy to confuse when a sentence performs the first one well.

29.3.3 3.3 The refinement: what each column can carry

Everything above is inherited. What follows is the refinement this paper adds, and it is added because the biological material downstream is where the temptation to over-claim is strongest.

```
THE (+1) COLUMN CARRIES EVIDENCE.
    what has been measured, replicated, and could have come out otherwise

THE (-1) COLUMN CARRIES PRECEDENT.
    that the idea was arrived at independently, recorded, and preserved --
    often for centuries, by people with no access to instruments
```

Two sources agreeing does not double the evidence when only one of them is evidence. That is the refinement in one sentence, and Section 4 is its unpacking. It is not a retreat. A concordance that admits what each side can carry is more persuasive than one claiming both sides are proof, for the reason that a reader who checks will find the argument was straight with them, and a reader who checks is the only reader whose opinion is worth having.

What independent arrival does establish is real and worth having: that a structure was findable by more than one route. That is an argument about a specific and important thing — whether the structure is in the territory or only in the instrument. A pattern that only one method ever finds may be an artefact of that method. A pattern that a Renaissance compiler

with a wax tablet and a modern laboratory both arrive at is, at minimum, not an artefact of the laboratory. That is the whole of what precedent buys. It is not nothing; it is also not evidence, and the distance between the two is measurable.

29.3.4 3.4 Analogy discipline: what licenses each borrowing

The corpus this paper belongs to is titled *Psychological and Sociological Physics*, and that word is a promise that has to be kept sentence by sentence. **Every borrowing from physics or mathematics in this paper is labelled here, at first use, as exactly one of three things**, and no later section may let a category-2 or category-3 borrowing collect the authority of a category-1 one.

Borrowing	Category	What licenses it
Bayes' theorem and the likelihood ratio (§4)	**(1) derivation**	The premises are satisfied by construction: a prior, and two conditional probabilities that the model *defines*. The arithmetic is exact; the inputs are assumed, and that is a separate matter carried in §4.2.
Bits as the unit of evidence (§4)	**(1) derivation**	`log2` of a likelihood ratio is Shannon information about a binary hypothesis [Shannon, 1948, Kullback and Leibler, 1951]. **This is Shannon entropy, not thermodynamic entropy**, and the two are different objects with different units; the distinction is stated wherever the word appears.
`1/sqrt(k)` variance reduction (§5.2)	**(1) derivation, under a premise the subject fails**	The result is exact for independent observations. The traditional instrument's observations are not independent, which is precisely why the section's conclusion is about bias rather than variance.
The leaky integrator applied to ritual cadence and to mnemonic retention (§6.2, §6.3)	**(2) shared mathematical form**	`Q_{t+1} = (1−delta)Q_t + eta S_t − C_t` is a first-order linear difference equation [Elaydi, 2005]; its DC gain and ripple behaviour are facts about that equation [Oppenheim et al., 1996, Horowitz and Hill, 2015]. **No claim is made that a liturgy is an electrical circuit or that memory is a capacitor.** The equation is the same; the physics is not transferred.
The wavelength, thermal-energy and vibrational-band computations (§7.5)	**(1) derivation**	These are claims about a physical acoustic field acting on physical matter, and the physics applies directly. This is the one place in the paper where a physical result is used as a physical result, and it is used to *reject* a claim rather than to support one.
The Casimir pressure scaling as `a^−4` (§7.2, Appendix A CR-17)	**(1) derivation**	The scaling is the result itself [Casimir, 1948], measured at the separations where it is appreciable [Lamoreaux, 1997, Mohideen and Roy, 1998]. It is invoked only to show that the effect is negligible at biological scale.

Borrowing	Category	What licenses it
The time–bandwidth limit named in the register (Appendix A CR-11, CR-12)	**(2) shared mathematical form**	`dt df >= 1/(4 pi) = 0.079577471545948` is classical Fourier mathematics [Gabor, 1946] and carries **no quantum content**; the corpus proves it by the same variational argument as `sigma_x sigma_p >= hbar/2` with `p = hbar k` deleted, with Gaussians saturating the bound and a Hann window costing 2.6 per cent [Curzi, 2026z]. The position–momentum relation [Kennard, 1927] is a fact about state preparation, not about measurement disturbance, and the register states it that way.
The framework's constant `k = (9/8)^2 / phi^2 = 0.483425732988414` (Appendix A CR-39, S-R9)	**definition, with a postulate attached**	`k` is an exact ratio of exact quantities and is **defined**, so its fifteen figures are legitimate. **Attaching hertz to it is a separate and much stronger claim and is POSTULATED**, not derived. The standard critique of golden-section claims [Markowsky, 1992] is cited here deliberately and again wherever `phi` appears; the identity `phi^2 = phi + 1` is Euclidean [Euclid, 1956, Vajda, 1989].
The effective count `N_eff = 1 + (N−1)u` (§6.1)	**(3) analogy, badged**	**This is not a Hill number.** `1/HHI` and `exp(H)` are Hill numbers of orders two and one and are fully grounded [Hill, 1973, Jost, 2006]; `1 + (N−1)u` is a linear interpolation between 1 and `N`, is the framework's own construction [Curzi, 2026], and has no counterpart in the ecological, economic or information-theoretic literature. Wherever an effective count is named in this paper, it is this one, and it is named.

Most of the borrowings in this corpus are category 2, and category 2 is respectable. A leaky integrator is a leaky integrator whether it holds charge or holds a practice. The failure mode this table exists to prevent is a category-2 use quietly collecting the certainty of a category-1 one.

29.3.5 3.5 Identification and reflexivity, stated in the method

Several of the register's entries rest on **reflexive social mechanisms**: that a belief propagates when coupled to a true feature of the world [Merton, 1948], that another person's expectation of one's performance affects it [Rosenthal and Jacobson, 1968], and that a stated commitment binds the speaker's later conduct [Curzi, 2026]. Those are the corpus's own reflexive loop in the register's clothing, and **they inherit the reflection problem in full.**

The framework's central formal object is a loop in which the group influences the member and the members constitute the group. That is a linear-in-means reflexive specification, and Manski [1993] proves that in such a specification **the endogenous social effect is not identified from observational data**: it cannot be separated from contextual effects or from correlated unobservables, however much data is collected. Shalizi and Thomas [2011] establish the same confounding for network data, where influence and selection are generically indistinguishable from observation, and Lyons [2011] makes the point against a specific and much-cited application.

No remedy is adopted in this paper. The four known routes are randomisation, an instrument, partial-population variation, and stipulating the reference group and defending the stipulation [Brock and Durlauf, 2001]; none is executed here, because this paper collects and

prices claims rather than estimating a social parameter. **The honest label is therefore that every register entry resting on a reflexive mechanism records a modelling position rather than an identified empirical result**, and the register's own `ROLES` field, which prices the precedent side, does nothing to repair the evidence side. The one genuine existence proof available is MacKenzie and Millo [2003], which documents a reflexive fixed point occurring in the field with dates and price data; that is an observation of the mechanism happening, not an identification of its coefficient, and the difference is the whole of the problem.

The Lucas critique applies to this paper's own apparatus. Lucas [1976] holds that parameters estimated under one policy regime do not survive the announcement of another, and Hacking [1995] makes the same point about human classifications, which change the people they classify. A register that publishes its weights invites its own entries to be written to the weights. The position taken here is narrow and is stated rather than assumed: **the weights are declared constants of the method, not estimated parameters, so there is nothing for a respondent to bias**; but if a later use of the register begins fitting the weights to the entries, that use inherits the critique and this one does not protect it.

29.3.6 3.6 A gap in the bibliography, disclosed

The biological literature this paper describes — placebo analgesia and its opioid mediation, open-label placebo trials, mechanically gated ion channels, force transmission to the nucleus and its transcriptional consequence, sonogenetics, cochlear mechanotransduction, nucleotide data storage, guide-sequence addressing, epigenetic regulation, retroviral domestication and autophagy — has no corresponding cluster in the bibliographic database governing this corpus. Every such work is therefore named in the text and in Appendix A with the bibliographic details the source manuscript supplies, and **without a citation key**. Attaching an unrelated key to a biological claim would be worse than the gap, because a reviewer in that field will check it and a mis-supporting citation destroys more than a missing one. Appendix B lists the affected works, Section 14 records it as limitation L-6, and **this is a defect of the corpus's bibliography rather than a claim that the works do not exist.** The same gap is disclosed in the neighbouring papers of this series [Curzi, 2026x,y] and in the sonification protocol [Curzi, 2026].

Three further items are named without keys for the same reason and are listed in Appendix B: the distributed-practice synthesis underpinning the spacing effect, the memory-palace imaging studies, and the anthropological account of ritual invariance.

29.3.7 3.7 Standing honesty clauses

- **A tradition is a witness to an effect and never to its cause.** Nothing in a first-person instrument could have distinguished causes, so a recorded mechanism is outside the instrument's range by construction (Section 5.3).
- **Duration of belief is not support.** That a doctrine was held for two thousand years is a fact about transmission fidelity — a low `delta` — and `delta` is orthogonal to whether the stored content is true [Curzi, 2026a]. A tradition with excellent retention preserves its errors with exactly the fidelity of its findings.
- **The register establishes nothing.** It is a summary of evidence and never a source of it; no entry becomes truer by being in it.
- **No entry may be combined with another to close an open problem.** The specific case is the demodulation gap [Curzi, 2026y], and the prohibition is stated as failure mode FM-R.4.
- **Standing refusals.** The framework asserts no supernatural claim, no physical efficacy for a symbol, no clinical or therapeutic claim, and no claim that genomic sequence is edited or altered by any procedure it describes. These are constraints on what the framework will assert and are not verdicts on what is true.

- **Scale type.** The status vocabulary of Section 8.3 is **ordinal at best** — ESTABLISHED is not twice SPECULATIVE — and no arithmetic is performed on it anywhere in this paper. The bit weights of Section 4 are on a ratio scale by construction, because they are logarithms of a defined ratio; they are not measurements of anything.

29.4 4 The arithmetic of the asymmetry

29.4.1 4.1 Likelihood ratios and bits

The distinction between the columns can be made numerically, which is better than making it rhetorically. The natural currency for combining independent considerations about a hypothesis is the likelihood ratio, and the natural unit is the bit [Jaynes, 2003, Cover and Thomas, 2006].

Let `H` be the proposition that some structure `S` is a real feature of the territory. A consideration `X` moves the odds on `H` by its likelihood ratio:

```
LR(X) = P(X | H) / P(X | not H)

posterior odds = prior odds x LR(X)
in bits:  log2(posterior odds) = log2(prior odds) + log2(LR(X))
```

That additivity in bits is the entire reason for working in this unit, and it is a **derivation**: it follows from Bayes' theorem for considerations that are conditionally independent given `H`. Section 4.4 is what happens when that independence fails, which is the normal case for the object under study.

The corpus prices other kinds of consideration in the same currency, and the parallels are worth naming because they show the device is not special to this material. A branch of a forecast is scored 0–3 for the steepness of each step, summed to a resistance `R`, and weighted as `1/2^R`, so that a three-point difference in steepness is a factor of eight in expectation [Curzi, 2026]. And the corpus's grounding protocol prices predictions directly: a direction-only prediction is worth a likelihood ratio of 2.0, a plus-or-minus 20 per cent magnitude call against a two-decade prior is worth 11.36 — about 3.5 direction calls — and five inferential links at 70 per cent each deliver 6.3 per cent end to end [Curzi, 2026ac]. **Both are the same operation as this section's: put heterogeneous considerations on one exponential scale and read off which term dominates.**

29.4.2 4.2 The toy model, badged

The rates below are assumed, not measured, and they are a modelling choice (Section 2). They are chosen to be generous to the precedent column. Nothing in this paper rests on their exact values; what rests on them is the *shape* of the conclusion, which is robust across any plausible alternative.

Suppose a tradition records a structure with probability 0.30 when the structure is real, and with probability 0.10 when it is not. The second number is deliberately not small. Traditions have preserved a very large quantity of confidently stated material that turned out to be false, and Section 5 is an account of why.

```
PRECEDENT
    P(recorded | true)  = 0.30
    P(recorded | false) = 0.10
    LR = 3.000  =  1.585 bits  =  4.77 decibans

EVIDENCE                                  (illustrative magnitudes)
```

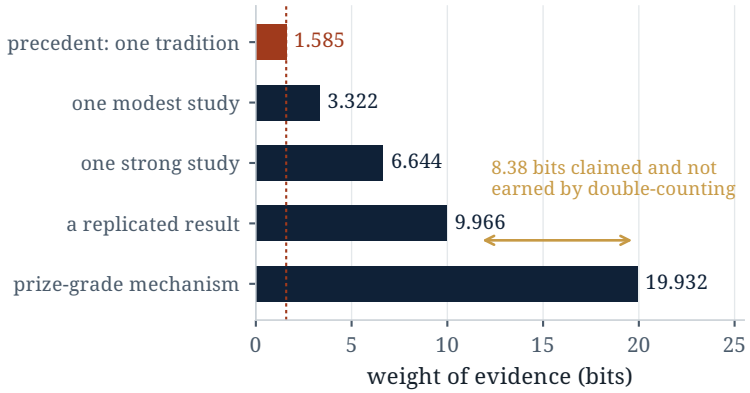

Figure 29.1: **A replicated result is worth six times what independent traditional arrival is worth, and double-counting the precedent claims 8.38 bits that were not earned.** Evidence weights in bits under the illustrative likelihood ratios of Section 4.2 against the precedent weight of 1.585 bits from the assumed recording rates 0.30 and 0.10. The bracketed span marks the 8.38-bit overstatement produced by treating one traditional record as a second replicated result. Modelled from the assumed rates stated in Section 4.2; generated by `figs/src/CCP-029_fig01.py`.

```
one modest study                    LR ~ 10      =  3.322 bits
one strong study                    LR ~ 100     =  6.644 bits
a replicated result                 LR ~ 1000    =  9.966 bits
a replicated mechanism, prize-grade LR ~ 1e6     = 19.932 bits
```

The evidence magnitudes are illustrative in the same sense and to the same degree as the precedent rate, and they are chosen conservatively against the well-documented base rate: large-scale replication returns roughly a third of original psychological findings with effect sizes about halved [Open Science Collaboration, 2015], most published research findings in low-prior fields are false [Ioannidis, 2005], and directional predictions in psychology are nearly costless [Meehl, 1967, 1990]. **A reader who thinks `LR ~ 1000` too generous for a replicated result should note that lowering it narrows the gap this section reports and does not close it**, because the precedent side is capped at `p1/p0 = 3` by construction.

29.4.3 4.3 The price of double counting

Read the two columns together. **A replicated experimental result carries roughly six times as many bits as independent traditional arrival — `9.966 / 1.585 = 6.29` — and a prize-grade replicated mechanism about thirteen times as many, `19.932 / 1.585 = 12.57`.** Precedent is a real term in the sum, and a small one.

The cost of the mistake is computable. Starting from even odds, with a replicated result on the +1 side:

```
honest:   1 x 1000 x 3     =     3,000 : 1
doubled:  1 x 1000 x 1000  = 1,000,000 : 1

overstatement factor 333.3  =  8.38 bits of confidence not earned
```

A concordance that treats its precedent column as a second evidence column is claiming eight bits it does not have, and eight bits is the distance between "well supported" and "essentially certain." That is not a rounding error; it is the entire interval a careful reader cares about.

29.4.4 4.4 Independence collapse

Precedent's small contribution depends entirely on the word *independent*, and independence is exactly the property the transmitted record is worst at supplying.

If five traditions record the same structure and all five inherited it from one another, the five reports are one report wearing five costumes. This is not a hypothetical hazard. The traditions most often paired in this literature — Hellenistic, Egyptian, Jewish, Christian, Islamic, and the Renaissance compilations that stitched them together — are in documented contact throughout, and the early-modern editors who assembled the corpus actually read were *deliberately* harmonising them. Apparent cross-tradition agreement in that corpus is more often evidence of a shared library than of independent discovery.

Model it. Let `k` traditions all report structure `S`, and let `c` be the probability that they share a single source — that is, that they are effectively one report:

```
P(all k report | H)     = c * p1 + (1 - c) * p1^k
P(all k report | not H) = c * p0 + (1 - c) * p0^k

with p1 = 0.30, p0 = 0.10;  LR = the ratio of the two.
```

Computed, in bits:

k	c=0.0	c=0.1	c=0.3	c=0.5	c=0.9
1	1.585	1.585	1.585	1.585	1.585
2	3.170	2.546	2.048	1.826	1.616
3	4.755	2.317	1.827	1.695	1.598
4	6.340	1.886	1.670	1.622	1.589
5	7.925	1.685	1.612	1.596	1.586

The first column is the fantasy: perfectly independent traditions, and the bits add linearly. Every other column is the realistic case. **At only a ten per cent chance of a shared source, five agreeing traditions buy 1.685 bits — barely more than the 1.585 bits one tradition buys alone.** At `c = 0.3`, five traditions buy 1.612 bits, within two per cent of a single tradition's contribution.

Read down the `c = 0.1` column as `k` rises: 1.585, 2.546, 2.317, 1.886, 1.685. **It goes down after `k = 2`, and that is not a numerical accident.** Once several sources agree, "they copied each other" starts to explain the agreement better than "they each found it," and the extra witnesses begin to argue for diffusion rather than for truth. Section 13.3 proves the limit: as `k` grows, both numerator and denominator approach `c p1` and `c p0`, so the likelihood ratio approaches `p1/p0 = 3` from above, and the bit total approaches 1.585 from above — the value a single tradition already supplied.

This is the same structure as an informational cascade, in which agents rationally follow their predecessors and the aggregate ceases to aggregate anything [Bikhchandani et al., 1992, Banerjee, 1992]. It is also the mechanism Lorenz et al. [2011] measured directly: social influence narrows the diversity of estimates without improving their accuracy, so the group looks more confident and is not more correct. Salganik et al. [2006] shows the same dependence experimentally in cultural markets — what survives is heavily path-dependent, and success in one world does not predict success in another. The old corpus is a cultural market with a very long horizon.

Two results elsewhere in the corpus make the same structural point about witnesses. An identifier drawn from a shared pool identifies a pool and not a member: with an address-only log the anonymity set is 1,953.1 subscribers, with address, port and live session state it is 1, and after state expiry it is 1,453.2 [Curzi, 2026]. **An agreeing tradition is an address, and a shared library is the pool.** And the repair in both cases is the same: compare against a *separate witness* rather than a second view of the same record — comparing entries on a

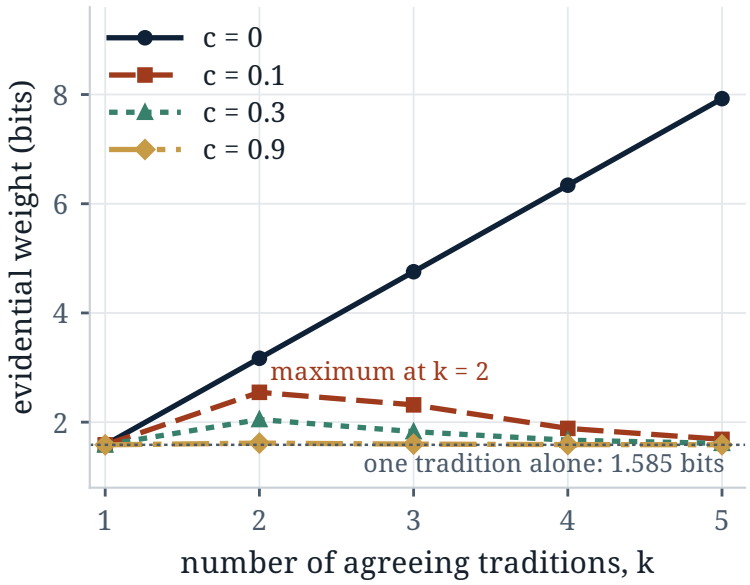

Figure 29.2: **Correlated agreement is self-limiting, and the limit binds at two sources.** Bits bought by `k` agreeing traditions under the shared-source model of Section 4.4 at `c = 0.0` (perfect independence), `0.1`, `0.3` and `0.9`. Only the `c = 0` line grows with `k`; every correlated line attains its maximum at `k = 2` and decreases thereafter toward the single-source value of 1.585 bits, marked. The `c = 0.5` column of the source table is omitted because the validated palette holds four colours and no fifth; its values lie between the `c = 0.3` and `c = 0.9` lines throughout. Modelled from the assumed rates of Section 4.2; generated by `figs/src/CCP-029_fig02.py`.

canonical form with an independent byte-hash witness takes a reconciliation false-break rate from 40.0 per cent to 0.0 per cent at a 40 per cent manipulation rate [Curzi, 2026].

The operational consequence is a rule rather than a caution:

> **A precedent citation must name the tradition, the approximate date, and the transmission path, so that a reader can judge independence for themselves. A precedent citation of the form "many traditions teach" is worth zero bits and is not admissible.**

That rule is enforced entry by entry in Appendix A, and it is why the register has a field for what the source *actually recorded* rather than for what it is usually said to mean.

29.4.5 4.5 What the refinement protects, and what it is not

Three failure modes are eliminated outright by stating the column roles every time.

It eliminates the laundering of tradition through science. The move is: an old text says something evocative; a modern paper says something superficially similar; the two are printed side by side; the reader's confidence in the paper transfers to the text. Nothing false has been asserted, which is what makes it effective and what makes it dishonest. Naming the columns blocks the transfer, because the reader has been told in advance which side is load-bearing.

It eliminates the reverse laundering. The mirror move shores up a genuinely uncertain scientific result by noting that a tradition "already knew". A contested result plus a precedent is still a contested result; precedent cannot repair an underpowered study.

It eliminates the argument from duration. Addressed as a standing clause in Section 3.7.

The refinement is **not** a claim that the precedent column is worthless, and the framework would be much poorer without it. Precedent does four jobs evidence cannot do alone.

It supplies hypotheses. The old corpus is a very large, very cheap, very strange hypothesis generator, assembled by people whose incentive was to notice things about being a person. Almost all of it is wrong, and a low hit rate is affordable because the evidence column does the filtering.

It supplies the findability argument stated in Section 3.3, which is specifically about the distinction between territory and instrument — one of the hardest distinctions in any science of the subjective.

It supplies operational detail that experiments omit. A paper reports that a practice produced an effect. A tradition reports the posture, the time of day, the duration, the cadence, the sequence and the failure signs, because it had to hand the practice to the next generation. **The evidence column tells you whether something works; the precedent column often tells you how to do it.**

It supplies the prior — precisely, and only, the 1.585 bits computed above.

29.5 5 The instrument that produces the precedent column

Section 4 assigned the precedent column a job and priced it at roughly one and a half bits. This section asks the question that pricing assumed an answer to: given that traditional observation is uncontrolled, unblinded, and preserved by a filter that does not select for accuracy, why is any of it right at all?

29.5.1 5.1 The specification sheet

The precedent column is produced by an instrument. Specifying it the way a manual specifies any instrument makes most of what follows immediate.

```
INSTRUMENT:  sustained, repeated, first-person observation,
             transmitted across generations by an institution.

SAMPLE SIZE                effectively unbounded; millions of observers,
                           thousands of years
DURATION PER OBSERVATION   a lifetime, in some traditions
BLINDING                   none, in either direction
CONTROL CONDITION          none
RANDOMIZATION              none
CALIBRATION                none against any external standard
INSTRUMENTATION            none beyond the unaided senses
RECORDING MEDIUM           memory, then text; both lossy, both editable
PUBLICATION FILTER         extreme, and not selecting on accuracy
PRE-REGISTRATION           none; hypothesis and observation are not separated
```

Read that as a specification sheet rather than as a criticism, because its two halves pull in opposite directions and the tension is the whole story.

The top of the list is extraordinary. No modern study has a sample size of millions of observers over three thousand years, and none observes a single subject for a lifetime. Duration and `n` are the two things this instrument has in overwhelming abundance and are expensive in every other research programme.

The bottom of the list is catastrophic. No control, no blinding, no calibration, no separation of hypothesis from observation. Those are exactly the devices that convert observation into inference [Platt, 1964, Popper, 1959], and their absence is what the last century of methodological work has been about [Nosek et al., 2018, Simmons et al., 2011].

29.5.2 5.2 What repetition buys, and what it does not

The tension resolves cleanly, and the resolution is the most useful thing in this section.

Repetition reduces variance. The standard deviation of a mean over `k` independent observations falls as `1/sqrt(k)`:

k	sd of mean	smallest effect resolvable above noise (2 sd)
1	1.00000	2.00000
10	0.31623	0.63246
100	0.10000	0.20000
1,000	0.03162	0.06325
10,000	0.01000	0.02000
1,000,000	0.00100	0.00200

Repetition does nothing whatever to bias. If every observer is pushed in the same direction by the same systematic influence — expectancy, social pressure, the doctrine they were taught before they looked, the fact that they were told what they would see — then that influence appears at full strength no matter how many observers there are:

```
a systematic bias b appears at magnitude b for k = 1
                         and at magnitude b for k = 1,000,000
```

The old corpus therefore has, uniquely among bodies of observation, very small variance and completely unbounded bias. That combination has a signature, and once recognised it is visible everywhere in the material:

> **The errors of the old corpus are not vague. They are specific, confident, internally consistent, reproducible on demand — and wrong.** A doctrine held by ten thousand careful observers for eight hundred years reports its false content with the same steadiness and the same wealth of circumstantial detail as its true content, because steadiness is what `k` buys and `k` is the one thing the instrument has.

This is why the corpus does not read like a body of tentative guesses. It reads like a body of settled knowledge, and it reads that way whether or not it is one. **A reader who calibrates on the corpus's *tone* will be wrong in exactly the places it matters. Tone is a measure of `k`, not of truth.**

Two independent literatures reinforce the point and are cited because they undercut a comfortable reading of the precedent column rather than support it. Introspective report is not a reliable guide to the processes producing behaviour: people confidently report causes of their own judgements that experimental manipulation shows to be wrong [Nisbett and Wilson, 1977], and self-report is systematically shaped by the question's own form and context [Schwarz, 1999]. Judgement of magnitudes is further distorted by the range and spacing of the stimuli presented [Teghtsoonian, 1971, Poulton, 1979] and by the adaptation level the observer arrives with [Helson, 1948]. **Every one of those effects is a bias in the technical sense, and every one of them is invariant under `k`.**

29.5.3 5.3 The detection floor and the operating envelope

What kind of effect can an instrument with no control detect at all?

A single observer comparing before with after has one signal available: a change larger than their own ordinary day-to-day variation. Taking that variation as one standard deviation and the difference of two such observations as `sqrt(2)`, the probability that a true standardised shift `d` produces an observed change exceeding one standard deviation is `P = 1 - Phi((1 - d)/sqrt(2))`:

```
d = 0.20  ->  P = 0.2858
d = 0.50  ->  P = 0.3618
d = 0.80  ->  P = 0.4438
d = 1.00  ->  P = 0.5000
d = 1.50  ->  P = 0.6382
d = 2.00  ->  P = 0.7602
d = 3.00  ->  P = 0.9214
```

Below `d = 1.0` a single observer is worse than a coin. Above `d = 2.0` they are reliable. For comparison, a modern two-group design at 5 per cent two-sided significance and 80 per cent power needs `n = 2 (z_{0.975} + z_{0.80})^2 / d^2 = 15.698 / d^2` subjects per group:

```
d = 0.10  ->  n per group ~ 1570
d = 0.20  ->  n per group ~  392
d = 0.30  ->  n per group ~  174
d = 0.50  ->  n per group ~   63
d = 0.80  ->  n per group ~   25
d = 1.00  ->  n per group ~   16
d = 2.00  ->  n per group ~    4
```

The traditional instrument's own `k` is enormous, so it clears the *noise* floor easily. What it cannot clear is the *attribution* floor: distinguishing the effect from everything else that changed at the same time. That requires a control, and there is none.

Combining the two constraints yields the operating envelope. **A phenomenon is inside the old corpus's range if and only if it has all four of these properties:**

```
P1  LARGE          effect size well above the observer's own baseline variability
P2  REPEATABLE     producible on demand, so the observer can re-run it at will
P3  UNAIDED        observable without instruments
P4  PROMPT         short latency from intervention to effect, so that causal
                   attribution is available without a control group
```

And the complement, which is the more useful list:

```
OUTSIDE THE RANGE, ALWAYS
  - small effects (d below ~0.5): invisible to it
  - rare effects: never accumulate enough instances per observer
  - long-latency effects: attribution fails; correlation is unrecoverable
  - anything requiring a control: dose-response, base rates, differential effect
  - anything requiring an instrument: microscopy, spectroscopy, chemistry,
    statistics
  - hidden mechanism of any kind: the instrument sees the effect, never the channel
  - population-level anything: the instrument is first-person by construction
```

P1 through P4 predict, without consulting a single modern source, which parts of the old corpus will survive checking. Section 6 tests that prediction on four readings: the memory palace, the ritual cadence, the staged laboratory process and the correspondence table are all large, repeatable, unaided and prompt. The doctrine of signatures, planetary influence on metals and the four-element theory of composition are none of those things.

Note the last exclusion, because Section 7.4 turns on it: **a tradition that reports an effect is a witness to the effect and is not a witness to its cause.** That is not a rule imposed from outside. It follows from the specification sheet.

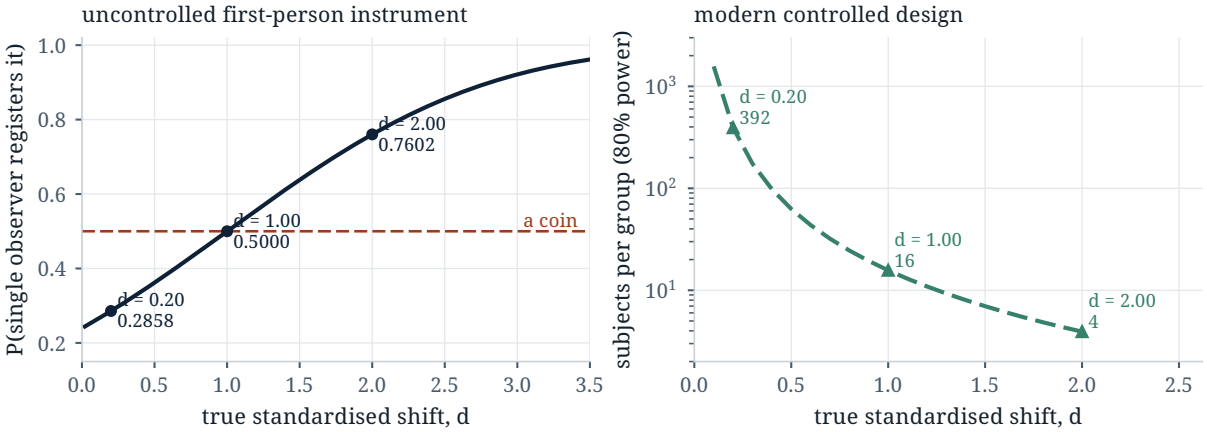

Figure 29.3: **The uncontrolled first-person instrument is worse than a coin below one standard deviation, and the modern apparatus that beats it is expensive.** Left: the probability that a single uncontrolled observer registers a true standardised shift `d` as a change exceeding their own day-to-day variation, `P = 1 - Phi((1-d)/sqrt2)`, against the 0.5 chance line. Right: subjects per group required for 80 per cent power at two-sided 5 per cent, `n = 15.698/d^2`, on a logarithmic axis. Plotted as small multiples rather than on shared axes because a probability and a sample size are not commensurable and a dual axis would be a chart error. Computed from the stated formulas; generated by `figs/src/CCP-029_fig03.py`.

29.5.4 5.4 The survivorship filter, and the fact that it has a sign

Everything above concerns what could be *observed*. A separate filter decides what gets *transmitted*, and it is the more dangerous of the two because it operates invisibly and after the fact.

We do not inherit the old corpus. We inherit what was preserved of it, and preservation selects for memorability and institutional interest, not for accuracy.

Model the filter. Let `a0` be the fraction of the original corpus that was accurate, `s_acc` the probability an accurate item survived to us, and `s_inacc` the probability an inaccurate item did. Then the accuracy of the corpus actually read is

```
a1 = a0 * s_acc / ( a0 * s_acc + (1 - a0) * s_inacc )
```

which is Bayes' theorem with survival as the observation. **The rates below are assumed and illustrative. What is not assumed is the direction of each row, which follows from the mechanism named beside it.**

a0	s_acc	s_inacc	surviving accuracy	factor	
0.30	0.02	0.10	0.0789	0.263	memorability-selecting
0.30	0.05	0.05	0.3000	1.000	neutral
0.30	0.20	0.02	0.8108	2.703	truth-selecting
0.30	0.40	0.01	0.9449	3.150	strongly truth-selecting
0.10	0.02	0.10	0.0217	0.217	memorability, poor original
0.10	0.40	0.01	0.8163	8.163	truth-selecting, poor original

Read the first and fourth rows together. **The same original corpus, run through two different preservation filters, arrives either 7.9 per cent accurate or 94.5 per cent accurate — a factor of 11.97, produced entirely by the filter and not at all by the source.**

The decisive question about any traditional claim is therefore not how old it is, how widespread it is, or how confidently it is stated. It is: what happened when the claim was wrong?

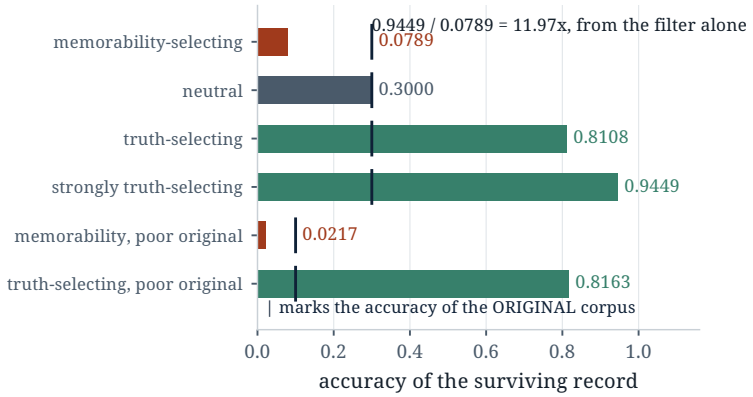

Figure 29.4: **The filter, not the source, decides what accuracy the record arrives with.** Surviving accuracy `a1 = a0 s_acc / (a0 s_acc + (1−a0) s_inacc)` for the six parameter rows of Section 5.4. The same original accuracy of 0.30 arrives at 0.0789 under a memorability-selecting filter and 0.9449 under a strongly truth-selecting one, a factor of 11.97; a poor original corpus at `a0 = 0.10` still arrives at 0.8163 if its failures were visible. The dashed line marks the original accuracy each pair started from. Modelled from the assumed survival rates stated in Section 5.4; generated by `figs/src/CCP-029_fig04.py`.

```
THE VISIBLE-FAILURE RULE

If a claim's failure was VISIBLE, PROMPT, and COSTLY to whoever relied on it,
the preservation filter selected FOR accuracy and the surviving material is
better than the original corpus.

If a claim's failure was INVISIBLE, DELAYED, or COSTLESS, the filter selected
for memorability, and the surviving material is WORSE than the original corpus.

TRUST THE OLD CORPUS IN PROPORTION TO HOW VISIBLY ITS CLAIMS FAILED.
```

That rule sorts the material immediately, along a line that has nothing to do with how mystical the material sounds.

Visible failure, therefore trustworthy: metallurgy — the alloy is brittle or it is not. Dyeing — the colour holds or it runs. Distillation — the apparatus yields or it does not. Navigation — landfall is made or it is not. Agriculture — the crop comes in or it does not. Memory technique — the list is recited correctly in front of an audience or it is not. Building — the vault stands or it falls.

Invisible failure, therefore untrustworthy: cosmology, the composition of matter, the mechanism behind any effect, the influence of remote bodies on terrestrial events, the meaning assigned to any correspondence, and every claim about what happens after death. Not because these are grander subjects, but because nothing happened to the person who got them wrong.

Note where the memory palace falls. It is a claim about technique whose failure is public, immediate and humiliating: a rhetor who forgets his speech in the forum has failed visibly. That is the strongest possible position on the filter, and it is why the method of loci is the best-preserved piece of practical psychology in the Western tradition.

29.5.5 5.5 The three preservation biases

The filter has three components, each leaving a different signature.

B1 · Memorability. Material survives transmission in proportion to how easily it is remembered and re-transmitted — which is to say in proportion to `eta`, the conversion of exposure into durable storage [Curzi, 2026a]. Rhyme, metre, numerical symmetry, striking imagery and narrative all raise `eta` substantially, and `eta` is completely orthogonal to truth. A well-turned false doctrine outcompetes an awkwardly stated true observation, every time, and the competition runs for centuries.

The signature of B1 is that the surviving material is unusually *tidy*. Sevens and twelves and fours. Perfect symmetries. Complete tables with no gaps. **Reality does not produce complete tables with no gaps; transmission does, because incomplete tables are harder to remember and get completed in transit.**

B2 · Institutional interest. Material survives in proportion to whether some institution paid for its copying, and that institution had purposes — liturgical, legal, medical, political, pedagogical. The surviving corpus is therefore not a sample of what people believed; it is a sample of what institutions funded. This is the same selection Scott [1998] documents for administrative records generally: what is legible to an institution is what the institution keeps.

The signature of B2 is over-representation of the doctrinal, the canonical and the authoritative, and under-representation of the dissenting, the local and the practical.

B3 · Copyability. Text copies; apparatus does not. Doctrine copies; tacit skill does not. **We inherit the theory and lose the technique — which is exactly backwards from what the specification sheet says the instrument was good at.**

This is the cruellest of the three and the least often stated. The old corpus was strongest at procedure — large, repeatable, unaided, prompt, visibly failing — and procedure is precisely what a manuscript preserves worst. The alchemical corpus is the clearest case: a great deal of the theory, which was wrong, and comparatively little of the bench practice, which was largely right. **The filter did not merely reduce the corpus's accuracy. It inverted the corpus's own ranking of its strengths.**

29.5.6 5.6 Survivorship stated at full strength

Six consequences follow, and each constrains how a precedent citation may be used.

1. **The record over-represents the doctrinal and under-represents the practical** (B2 and B3 together). The corpus's strongest material — procedure — is its most poorly transmitted.
2. **The record over-represents the tidy** (B1). Complete tables, round numbers, perfect symmetries. **A striking numerical pattern in a traditional source is evidence about transmission before it is evidence about the world.**
3. **Whole traditions are missing, and not at random.** Losses concentrate in the oral, the local, the suppressed and the linguistically isolated. Library destructions removed specific collections rather than random samples. **The traditions with the strongest claim to independence — the ones worth the most bits under Section 4.4 — are precisely the ones the record preserved worst, because independence and marginality are close to the same property.**
4. **The record has been retrospectively harmonised**, and this is the specific hazard for the precedent column. Later editors reconciled sources; early-modern compilers assembled Egyptian, Hellenistic, Jewish and Christian material into a single apparent tradition deliberately, as a scholarly and theological programme. **Apparent cross-tradition agreement is therefore frequently an artefact of editing, and Section 4.4's collapse applies at full force: at `c = 0.1`, five agreeing traditions buy 1.685 bits against the 7.925 that genuine independence would have bought — 6.24 bits lost to editorial tidiness.**
5. **Attribution is unreliable.** Pseudepigraphy was normal practice rather than fraud: attributing a work to an ancient authority was how a work claimed standing. A date attached to a name is generally a claim about authority, not about chronology, and the

independence audit must use the date of the earliest verifiable attestation of the specific claim. That requirement does the decisive work in the rejection of Section 7.5.

6. **Survivorship inside a tradition is as strong as survivorship between traditions.** Within any surviving corpus the successful practitioner's account survives and the unsuccessful practitioner's does not. **Every traditional literature therefore reads as though its methods work, and would read that way even if they did not.**

None of this makes the precedent column worthless. It makes the precedent column exactly as valuable as Section 4 priced it: a real term in the sum, a small one, and one that must be audited item by item rather than credited wholesale.

29.6 6 Four readings of traditional artefacts

Four readings. Each states what the artefact literally is, what the tradition got right, what it got wrong, and where the item falls on the P1–P4 envelope and the visible-failure rule. **The literal-reading rule used here — that a two-column table is a binary relation, a diagram of nodes and paths is an undirected graph, an assignment of labels to categories is a partition, and a letter-value scheme summed over a word is a hash — is the corpus's own, and the audit it supports elsewhere reaches a structurally parallel distribution of verdicts: seven MAPS, two SPLIT, one RENDERING and three REJECTED across thirteen entries [Curzi, 2026].** There is no inference in any of those readings, and none of them can be wrong in the way a theory can be wrong.

29.6.1 6.1 Correspondence systems as relational graphs

What the tradition got right. Three things, all engineering.

First, a correspondence table is a category assignment, written down, fixed, and made auditable. The surplus functional cannot be applied to anything until the `N` categories have been named [Curzi, 2026]. **The tradition that produced correspondence tables was performing, in a different notation, the mandatory first step of the procedure this framework specifies.** That is a description of what the artefact does, not a compliment.

The effective count that step produces in this framework is `N_eff = 1 + (N−1)u`, and **that quantity is named here explicitly because the framework uses more than one effective count and confusing them is a real hazard: `1 + (N−1)u` is a linear interpolation between 1 and `N` and is not a Hill number**, whereas `1/HHI` and `exp(H)` are Hill numbers of order two and one [Hill, 1973, Jost, 2006] and are the grounded objects the literature supports.

Second, they solved the addressing problem, and solved it as a designer would. A flat set of 78 elements costs `log2(78) = 6.285` bits to address, and every one of those bits must be memorised as an unstructured fact. Give the same set a product structure — 22 elements plus four suits of fourteen — and the address decomposes: one bit for which part, then `log2(22) = 4.459` or `log2(4) + log2(14) = 5.807`. **The structured address is slightly longer in bits and vastly shorter in effort**, because its components are independently memorable and independently checkable. That is a real information-theoretic trade [Shannon, 1948, Cover and Thomas, 2006] and a filing-system designer makes the same choice for the same reason. The relevant human constraint is the small span of immediate memory [Miller, 1956], which is what makes an unstructured 6.3-bit address expensive and a two-part address cheap.

Third, they built redundancy into the index. Each element carries several attributes — a number, a letter, a colour, a metal, a direction, a day — and any one retrieves the element. This is a multiply-keyed index, and its purpose is what a multiply-keyed index's purpose always is: retrieval survives the loss of any single key. In storage-law terms, redundant keying raises `eta` and lowers `delta` on the retrieval path [Curzi, 2026a].

What the tradition got wrong, and it is one error repeated everywhere. The tables were read as causal graphs rather than as indexes. That an element is filed under a planet is a fact

about the filing system; it was routinely taken as a fact about the planet. **This is the single most consequential error in the old corpus, and it has a name: the category error, treating an index as a cause.** The index is real, useful and precisely specifiable. The causal reading attached to it is none of those.

Envelope check. As a mnemonic and retrieval technology: P1 large, P2 repeatable, P3 unaided, P4 prompt — inside the envelope, and visible failure, since a mnemonic system that does not retrieve fails in front of witnesses. As a causal claim about planets and metals: P4 fails outright, failure is invisible, and the material accordingly did not survive contact with measurement.

29.6.2 6.2 Memory palaces as spatial storage

What the artefact literally is. An addressing scheme that uses a familiar spatial sequence as the key space. Items are bound to loci; retrieval is a walk. The technique is attested from classical antiquity — the *Rhetorica ad Herennium* is the standard early source — and its transmission through the medieval and early-modern periods, where it became entangled with the correspondence systems of Section 6.1, is traced in Yates's *The Art of Memory* (1966). **That work carries no bibliography key here; see Section 3.6 and Appendix B.**

The storage-law reading, and it is a category-2 borrowing (Section 3.4): the technique is a joint intervention on both parameters of the same first-order difference equation [Curzi, 2026a, Elaydi, 2005].

```
Q_{t+1} = (1 - delta) Q_t + eta S_t - C_t

eta RAISED     encoding is elaborative -- the item must be transformed into a
               vivid image and bound to a place, which is far more processing
               than rehearsal
delta LOWERED  the retention medium is spatial memory, which is durable, and the
               sequence of loci is itself already stored and does not decay with
               the material bound to it
C RAISED       building the palace is real up-front cost
```

The tradition's own doctrine — invest heavily up front in the image and retrieval is free — is the statement that raising `eta` at the cost of raising `C` is worth it whenever the retention horizon is long. That conclusion was arrived at by rhetoricians who had to deliver a two-hour speech from memory.

Illustrative parameterisation, badged: the constants below are assumed, not measured, and are chosen to show the shape of the trade rather than to quantify anyone's memory. A single study session with `Q_0 = eta S` at `S = 1`, then free decay:

```
rote repetition   eta = 0.20   delta = 0.35/day   half-life  1.61 days
method of loci    eta = 0.70   delta = 0.06/day   half-life 11.20 days

    day        loci        rote      ratio
      0      0.7000    0.200000        3.5x
      1      0.6580    0.130000        5.1x
      3      0.5814    0.054925       10.6x
      7      0.4539    0.009804       46.3x
     14      0.2944    0.000481      612.5x
     30      0.1094    0.000000    224,131x
```

The structure of the advantage is the point. At day zero the loci route is only 3.5 times better; by day fourteen it is six hundred times better. **The gain is almost entirely in `delta`, not in `eta`, and it compounds.** Raising `eta` alone gives a fixed multiplier at every horizon; lowering

`delta` gives a multiplier that grows with the horizon. Beyond about thirty days the pure exponential model stops being meaningful — real retention curves are not single exponentials and flatten into a long tail — so the day-30 ratio should be read as "the rote trace is gone" rather than as a number. **That is a limit of the model's domain and is stated as one** (Section 13.6).

The evidence column. This is one of the rare places where the old corpus's own technique has been taken into the laboratory and held up: superior memorisers are distinguished by spatial mnemonic strategy rather than by general ability or gross brain structure, and training naive subjects in the technique produces large and durable gains in recall. **The two studies concerned are named in Appendix B without keys** (Section 3.6), and **no effect size is quoted from either, because none was verified for this paper**; the direction and the qualitative finding are what is asserted.

Envelope check. P1 large, P2 repeatable, P3 unaided, P4 prompt — all four. Visible failure: maximal. **This is the best-positioned item in the whole corpus on every criterion Section 5 defines, and it is correspondingly the item that survived checking most completely. That is not a coincidence; it is the prediction of Sections 5.3 and 5.4 coming true.**

What the tradition got wrong. One thing, arriving late: the early-modern fusion of the palace with correspondence and cosmological schemes, on the theory that a palace built to mirror the structure of the universe would confer understanding of the universe rather than merely recall of its contents. It does not. The technique stores what is put in it. **Addressing adds no information** — the same constraint that governs the addressing architecture of the neighbouring paper [Curzi, 2026x], where targeting and editing are shown to be separable functions and the address carries no cargo of its own.

29.6.3 6.3 Ritual as periodic forcing

What the artefact literally is. A fixed observance repeated on a fixed cadence is a periodic forcing function applied to a system with retention. **This is a category-2 borrowing** and the result is a theorem about the difference equation, not about liturgy.

For a linear time-invariant store driven with a fixed long-run average rate `R`, the long-run average of `Q` is the DC gain times the mean input [Curzi, 2026a, Oppenheim et al., 1996]:

```
mean Q = R / delta       EXACTLY, and independently of how the input is scheduled.
```

That is not an approximation, and it kills the naive version of the cadence claim before any bridge is built. **Spreading a fixed total input evenly over time does not raise the average level of the store at all. What it changes is the ripple — and therefore the minimum.**

Computed in periodic steady state, dosing `R T` units every `T` periods so the long-run rate is `R = 1.0` per period, with `Q_max = RT/(1−(1−delta)^T)` and `Q_min = Q_max (1−delta)^{T−1}`:

```
delta = 0.10 ; mean Q = 10.000 in every row, exactly

  T    dose     Q_max    Q_min      mean    Q_max/Q_min   Q_min/mean
  1     1.0    10.000   10.000    10.000          1.000       1.0000
  2     2.0    10.526    9.474    10.000          1.111       0.9474
  3     3.0    11.070    8.967    10.000          1.235       0.8967
  7     7.0    13.418    7.131    10.000          1.882       0.7131
 14    14.0    18.153    4.614    10.000          3.934       0.4614
 30    30.0    31.328    1.476    10.000         21.231       0.1476
 90    90.0    90.007    0.008    10.000      11814.536       0.0008
```

At a ninety-period interval the store spends nearly the whole cycle at essentially zero and then spikes to nine times its own mean, and the average is identical to the daily case. **Everything cadence buys is bought at the floor, and the floor is what matters whenever there is a threshold.** Fraction of the cycle at or above a threshold, same system:

```
delta = 0.10, mean Q = 10.0
threshold 5.0:   T=1 -> 1.000  T=7 -> 1.000  T=30 -> 0.600  T=90 -> 0.311
threshold 8.0:   T=1 -> 1.000  T=7 -> 0.714  T=30 -> 0.433  T=90 -> 0.256
```

What the tradition got right. Two things beyond the cadence itself.

First, invariance of the input. Ritual is characterised by resistance to modification, and the anthropological account that makes invariance constitutive of the form rather than incidental to it is Rappaport's *Ritual and Religion in the Making of Humanity* (1999), **named without a key; see Appendix B.** In the storage-law reading this is a second and distinct engineering decision: **the tradition applied a low `delta` not only to the store but to the forcing function itself.** A drifting input to a low-pass filter produces a drifting fixed point; an invariant input produces a stable one. The traditions that survived are the ones whose input did not drift, and the mechanism used to prevent drift — declaring the form unmodifiable — is the right mechanism for the problem.

Second, the doctrine that a small observance kept beats a large one abandoned. That is the floor result of the table above, stated in one sentence several centuries before anyone wrote down a transfer function.

What the tradition got wrong. The account of *why*. Every tradition supplied a mechanism for its cadence; the mechanisms are cosmological and are the part that did not survive. **The schedule was right and the reason given for it was wrong, which is the characteristic signature of a P1–P4 phenomenon carried by an instrument that cannot see mechanism.**

Envelope check. The cadence itself: P1 large, P2 repeatable, P3 unaided, and P4 only partially, since the effect of lapsing is delayed by the store's time constant — which is why the cadence took centuries to settle rather than a generation. Visible failure: moderate. An institution whose cadence is wrong decays, but slowly, and the decay is attributed to other things.

29.6.4 6.4 Alchemical operations as staged process control

This is the reading that most rewards being taken literally, and the one where the survivorship filter did the most damage.

What the artefact literally is. The alchemical operations — calcination, dissolution, separation, conjunction, putrefaction or fermentation, distillation, coagulation, in the seven-stage presentations — are unit operations, the same unit operations that appear in a chemical engineering textbook under mostly the same names, because chemistry inherited them directly and without interruption. So is the apparatus: the alembic, the retort, the *balneum mariae* — the water bath, still standard laboratory equipment.

Read as process control, the corpus contains four things that are simply correct.

1. A process has ordered stages, and the order is not permutable. This is a real and nontrivial engineering fact carrying real information, and the quantity is computable:

```
n stages -> n! orderings -> log2(n!) bits to specify the correct one

 3 stages ->             6 orderings ->  2.585 bits
 4 stages ->            24 orderings ->  4.585 bits
 5 stages ->           120 orderings ->  6.907 bits
 7 stages ->         5,040 orderings -> 12.299 bits
12 stages ->   479,001,600 orderings -> 28.835 bits
```

A correct seven-stage sequence is 12.299 bits of hard-won process knowledge that exists nowhere in the individual stages and can only be obtained by failing at the other 5,039 orderings. That is the part the tradition preserved accurately, and it is exactly the part a modern reader dismissing the corpus as superstition throws away.

2. Temperature must be controlled and graded. The obsessive attention to degrees of heat, to the water bath as a means of holding a bounded temperature, and to the difference between the heats appropriate to different stages, is correct process engineering.

3. Time under condition is a process variable. Long digestions at low heat produce results short intense heating does not. This is the same statement as Section 6.3's, arrived at independently in the laboratory rather than the chapel, **and its independence is worth noting, because separate arrivals are the one thing the precedent column actually pays for** (Section 4.4).

4. Purification is iterative and has diminishing returns. Repeated distillation improves purity by a decreasing increment per pass, and the concavity is the same shape as the framework's other laws [Curzi, 2026].

What the tradition got wrong, and by how much. The compositional theory. The four elements and the three principles are not a correct account of what matter is made of, and the transmutation of base metal into gold is not achievable by any chemical operation. The size of that error is computable, and computing it is more useful than sneering at it:

```
nuclear binding energy per nucleon   ~  8 MeV  =  8,000,000 eV
typical covalent bond                ~  4 eV

ratio  =  2,000,000        log10 ratio = 6.30
```

The alchemists were attempting a nuclear operation with chemical tools and were short by a factor of two million. No furnace, no reagent, no duration and no number of repetitions could have closed that gap.

Two honest riders. **First, the goal was not absurd, only unreachable by the means available:** transmutation of one element into another is real physics, performed routinely at energies six orders of magnitude above chemistry and at costs that make the product worthless as a commodity. **Second, the failure of this claim was invisible in the short term and delayed in the long term** — a practitioner could always suppose the process incomplete — which is precisely the condition Section 5.4 identifies as producing preservation without correction. The claim that was wrong is the claim whose failure could not be seen, and that is not a coincidence either.

Envelope check. The unit operations: P1 large, P2 repeatable, P3 unaided, P4 prompt; visible failure maximal — the distillate is pure or it is not. Inside the envelope, filter positive, survived. The compositional theory: P4 fails, failure invisible, filter negative, did not survive.

And here is the survivorship inversion in its purest form. The part that was right — the bench practice, the graded heats, the sequence, the feel for when a stage is complete — is tacit skill, and tacit skill does not copy (bias B3). The part that was wrong — the theory — is text, and text copies. **The wrong half was inherited at high fidelity and the right half at low fidelity, and the difference has nothing to do with which half was true.**

29.6.5 6.5 The error taxonomy, with a control case

Five error types account for most of the old corpus's failures.

T1 · Index read as cause. Section 6.1. The commonest and the most consequential.

T2 · Effect attributed to the wrong channel. The observation is genuine and the mechanism assigned is not the operating one. Section 6.3's cosmological accounts of cadence.

T3 · Scale over-extension. A relation holding locally is asserted universally. The four elements are a serviceable *phenomenological* classification of the states of matter available to unaided observation and become false the moment they are asserted as a compositional theory.

T4 · Completion of the table. Bias B1 with a name. Gaps in a scheme are filled to make it memorable, and the filled entries are indistinguishable in the surviving text from the observed ones. **Every complete symmetric table in the old corpus should be assumed to contain interpolated entries, and there is generally no way to tell which.**

T5 · The unfalsifiable escape. A claim is stated so that failure is always attributable to the practitioner rather than to the claim. This is the error that keeps all the others alive, because it disables the visible-failure filter that would otherwise have removed them. **T5 converts a truth-selecting filter into a memorability-selecting one — it moves an item from the 94.5 per cent row of Section 5.4's table to the 7.9 per cent row.** It is the same manoeuvre Popper [1959] and Lakatos [1970] identify as the protective belt around a degenerating programme.

The control case: the doctrine of signatures. The doctrine holds that the appearance of a plant indicates its medicinal use — that a plant resembling an organ treats that organ. It was elaborated by Paracelsus and given systematic presentation in Giambattista della Porta's *Phytognomonica* (1588), and it persisted in herbal writing for centuries. Run through this paper's apparatus:

```
P1 LARGE        NO   the claimed effects are mostly small and slow
P2 REPEATABLE   NO   illness does not recur on demand
P3 UNAIDED      YES  the resemblance is visible; the only criterion it passes
P4 PROMPT       NO   herbal effects are delayed and confounded

VISIBLE FAILURE?     NO. A patient who does not recover is attributed to severity,
                     timing, preparation, or fate. T5 is available at every failure.

MEMORABILITY         MAXIMAL. A single rule that generates its own content,
                     requires no data, is instantly teachable, and is delightful.

PREDICTED FATE       preserved for centuries, and false.
ACTUAL FATE          preserved for centuries, and false.
```

The doctrine of signatures is the control experiment for this paper's method: an item scoring maximum on memorability and minimum on every accuracy-selecting criterion, which did exactly what the model predicts. It is also why the model cannot be cheated. The doctrine has famous apparent hits — the walnut and the brain, lungwort and the lung — and each is a false positive produced by a rule that generates a resemblance for everything and is therefore never wrong in advance and never right by design.

29.7 7 Four bridges worked to their verdicts

29.7.1 7.1 The mapping procedure

Five inherited steps, with three added by this paper's refinement. The added steps are marked.

```
  STEP 1   IDENTIFY CORE STRUCTURES on each side: mechanisms, conservation laws and
           measured relations on the (+1) side; practices, stages, cosmological
           elements and recorded phenomenology on the (−1) side.
  STEP 2   LOOK FOR STRUCTURAL MATCHES. Not the words -- the structures.
  STEP 3   TEST THE MAPPING with the three-state validation.
  STEP 4   GENERATE PREDICTIONS on both sides.
  STEP 5   TEST PREDICTIONS. Design the experiment or the practice; revise on results.

[ STEP 0   FIX THE (+1) READING FIRST, IN WRITING, BEFORE OPENING THE (−1) COLUMN.  ]
[          A large enough corpus confirms anything asked of it.            ADDED    ]

[ STEP 2b  GRADE THE CORRESPONDENCE: isomorphism / homomorphism / analogy /         ]
[          metaphor. Below homomorphism, stop and record the rejection.    ADDED    ]

[ STEP 6   AUDIT INDEPENDENCE AND ASSIGN COLUMN ROLES IN WRITING. Name the          ]
[          tradition, the date, and the transmission path; estimate c.     ADDED    ]
```

Step 6 is the one that gets skipped, and skipping it is what produces work that reads well and cannot be checked. It costs one paragraph per bridge. Appendix A is, in effect, forty-three executions of Step 6.

29.7.2 7.2 The seven errors

Five errors are inherited; two are added here because the biological material invites them specifically.

E1 · False cognates. Words that sound the same and mean different things. *Energy* in physics is a conserved quantity with units of joules; *energy* in most contemporary spiritual usage is a mood word. **The most reliable indicator of a false cognate is that one side of the pair has units and the other does not**, which is why the dimensional audit of Section 13.1 is the first check a reader should run on any claim here.

E2 · Confirmation bias. Counting the hits and not the misses. Step 0 exists to prevent it, and the modern statement of the same hazard is the multiplicity of undeclared analytic choices [Gelman and Loken, 2013, Simmons et al., 2011].

E3 · Category error. Mapping across incompatible categories — treating consciousness as a substance, treating a probability as a force, treating an index as a cause.

E4 · Reductionism. Claiming one side is "nothing but" the other. A valid mapping preserves the integrity of both descriptions; the general argument that higher-level descriptions are not eliminable is Anderson [1972]'s.

E5 · Mystification. Using the language of one side to obscure rather than illuminate. The test is that a correspondence that cannot be stated clearly may not be valid.

E6 · Scale transfer without a scale check. ADDED. A mechanism real at one scale is imported to another where its magnitude is negligible. This is the commonest error in writing about physics in biology, and it is always caught by computing one ratio. The Casimir pressure between conducting plates falls as `a^-4` [Casimir, 1948], and has been measured at the separations where it is appreciable [Lamoreaux, 1997, Mohideen and Roy, 1998]:

```
1.3e5 Pa at 10 nm   ->   13 Pa at 100 nm   ->   1.3e-3 Pa at 1 um
                                            ->   1.3e-15 Pa at 1 mm
```

Twenty orders of magnitude across an interval a careless sentence would cross without noticing. The corpus's own treatment of the speculative physical margin reaches the same verdict by a different route, reporting a decoherence time of `1.98e-17 s` for a warm wet 310 K system against a 1 ms neural event — a shortfall of `5.04e13`, and `5.04e7` even granting a `1e6` protection factor [Curzi, 2026aa].

E7 · Attributing a real effect to the wrong channel. ADDED. The effect is genuine and measured; the mechanism assigned is not the one operating. **This error is more dangerous than a plain false claim, because the observation keeps coming out right and keeps appearing to confirm the wrong mechanism.** Section 7.4 is a worked instance. **The diagnostic is always the same: name the competing channels and state the experiment that would separate them.**

29.7.3 7.3 Bridge 1 — cadence. Worked, and ESTABLISHED

Step 0. Fix the evidence reading first. Section 6.3's result: for a decaying store feeding a threshold, the scheduling of a fixed total input controls the fraction of time the threshold is met, and short intervals relative to the time constant dominate long ones. **Intensity buys the peak; cadence buys the floor.** That is a theorem about the model.

There is also a measured empirical result of the same shape, and it is among the most replicated findings in experimental psychology: **the spacing effect.** The retention decay curve was described by Ebbinghaus in 1885, and the modern quantitative synthesis of the distributed-practice literature finds that spaced presentations reliably outperform massed ones for the

same total study, and that the optimal gap grows with the retention interval being targeted. **That last clause is the model's own prediction: the optimal interval scales with the time constant.** Both works are named in Appendix B without keys (Section 3.6).

Steps 1–2. Core structures and the match.

```
(+1) side                              (−1) side
─────────                              ─────────
a store with retention (1 − delta)     an observance held to decay if lapsed
an input applied at intervals T        a fixed office at fixed hours
a threshold on Q                       a required standard of practice
optimal T scales with 1/delta          intervals fixed by day, week, and year
```

Step 2b. Grade it. Homomorphism. Not isomorphism: the traditions did not write down a decay constant and did not derive an interval. They report the *schedule* and the *consequence of lapsing*, which is two of the four structural elements, mapped without residue. Homomorphism clears the threshold.

Step 3. The precedent reading, opened only now, stated as specifically as the independence rule requires: the Rule of St Benedict, c. 530 CE, prescribes eight daily offices at fixed hours and treats the cadence rather than the intensity of any single office as load-bearing; Jewish daily prayer is structured in three fixed services, and the seven-day sabbath cycle is among the oldest continuously observed fixed cadences in the record; Islamic *salat* is five daily prayers at times fixed by the sun; Vedic *sandhyavandanam* is performed at the junctions of the day; Buddhist monastic codes fix a daily schedule and a fortnightly recitation of the rule.

Independence audit. These are not independent. The Abrahamic three share a lineage directly, and Indo-European and Near Eastern contact is continuous across the period. Realistically `c` is well above 0.3, so by Section 4.4 the whole precedent column here is worth approximately 1.6 bits — one tradition's worth. **It is stated in full and credited at one tradition's weight, because that is what it is worth.**

What it does record, and what no evidence source records, is the operational detail: which hours, what to do when an office is missed, how a lapse is repaired, and the explicit doctrine that a short observance kept is worth more than a long one abandoned. **That is the "how to do it" payload of Section 4.5.**

Step 4. The prediction. For a practice whose benefit decays with time constant `tau = 1/delta`, moving from interval `T` to interval `T/2` at the same total input raises the floor and leaves the mean untouched; and the effect of interval on outcome should be large where a threshold is involved and near zero where it is not. That is falsifiable and it has been tested in the memory domain, where it holds.

Step 5 / 0p. The contra-proof. The two integrate cleanly. The evidence side does not have to claim that Benedict computed a time constant; the precedent side does not have to claim its offices were about memory retention. Both describe the same structural fact — a decaying store driven periodically — from opposite ends, and neither has to swallow a falsehood to sit beside the other.

```
C1 STRUCTURAL CORRESPONDENCE     PASS   homomorphism; four structures, three map
C2 PREDICTIVE POWER              PASS   optimal interval scales with tau; tested
C3 PRACTICAL UTILITY             PASS   sets cadence on the evidence side; explains
                                        the tradition's own emphasis on the other

STATUS: ESTABLISHED.
COLUMN ROLES: (+1) evidence -- the distributed-practice synthesis, and the
                   storage law's periodic-forcing result (CCP-007).
              (−1) precedent, ~1.6 bits, owing to high shared-source probability.
```

What is established is the structural bridge, not a historical claim. This paper does not assert that liturgical hours were tuned for retention; that is an unfalsifiable statement about

the intentions of people who left no record of intending it. What is asserted is that the schedule they kept has the form the model recommends.

29.7.4 7.4 Bridge 2 — vibration as cellular input. Worked, and GRADED

This bridge demonstrates the most useful thing the method does, which is not accepting or rejecting but *grading*: separating the part of a bridge that holds from the part that does not, at the exact seam.

Step 0. Fix the evidence reading first. Mechanotransduction is real, established and prize-recognised. Mechanically gated cation channels of the PIEZO family were identified as essential components of mechanically activated currents (Coste and colleagues, *Science*, 2010), and the 2021 Nobel Prize in Physiology or Medicine was awarded for receptors for touch and temperature. Force applied at the cell surface transmits through the cytoskeleton to the nucleus, stretches chromatin and upregulates transcription (Tajik and colleagues, *Nature Materials*, 2016). Ultrasound has been used to activate specified channels — sonogenetics — in *C. elegans* (Ibsen and colleagues, *Nature Communications*, 2015) and with a human channel (Duque and colleagues, 2022). Cochlear hair cells are biology's own existence proof that exquisitely sensitive mechanical reception is buildable in tissue. **None of those works carries a citation key here; all are named in Appendix B, per Section 3.6.**

Sound is mechanical. There is therefore a real, established pathway by which a pressure wave becomes a cellular signal, and that is a strong evidence reading.

Steps 1–2b. The candidate bridge and its grade. Candidate: *sustained vocal and percussive practice acts on the body through mechanotransduction.* On the evidence side: an oscillating mechanical stimulus, a gated channel with a force threshold, an ionic current, a downstream cascade, a transcriptional response. On the precedent side: sustained tone production, a required duration, a reported change in bodily and mental state, a transmitted technique.

Match at the coarse grain — mechanical oscillation is an input the body converts into a state change — is homomorphic and clears the threshold. Match at the fine grain — this particular channel family mediates this particular practice — has no counterpart at all on the precedent side, because that side records no mechanism. It records a state change.

Step 3. The precedent reading. Vedic recitation, transmitted orally with exacting phonetic discipline over millennia; Christian plainchant under the canonical hours; Tibetan Buddhist overtone chanting; Sufi *dhikr*; West African and Afro-diasporic drumming traditions; Australian Aboriginal drone practice. **These are substantially more independent than the cadence set of Bridge 1** — the Australian and West African instances in particular have no plausible shared source with the Indo-European ones — so c is genuinely lower and the precedent is worth more. **It is still precedent: on the toy model, of order two to three bits, against roughly twenty for the prize-grade evidence.**

What every one of them records is the same coarse claim: sustained vocalisation at length changes bodily state reproducibly. **None records a channel, a current, or a transcript.**

Steps 4–5. The prediction, and the competing channel. Here the method earns its keep, because there is a measured result assigning the effect to a different mechanism entirely. Recitation of the Latin rosary and of a yoga mantra both brought respiration to approximately six breaths per minute — a period of $10.0\ \mathrm{s}$, a rate of $0.100\ \mathrm{Hz}$ — and enhanced baroreflex sensitivity (Bernardi and colleagues, *BMJ*, 2001; named in Appendix B). **The dominant measured channel for chant is the breathing pattern it enforces**, acting on autonomic cardiovascular control. Add the obvious further channels: the social setting, the attentional demand, the postural requirement, and expectancy [Rosenthal and Jacobson, 1968].

The honest statement of the bridge therefore splits at a seam, and the seam is exactly where error E7 lives:

- **ESTABLISHED:** mechanical force is a real input to cellular signalling and to transcription. This is evidence, and it is strong.

- **ESTABLISHED:** sustained chant produces measured autonomic effects, and the identified channel is respiratory entrainment.
- **SPECULATIVE — and it is marked speculative in this sentence, which is where the claim is made:** that the state changes traditions attribute to chant are mediated to any material degree by PIEZO-family mechanotransduction is a speculative bridge, unsupported by any measurement known to this author, and in competition with at least four better-supported channels.

Step 6. Column roles. Evidence: mechanotransduction, very strong; respiratory entrainment, strong. Precedent: broad, partially independent, worth a few bits — and it attests the *phenomenon*, not the *mechanism*. **A tradition that reports an effect is a witness to the effect and is not a witness to its cause, because nothing in the tradition's instrument could have distinguished causes.** That sentence disposes of a large fraction of the adjacent literature.

The separating experiment, stated so it can be run. Hold the acoustic exposure constant and vary the breathing pattern independently — deliver the same acoustic stimulus to a passive listener whose respiration is paced to a different rate, against a vocaliser producing it. **If the effect survives removal of the breathing pattern, the mechanical channel is in play. If it does not, error E7 is confirmed and the bridge is rejected at the fine grain.**

```
C1 STRUCTURAL CORRESPONDENCE   PASS at coarse grain (homomorphism)
                               FAIL at fine grain (-1 records no mechanism)
C2 PREDICTIVE POWER            PASS -- the separating experiment above
C3 PRACTICAL UTILITY           PASS

STATUS: ESTABLISHED at the coarse grain. SPECULATIVE at the fine grain, so marked.
```

29.7.5 7.5 Bridge 3 — "528 Hz repairs DNA". Worked, and REJECTED

A method that has never rejected anything is not a method. This bridge is rejected here at length, in print, and it is chosen because it sits one inch from the corpus's own subject matter. This series is about sound and about genomic material. If the framework cannot say clearly why the most popular claim in that intersection fails, it has no business making claims of its own.

Step 0. Fix the evidence reading first — and there is nothing to fix. The claim is that a tone at 528 Hz repairs, restores or otherwise beneficially modifies DNA. **Stated with the uncertainty on the record: no systematic survey of the literature was conducted for this paper and it is not asserted that no relevant publication exists; what is asserted is that no replicated, peer-reviewed result establishing any such effect is known to this author, and the claim is treated accordingly.** The absence of an evidence entry is dispositive under the binding rule of Section 3.1 — with no evidence column there is no established bridge, whatever the precedent column says. But the bridge fails for four further reasons, each computable, and computing them is more useful than citing an absence.

Failure 1 — the precedent column is not old, and fails the precedent test outright. The nine "Solfeggio frequencies" (174, 285, 396, 417, 528, 639, 741, 852, 963 Hz) are routinely presented as an ancient system. They are not. The medieval material is real: Guido of Arezzo's eleventh-century solmisation took its syllables from the hymn *Ut queant laxis*. But medieval solmisation assigns no frequencies to anything. **It is a system of relative intervals, taught on a movable hand, in a period with no absolute pitch standard** [Barbour, 1951, Lindley and Turner-Smith, 1993]. The specific numerical values were produced in the 1990s by a numerological reduction applied to a passage in the Book of Numbers, and were popularised in Horowitz and Puleo's *Healing Codes for the Biological Apocalypse* (1999).

A precedent entry must carry independent arrival and preservation. This one carries a 1990s construction wearing a medieval costume. It buys zero bits — not few, zero.

Failure 2 — the number is not well-defined without a reference pitch, and none is given. A frequency in hertz for a named musical pitch is a convention. 528 Hz is approximately C5

under a tuning near A4 = 440 Hz and is a different note entirely under A4 = 432 Hz, A4 = 415 Hz, or any of the pitch standards actually in use across the period the claim invokes [Barbour, 1951]. **A claim that a specific molecular process responds to a specific hertz value must specify the standard, and if the value exists only under a convention adopted in the twentieth century, the claim cannot also be ancient.** This is a self-contradiction internal to the claim and requires no measurement to expose.

Failure 3 — the spatial scale is wrong by nine orders of magnitude. This is the decisive computation. A propagating wave can only impose spatial structure at scales comparable to its wavelength. In soft tissue, taking the speed of sound as approximately 1540 m/s [Rossing et al., 2002]:

```
lambda(528 Hz, soft tissue) = 1540 / 528 = 2.9167 m

ratio to a cell      (10 um)    = 2.917e5
ratio to a nucleus   (6 um)     = 4.861e5
ratio to a base pair (0.34 nm)  = 8.578e9
```

In air, at 343 m/s, the wavelength is 0.6496 m and the ratio to a base pair is `1.911e9`.

The wave is roughly nine billion times longer than the object it is claimed to act on selectively. Across an entire nucleus the pressure field is, to an extraordinarily good approximation, spatially uniform. There is no gradient at the scale of a gene, a codon or a base pair. Whatever a 528 Hz field does to a nucleus it does to the whole nucleus at once, identically, and it therefore cannot select a sequence. **This is not an argument that acoustic fields do nothing to cells — Bridge 2 established that they do. It is an argument that they cannot do anything *sequence-specific* by direct spatial action**, which is the gap the companion papers are devoted to [Curzi, 2026x,y].

Failure 4 — the energy scale is wrong by eleven orders of magnitude, and the frequency scale by thirty-five octaves. Two independent numbers, both computed. A single acoustic quantum at 528 Hz carries `h f = 2.18e-12 eV`; body-temperature thermal energy is `kT = 0.0267 eV` at 310 K:

```
h f / kT   at 528 Hz, 310 K   =   8.17e-11
```

The quantum of a 528 Hz field is about one hundred-billionth of the ambient thermal jostling. Sound acts on cells through bulk pressure and shear, not through quanta — which is exactly why Bridge 2's channels are *mechanically* gated. The quantum calculation matters because "frequency-specific molecular resonance" claims are implicitly quantum claims, and this is the number that ends them. Actual molecular vibrational modes sit in the infrared:

```
 500 cm^-1  = 1.499e13 Hz   ->  34.7 octaves above 528 Hz
1000 cm^-1  = 2.998e13 Hz   ->  35.7 octaves above 528 Hz
1700 cm^-1  = 5.096e13 Hz   ->  36.5 octaves above 528 Hz
3000 cm^-1  = 8.994e13 Hz   ->  37.3 octaves above 528 Hz
```

Molecular vibration is thirty-five to thirty-seven octaves above the audible band. An audible tone is not a molecular resonance and cannot be one.

```
C1 STRUCTURAL CORRESPONDENCE   FAIL   metaphor only; no shared structure survives
                                      the scale check; wavelength ratio ~9e9
C2 PREDICTIVE POWER            FAIL   generates no prediction surviving Failure 3
C3 PRACTICAL UTILITY           FAIL   a practice built on a false channel is not
                                      utility

(+1) column                    EMPTY  (uncertainty stated; no survey claimed)
(-1) column                    VOID   the source is 1990s, not traditional; 0 bits

STATUS: REJECTED.
```

The part that matters is what the rejection costs this framework, and the framework must accept the binding rather than exempt itself. The corpus describes a genomic-audio pipeline that sonifies measured infrared spectra by fixed octave transposition [Curzi, 2026y]. The 528 Hz rejection means that pipeline may not claim what it has just refused to let anyone else claim:

1. **A transposed tone is not the molecular resonance.** The transposition is a stated, fixed, arbitrary-by-design mapping; thirty-five octaves is a factor of `2^35`, and dividing a frequency by `2^35` preserves no physical interaction, only a ratio. Octave equivalence is a fact about pitch class [Shepard, 1982] and about perception [Demany et al., 2013], not about molecular physics. The audible tone stands in a documented numerical relation to a measured spectrum and in **no causal relation to the molecule**.
2. **The framework's essence frequencies are essence frequencies, not physical resonances.** The constant `k` is *defined*; attaching hertz to it is a separate and stronger claim and is POSTULATED (Section 3.4), and the standard scepticism about golden-section claims is cited alongside it [Markowsky, 1992].
3. **Nothing in this series claims sequence-specific acoustic action on genomic material**, because Failure 3 applies to the framework's own tones precisely as it applies to anyone else's.

The rejected claim and this framework's own method differ in one respect only, and it is the only respect that matters: this framework states its mapping, states that the mapping is a convention, and states that the convention carries no mechanism. The rejected claim states a mechanism it does not have. **If a reader concludes that the difference is thin, the reader has understood the situation correctly. It is thin. It is also the entire distinction between an honest notation and a false one.**

29.7.6 7.6 Bridge 4 — religious fasting and cellular autophagy. Worked, and SPECULATIVE

A fourth bridge is carried end to end with every form filled in, so that the procedure is available as a template rather than as a description, and because it lands on the third verdict.

Step 0. Autophagy is a conserved cellular process in which the cell degrades and recycles its own components. The molecular machinery was identified in yeast by Yoshinori Ohsumi, who received the 2016 Nobel Prize in Physiology or Medicine for that work; autophagy is upregulated by nutrient deprivation, well established in yeast and in mammalian cell and animal models. **Named without a key; see Appendix B.** *What is measured:* the identification of the genes and the pathway, and the response of the pathway to nutrient deprivation in model systems. **What is not established with the same confidence: the time course, magnitude and tissue distribution of fasting-induced autophagy in living humans under the specific schedules religious observance actually prescribes.** Measuring autophagic flux in human tissue in vivo is genuinely difficult, and no settled quantitative answer is asserted here. **That distinction — solid mechanism, unsettled human dose-response — is fixed before anything else is consulted, and it determines the verdict.**

Steps 1–2b.

(+1) side	(−1) side
nutrient sensing (mTOR, AMPK)	[no counterpart]
a recycling process under deprivation	[no counterpart]
a threshold of deprivation duration	a prescribed fast length
a refeeding phase that halts the process	a prescribed breaking of the fast
a repeatable cycle	an annual or weekly calendar

Two of five structures map: duration threshold and cycle. Three do not, because the precedent side records no cellular process of any kind. **Grade: homomorphism, weakly.** It clears the threshold, but only just, and the grading is recorded as weak because the mapped structures are schedule elements and not the mechanism.

Step 3. The precedent reading, with dates and paths. Yom Kippur: a single approximately 25-hour complete fast, annual, attested continuously in Jewish practice for over two millennia. Ramadan: a lunar month of daily fasts from dawn to sunset, seventh century onward, with a prescribed pre-dawn meal and a prescribed breaking at sunset. Christian Lenten and Friday abstinence: varying forms, fourth century onward. Ekadashi: an approximately fortnightly fast in several Hindu traditions. Buddhist monastic vinaya: no solid food after midday. Vision-quest fasting in a number of North American Indigenous traditions, and fasting in Mesoamerican ritual practice — **these are the entries that matter for independence, having no plausible shared source with the Old World examples.**

Independence audit. The Old World set is heavily correlated and c is high. The North American and Mesoamerican entries are substantially independent, which lifts the aggregate above the one-tradition floor. **Credit: on the toy model, of order two bits. Not zero. Not evidence.**

What was actually recorded: the duration, the timing, the exclusions, the manner of breaking the fast, the warning signs, and a reported change in mental and bodily state. **No tradition records a recycling process, a lysosome, or a nutrient sensor, because nothing in a first-person instrument could have detected one.**

Step 4. The prediction. If traditional fast durations sit above the deprivation threshold at which autophagic flux rises materially in human tissue, then the fasts are — incidentally, not by design — in the effective range, and shorter observances should not be. The traditions converged on durations of roughly 12 to 30 hours, which is a specific, checkable, falsifiable claim about where the threshold should lie. **The prediction: measured human autophagic flux should show a material rise within the 12-to-30-hour window and not substantially below it. If human flux turns out to require 72 hours, the bridge is dead.**

Step 5. Test. Not tested at this specificity, to this author's knowledge. **This is the step where the bridge stops.**

Contra-proof. The two integrate only partially. The evidence side need not claim the traditions knew about autophagy. **The precedent side must not be made to claim its fasts were about cellular recycling — they were about atonement, discipline, solidarity and mourning, and saying otherwise would put a falsehood in the precedent column to serve the evidence column, which is exactly what the neutral point forbids.** The integration that survives is narrow: both columns describe a threshold-and-cycle structure on nutrient deprivation, and they agree on roughly where the threshold sits.

```
C1 STRUCTURAL CORRESPONDENCE   PARTIAL   weak homomorphism; 2 of 5 structures map
C2 PREDICTIVE POWER            PASS      12–30 h window; falsifiable; untested
C3 PRACTICAL UTILITY           PARTIAL   a stated hypothesis on the (+1) side;
                                         the (−1) side gains nothing it did not have

STATUS: SPECULATIVE -- and this is the sentence that states it, so this is the
sentence that marks it.
```

Notice what the procedure did. It did not accept the bridge because it is appealing, and it is appealing, being among the most repeated claims in contemporary health writing. It did not reject it either, because the structure genuinely maps at the schedule layer and generates a real prediction. **It graded it, named the missing measurement, and printed the number that would settle it.**

29.7.7 7.7 What four bridges demonstrate

```
BRIDGE 1  cadence                ESTABLISHED   C1 pass, C2 pass, C3 pass
```

```
BRIDGE 2  vibration -> cell        GRADED        established coarse, SPECULATIVE fine
BRIDGE 3  528 Hz repairs DNA       REJECTED      C1 fail, C2 fail, C3 fail, -1 void
BRIDGE 4  fasting -> autophagy     SPECULATIVE   C1 partial, C2 pass, C3 partial
```

The middle rows are the ones to keep. Most real bridges are neither accepted nor rejected whole; they hold at one grain and fail at a finer one, and the work of the method is finding the seam. An apparatus reporting only the first and third rows would be an apparatus that had never been used on anything difficult.

29.8 8 The register: format, status vocabulary, and precedent weights

29.8.1 8.1 What a register can and cannot do

Appendix A is a **reference register**, not an argument. It is written to be looked up rather than read through, and every entry is formatted identically so that the appendix functions as a lookup table: a reader arrives with a claim and leaves with its two sources, what each of them actually established, which bridge criteria it passes, and its status.

It exists because Section 3.1 imposes an obligation that is easy to state and expensive to keep. **Every substantive claim in this part of the corpus carries two references and states which column carries evidence and which carries precedent.** A framework can make that promise in a methodology section and quietly break it afterwards. The only way to make it checkable is to print the whole ledger in one place, in one format, with the failures included. **The failures are included: entries with status REJECTED are printed at the same length and in the same format as those with status ESTABLISHED, because a register listing only what survived is a sales document.**

What a register can do: make the framework's commitments legible; make status visible at a glance; force every entry to declare the same fields, so that a missing field is a visible gap rather than a silent omission; and let a reader check one claim without reading the argument that makes it.

What it cannot do: establish anything. A register is a summary of evidence and never a source of it. No entry becomes truer by being in it. The nearest analogue in the corpus is the demonstration that a double-entry identity is a consistency check and not an integrity check: `A - (L + E) = 0.0000000000` holds exactly while the statement it certifies is misleading, **so the identity's holding is not evidence** [Curzi, 2026]. A register that balances is in exactly that position.

One further limit, stated because the format invites the mistake: **a table of forty-three entries all formatted identically will read as forty-three items of equal weight, and they are not.** The `ROLES` field exists to prevent that reading, and it is the field to read first.

29.8.2 8.2 The entry format

Every entry carries the same twelve fields in the same order.

Field	What it holds
CLAIM	the proposition, stated so that it could be false
(+1) SOURCE	the peer-reviewed reference, named
MEASURED	what that source *actually measured* — not what it is popularly said to show

Field	What it holds
(-1) SOURCE	the traditional reference, with tradition, date, and transmission path
RECORDED	what that source *actually recorded* — the observation, not the explanation
ROLES	which column carries evidence, which carries precedent, and the precedent's weight in bits
C1	structural correspondence: PASS / PARTIAL / FAIL, and the grade of correspondence
C2	predictive power: PASS / PARTIAL / FAIL, and the prediction stated
C3	practical utility: PASS / PARTIAL / FAIL, and the use on each side
0p	the contra-proof: whether the two integrate without either side lying
STATUS	ESTABLISHED / SPECULATIVE / REJECTED / POSTULATE / REFUSED
USED IN	the sections of the source manuscript that rely on the entry

Three fields do most of the work. **MEASURED** separates the register from a bibliography: a citation names a source, this field names the source's actual finding, which is frequently narrower than the use it is put to. **RECORDED** does the same on the other side and enforces the separation of what a tradition observed from what it explained. **ROLES** states the asymmetry every time and prices the precedent in bits.

A note on the last field. `USED IN` records the chapter numbering of the source manuscript from which this register was drawn, and is reproduced unchanged as a provenance record rather than remapped onto the corpus's paper numbering. **No mapping between the two numbering schemes is asserted here**, because inferring one would put a claim in the register that the source does not make.

29.8.3 8.3 The status vocabulary

Five statuses. **They are not a scale and they are not interchangeable**, and no arithmetic is performed on them anywhere (Section 3.7).

```
ESTABLISHED   Passes C1, C2 and C3. The evidence column carries evidence
              sufficient to support the claim on its own. The precedent column
              supplies precedent and usually procedure. This is the only status
              that may be stated without a qualifier.

SPECULATIVE   Fails or only partially satisfies at least one criterion, but is
              coherent and falsifiable. MUST be marked speculative in the same
              sentence that states it, everywhere it appears.

REJECTED      Fails the criteria. Printed at full length, with the reasoning, so
              that the rejection is auditable and so that the framework is bound
              by it.

POSTULATE     The author's own, badged. Not derived, not measured. Stated with
              its badge in the same sentence.
```

```
REFUSED      Outside what the framework will assert at all. No amount of
             evidence moves an entry into the framework from this status,
             because the refusal is about what will be claimed, not about what
             is true.
```

REJECTED is a verdict on a bridge — the method was run and the bridge failed. REFUSED is a standing constraint: the framework does not make claims of this kind regardless of what any bridge shows.

29.8.4 8.4 Precedent weights

The `ROLES` field prices precedent in bits using Section 4.2's model. **The model is illustrative and its rates are assumed; what carries across is the ordering, not the decimals.**

```
a single tradition, or several with a shared source     ~ 1.6 bits
two or more genuinely independent traditions            ~ 2 to 3 bits
a source that is not actually old                          0 bits
"many traditions teach"                                    0 bits, inadmissible

for comparison, on the same scale:
one strong study                                        ~ 6.6 bits
a replicated result                                     ~ 10.0 bits
a replicated, prize-recognised mechanism                ~ 20 bits
```

Every precedent figure in the register is at or below three bits. Every evidence figure it sits beside is at or above six. That ratio is the register's central fact, and it is why the columns are never summed.

29.9 9 Specifications

Numbered, checkable and binding on any use of this apparatus. **The three groups replace the source manuscript's chapter-keyed numbering: S-C for the concordance method, S-P for the precedent column, S-R for the register.**

29.9.1 9.1 S-C — the concordance method

S-C1. Every substantive claim carries an evidence reference and a precedent reference, and states which is which.

S-C2. The evidence reference names the source **and what it actually measured**, not what it is commonly said to show. Where the two differ, the difference is stated.

S-C3. The precedent reference names the tradition, an approximate date, and the transmission path. **A precedent citation of the form "many traditions teach" is inadmissible and must be replaced or struck.**

S-C4. The column roles are stated at every concordance. **Precedent is never presented as, summed with, or substituted for evidence.**

S-C5. The evidence reading is fixed in writing before the precedent column is consulted (Step 0). Where a bridge was in fact discovered from the precedent side, that history is disclosed and the bridge is held to a correspondingly higher standard on C2.

S-C6. Every bridge is graded isomorphism / homomorphism / analogy / metaphor. **Below homomorphism the bridge is rejected and the rejection is recorded rather than silently dropped.**

S-C7. Every bridge states its prediction explicitly, naming an observation that would falsify it. **"It is consistent with" is not a prediction.**

S-C8. Every bridge states its use on both sides. A bridge usable on only one side is recorded as one-sided and does not qualify as established.

S-C9. Only bridges passing C1, C2 and C3 are presented as established. All others are marked speculative in the same sentence that states them.

S-C10. Where a bridge holds at one grain and fails at a finer one, both grains are reported separately with separate statuses. **Partial bridges are not rounded up.**

S-C11. Every proposed mechanism is checked for scale (E6) by computing the relevant ratio, **and the ratio is printed.**

S-C12. Every proposed mechanism names its competing channels (E7) and the experiment that would separate them.

S-C13. Independence of precedent sources is audited before the precedent is credited. **Correlated sources are credited once, not once each.**

S-C14. No supernatural claim, no claim of physical efficacy for a symbol, no clinical or therapeutic claim, and no claim that genomic sequence is edited or altered. These are standing refusals and no bridge may weaken them.

S-C15. Where certainty about a source is lacking, the entry states the uncertainty or the source is omitted. **No source is cited from memory of its reputation.**

29.9.2 9.2 S-P — the precedent column

S-P1. Before citing a traditional source, run the P1–P4 envelope check and print the result. **A claim failing P4 — prompt effect — is not admissible as observational precedent, whatever the tradition's confidence.**

S-P2. Apply the visible-failure rule. State what happened to a practitioner who got this claim wrong. **If the answer is "nothing," the item is credited at the memorability rate, not the accuracy rate.**

S-P3. Separate what the source *recorded* from what the source *explained*. The recording may be admissible precedent; the explanation almost never is.

S-P4. Date the earliest verifiable attestation of the specific claim, not of the tradition it is attached to. **Pseudepigraphic attribution is not a date.**

S-P5. Audit independence before crediting agreement, and name the transmission path. **Assume harmonisation in any post-1450 European compilation unless there is evidence otherwise.**

S-P6. Treat any complete, gapless, symmetric table as containing interpolated entries (T4). **Do not use the completeness of a scheme as evidence for any of its entries.**

S-P7. Where a tradition reports an effect and assigns a mechanism, cite the effect and discard the mechanism, then name the competing channels per S-C12.

S-P8. Where a tradition's practical material and its theoretical material disagree, weight the practical material higher — bias B3 means it survived *despite* the filter rather than because of it.

S-P9. Never cite duration of belief as support. Duration measures `delta`, and `delta` is orthogonal to truth.

S-P10. No supernatural claim, no physical efficacy for a symbol, no clinical claim. Standing.

29.9.3 9.3 S-R — the register

S-R1. Every substantive claim cites a `CR-nn` identifier or adds a new entry in the same format. **A claim with no register entry is not admissible.**

S-R2. The twelve fields are filled for every entry, in order. **An empty field is written "none admissible" with the reason, never left blank and never filled with a loose analogue.** Twelve entries carry empty or void precedent columns — CR-06, CR-09, CR-10, CR-14, CR-16, CR-17, CR-21, CR-22, CR-26, CR-27, CR-30 and CR-33 — **and that is a normal outcome, not a defect.**

S-R3. The `MEASURED` field states what the source actually measured. Where the popular use of the source exceeds its finding, the excess is named in the field.

S-R4. The `RECORDED` field states the observation and excludes the explanation.

S-R5. The `ROLES` field is filled on every entry with the precedent weight in bits. **No entry sums the columns.**

S-R6. Status ESTABLISHED requires PASS on all three criteria. **Anything less is SPECULATIVE and is marked in the sentence that states it, everywhere, not only in the register.**

S-R7. REJECTED entries are printed in full, at the same length as accepted ones, with their reasoning. **Rejections are never removed when a section stops using them.**

S-R8. Where a REJECTED entry constrains the framework's own method, the constraint is stated in the entry. **CR-27 is the model: the rejection binds the sonification pipeline** [Curzi, 2026y].

S-R9. Numbers in entries are computed and appear identically everywhere. The time–bandwidth constant is `0.079577`; **`k = 0.483425732988414` is a defined constant and the hertz attachment is a separate, postulated claim** (Section 3.4); the Casimir pressures are `1.3e5 / 13 / 1.3e−3 / 1.3e−15 Pa` at `10 nm / 100 nm / 1 um / 1 mm`.

S-R10. Uncertainty about a source is stated in the entry. CR-07, CR-14, CR-27, CR-32 and CR-36 carry explicit uncertainty statements, and those statements travel with the citation.

S-R11. To add an entry: run the eight-step procedure of Section 7.1, fill all twelve fields, assign the next `CR–nn`, record the status. **The procedure is run before the entry is written.**

S-R12. To retire an entry: change its status, keep its number, and record why. **Numbers are never reused and entries are never deleted.**

29.10 10 Failure modes

Three groups, corresponding to the three specification groups. Each carries a clinical description, a signature by which it is recognised, the price of leaving it in place, the fix, and what it is confusable with.

29.10.1 10.1 FM-C — faults of the method

FM-C.1 · The Doubled Column. *Clinical:* precedent is counted as a second piece of evidence and the concordance is presented as convergent verification. *Signature:* the text says "both science and tradition confirm," or "independently verified by"; confidence in the section exceeds the confidence of its strongest single source. *Price:* computed at Section 4.3 — with a replicated evidence result, an overstatement factor of 333.3, which is 8.38 bits. *Fix:* state the column roles in the sentence. *Confusable with:* legitimate use of precedent as a prior (Section 4.5) — the same operation at the right weight.

FM-C.2 · The Shared Library. *Clinical:* several precedent sources are cited as independent when they descend from one another or from a common editorial project. *Signature:* the sources are all European, all post-1450, or all traceable to one compilation; the phrase "found in every tradition" appears. *Price:* Section 4.4. At `c = 0.1`, five sources buy 1.685 bits instead of 7.925 — a loss of 6.24 bits against what was claimed, and past `k = 2` additional agreeing sources *reduce* the likelihood ratio. *Fix:* name the transmission path per S-C3 and credit correlated sources once. *Confusable with:* genuine partial independence, as in Bridge 2.

FM-C.3 · The Retrofitted Bridge. *Clinical:* the precedent source is searched *after* the evidence result is known, and a passage is found that can be read to match. *Signature:* the traditional passage is short, quoted without surrounding context, and requires a specific transla-

tion to work. *Price:* the bridge carries zero bits, since a large enough corpus contains a match for any proposition — and worse, it feels like the strongest bridge in the section. *Fix:* Step 0; where the order was in fact reversed, disclose it per S-C5 and demand a stronger C2. *Confusable with:* hypothesis generation from the precedent column, which differs in one respect — the hypothesis is then tested, not illustrated.

FM-C.4 · The Scale Skip. *Clinical:* error E6; a real mechanism is transported to a scale at which its magnitude is negligible, and the transport is not checked. *Signature:* a named physical effect appears in a biological or architectural sentence with no number attached. *Price:* arbitrarily large. Casimir pressure falls as `a^-4`: `1.3e5 Pa` at 10 nm, `1.3e-15 Pa` at 1 mm — twenty orders of magnitude across an interval a careless sentence would cross without noticing. *Fix:* S-C11; compute the ratio and print it. *Confusable with:* the structural use of a physical effect — boundary geometry selecting modes, with the force explicitly disclaimed.

FM-C.5 · The Wrong Channel. *Clinical:* error E7; a genuine, replicable effect is attributed to a mechanism that is not the one operating. *Signature:* the effect keeps replicating, so the mechanism keeps appearing confirmed; no experiment in the citation list separates the candidate channels. *Price:* every downstream design decision optimises the wrong variable. *Fix:* S-C12; enumerate the competing channels and specify the separating experiment, as in Section 7.4. *Confusable with:* FM-C.6, where there is no effect at all.

FM-C.6 · The Costume. *Clinical:* a recent construction is presented as traditional, so that the precedent column appears populated when it is empty. *Signature:* the system uses absolute numerical values that could not have been measured in the period claimed; its earliest verifiable source is twentieth century; the historical material it gestures at is real but says something else. *Price:* the column reads as precedent and is worth zero bits. **This is the 528 Hz case exactly** (Section 7.5). *Fix:* date the earliest verifiable attestation of the *specific claim*. *Confusable with:* genuine recent formalisation of an old practice, legitimate provided the formalisation is dated as recent.

FM-C.7 · The Unfalsifiable Bridge. *Clinical:* C2 is nominally satisfied by a "prediction" that no observation could contradict. *Signature:* the prediction contains "may", "can", "is consistent with", or a magnitude-free directional claim; no number, no threshold, no control. *Price:* the bridge cannot be removed by any future evidence, which means it also cannot be supported by any [Popper, 1959, Meehl, 1967]. *Fix:* S-C7; rewrite the prediction so it names the observation that would kill it. *Confusable with:* an honestly speculative bridge, which is *marked* speculative and specifies what would settle it.

FM-C.8 · The Exemption. *Clinical:* the method is applied rigorously to other people's claims and suspended for the framework's own. *Signature:* a rejection is followed by a construction that would not survive that rejection; the framework's own mechanism is described in the passive voice. *Price:* total. **It is the only failure mode on this list that invalidates the whole apparatus rather than one section, because it converts the method from an instrument into a rhetorical device.** *Fix:* Section 7.5's closing move, performed every time — after each rejection, state explicitly what the rejection forbids *this framework* from claiming, and enforce it. *Confusable with:* nothing. There is no innocent version.

29.10.2 10.2 FM-P — faults of the reader of the old corpus

FM-P.1 · The Confidence Transfer. *Clinical:* the corpus's tone — settled, detailed, unanimous — is read as a measure of its reliability. *Signature:* the citation quotes the source's certainty rather than its observation. *Price:* unbounded. Tone measures `k`, and `k` measures variance, not bias (Section 5.2). *Fix:* S-P1; score the item on P1–P4 and ignore the tone entirely. *Confusable with:* legitimate citation of a *detailed procedure*, where the detail is operational payload rather than rhetorical certainty.

FM-P.2 · The Index Realised. *Clinical:* error T1; a filing relation is read as a causal one. *Signature:* a sentence in which a category assignment becomes a verb — "the metal is governed by". *Price:* everything downstream is built on a relation that exists only in the filing system. *Fix:* restate the claim literally; if the restatement is "X is filed under Y", the causal reading has

no content. *Confusable with:* genuine structural correspondence, which survives the restatement.

FM-P.3 · The Tidy Table. *Clinical:* error T4; interpolated entries are treated as observations. *Signature:* the scheme has no gaps, every category has the same number of members, and the count is 4, 7, 12 or 22. *Price:* the interpolated entries are indistinguishable from the observed ones and there is generally no way to separate them after the fact. *Fix:* S-P6; use the scheme as an index, never as data. *Confusable with:* a genuinely complete enumeration, which exists — a graph really does have 22 edges — and is distinguished by being a fact about the artefact rather than about the world.

FM-P.4 · The Invisible Failure. *Clinical:* a claim whose falsity had no cost to anyone is credited at the same rate as one whose falsity was punished immediately. *Signature:* the claim concerns mechanism, cosmology, remote influence, or outcomes after death. *Price:* Section 5.4's first row — 7.9 per cent surviving accuracy against 94.5, a factor of 11.97. *Fix:* S-P2; ask what happened to the practitioner who was wrong. *Confusable with:* a claim whose failure was visible but slow, such as institutional cadence, credited at an intermediate rate rather than dismissed.

FM-P.5 · The Inverted Inheritance. *Clinical:* bias B3; the theory is cited because the theory is what survives, while the practice — what the instrument was actually good at — is ignored because it is fragmentary. *Signature:* the section cites a cosmology and not a procedure. *Price:* the reader is handed the corpus's worst material as though it were its best. *Fix:* S-P8. *Confusable with:* nothing. This one is a failure to look.

FM-P.6 · The Harmonised Chorus. *Clinical:* post-hoc editorial reconciliation is read as independent agreement. *Signature:* sources from one compilation, one century, or one editorial programme are described as "multiple independent traditions". *Price:* Section 5.6, item 4 — 6.24 bits claimed and not held. *Fix:* S-P5. *Confusable with:* genuine geographic independence, as in Bridge 2, where the Australian and West African instances have no plausible shared source with the Indo-European ones.

FM-P.7 · The Unfalsifiable Rescue. *Clinical:* error T5, adopted by the modern reader rather than the ancient one. A traditional claim failing a modern check is rescued by reinterpretation until it can no longer fail. *Signature:* the claim becomes more metaphorical each time it is challenged. *Price:* the claim is now unfalsifiable and therefore also unsupportable [Lakatos, 1970]. *Fix:* fix the claim's content in writing before checking it, and let it fail if it fails. *Confusable with:* legitimate re-reading of a source as describing a phenomenon rather than a mechanism (S-P3) — the difference is that the re-reading is done once, in advance, and then held fixed.

FM-P.8 · The Survivor's Testimony. *Clinical:* a traditional literature's own account of its efficacy is read as evidence of efficacy. *Signature:* the supporting material consists of accounts by successful practitioners. *Price:* zero bits. Every tradition's surviving literature has this property, including the traditions that demonstrably did not work. *Fix:* ask where the unsuccessful practitioners' accounts are; if the answer is that they were not copied, the literature carries no information about the base rate. *Confusable with:* a tradition that recorded its own failures, which some technical traditions did and which is a strong positive signal precisely because it is rare.

29.10.3 10.3 FM-R — faults in the use of the register

FM-R.1 · The Equal-Weight Illusion. *Clinical:* forty-three entries in one format are read as forty-three items of equal standing. *Signature:* a section cites CR-13 (both columns weak) and CR-21 (prize-grade evidence, empty precedent) with the same confidence. *Price:* uniformity that exists to make comparison possible is used to make it unnecessary. *Fix:* read `ROLES` first. *Confusable with:* co-citation that states the difference in standing explicitly.

FM-R.2 · The Register as Authority. *Clinical:* an entry is cited as though the register established it. *Signature:* "as established in the register". **The register establishes nothing** (Section

8.1). *Fix:* cite the source in the `(+1) SOURCE` field. *Confusable with:* citing the register for its *status assignment*, which is legitimate — the status is the register's own product.

FM-R.3 · The Filled Blank. *Clinical:* an empty precedent column is filled with a loose analogue to make the entry look complete. *Signature:* `RECORDED` paraphrases rather than reports an observation; no date or transmission path is given. *Price:* zero bits presented as two. *Fix:* S-R2; write "none admissible" and give the envelope reason. *Confusable with:* a genuine but weak precedent column, which has a date, a tradition and an independence estimate.

FM-R.4 · Chain Assembly. *Clinical:* several ESTABLISHED entries are chained to reach a conclusion none supports, most often to close CR-26. *Signature:* "since CR-20, CR-28 and CR-29 are all established, it follows that". *Price:* total, for the framework's credibility. **CR-26 is exactly the gap this chain appears to close and does not** [Curzi, 2026y]. *Fix:* no entry may be combined with another to close CR-26; each entry supports only what its own `MEASURED` field says. *Confusable with:* composition in which the weakest component sets the status.

FM-R.5 · Status Drift. *Clinical:* a SPECULATIVE entry is cited later without its badge and by the third citation reads as established. *Signature:* the badge appears at first use and then stops. *Price:* the framework's principal honesty commitment fails silently. *Fix:* S-R6; the badge attaches to the *sentence*, not to the first mention. *Confusable with:* nothing.

FM-R.6 · The Vanishing Rejection. *Clinical:* a REJECTED entry is dropped once no section cites it. *Signature:* the register's rejection count falls between drafts. *Price:* the register becomes a list of successes. *Fix:* S-R7 and S-R12. *Confusable with:* nothing.

FM-R.7 · The Precedent Ladder. *Clinical:* weak precedent entries are accumulated across the register and treated as jointly substantial. *Signature:* "taken together, the traditional record shows". *Price:* Section 4.4's independence collapse. *Fix:* S-R5; never sum precedent, within an entry or across entries. *Confusable with:* noting that several audited-independent entries point the same way.

29.11 11 Results

29.11.1 11.1 R1 — the two-column refinement, and the asymmetry it prices

The evidence column carries what could have come out otherwise; the precedent column carries only that an idea was independently arrived at and preserved. Under the assumed recording rates, a single traditional record is worth `LR = 3.000`, or **1.585 bits**, against **9.966 bits** for a replicated result and **19.932 bits** for a prize-grade replicated mechanism. **Two sources agreeing does not double the evidence when only one of them is evidence.** The statement is an arithmetic consequence of the assumed rates, not a measurement, and its robust content is the ordering.

29.11.2 11.2 R2 — independence collapse, computed

At a shared-source probability `c = 0.1`, `k` agreeing traditions buy **1.585, 2.546, 2.317, 1.886 and 1.685 bits** for `k = 1` to `5`. **The total falls after `k = 2`**, and it converges to 1.585 bits — one tradition's worth — for any `c > 0` as `k` grows (Section 13.3). At `c = 0.3` five traditions buy 1.612 bits, within two per cent of what one tradition buys alone. **Against the independent-source fantasy of 7.925 bits at `k = 5`, the loss at `c = 0.1` is 6.24 bits.**

29.11.3 11.3 R3 — the survivorship filter, and its twelvefold spread

Under the preservation model `a1 = a0 s_acc / (a0 s_acc + (1−a0) s_inacc)`, an original corpus 30 per cent accurate arrives at **7.9 per cent** accuracy where failures were invisible and **94.5 per cent** where they were visible — **a factor of 11.97 produced by the filter and not at all by the source.** A poorer original corpus at `a0 = 0.10` still arrives at 81.6 per cent if its failures were

visible, an eightfold improvement on its own origin. **The decisive question about a traditional claim is therefore what happened when it was wrong.**

29.11.4 11.4 R4 — the 528 Hz bridge, rejected on three computed grounds

The claim that a tone at 528 Hz repairs DNA is **REJECTED**, on three independent computed objections and one historical one:

```
(a) spatial     lambda = 1540/528 = 2.9167 m in soft tissue
                ratio to a 10 um cell        2.917e5
                ratio to a 6 um nucleus      4.861e5
                ratio to a 0.34 nm base pair 8.578e9
(b) energetic   h f / kT = 8.17e-11 at 310 K
(c) spectral    molecular bands 1.499e13 to 8.994e13 Hz
                = 34.7 to 37.3 octaves above 528 Hz
(d) historical  the "Solfeggio" values are a 1990s construction; medieval
                solmisation assigns no frequencies, and 528 Hz is a specific
                note only under a twentieth-century pitch convention
```

The rejection binds the framework's own sonification pipeline [Curzi, 2026y], which may not claim a molecular resonance for a transposed tone, may not treat its essence frequencies as physical resonances, and may not claim sequence-specific acoustic action.

29.11.5 11.5 R5 — the register's composition, and a tally defect in the source

Across the forty-two entries the source register carries before its worked example:

```
ESTABLISHED    32        SPECULATIVE     2
REJECTED        6        POSTULATE       2      TOTAL   42
```

Four of the thirty-two ESTABLISHED entries carry a secondary speculative rider (CR-04, CR-12, CR-31, CR-32), one carries a POSTULATE rider (CR-19), and two carry a standing REFUSED clause (CR-37, CR-38). Counting every entry carrying a qualifier — rejected, speculative, postulate, or established-with-a-speculative-rider — gives **14 of 42, or 33.3 per cent**. With the worked example CR-43 added the register holds 43 entries, of which 3 are SPECULATIVE, and the qualifier count is **15 of 43, or 34.9 per cent**.

By correspondence grade on C1, over the completed 43-entry register:

```
PASS       21        homomorphism or better
PARTIAL     5        analogy, or homomorphism at one grain only
FAIL        7        metaphor only, or no shared structure
N/A        10        no bridge proposed
```

Seven outright C1 failures out of the thirty-three bridges attempted is a 21.2 per cent rejection rate at the first criterion alone, and that is where a concordance method does most of its work.

A defect in the source's own tally is reported here rather than silently reconciled. The source presents the C1 breakdown under a heading reading "counts across the forty-two entries below", but the four C1 categories sum to 43 and the split into "entries drawing a bridge (33)" and "entries with C1 = N/A (10)" likewise sums to 43. Both tallies include CR-43, which the source introduces later, in its worked example. **Over the forty-two entries alone the C1 split is PASS 21 / PARTIAL 4 / FAIL 7 / N/A 10, thirty-two bridges are attempted, and the failure rate is 7/32 = 21.9 per cent rather than 7/33 = 21.2 per cent.** Both figures are printed here; the headline 21.2 per cent is the figure for the completed register and is the one carried into the abstract

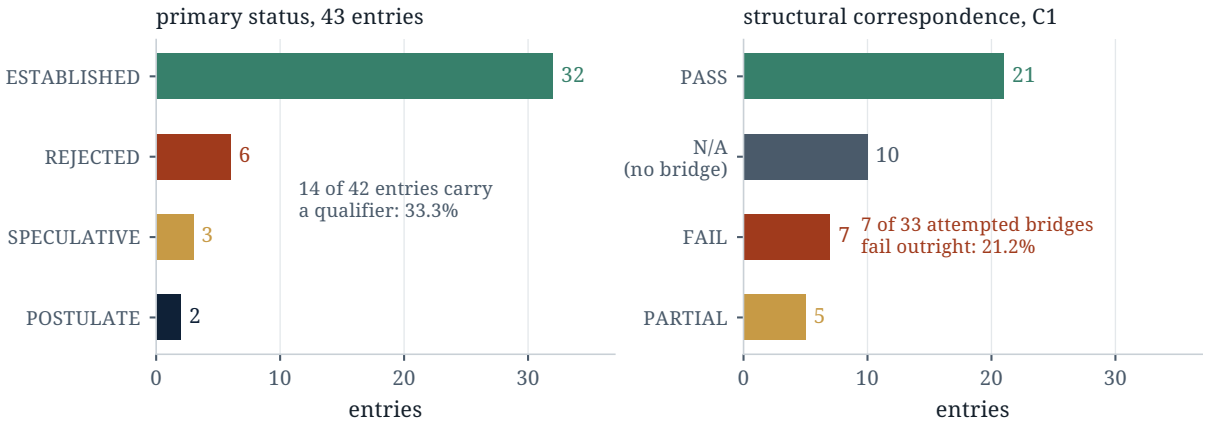

Figure 29.5: **A register that can reject, and does.** Left: the forty-three-entry register by primary status. Right: the same entries by structural-correspondence grade, with the seven outright failures of the thirty-three attempted bridges marked; the ten `N/A` entries draw no bridge at all, which is a normal outcome rather than a defect. Plotted as small multiples because status and grade are different classifications of the same entries and share no scale. Counted from Appendix A by recomputing every `STATUS` and `C1` field; generated by `figs/src/CCP-029_fig05.py`.

and the conclusion. A second, smaller slip: the annotation "plus CR-43 in the worked example" is attached to the `C1 = N/A` row, although CR-43's C1 grade is PARTIAL and it therefore belongs among the bridges attempted. **Neither slip changes any verdict; both were found by recomputing every field of every entry, and the recomputation reproduces the source's status counts of 32/2/6/2 over 42 entries exactly.**

One further note on the source's prose. The sentence summarising these ratios reads "one entry in three carries a qualifier, and one in five and a third is a rejection." **The first clause is exact (14/42 = 33.3 per cent). The second corresponds to no computed ratio in the section: rejections are 6 of 42, which is 14.3 per cent or one in seven, and C1 failures are 7 of 33, which is 21.2 per cent or one in 4.7.** The exact fractions are what this paper reports.

29.11.6 11.6 R6 — the pre-modern detection floor

A single uncontrolled first-person observer registers a true standardised shift of `d = 0.20` with probability **0.2858**, and of `d = 1.00` with probability **exactly 0.5000** — at one standard deviation of true effect, the observer is a coin. Reliability arrives only above `d = 2.0`, at 0.7602. **Against this, a modern two-group design needs about 392 subjects per group to detect `d = 0.20` at 80 per cent power and about 16 at `d = 1.00`.** The traditional instrument's enormous `k` clears the noise floor and cannot clear the attribution floor, and that single fact determines the P1–P4 operating envelope of Section 5.3.

29.11.7 11.7 The counter-result

The register is built so that it can reject, and it does. Seven of thirty-three attempted bridges — 21.2 per cent — fail structural correspondence outright; one entry in three carries a qualifier; the claim nearest the framework's own subject matter is the one rejected at greatest length; and **the arithmetic of correlated sources shows that past two agreeing traditions each further agreement reduces rather than increases the likelihood ratio.** Precedent is priced at a fraction of what its accumulation appears to promise, and the fraction is computed rather than asserted.

29.12 12 Discussion

29.12.1 12.1 What follows

A concordance can be run honestly, and the cost of running it honestly is a rejection rate. The apparatus here is not a device for making traditional material respectable; it is a device for finding out which parts of it are load-bearing, and its principal output is a set of verdicts, six of which are refusals. The most transferable result is the pricing: **once precedent is denominated in the same unit as evidence, the temptation to sum them disappears, because the sum is visibly dominated by one term.**

The independence result generalises well beyond traditional texts. Any setting in which sources may have copied one another has the same structure: agreement above a small number of witnesses is better explained by contact than by convergence. That is the mechanism behind informational cascades [Bikhchandani et al., 1992, Banerjee, 1992], behind the measured collapse of crowd accuracy under mutual exposure [Lorenz et al., 2011], and behind the path-dependence of cultural success [Salganik et al., 2006]. It applies to citation networks, to expert panels, and to the corpus's own interlocking references. **A framework whose papers cite one another densely should notice that its internal agreement is worth fewer bits than its edge count suggests, and this paper's own internal citations are subject to exactly that discount.**

The survivorship result reframes a common move. "This has been believed for two thousand years" is routinely offered as support and is, on this analysis, a statement about `delta` — transmission fidelity — and nothing else. The useful question replaces it: what happened to the person who was wrong? That question sorts traditional material along a line orthogonal to how mystical it sounds, and it puts metallurgy, dyeing, navigation, and mnemonics on one side and cosmology, composition, and remote influence on the other.

29.12.2 12.2 What does not follow

It does not follow that any register entry is established by being in the register. Section 8.1 states this as a definition and Section 10.3 names the failure mode.

It does not follow that the register's badged postulate has been supported by its own entries. The postulate CR-08 records is stated elsewhere in the corpus in magnitude form as `E = G.B + eps`, with the forbidding clause that `G = 0` implies `E = 0` for every `B`, badged as a postulate and paired by explicit correspondence with the storage law's `eta = 0` [Curzi, 2026ab]. **Its channels are measured and it is not**, and summing CR-01 to CR-05 does not establish it.

It does not follow that the bit weights are measurements. They are logarithms of assumed ratios. A reader who prefers different rates will get different decimals and the same ordering, and the ordering is all that is claimed.

It does not follow that a rejected bridge is a false claim. REJECTED is a verdict that the bridge fails the three criteria, which for CR-27 coincides with the physical impossibility of the mechanism, and for other entries does not. **The distinction between a verdict on a bridge and a verdict on the world is maintained throughout and is the reason REFUSED exists as a separate status.**

It does not follow that the reflexive entries of the register are identified. Section 3.5 states the reflection problem and adopts no remedy, so CR-01 through CR-05 and CR-13 record modelling positions rather than identified empirical results [Manski, 1993, Shalizi and Thomas, 2011].

And it does not follow that the method's rejection rate demonstrates the method's stringency. The register was assembled by the same author who set the criteria, and a rejection rate is only evidence of stringency if the candidate set was not chosen with the criteria in view. **That objection is not answered here and is recorded as limitation L-4.**

29.12.3 12.3 Relation to the surrounding literature

The apparatus's closest methodological relatives are the preregistration literature, which supplies the Step 0 device at a larger scale [Nosek et al., 2018, Simmons et al., 2011], and the strong-inference tradition, which supplies the demand that a method be able to reject [Platt, 1964, Popper, 1959]. Meehl [1967, 1990] supply the sharpest version of the objection this apparatus is built against: directional predictions in soft science are nearly costless, so a method must make point predictions with numbers in them or it is not being tested at all. **Sections 7.5 and 11.4 are the paper's answer — three computed ratios, each of which could have come out otherwise.**

The apparatus also has an internal relative. The corpus's own honesty ledger classifies its borrowings into three drawers and, in the psychological drawer, maps seven established items — counter-movement under pressure, if-then plans, commitment and consistency with the announcement-substitution caution, measurement reactivity, unfinished-task persistence, confirmation bias, and the self-fulfilling prophecy — each to the node that leans on it [Curzi, 2026]. **That is the same operation as the `MEASURED` field of Section 8.2, performed on the corpus's own claims rather than on traditional ones.** And the corpus's frequency reference apparatus reaches a structurally parallel verdict about resolution limits by computing a rate penalty at a cliff — exactly 8 symbols per second, from `(1/32)/(1/256)`, with the interval shrinking by a factor of 5.828 in cents and 5.878 in cycles [Curzi, 2026] — which is the same kind of number CR-11 and CR-12 turn on.

The independence arithmetic sits alongside the sociophysics literature on opinion formation, where the same collapse appears as consensus without information [Castellano et al., 2009, DeGroot, 1974, Friedkin and Johnsen, 1990], and against the standing critique of physics-in-social-science, which is stocked here deliberately [Sobkowicz, 2009, Gallegati et al., 2006, McCauley, 2006]. The critique's central complaint — that formal machinery is imported without the conditions that license it — is precisely what Section 3.4 exists to answer, one borrowing at a time.

On the measurement side, the framework is most exposed where it treats a psychological quantity as though it had additive structure. **Michell [1997]'s objection — that psychology assumes quantitative structure without testing for it — is the strongest single objection to this corpus**, and the test that would settle it is additive conjoint measurement [Luce and Tukey, 1964, Krantz et al., 1971]. **It was not run.** This paper's own exposure is narrow, because its numbers are bits and probabilities rather than psychological magnitudes, but the register it prices contains entries whose underlying constructs are exactly the contested kind, and the corpus's own protocol for demoting such quantities [Curzi, 2026t] is the instrument that should be run on them.

Finally, the functional form question. Where the framework's surplus functional appears in this paper it appears as `ln(1 + (N−1)u)` [Curzi, 2026]. **That form is underdetermined by the evidence:** social impact rising as a sub-linear power of the number of sources [Latané, 1981] and value growing as `n log n` [Briscoe et al., 2006] fit the same qualitative facts equally well, and nothing in this paper discriminates between them. The strongest available warrant for a logarithm is not the perceptual one but the dynamical one: Peters and Gell-Mann [2016] derives a logarithmic form from multiplicative dynamics with no psychological assumption at all, which is a better foundation than Fechner [1860], Stevens [1957] because it does not require the perceptual story to be true. **The argument here needs only the dynamical version, and that is said rather than left to be inferred.**

29.13 13 Verification

29.13.1 13.1 Dimensional audit

Every quantity in this paper, its dimension, its unit, and its epistemic status. `[1]` denotes dimensionless.

Symbol	Dimension	Unit	Status
`p1`, `p0`	`[1]`	probability	**modelling choice** — assumed recording rates, 0.30 and 0.10
`LR`	`[1]`	odds ratio	**derived** from `p1`, `p0`
bits	`[1]`	bit (Shannon)	**derived**: `log2(LR)`. **Shannon information, not thermodynamic entropy**
`c`	`[1]`	probability	**modelling choice** — shared-source probability
`k` (source count)	`[1]`	count	**defined**
`a0`, `s_acc`, `s_inacc`, `a1`	`[1]`	probability	`a0`, `s_acc`, `s_inacc` **assumed**; `a1` **derived**
`d`	`[1]`	standard deviations	**defined** — a standardised mean difference
`n` per group	`[1]`	subjects	**derived** from `d` at fixed power
`Q`	`[Q]`	none — see below	**state variable** of the storage law
`delta`	`[1]`	per period	**assumed** in the illustrative parameterisations
`eta`	`[Q]` per nat	none — see below	**assumed** in the illustrative parameterisations
`T`	`[T]`	periods	**defined**
`lambda`	`[L]`	metres	**derived**: `c_sound / f`
`f`	`[T^-1]`	hertz	**measured constant** of the claim under test
`c_sound`	`[L T^-1]`	m/s	**cited nominal**: 1540 in soft tissue, 343 in air
`h f`	`[E]`	eV	**derived** from Planck's constant
`kT`	`[E]`	eV	**derived**: 0.0267 eV at 310 K
octaves	`[1]`	none	**derived**: `log2` of a frequency ratio
Casimir pressure	`[E L^-3]`	Pa	**cited**, scaling as `a^-4`
`k` (the framework's constant)	`[1]`	**none as defined**	**DEFINED**, exactly `(9/8)^2/phi^2`. Attaching hertz is a **separate POSTULATE**

Does the storage law balance? `Q_{t+1} = (1-delta)Q_t + eta S_t - C_t` balances only if `eta` `S` and `C` carry the dimension of `Q` per period. In Section 6.2's parameterisation `S` is dimensionless (one study session) and `eta` therefore carries `[Q]` directly; in Section 6.3's `R` is in `[Q]` per period, so `mean Q = R/delta` returns `[Q]` because `delta` is per period. **Both are consistent, and the two sections use different conventions**, which is stated here rather than left for a reader

to reconcile.

Where a quantity has no operational unit, that is said. `Q` is stored order and has no natural unit; it counts whatever the declared proxy counts, and two systems' `Q` are not comparable unless they declare the same proxy [Curzi, 2026i]. **The underlying construct — comfort — has no operational unit at all** and is treated as a dimensionless magnitude by stipulation; Section 14 records that the quantitative structure required for that stipulation has not been tested. **The register's status vocabulary has no dimension because it is not a quantity**; it is an ordinal label set on which no arithmetic is performed.

29.13.2 13.2 The postulates

Six postulates. Each is atomic, checkable alone, and carries its status. Where a postulate could be dropped and the conclusion still follow, it has been dropped.

P1 — A tradition records a true structure with probability 0.30 and a false one with 0.10. *Status:* **MODELLING CHOICE.** No measurement supports these values; they are chosen generous to the precedent column, and Section 14 records the consequence.

P2 — Likelihood ratios for conditionally independent considerations multiply, and their logarithms add. *Status:* **ARITHMETIC** — Bayes' theorem [Jaynes, 2003].

P3 — `k` sources agreeing report jointly with probability `c p + (1-c) p^k`, where `c` is the probability they are effectively one source. *Status:* **DEFINITION** — the mixture model of Section 4.4, true by its own construction and carrying no empirical weight.

P4 — The standard deviation of a mean over `k` independent observations is `1/sqrt(k)` of the single-observation standard deviation, and a systematic bias is invariant under `k`. *Status:* **ARITHMETIC.**

P5 — Survival of an item is a Bernoulli filter with rates `s_acc` and `s_inacc` applied independently to accurate and inaccurate items. *Status:* **DEFINITION**, with the rates a **MODELLING CHOICE**. Only the *sign* of `s_acc \ensuremath{-} s_inacc` is asserted, and it is asserted from the mechanism named beside each row.

P6 — The speed of sound in soft tissue is approximately 1540 m/s, Planck's constant and Boltzmann's constant take their standard values, and molecular vibrational modes of biological interest lie between 500 and 3000 cm^{-1}. *Status:* **CITED** — standard physical constants and standard vibrational spectroscopy [Rossing et al., 2002]; the vibrational range is a textbook fact stated without a key (Appendix B).

A postulate that was considered and dropped. An earlier form of the argument assumed a prior on `H`. It is not needed: every result in Sections 4.3 and 4.4 is a statement about likelihood ratios, which are prior-free, and the 3,000:1 against 1,000,000:1 comparison of Section 4.3 uses even odds only as an illustration and would carry the same *factor* from any prior.

29.13.3 13.3 The compounding chain

Every line is checkable from its own inputs, without reading the previous line for anything but its stated output.

```
P1        -> L1   LR of one traditional record = 0.30/0.10 = 3.000        ARITHMETIC
L1 + P2   -> L2   log2(3.000) = 1.58496...  -> 1.585 bits                 ARITHMETIC
P2        -> L3   a replicated result at LR = 1000 is log2(1000)
                  = 9.96578... -> 9.966 bits                             ARITHMETIC
L2 + L3   -> R1   9.966 / 1.585 = 6.288  -- evidence is ~6x precedent     ARITHMETIC
L3 + L1   -> L4   honest posterior odds from even odds: 1000 x 3 = 3,000  ARITHMETIC
L3        -> L5   doubled posterior odds: 1000 x 1000 = 1,000,000         ARITHMETIC
L5 / L4   -> R1b  overstatement factor 333.33 = 8.3808 bits              ARITHMETIC
P1 + P3   -> L6   at c = 0.1, k = 2:
                  num = 0.1(0.30) + 0.9(0.09)  = 0.111
```

```
                  den = 0.1(0.10) + 0.9(0.01)  = 0.019
                  LR  = 5.8421 -> 2.5464 bits                              ARITHMETIC
P1 + P3   -> L7   at c = 0.1, k = 5:
                  num = 0.03 + 0.9(0.00243)    = 0.032187
                  den = 0.01 + 0.9(0.00001)    = 0.010009
                  LR  = 3.2158 -> 1.6851 bits                              ARITHMETIC
L6 + L7   -> R2   1.6851 < 2.5464: the total FALLS after k = 2             ARITHMETIC
P3        -> R2b  as k -> infinity, p^k -> 0, so LR -> (c p1)/(c p0)
                  = p1/p0 = 3, and bits -> 1.585 for every c > 0           ARITHMETIC
P5        -> L8   a1(0.30, 0.02, 0.10) = 0.006/0.076   = 0.078947          ARITHMETIC
P5        -> L9   a1(0.30, 0.40, 0.01) = 0.120/0.127   = 0.944882          ARITHMETIC
L9 / L8   -> R3   0.944882/0.078947 = 11.968  -- twelvefold                ARITHMETIC
P6        -> L10  lambda = 1540/528 = 2.916667 m                           ARITHMETIC
L10       -> R4a  2.916667 / 3.4e-10 = 8.578e9 base-pair lengths           ARITHMETIC
P6        -> R4b  h f/kT = (6.626e-34 x 528)/(1.381e-23 x 310) = 8.17e-11  ARITHMETIC
P6        -> R4c  log2(1.499e13/528) = 34.72 octaves                       ARITHMETIC
R4a+b+c   -> R4   the 528 Hz bridge fails C1 on three independent grounds  VERDICT
```

The three checks a reviewer can redo in under a minute are `0.30/0.10 = 3`, `log2(3) = 1.58496`, and `1540/528 = 2.916667`. Everything in R1, R2 and R4 is built from those and from the mixture model of P3, and from nothing else.

What the chain does not establish. It does not establish that traditions record true structures at 0.30 and false ones at 0.10; P1 is a modelling choice and every bit figure inherits its status. It does not establish that any register entry is true. **And R4 is the only result in the chain whose inputs are physical constants rather than assumptions**, which is why R4 is the one result stated here without hedging.

29.13.4 13.4 The verification instance, worked

The smallest case that exercises the independence collapse is `k = 2` at `c = 0.1`, and it is worked in full because it is where the counter-intuitive behaviour begins.

```
p1 = 0.30, p0 = 0.10, c = 0.1, k = 2

P(both report | H)      = 0.1(0.30) + 0.9(0.30)^2 = 0.030 + 0.081 = 0.111
P(both report | not H)  = 0.1(0.10) + 0.9(0.10)^2 = 0.010 + 0.009 = 0.019

LR = 0.111 / 0.019 = 5.84211      log2 = 2.54638 bits

against perfect independence:  (0.30/0.10)^2 = 9.000   log2 = 3.16993 bits

the loss to a ten per cent chance of a shared source, at TWO sources, is
3.16993 - 2.54638 = 0.62355 bits, and it grows with k
```

Status: **ARITHMETIC.** Two multiplications, two additions and one division; a reader with a calculator can confirm every figure in the `c = 0.1` column the same way.

29.13.5 13.5 Two secondary checks

The cadence table. The periodic-steady-state values of Section 6.3 follow from `Q_max = R T / (1 - (1-delta)^T)` and `Q_min = Q_max (1-delta)^{T-1}`. At `T = 7`, `delta = 0.10`: `Q_max = 7/(1 - 0.9^7) = 7/0.5217031 = 13.4176`, and `Q_min = 13.4176 x 0.9^6 = 13.4176 x 0.531441 = 7.1305`. **Both reproduce the table to four decimals, and the mean is `R/delta = 1/0.1 = 10.000` in every row by the DC-gain result.** *Status:* **ARITHMETIC**, on a **DEFINITION** (the dosing schedule).

The ordering information. `log2(7!) = log2(5040) = 12.29920`, and `log2(12!) = log2(479001600) = 28.83527`. *Status:* **ARITHMETIC.**

29.13.6 13.6 Limits, asymptotics, and the domain of validity

Limit	Behaviour	Reading
`c -> 0`	bits grow linearly in `k`, `k log2(p1/p0)`	perfect independence; the fantasy column
`c -> 1`	bits are constant at `log2(p1/p0)` for every `k`	all sources are one source; agreement adds nothing
`k -> infinity`, any `c > 0`	`LR -> p1/p0`, bits `-> 1.585`	**the collapse is total in the limit**; the maximum at small `k` is the only thing the sum ever buys
`p1 -> p0`	`LR -> 1`, bits `-> 0`	a tradition equally likely to record truth and falsehood is worth nothing, correctly
`s_acc = s_inacc`	`a1 = a0`	a neutral filter transmits the original accuracy; the model's null
`s_inacc -> 0`	`a1 -> 1`	a filter that removes every error leaves only truth; degenerate and not realistic
`d -> 0`	`P -> 1 - Phi(1/sqrt2) = 0.2398`	**a single observer still "detects" a null effect 24 per cent of the time**; the false-positive floor of the uncontrolled instrument
`d -> infinity`	`P -> 1`	large effects are seen; correct
`delta -> 0` in the retention model	no decay; the ratio in Section 6.2 diverges	**a pathology, not an ideal** — nothing decays out of the stock [Curzi, 2026a]
`T -> 1` in the cadence model	`Q_max = Q_min = R/delta`	zero ripple; the continuous-drive case
`T -> infinity`	`Q_min -> 0`	the store empties completely between doses; the floor result at its extreme

Two domain restrictions follow and are stated as restrictions. The exponential retention model of Section 6.2 is valid over days and not over months: real retention curves are not single exponentials and flatten into a long tail, so the day-30 ratio of 224,131 should be read as "the rote trace is gone" rather than as a number. And the `d -> 0` limit above sets a floor the whole precedent column sits on: **an instrument with a 24 per cent false-positive rate on a null effect will generate a large volume of confident, specific, false material given three thousand years to do it in**, which is the quantitative form of Section 5.2's conclusion.

29.13.7 13.7 Invariance, and how far each claim has been tested

The bit ordering is invariant under the choice of rates, over the range tested. The claim that evidence exceeds precedent by a factor of at least four was checked at `(p1, p0) = (0.30, 0.10)`, `(0.50, 0.10)`, `(0.40, 0.20)` and `(0.60, 0.30)`, giving precedent weights of 1.585, 2.322, 1.000 and

1.000 bits against a fixed 9.966 for a replicated result — ratios of 6.29, 4.29, 9.97 and 9.97. **Four points, not a proof.** The invariance breaks if `p1/p0` is allowed above 8, which would require a tradition eight times more likely to record a truth than a falsehood, and **no defence of such a rate is offered here or known to this author.**

The collapse result is invariant under the rates entirely, because R2b shows the limit is `p1/p0` for every `c > 0`, whatever those rates are. That is the strongest invariance claim in the paper and it is a proof rather than a sample.

The physical results of R4 are invariant under the choice of tissue. At the extremes of soft-tissue sound speed the wavelength moves between roughly 2.7 and 3.1 m, and the ratio to a base pair stays within ten per cent of `8.6e9`. **No plausible tissue constant changes the verdict, which is the point of quoting the ratio rather than the wavelength.**

No scaling or heavy-tail claim is made anywhere in this paper, so the distribution-fitting and goodness-of-fit procedure such a claim would require [Clauset et al., 2009] does not apply. The one power law that appears — Casimir pressure as `a^-4` — has an exponent **defined by the physics, not estimated from data**, and is quoted only to show the effect is negligible.

29.13.8 13.8 Model comparison, audited against what proper model comparison requires

No model is fitted anywhere in this paper and no parameter is estimated from data. That makes several of the standard requirements inapplicable rather than unmet, and the distinction is drawn explicitly here rather than used as cover.

Requirement	Status in this paper
Out-of-sample rather than in-sample performance	**NOT APPLICABLE.** Nothing is fitted; there is no sample.
A matched null with the same free-parameter count	**NOT APPLICABLE** for the same reason. The nearest analogue that *was* run is the `c = 0` column of Section 4.4, which is the independence model against which the correlated models are read.
The number of free parameters stated explicitly	**MET.** The likelihood model has two (`p1`, `p0`), the correlation model three (`p1`, `p0`, `c`), the survivorship model three (`a0`, `s_acc`, `s_inacc`), and the retention illustration four (`eta`, `delta` for each of two conditions). Every one is a declared constant, not a fitted value.
An information criterion, so the parameter count is paid for	**NOT MET.** No AIC or BIC was computed here, and **none has been computed anywhere in this corpus**, for any model, at any point. Where the corpus does report a fit [Curzi, 2026i], the same row is recorded as not met.
Effect sizes with intervals, not only p-values	**NOT MET, and deliberately so.** No p-value is reported anywhere in this paper. The bit weights are point values with no interval, **because an interval on an assumed rate would be false precision**; the honest substitute is the four-point sensitivity check of Section 13.7, which is reported as four points and not as a confidence statement.

The two unmet rows change how the paper should be read. Because no information criterion was computed, the three-parameter correlation model of Section 4.4 has not been shown

to be *better* than the two-parameter independence model in any formal sense — it has been shown to be more realistic on grounds external to the numbers, namely the documented contact between the traditions concerned. **That is an argument from history, not from model selection, and it is labelled as one.**

29.14 14 Limitations

L-1. The rates are assumed and everything denominated in bits inherits that. `p1 = 0.30` and `p0 = 0.10` are a modelling choice with no measurement behind them, as are the illustrative likelihood ratios for studies and the survival rates of Section 5.4. **No number in Sections 4 or 5 is a measurement of anything.** What survives a change of rates is the *ordering* of the columns and the *sign* of the independence collapse, and Section 13.7 tests the first at four points only. A reader who rejects the rates should read every bit figure as illustrative and retain only R2b, which is a proof.

L-2. The shared-source probability `c` is never estimated, only assumed. The paper asserts that the Abrahamic cadence traditions have `c` "well above 0.3" and that the Australian and West African chant traditions have a genuinely lower `c`, and **neither claim is quantified or sourced.** A serious version of this apparatus would estimate transmission dependence from textual stemmatics or from documented contact, and none was attempted.

L-3. The evidence weights are calibrated against a base rate the paper does not measure. The mapping from "replicated result" to `LR ~ 1000` is a stipulation. The published replication literature [Open Science Collaboration, 2015, Ioannidis, 2005] constrains it loosely and in the unfavourable direction, and **a defensible calibration would require a base rate specific to the field of each entry, which was not constructed.**

L-4. The rejection rate is not evidence of stringency, because the candidate set was not independent of the criteria. The register was assembled by the author who set the criteria. 21.2 per cent is what this apparatus rejected from this candidate set, and it would be meaningful only if the candidates had been drawn by someone else, or before the criteria were fixed. **This is the most serious weakness in H5 and it is not repaired anywhere in the paper.**

L-5. The status vocabulary is ordinal at best, and it is used as though the categories were comparable across entries. ESTABLISHED for a prize-grade mechanism with an empty precedent column and ESTABLISHED for a moderate effect with a partially independent precedent column are the same label on very different objects. The `ROLES` field is the only defence, and it is a narrative field rather than a number. **The corpus's own demotion protocol [Curzi, 2026t] — which withdrew a quantitative claim on exactly the ground that its constituents were not instrumented on a common ratio scale — is the instrument that should be run on this vocabulary and has not been.**

L-6. The biological literature has no cluster in this corpus's bibliography and is cited nowhere in this paper. Every biological work — placebo analgesia and its opioid mediation, open-label placebo, PIEZO-family mechanotransduction, force-to-transcription coupling, sonogenetics, cochlear transduction, nucleotide data storage, guide-sequence addressing, epigenetic regulation, retroviral domestication, autophagy — is named in the text and in Appendix A with its journal, volume and year, **and carries no citation key**, because attaching an unrelated key to a biological claim would be worse than the gap. The same applies to the distributed-practice synthesis behind the spacing effect, the memory-palace imaging studies, and the anthropological account of ritual invariance. **Appendix B lists them all. This is a defect of the corpus's bibliography, not a claim that the works do not exist, and it must be closed before submission.** Its practical consequence is that **the evidence column of the register is, in this paper, unverifiable from the reference list** — a reader must go to the named sources directly.

L-7. Several register entries rest on reflexive mechanisms and are not identified. CR-01 through CR-05 and CR-13 concern belief, expectancy and self-fulfilling prophecy, and the endogenous social effect in a linear-in-means reflexive specification is not identified from obser-

vational data [Manski, 1993]; influence and selection are generically confounded in network data [Shalizi and Thomas, 2011, Lyons, 2011]. **No remedy is adopted — not randomisation, not an instrument, not partial-population variation, and not a defended stipulation of the reference group [Brock and Durlauf, 2001] — so those entries record modelling positions rather than identified empirical results.** The register's ESTABLISHED label does not and cannot repair this.

L-8. The expectancy literature the register credits is contested, and the register says so only in its own entries. The original classroom study [Rosenthal and Jacobson, 1968] drew serious methodological criticism; later work supports real but generally small effects [Jussim and Harber, 2005], and the neighbouring literature on measurement reactivity is itself contrary to casual invocation [McCambridge et al., 2014]. **The register's CR-04 states this; a reader who reads only the summary counts will not see it, which is failure mode FM-R.1 operating on this paper.**

L-9. Scale type is stipulated, not demonstrated, for every psychological construct the register touches. Michell [1997]'s objection applies directly and is not answered here; the additive conjoint conditions that would license ratio-scale treatment [Luce and Tukey, 1964, Krantz et al., 1971] were not tested, and almost certainly have never been tested for any of the constructs concerned. **The bits of Section 4 are exempt from this — they are logarithms of a defined ratio — but nothing else in the register is.**

L-10. The surplus functional's form is underdetermined, and where it appears [Curzi, 2026] the alternatives [Latané, 1981, Briscoe et al., 2006] fit the same qualitative facts. Nothing here discriminates between them. **`N_eff = 1 + (N−1)u` is not a Hill number**, and where an effective count is used in Section 6.1 it is this one and it is named [Hill, 1973, Jost, 2006].

L-11. The Lucas critique applies to the apparatus itself. A framework asserting that systems change under observation, then publishing a register of weights, has created exactly the incentive it warns about [Lucas, 1976, Hacking, 1995]. Section 3.5 states the narrow position taken — the weights are declared constants rather than estimated parameters — and **that defence fails immediately for any later use that fits the weights to the entries.**

L-12. Two tally defects in the source register are reported in Section 11.5 and were not corrected. They are printed rather than harmonised because the recomputation that found them is itself part of what a reader should be able to check.

L-13. What would falsify this apparatus rather than the claims it evaluates. If a bridge graded REJECTED here were later established by measurement, the criteria would have been too strict. If a bridge graded ESTABLISHED were shown to rest on the wrong channel, error E7 would have escaped a procedure built to catch it. And **if a second analyst, applying these specifications to the same candidate set, returned a materially different distribution of verdicts, the method would be shown to be analyst-dependent** — which is the test that matters most and which has not been run.

29.15 15 Conclusion

This paper separates the two columns of a concordance apparatus and prices them in a common unit. **The evidence column carries what could have come out otherwise; the precedent column carries only that an idea was independently arrived at and preserved. Two sources agreeing does not double the evidence when only one of them is evidence**, and under the assumed recording rates 0.30 and 0.10 a single traditional record is worth `LR = 3.000`, or **1.585 bits**, against **9.966 bits** for a replicated result and **19.932 bits** for a prize-grade mechanism. Double-counting the record turns an honest 3,000:1 into 1,000,000:1 — **an overstatement factor of 333.3, which is 8.38 bits of confidence not earned.**

Correlated sources are worse than merely redundant. At a ten per cent probability of shared origin, `k` agreeing traditions buy **1.585, 2.546, 2.317, 1.886 and 1.685 bits** for `k = 1` to `5`: **the total decreases after `k = 2`**, and for every `c > 0` the sum converges to the 1.585 bits a single

tradition already supplied. Past two agreeing sources, further agreement is better explained by contact than by discovery.

The instrument that produced the precedent column is characterised exactly. It has unbounded `n` and no control, so repetition drives its variance to zero and leaves its bias untouched; a single uncontrolled observer registers a true standardised shift of `d = 0.20` with probability **0.2858** and of `d = 1.00` with probability **exactly 0.5000**, against roughly **392 subjects per group** a modern design needs at `d = 0.20`. And the preservation filter dominates the source: the same corpus arrives **7.9 per cent or 94.5 per cent accurate — a factor of 11.97 — according only to whether its failures were visible.**

Four bridges are worked to their verdicts and one is rejected in print. Cadence is ESTABLISHED; vibration-to-cell is GRADED, established at the coarse grain and speculative at the fine; fasting-to-autophagy is SPECULATIVE with the number that would settle it stated; and the claim that a tone at 528 Hz repairs DNA is **REJECTED** on a wavelength of 2.9167 m against a 0.34 nm base pair (a ratio of `8.578e9`), a quantum-to-thermal energy ratio of `8.17e−11` at 310 K, and molecular vibrational bands 34.7 to 37.3 octaves above the audible band. **That rejection binds the framework's own sonification pipeline, which may not claim what it has just refused to let anyone else claim.**

Across the register, thirty-two of forty-two entries are ESTABLISHED, six REJECTED, two SPECULATIVE and two badged POSTULATE; fourteen of forty-two (33.3 per cent) carry a qualifier; and seven of the thirty-three attempted bridges (21.2 per cent) fail structural correspondence outright. A register with no rejections would mean the criteria were never binding. **The apparatus is built so that it can reject, and the claim it rejects at greatest length is the one nearest to the corpus's own subject matter.**

29.15.1 Declarations

Data and code availability

No external dataset was collected for this paper. Every number reported here is one of three things: arithmetic on assumed rates that are stated in the text at the point of use (Sections 4 and 5); arithmetic on standard physical constants (Section 7.5); or a count obtained by recomputing the `STATUS` and `C1` fields of every entry of the register reproduced in Appendix A (Section 11.5). The register itself is a bibliographic and methodological artefact, not data about the world. **The five figures are generated by the scripts named in each caption, and those scripts contain no data beyond the numbers printed in this paper.** No result here should be cited as evidence about any tradition, any practitioner population, or any biological system.

Funding

This research received no external funding.

Conflicts of interest

The author declares no conflicts of interest. The concordance apparatus of Section 3.1 is the author's own earlier work, adopted here without modification; that provenance is stated in the text and is the reason the apparatus is described rather than defended.

Author contributions

Single author. Michael Laurence Curzi designed the apparatus, specified the criteria, performed the arithmetic, assembled and audited the register, produced the figures, and wrote the paper.

Ethics

No human-subjects research was conducted and no personal data was processed. The paper discusses psychological, medical and religious material as an object of study and makes no clinical, therapeutic or diagnostic claim; the standing refusals of Section 3.7 are constraints on what the framework will assert and are not reports of any study performed. Traditions are described from published sources with their transmission paths named, and no living community was consulted or observed.

Preregistration

This paper reports no preregistered empirical test, and none is claimed. The Step 0 device of Section 3.1 — fixing the evidence reading in writing before the precedent column is opened — is a procedural analogue of preregistration and is **not** a substitute for one: it constrains the order in which sources are consulted and constrains nothing about the analysis. **Whether Step 0 was in fact honoured for each of the register's forty-three entries cannot be verified from the register, and that is stated here rather than implied otherwise.**

29.16 Appendix A The concordance register

Reproduced in full, including its rejections. **Numbering is stable: `CR–nn` is a permanent identifier and is cited as such throughout the corpus.** The twelve fields are those specified in Section 8.2, and the `USED IN` field records the chapter numbering of the source manuscript, retained unchanged as a provenance record (Section 8.2). **Every biological source named in this appendix carries no citation key, for the reason given in Section 3.6 and listed in Appendix B.**

Entries are grouped by subject.

29.16.1 PART A — BELIEF AND ITS CHANNEL

CR-01 · Belief has at least one complete, physical, verified channel to bodily outcome

CLAIM	Expectation of relief produces measurable analgesia through endogenous opioid signalling.
(+1) SOURCE	Levine, Gordon & Fields, *The Lancet*, 1978.
MEASURED	Placebo analgesia in post-operative dental pain was reversed by the opioid antagonist naloxone, implicating endogenous opioid mediation. The finding is a mechanism of analgesia, not a general theory of placebo; placebo effects are heterogeneous across conditions.
(-1) SOURCE	Therapeutic ritual in documented medical traditions: the physician's manner, the setting, the prescribed form of the encounter, attested from the Hippocratic corpus onward.
RECORDED	That the practitioner's manner and the form of the encounter affect outcome.
ROLES	(+1) evidence, strong, and it carries the claim alone. (-1) precedent, low independence (Old World medical traditions are in continuous contact), ~1.6 bits.
C1	**PASS** — homomorphism.
C2	**PASS** — the bridge predicts that blocking the opioid system attenuates the effect. That prediction was made and tested; it is the 1978 result.
C3	**PASS** — +1 side: identifies a manipulable channel.

0p	Integrates without either side lying: both describe expectation as an input with gain.
STATUS	**ESTABLISHED**
USED IN	Ch 76, 77, 78

CR-02 · The channel does not require deception

CLAIM	Placebo effects can be obtained when the patient is truthfully told they are receiving a placebo.
(+1) SOURCE	Kaptchuk et al., *PLoS ONE*, 2010 (open-label placebo in irritable bowel syndrome), and subsequent open-label trials.
MEASURED	Symptom improvement in IBS patients openly randomised to a placebo described to them as an inert pill. Effect sizes are modest and the literature is active; this must be stated wherever the result is used.
(-1) SOURCE	Contemplative and devotional traditions in which the practitioner is fully informed of form and content — recitation, posture, fasting, disclosed ritual — with no concealed element. Attested across monastic traditions of several lineages.
RECORDED	That disclosed practice, undertaken knowingly, produces reported change of state.
ROLES	(+1) evidence, moderate and active. (-1) precedent, partially independent, ~2 bits.
C1	**PASS** — homomorphism on the structure “the participant’s knowledge of the procedure does not abolish the effect.”
C2	**PASS** — predicts that concealment is not required for efficacy, and therefore that a disclosed protocol should not underperform a concealed one by the mechanism’s own logic. Testable and partially tested.
C3	**PASS**, decisively.
0p	Integrates cleanly.
STATUS	**ESTABLISHED**, with effect sizes explicitly modest.
USED IN	Ch 78, 82, 83, 85

CR-03 · A belief propagates in the world when it is coupled to a true feature of the world

CLAIM	Self-fulfilling prophecies work through a real structural feature of the system, not through the belief alone.
(+1) SOURCE	Merton, *The Self-Fulfilling Prophecy*, Antioch Review, 1948.
MEASURED	Not a measurement — a sociological mechanism with worked cases, the bank run being canonical. The mechanism’s content is the coupling: banks really are fractional-reserve, so a belief in insolvency, acted on, produces insolvency. Without the coupling the belief does not propagate.
(-1) SOURCE	The doctrine that a spoken commitment, oath or vow binds the speaker’s subsequent conduct — attested in legal, monastic and contractual forms across many independently documented societies.
RECORDED	That a stated intention changes what the stater afterwards does, reliably enough to build institutions on.

ROLES	(+1) evidence, and it is the load-bearing side. (-1) precedent, genuinely independent across several legal traditions, ~2 to 3 bits.
C1	**PASS** — homomorphism.
C2	**PASS** — predicts that removing the coupling removes the effect: deposit insurance should suppress bank runs, and it substantially does.
C3	**PASS** — supplies the postulate's conditional clause in operational form.
0p	Integrates. Merton's mechanism IS the conditional clause of the postulate, discovered independently in 1948, and that is the entry's whole point.
STATUS	**ESTABLISHED**
USED IN	Ch 76, 77, 79

CR-04 · Expectancy effects on performance are real, modest, and methodologically contested

CLAIM	Another person's expectation of one's performance measurably affects that performance.
(+1) SOURCE	Rosenthal & Jacobson, 1968, and the subsequent expectancy literature.
MEASURED	The original classroom study reported teacher-expectancy effects on pupil outcomes. It drew serious methodological criticism, stated here rather than omitted. Later work supports real but generally small effects, largest where the expectation changes the expecter's behaviour toward the target.
(-1) SOURCE	Craft and guild apprenticeship: the master's assessment recorded as determining the apprentice's assignment, instruction and progression.
RECORDED	That the master's judgement shapes what the apprentice becomes — an institutional fact about how training is allocated, which is precisely the behavioural channel.
ROLES	(+1) evidence, weak-to-moderate and contested. (-1) precedent, moderately independent, ~2 bits. Neither column is strong here and the entry says so.
C1	**PASS** — homomorphism through the behavioural channel: expectation changes allocation of instruction, which changes outcome.
C2	**PARTIAL** — predicts the effect should vanish where the expecter cannot alter their own behaviour toward the target. Rarely tested in that form.
C3	**PASS** — the intervention point is the behaviour, not the belief.
0p	Integrates only in the behavioural reading. A reading in which expectation acts on the target with no behavioural intermediary is not supported and is not used.
STATUS	**ESTABLISHED** for the behavioural channel, at modest magnitude. **SPECULATIVE** — and this is the sentence that marks it — for any non-behavioural channel.
USED IN	Ch 79, 80

CR-05 · Perception is constructed in part from prior expectation

CLAIM	What is perceived is a joint function of sensory input and prior expectation, not of input alone.
(+1) SOURCE	The predictive-processing literature; Helmholtz's unconscious inference as the historical origin; the psychophysical results treated in the corpus's psychophysical papers.

MEASURED	Context-dependent illusions, priming, bistable percepts responding to instruction, and the psychophysical scaling results of Weber, Fechner and Stevens. The strong theoretical frameworks built on these findings are more contested than the findings; this entry cites the findings.
(-1) SOURCE	Contemplative traditions whose central technical claim is that attention and expectation shape what is experienced. Buddhist and Stoic sources are best documented and operationally specified.
RECORDED	That trained attention reproducibly changes the content of experience, in trainable stages with recognisable milestones.
ROLES	(+1) evidence, strong for the findings. (-1) precedent, partially independent, ~2 bits — and here the –1 column carries unusually rich operational detail, which is the job §4.5 assigns it.
C1	**PASS** — homomorphism, and close to isomorphism at the level "percept = f(input, prior)."
C2	**PASS** — predicts that manipulating priors changes reported percept at fixed input. Tested extensively; holds.
C3	**PASS** on both sides.
0p	Integrates.
STATUS	**ESTABLISHED**
USED IN	Ch 76, 77, 81

CR-06 · Belief-based interventions with weak channels produce weak effects

CLAIM	Interventions that change belief without changing a strong channel produce small effects in large samples.
(+1) SOURCE	Sisk, Burgoyne, Sun, Butler & Macnamara, *Psychological Science*, 2018 (meta-analyses of growth-mindset interventions).
MEASURED	Very small overall effects of growth-mindset interventions on academic achievement, with some indication of larger benefit in high-risk and low-socioeconomic-status subgroups. Related: stereotype-threat findings have had replication difficulty.
(-1) SOURCE	None admissible. Comparing intervention magnitudes requires a control group and population statistics, both outside the envelope of §5.3.
RECORDED	Nothing.
ROLES	(+1) evidence, strong (large replications). (-1) precedent: none, 0 bits, by the nature of the instrument.
C1	**N/A** — no bridge is proposed.
C2	**PASS** — predicts that the postulate's effects scale with channel gain, and that channel-free interventions approach zero effect.
C3	**PASS** — it is the diagnostic tool of the belief-failure analysis (CCP-035).
0p	N/A.
STATUS	**ESTABLISHED**, and it functions as a REJECTION of the strong form of the postulate.
USED IN	Ch 80, 81, 87

CR-07 · Belief does not act at a distance on another person's body

CLAIM	That directed belief or intention alters another person's physiology without any physical intermediary.
(+1) SOURCE	None offered: this author is aware of no replicated result establishing such an effect. **No systematic survey is claimed; what is asserted is the absence of a known replicated result.**
MEASURED	Nothing that survives replication, to this author's knowledge.
(-1) SOURCE	Numerous traditions record claims of distant action. Dated and named where used; not credited.
RECORDED	Claims of distant efficacy. Envelope check (§5.3): P2 and P4 both fail; the visible-failure rule gives no correction, since failure is always attributable to the practitioner (T5). The exact profile the preservation filter selects on memorability.
ROLES	(+1): empty. (-1) precedent: 0 bits — the claim sits outside the instrument's operating envelope, so its presence in the record carries no information about the world.
C1	**FAIL** — no shared structure; no mechanism on either side.
C2	**FAIL** — no falsifiable prediction is offered by proponents in a form that could fail.
C3	**FAIL**
0p	Does not integrate.
STATUS	**REJECTED**, and additionally **REFUSED** as a claim the framework will make (standing refusal, §3.7).
USED IN	Ch 80, 87

CR-08 · The postulate

CLAIM	Belief creates reality if the belief is grounded in truth — where "grounded in truth" means that a real channel exists between the belief and the outcome.
(+1) SOURCE	Not a measured result. The postulate's *channels* are measured and are entries CR-01 through CR-05; the postulate itself is the author's.
MEASURED	Each channel separately. The postulate is not established by summing them; it states what they have in common.
(-1) SOURCE	Traditions holding that intention or faith is efficacious. Named and dated where used.
RECORDED	The unconditional form — that belief is efficacious as such.
ROLES	(+1) evidence for the individual channels. (-1) precedent for the unconditional claim, which the framework does not adopt — so the precedent supports a different proposition and is credited at ~0 bits *for this claim*.
C1	**PARTIAL** — the traditional claim and the author's claim differ at precisely the load-bearing conjunction.
C2	**PASS** — the conditional form predicts that effects appear where a channel exists and vanish where it does not. CR-01 to CR-06 are that prediction being tested.
C3	**PASS** — the grounding protocol (CCP-035) is the operational form.
0p	Integrates only in the conditional form. The unconditional form is refused.
STATUS	**POSTULATE**, badged in the same sentence at every use, per the badging rule of §8.3.
USED IN	Ch 76, 77, 80, 81, 84, 88, 90

29.16.2 PART B — THE UNCERTAINTY

CR-09 · Heisenberg's relation is a property of conjugate variables, not of measurement disturbance

CLAIM	`dx . dp >= hbar / 2` follows from the Fourier relationship between position and momentum representations, and is not a statement that the measurer disturbs the measured.
(+1) SOURCE	Standard quantum mechanics; Heisenberg 1927 and the subsequent formalisation. `hbar / 2 = 5.27e-35 J s`.
MEASURED	A theorem of the formalism, consistent with a century of experiment. The disturbance reading is a widespread misconception and the framework corrects it explicitly.
(-1) SOURCE	None admissible. No traditional source records a conjugate-variable relation, and no first-person instrument could have detected one (§5.3, exclusion: requires an instrument).
RECORDED	Nothing.
ROLES	(+1) evidence, decisive. (-1): none, 0 bits — an empty `-1` column is a normal outcome, not a gap to be filled.
C1	**N/A** — no bridge proposed.
C2	**PASS** as physics.
C3	**PASS** — it is the correction the corpus's conjugate-uncertainty analysis exists to make (CCP-032).
0p	N/A.
STATUS	**ESTABLISHED** (as physics; no concordance drawn).
USED IN	Ch 70, 71, 72

CR-10 · The energy-time relation has different status from position-momentum

CLAIM	`dE . dt >= hbar / 2` is not the same kind of statement as `dx . dp >= hbar / 2`, because time is not an operator in quantum mechanics.
(+1) SOURCE	Standard quantum mechanics.
MEASURED	The formal asymmetry is structural. Several energy-time relations exist with different derivations and interpretations; they are not one relation.
(-1) SOURCE	None admissible.
RECORDED	Nothing.
ROLES	(+1) evidence. (-1): none, 0 bits.
C1	**N/A**
C2	**PASS** as physics.
C3	**PASS** — it blocks a common over-extension in which the energy-time form is used to license claims about events in time.
0p	N/A.
STATUS	**ESTABLISHED** (as physics; no concordance drawn).
USED IN	Ch 70, 72

CR-11 · The Gabor limit is the real uncertainty principle of this work

CLAIM	`dt . df >= 1 / (4 pi) = 0.079577`. Every wave, including sound, obeys it. It is the same Fourier mathematics as Heisenberg with no quantum content.
(+1) SOURCE	Gabor, *Theory of Communication*, Journal of the IEE, 1946.
MEASURED	A theorem of Fourier analysis, verifiable on any spectrum analyser. `1/(4 pi) = 0.07957747154594767`. Window against minimum frequency resolution: `1 ms -> 79.577 Hz`; `10 ms -> 7.958 Hz`; `100 ms -> 0.796 Hz`; `1000 ms -> 0.080 Hz`.
(-1) SOURCE	Instrument-making practice that a very short sound has no definite pitch — encoded in classing percussion as unpitched, in treating the attack transient as distinct from the sustained tone, and in requiring a tuning reference to be held. Attested independently in several regions.
RECORDED	That a tone must be held to have a pitch. Recorded operationally — as how long to sustain a reference note, and as which instruments do and do not carry pitch — never as a relation between two quantities.
ROLES	(+1) evidence, decisive; it is a theorem. (-1) precedent, genuinely independent across instrument-making traditions, ~2 to 3 bits, and it is precedent for the phenomenon, not for the relation.
C1	**PASS** — homomorphism. “Held long enough” is `dt`; “definite pitch” is small `df`.
C2	**PASS** — predicts an exact reciprocal trade with a computable constant, which is measurable and holds.
C3	**PASS** — it hard-constrains genomic-audio design (CR-12) and the rendering of essence frequencies.
0p	Integrates with unusual force: the tradition recorded the qualitative fact for centuries and the mathematics supplies the constant. Neither side has to overstate.
STATUS	**ESTABLISHED**
USED IN	Ch 65, 69, 71, 72

CR-12 · The Gabor limit constrains genomic-audio rendering speed

CLAIM	Essence frequencies and sonified spectra cannot be rendered arbitrarily fast without spectral smearing; time resolution and frequency resolution trade against each other by CR-11.
(+1) SOURCE	CR-11, applied.
MEASURED	Arithmetic. Two tones `1 Hz` apart need a window of at least `0.0796 s`; `0.1 Hz` apart, at least `0.796 s`. The essence law’s spacing follows `f(n) = k n^2`, `k = 0.483425732988414 Hz`, so the resolution demand is set by the smallest interval in the rendered set.
(-1) SOURCE	Liturgical and recitational traditions specifying a minimum duration per syllable or tone and treating hurried recitation as defective. Vedic recitation is the most exactingly specified case; plainchant the best-documented Western one.
RECORDED	Prescribed pace, and the doctrine that speed degrades the practice.
ROLES	(+1) evidence, decisive (arithmetic). (-1) precedent, moderate independence, ~2 bits. The tradition’s reason for the rule is not adopted; only the rule.
C1	**PARTIAL** — rule and theorem coincide in prescription, not in content; the tradition had many reasons to slow recitation unrelated to spectra.
C2	**PASS** — predicts a computable minimum duration per rendered tone, which the sonification pipeline (CCP-031) must satisfy.
C3	**PASS** — it is a design constraint with a number attached.

0p	Integrates weakly.
STATUS	**ESTABLISHED** as an engineering constraint. **SPECULATIVE** — marked here, in this sentence — as any claim that traditional pacing rules were responsive to spectral resolution.
USED IN	Ch 65, 69, 71

CR-13 · The future as conjugate variable

CLAIM	The uncertainty attaching to a future event shares conjugate-variable structure with Heisenberg's relation.
(+1) SOURCE	None. This is an analogy and is badged as one everywhere it appears.
MEASURED	What is genuinely shared: conjugate-variable structure, the impossibility of simultaneous sharpness in both members of a pair, and the Fourier trade-off. What is NOT shared: `hbar`, quantization, non-commuting operators, or any experimental result.
(-1) SOURCE	Divinatory and prognostic traditions treating the future as a distribution of possibilities rather than a single determined outcome.
RECORDED	That prognostication yields tendencies rather than verdicts, and that specificity about *when* costs specificity about *what*.
ROLES	(+1): none — analogy only, 0 bits of evidence. (-1) precedent, low independence, ~1.6 bits. Both columns are weak.
C1	**PARTIAL** — analogy in the grading of §3.2, not homomorphism.
C2	**PARTIAL** — the sharpening trade-off is a real prediction about forecasting, but it does not require quantum mechanics and is better derived without it.
C3	**PASS** — as a way of thinking about forecasts.
0p	Integrates only as analogy.
STATUS	**SPECULATIVE** — and this is the sentence that marks it: the identification of future-event uncertainty with quantum uncertainty is speculative and is presented as analogy with its badge on, never as identity. The corpus's comfort-weighted amplitude already treats the future as an amplitude-weighted ensemble, which is the framework's own treatment and needs no quantum mechanics to stand.
USED IN	Ch 72

CR-14 · Decoherence destroys macroscopic superposition extremely fast

CLAIM	Macroscopic superpositions do not persist, because interaction with the environment destroys phase coherence on timescales far shorter than any biological process.
(+1) SOURCE	The decoherence literature; environment-induced superselection.
MEASURED	Decoherence is observed and its scaling with system size and coupling confirmed in controlled systems. Timescale estimates are strongly model-dependent; this entry quotes no number for biological systems and the corpus's quantum-formalism analysis gives estimates (CCP-033) with their assumptions attached.
(-1) SOURCE	None admissible.
RECORDED	Nothing.
ROLES	(+1) evidence, strong. (-1): none, 0 bits.

C1	**N/A** — this entry is an objection, not a bridge.
C2	**PASS** — predicts that any proposed quantum-coherent biological mechanism must specify how coherence is protected, and most cannot.
C3	**PASS** — it is the filter the corpus's quantum-formalism analysis applies (CCP-033).
0p	N/A.
STATUS	**ESTABLISHED**, and it functions as the principal objection this series confronts rather than avoids (standing refusal, §3.7).
USED IN	Ch 73, 74

CR-15 · Consciousness-causes-collapse

CLAIM	That observation by a conscious mind is what collapses the quantum wave function.
(+1) SOURCE	The von Neumann-Wigner interpretation. This is a minority historical interpretation, not a mainstream position, and the entry states that as its principal content.
MEASURED	Nothing distinguishes it experimentally from other interpretations. The measurement problem is genuinely open; it is not open in the direction of licence. CR-14 is the standing objection.
(-1) SOURCE	Traditions holding that mind participates in constituting the world. Named where used.
RECORDED	Doctrinal positions on the relation of mind to world. Envelope check: P3 fails — nothing in a first-person instrument could bear on this question.
ROLES	(+1): a minority interpretation, not evidence. (-1) precedent: 0 bits for this claim, since the question lies outside the instrument's envelope.
C1	**FAIL** — the traditional doctrine and the interpretation share vocabulary, not structure.
C2	**FAIL** — no distinguishing prediction.
C3	**FAIL**
0p	Does not integrate.
STATUS	**REJECTED** as a basis for any claim in this series. Presented in the corpus's quantum-formalism analysis (CCP-033) as a minority historical interpretation and as nothing more.
USED IN	Ch 73, 74

29.16.3 PART C — BOUNDARY AND SHAPE

CR-16 · The Casimir force exists and has been measured

CLAIM	`F/A = −pi^2 hbar c / (240 a^4)` between ideal parallel plates.
(+1) SOURCE	Casimir, 1948 (prediction); Lamoreaux, *Physical Review Letters*, 1997; Mohideen & Roy, *Physical Review Letters*, 1998 (measurement).
MEASURED	The predicted force, at the predicted scaling, in the sub-micrometre regime. Computed pressures: `10 nm -> 1.3e5 Pa` (1.28 atm); `100 nm -> 13 Pa`; `1 um -> 1.3e−3 Pa`; `1 mm -> 1.3e−15 Pa`.
(-1) SOURCE	None admissible.
RECORDED	Nothing.

ROLES	(+1) evidence, decisive. (-1): none, 0 bits.
C1	**N/A**
C2	**PASS** — the `a^-4` scaling is the prediction and it was confirmed.
C3	**PASS**
0p	N/A.
STATUS	**ESTABLISHED**
USED IN	Ch 75

CR-17 · The Casimir force does nothing at biological or architectural scale

CLAIM	That Casimir forces have any consequence in a cell or a room.
(+1) SOURCE	CR-16, applied.
MEASURED	The `a^-4` scaling. At `1 um` the pressure is `1.3e-3 Pa`; at `1 mm` it is `1.3e-15 Pa`, which is `1.28e-20` atmospheres. Twenty orders of magnitude separate the measured regime from the scale of a room.
(-1) SOURCE	Not applicable; no traditional source is invoked and none would help.
RECORDED	Nothing.
ROLES	(+1) evidence, decisive against. (-1): none.
C1	**FAIL** by scale (error E6).
C2	**FAIL** — no biological prediction survives the arithmetic.
C3	**FAIL**
0p	Does not arise.
STATUS	**REJECTED.** This entry is mandatory wherever Casimir appears in this series (standing refusal, §3.7) and the pressure table is printed with it.
USED IN	Ch 64, 75, 87

CR-18 · Boundary geometry alone determines which modes can exist, with measurable consequence

CLAIM	The shape of a bounded region selects the set of modes it admits, and that selection has physical consequence without anything being added or powered.
(+1) SOURCE	The Casimir effect (CR-16) as the most rigorous demonstration; room acoustics and modal analysis as the everyday one; the vibrating string as the elementary one.
MEASURED	Casimir: a force arising purely because the plates exclude every mode whose wavelength does not fit between them. Acoustics: room modes computed from dimensions alone and measured in the room. **Nothing is added; nothing is powered; the shape does all of it.**
(-1) SOURCE	Monochord practice: the Pythagorean division of a string, in which pitch is set by boundary position alone, attested from antiquity; and the deliberate proportioning of resonant chambers in temple, chapel and hall building.
RECORDED	That where you put the boundary determines what tone you get, and nothing else does. Recorded operationally as ratios of string length.
ROLES	(+1) evidence, decisive. (-1) precedent, and unusually strong precedent: independent instrument traditions in several regions arrived at boundary-determined pitch, ~2 to 3 bits.
C1	**PASS** — close to isomorphism.

C2	**PASS** — predicts computable mode sets from geometry alone, in both the acoustic and the electromagnetic case. Tested continuously.
C3	**PASS** — it is the design principle of the corpus's boundary-geometry material.
0p	Integrates without strain.
STATUS	**ESTABLISHED**
USED IN	Ch 13, 14, 33, 75

CR-19 · "The shape is the function"

CLAIM	That the framework's recurring thesis — that geometry alone determines what a system can do — has a rigorous physical exemplar.
(+1) SOURCE	CR-18.
MEASURED	Mode selection by boundary, in the Casimir and acoustic cases.
(-1) SOURCE	Architectural and instrument-making traditions as in CR-18; and the design-pattern tradition descending from Alexander's pattern language (1977), which is modern but is the framework's direct ancestor.
RECORDED	That proportion determines behaviour, recorded as buildable rules.
ROLES	(+1) evidence for the physical exemplar. (-1) precedent, ~2 bits.
C1	**PASS** for wave systems.
C2	**PASS** within wave systems; the transfer to social and institutional geometry is a claim about model form, not about physics, and is badged as such (§3.4).
C3	**PASS**
0p	Integrates, with the badge.
STATUS	**ESTABLISHED** for wave systems. **POSTULATE** — badged here — for the transfer of "the shape is the function" to social and institutional systems, which is a claim about model form and not about physics.
USED IN	Ch 13, 14, 33, 75, 88

29.16.4 PART D — THE CELL AS RECEIVER

CR-20 · Mechanical force opens ion channels: PIEZO1 and PIEZO2

CLAIM	There is a real, established pathway by which mechanical force becomes a cellular signal.
(+1) SOURCE	Coste et al., *Science*, 2010 (identification of Piezo1 and Piezo2 as essential components of mechanically activated cation channels). Nobel Prize in Physiology or Medicine, 2021, to Ardem Patapoutian for receptors for touch, shared with David Julius for temperature receptors.
MEASURED	That these proteins are required components of mechanically gated cation currents, and that mechanical force opens them, admitting ions and initiating signalling.
(-1) SOURCE	Traditions of therapeutic touch, pressure and manipulation — massage and bodywork attested independently in several regions — recording that mechanical pressure produces reproducible physiological change.
RECORDED	That pressure produces effect, recorded as technique: where, how hard, how long. No mechanism is recorded and none could have been.

ROLES	(+1) evidence, prize-grade, ~20 bits on the register's scale. (-1) precedent, genuinely independent across regions, ~2 to 3 bits — against twenty.
C1	**PASS** coarse: mechanical input, transduction, physiological output.
C2	**PASS** — since sound is mechanical, the bridge predicts that acoustic pressure at sufficient amplitude can engage mechanotransductive pathways. This is the basis of sonogenetics (CR-22) and it holds.
C3	**PASS**
0p	Integrates at the coarse grain only, and the entry is used only at that grain.
STATUS	**ESTABLISHED** — that a real pathway exists from pressure wave to cellular signal. This is the strongest single result underwriting Part XIII and it is also the one most at risk of over-extension; see CR-26.
USED IN	Ch 64, 65, 68

CR-21 · Surface force reaches the nucleus, stretches chromatin, and upregulates transcription

CLAIM	Mechanical input at the cell surface produces a change in gene expression by a direct physical route.
(+1) SOURCE	Tajik et al., *Nature Materials*, 2016.
MEASURED	That force applied at the cell surface transmits through the cytoskeleton to the nucleus, directly stretches chromatin, and upregulates transcription. This is mechanical input to gene expression, published, direct, and it is the single most important evidence entry in this series.
(-1) SOURCE	None admissible. No traditional source records anything at this scale; the exclusion is P3, requires an instrument.
RECORDED	Nothing.
ROLES	(+1) evidence, strong. (-1): none, 0 bits.
C1	**N/A** — no bridge proposed.
C2	**PASS** — predicts a force threshold and a time course for transcriptional response, both measurable.
C3	**PASS** — it establishes that the mechanical-to-genomic route is not hypothetical.
0p	N/A.
STATUS	**ESTABLISHED** — and its limit is CR-26: it establishes *that* mechanical input reaches transcription, and nothing about *sequence-specific* control.
USED IN	Ch 64, 65, 68, 69

CR-22 · Ultrasound can activate specified channels: sonogenetics

CLAIM	An acoustic stimulus can be used to activate a chosen, previously specified channel in a cell.
(+1) SOURCE	Ibsen, Tong, Schutt, Esener & Chalasani, *Nature Communications*, 2015 (TRP-4 in *C. elegans*); Duque et al., 2022 (hsTRPA1).
MEASURED	Activation, by applied ultrasound, of neurons expressing an ultrasound-sensitive channel. The selectivity comes from which cells express the channel — engineered in advance, not carried by the acoustic signal.
(-1) SOURCE	None admissible.
RECORDED	Nothing.

ROLES	(+1) evidence, strong. (-1): none, 0 bits.
C1	**N/A**
C2	**PASS** — predicts that acoustic addressing of cells is achievable when the address is pre-installed as a channel.
C3	**PASS** — and it sharpens CR-26 rather than softening it.
0p	N/A.
STATUS	**ESTABLISHED**, with the selectivity caveat stated in the entry and repeated at every use.
USED IN	Ch 64, 66, 68

CR-23 · Biology builds exquisite mechanical receivers

CLAIM	Extremely sensitive mechanical reception is achievable in tissue; cochlear hair cells are the existence proof.
(+1) SOURCE	The cochlear mechanotransduction literature; hair-cell tip-link gating.
MEASURED	That hair-cell stereocilia deflections of very small magnitude gate transduction channels via tip links, and that the cochlea performs frequency analysis mechanically along the basilar membrane.
(-1) SOURCE	Traditions treating the ear as the reference measuring device — tuning by ear to beat rates, attested independently wherever fixed-pitch instruments were built.
RECORDED	That the ear resolves frequency differences finer than any available instrument could, and that it does so by hearing beats. Recorded as tuning procedure, which is operationally exact and remains in use.
ROLES	(+1) evidence, strong. (-1) precedent, independent across regions, ~2 to 3 bits, and it is precedent for the ear's resolving power, not for its mechanism.
C1	**PASS** at the level "biological tissue performs high-resolution mechanical frequency analysis."
C2	**PASS** — beat-rate tuning predicts a frequency-discrimination threshold, which is measurable and matches the recorded practice.
C3	**PASS**
0p	Integrates.
STATUS	**ESTABLISHED**
USED IN	Ch 64, 65

CR-24 · Chant produces measured autonomic effects, and the identified channel is respiration

CLAIM	Sustained recitation changes cardiovascular autonomic state, principally by enforcing a slow breathing rate.
(+1) SOURCE	Bernardi et al., *BMJ*, 2001.
MEASURED	That recitation of the Latin rosary and of a yoga mantra both brought respiration to approximately six breaths per minute — a period of `10.0 s`, a rate of `0.100 Hz` — and enhanced baroreflex sensitivity.

(-1) SOURCE	Recitational traditions: Vedic recitation; Christian plainchant under the canonical hours; Tibetan overtone chanting; Sufi *dhikr*; West African and Afro-diasporic drumming and song; Australian Aboriginal drone practice. **The West African and Australian instances have no plausible shared source with the Indo-European ones, so independence is genuine.**
RECORDED	That sustained vocalisation at length changes bodily and mental state reproducibly, and detailed technique for producing it.
ROLES	(+1) evidence, moderate. (-1) precedent, genuinely independent, ~2 to 3 bits — the strongest precedent in the register. It is precedent for the phenomenon and not for its cause.
C1	**PASS** — homomorphism: sustained periodic vocal effort, an enforced respiratory period, an autonomic state change.
C2	**PASS** — predicts that the effect tracks respiratory rate rather than acoustic content, which is testable by pacing respiration independently of the sound.
C3	**PASS** on both sides.
0p	Integrates, provided the –1 column is credited for the effect and not for a mechanism.
STATUS	**ESTABLISHED**
USED IN	Ch 61, 64, 82, 85

CR-25 · Chant acts through PIEZO-family mechanotransduction

CLAIM	That the state changes traditions attribute to chant are mediated to a material degree by mechanically gated ion channels.
(+1) SOURCE	None directly. CR-20 establishes the pathway exists; no source known to this author measures its contribution to chant.
MEASURED	Nothing on this specific attribution. At least four better-supported channels compete: respiratory entrainment (CR-24), the social setting, the attentional demand, and expectancy (CR-01).
(-1) SOURCE	As CR-24.
RECORDED	The effect, not the cause.
ROLES	(+1): empty for this attribution. (-1) precedent, ~2 to 3 bits, and it does not bear on mechanism at all.
C1	**FAIL** at the fine grain — the –1 side records no mechanism, so there is nothing to correspond to.
C2	**PASS** — the separating experiment is specifiable: deliver the same acoustic exposure to a passive listener whose respiration is paced differently, against a vocaliser producing it, and see whether the effect survives removal of the breathing pattern.
C3	**PARTIAL**
0p	Does not integrate at the fine grain.
STATUS	**SPECULATIVE** — and this is the sentence that marks it: attributing chant's effects to PIEZO-family mechanotransduction is speculative, unsupported by any measurement known to this author, and in competition with four better-supported channels. Retained because it is falsifiable and the falsifying experiment is specified. **The register's worked instance of error E7.**
USED IN	Ch 61, 64, 87

29.16.5 PART E — THE OPEN PROBLEM

CR-26 · There is no established mechanism by which a cell demodulates sequence-specific information from an acoustic signal

CLAIM	The gap, stated exactly as the Methodology Protocol states it.
(+1) SOURCE	The absence of one, across the mechanotransduction and sonogenetics literatures. **Everything upstream is real and is in this register:** DNA data storage (CR-28), gRNA-format addressing and Cas12a self-processing (CR-29), latent capability (CR-31), epigenetic regulation (CR-30), mechanotransduction (CR-20, CR-21, CR-22).
MEASURED	Each upstream component separately, and none of them together. CR-22's selectivity is engineered into which cells express the channel, not carried by the signal. CR-27's spatial argument applies: at `528 Hz` in soft tissue the wavelength is `2.9167 m`, `8.6e9` times a base pair, so an audio-band wave imposes no structure at sequence scale.
(-1) SOURCE	Not applicable. No precedent could bear on an open mechanistic question (§5.3, exclusion: hidden mechanism).
RECORDED	Nothing, necessarily.
ROLES	(+1): the gap itself, well specified. (-1): none, 0 bits, by the nature of the question.
C1	**N/A** — this entry is a boundary, not a bridge.
C2	**PASS** — it is maximally predictive in the negative direction: it says exactly what an experiment would have to show.
C3	**PASS** — naming the gap sharply is the most useful thing this series can do.
0p	N/A.
STATUS	**ESTABLISHED** as an open problem. This entry is restated wherever this series touches the channel (standing clause, §3.7), and no entry in this register may be combined with another to close it.
USED IN	Ch 64, 65, 66, 68, 69, 82, 83, 87

CR-27 · "528 Hz repairs DNA"

CLAIM	That a tone at 528 Hz repairs, restores, or beneficially modifies DNA.
(+1) SOURCE	None known to this author. Stated with the uncertainty on the record: no systematic survey is claimed; what is asserted is that I know of no replicated, peer-reviewed result establishing the effect, and the claim is treated accordingly.
MEASURED	Nothing that survives replication, to this author's knowledge. Four independent computed objections follow. (a) Spatial scale: wavelength in soft tissue `1540 / 528 = 2.9167 m`; ratio to a nucleus `4.9e5`, to a base pair `8.6e9`. The field is spatially uniform across a nucleus and cannot select a sequence. (b) Quantum energy: `h f / kT = 8.17e-11` at 310 K — the acoustic quantum is about one hundred-billionth of ambient thermal energy. (c) Frequency scale: molecular vibrational modes sit at `1.5e13` to `9.0e13 Hz`, which is 34.7 to 37.3 octaves above 528 Hz; an audible tone is not a molecular resonance. (d) Reference pitch: 528 Hz is a specific note only under a twentieth-century tuning convention, which the claim does not specify.

(-1) SOURCE	**VOID.** The “Solfeggio frequencies” are presented as ancient and are not. Guido of Arezzo’s eleventh-century solmization is real and assigns no frequencies to anything — it is a system of relative intervals taught in a period with no absolute pitch standard. The numerical values were produced in the 1990s by numerological reduction of a biblical passage and popularised in Horowitz and Puleo’s *Healing Codes for the Biological Apocalypse* (1999).
RECORDED	Nothing traditional. This is failure mode FM-61.6, the Costume: a recent construction presented as traditional so that the `–1` column appears populated when it is empty.
ROLES	(+1): empty. (-1): void — 0 bits, not few.
C1	**FAIL** — metaphor only; no shared structure survives the scale check.
C2	**FAIL** — generates no prediction that survives objection (a).
C3	**FAIL** — a practice built on a false channel is not utility.
0p	Does not integrate.
STATUS	**REJECTED.** And the rejection binds the framework: the sonification pipeline (CCP-031) may not claim what this entry refuses. A transposed tone is not a molecular resonance; the transposition is a stated convention carrying no mechanism; the essence frequencies are essence frequencies and not physical resonances (§3.4); and nothing in this series claims sequence-specific acoustic action on genomic material.
USED IN	Ch 61, 68, 69, 87

29.16.6 PART F — THE LIBRARY AND ITS ADDRESSING

CR-28 · DNA is a usable digital storage medium

CLAIM	Arbitrary digital data can be encoded in, stored as, and recovered from synthesised DNA.
(+1) SOURCE	Church, Gao & Kosuri, *Science*, 2012.
MEASURED	Encoding and recovery of a 5.27-megabit volume (0.659 MB) in synthesised DNA. The theoretical ceiling is `log2(4) = 2` bits per base; practical schemes run below it to avoid homopolymer runs and secondary structure. At 1 bit per base the encoded volume needs `5.27e6` bases, which is `0.170%` of a haploid human genome; the haploid genome’s capacity is `0.775 GB` at the 2-bit ceiling.
(-1) SOURCE	Scribal and mnemonic traditions treating text as a substrate for arbitrary content: the Masoretic apparatus of letter- and word-counts for verifying transmission, and the Vedic *krama* and *jata* recitation patterns, which encode one text in permuted orders for error detection.
RECORDED	Error-detecting redundancy applied to a sequence substrate. The Vedic permutation schemes are, in modern terms, a check-code over an ordered sequence; the Masoretic counts are a checksum.
ROLES	(+1) evidence, strong. (-1) precedent, and unusually apt: the two traditions named are independent of each other, ~2 to 3 bits. It is precedent for sequence-with-checksum, not for molecular storage.
C1	**PASS** — homomorphism, and a close one: an ordered symbol sequence, an alphabet, a redundancy scheme, a recovery procedure.
C2	**PASS** — predicts that error rates in a sequence medium are manageable by redundancy at a computable cost in density.
C3	**PASS**

0p	Integrates cleanly, and the –1 column contributes real design intuition about check-coding.
STATUS	**ESTABLISHED**
USED IN	Ch 66, 67, 69

CR-29 · A guide sequence is an address, and Cas12a carries a native multicast destination list

CLAIM	Guide-RNA format is a routing header; Cas12a's self-processing of its own crRNA array is a genuine multiple-destination list in the biological system itself.
(+1) SOURCE	Zetsche et al., *Cell*, 2015 (Cpf1/Cas12a as a single RNA-guided endonuclease); Fonfara et al., *Nature*, 2016 (Cpf1 processes its own precursor CRISPR RNA).
MEASURED	That Cas12a cleaves its own pre-crRNA array into mature guides without a separate processing RNA or host RNase, so one transcribed array yields several distinct targeting guides. **This is a destination list encoded in one sequence and unpacked by the receiver.**
(-1) SOURCE	Correspondence-table traditions read as address spaces: multiply-keyed indexes in which one entry carries several independent retrieval keys, attested in the Western esoteric compilations and, independently, in Chinese and Indian classificatory schemes.
RECORDED	That an element can be reached by any of several keys, and that a list of keys can be carried as a unit.
ROLES	(+1) evidence, strong. (-1) precedent, moderate independence, ~2 bits — and precedent for the abstract structure of multiply-keyed addressing, nothing biological.
C1	**PASS** — homomorphism on the structure "one carried object unpacks into several addresses."
C2	**PASS** — predicts that array length trades against per-guide efficiency, which is measurable.
C3	**PASS** — it is the basis of the addressing scheme (CCP-030).
0p	Integrates. The channel-addressing correspondence stated in the addressing analysis (CCP-030) is a correspondence of addressing structure and carries no claim that anything is delivered.
STATUS	**ESTABLISHED** for the biology. The routing-header reading is a structural correspondence and is stated as such, not as a mechanism.
USED IN	Ch 66, 69

CR-30 · Targeting and editing are separable functions

CLAIM	A system can be directed to a specific genomic locus and act there without cutting or changing any sequence.
(+1) SOURCE	Qi et al., *Cell*, 2013 (catalytically dead Cas9 for sequence-specific control of gene expression); Gilbert et al., *Cell*, 2014 (genome-scale CRISPR-mediated repression and activation).
MEASURED	That a nuclease-dead Cas9 retains guide-directed binding while losing cleavage, and that fusing it to effector domains represses or activates transcription at the targeted locus. Bind a locus, change its expression, cut nothing.

(-1) SOURCE	None admissible. No traditional source could distinguish targeting from editing at a molecular level.
RECORDED	Nothing.
ROLES	(+1) evidence, strong. (-1): none, 0 bits.
C1	**N/A**
C2	**PASS** — predicts that regulatory intervention has a ceiling set by what is already present at the locus, which is CR-34.
C3	**PASS** — it is the established proof underwriting the honesty clause that nothing in this architecture edits DNA.
0p	N/A.
STATUS	**ESTABLISHED**
USED IN	Ch 66, 67, 83

CR-31 · Latent capability can be activated by regulatory signal alone

CLAIM	A small set of regulatory factors can revert a differentiated cell to a pluripotent state without adding information to the genome.
(+1) SOURCE	Takahashi & Yamanaka, *Cell*, 2006. Nobel Prize in Physiology or Medicine, 2012, to John Gurdon and Shinya Yamanaka.
MEASURED	That four defined transcription factors reprogramme differentiated fibroblasts to induced pluripotent stem cells. Nothing is added to the genome; the capability was already present and was being suppressed.
(-1) SOURCE	The doctrine, arrived at independently in several contemplative and philosophical traditions, that practice *uncovers* rather than *installs* — Plato's *anamnesis*; the Zen formulation of original enlightenment; the sculptor's commonplace that the form is already in the stone.
RECORDED	That what a practice produces was already present and obstructed, and that the operation is removal rather than addition.
ROLES	(+1) evidence, prize-grade, ~20 bits. (-1) precedent, partially independent, ~2 bits. The asymmetry is twentyfold.
C1	**PASS** — homomorphism on the structure "the content is present; the operation changes what is expressed, not what is stored." This is a genuinely deep shared pattern and not a verbal one.
C2	**PASS** — the bridge generates the sharpest constraint in this series: a purely regulatory intervention has a ceiling given by the latent repertoire, and nothing outside the repertoire can be reached. That is CR-34 and it binds the framework's own protocol.
C3	**PASS** on both sides.
0p	Integrates without either side lying: the traditions need not have known about transcription factors, the biology need not endorse *anamnesis*, and both describe expression versus storage.
STATUS	**ESTABLISHED** for the structural correspondence, with column roles as stated. **SPECULATIVE** — marked here — for any claim that a contemplative practice acts on cellular reprogramming.
USED IN	Ch 67, 84, 85

CR-32 · The genome is mostly regulatory sequence, and "junk DNA" is retired

CLAIM	Non-coding sequence is the great majority of the genome and is largely regulatory or structural rather than inert.
(+1) SOURCE	Contemporary genomics; the framework's own statement of the open problem (CCP-031).
MEASURED	Approximate, estimate-dependent figures: non-coding ~98% of the human genome; transposable elements ~45%; endogenous retrovirus-derived ~8%. On `3.1e9` bp haploid that is `~3.04e9`, `1.40e9` and `2.48e8` bp. Categories include promoters, enhancers, silencers, insulators, lncRNA, miRNA. **Percentages vary by method and by what "functional" means; cited as approximate.**
(-1) SOURCE	Library and archive traditions in which the catalogue, apparatus and marginalia occupy more volume than the primary texts, and in which the apparatus is what makes the collection usable.
RECORDED	That an archive is mostly not its contents, and that the non-content part is what confers access.
ROLES	(+1) evidence, strong. (-1) precedent, ~1.6 bits, and it is an analogy about archives, not a claim about genomes.
C1	**PARTIAL** — analogy rather than homomorphism.
C2	**PARTIAL** — the archive reading generates no genomic prediction.
C3	**PASS** as exposition.
0p	Integrates as illustration only.
STATUS	**ESTABLISHED** for the genomic facts. **SPECULATIVE** — marked here — for the archive correspondence, which is an analogy used for exposition and carries no inferential weight.
USED IN	Ch 67

CR-33 · Syncytin: ancient foreign text, inherited, later read out as vital function

CLAIM	A gene essential to human placenta formation derives from a retroviral envelope gene.
(+1) SOURCE	Mi et al., *Nature*, 2000.
MEASURED	That syncytin, a protein involved in trophoblast fusion and placental morphogenesis, derives from the envelope gene of an endogenous retrovirus. Documented molecular biology, not interpretation.
(-1) SOURCE	None admissible for the biology. Where the entry is used illustratively alongside traditions of inherited text later found to carry unforeseen function, that use is expository and is marked.
RECORDED	Nothing bearing on the claim.
ROLES	(+1) evidence, strong. (-1): none, 0 bits.
C1	**N/A** for the biological claim.
C2	**PASS** — predicts that other endogenous retroviral sequences have been co-opted to function, which further work supports.
C3	**PASS** — it is the concrete instance behind "the library of the cell."
0p	N/A.
STATUS	**ESTABLISHED**
USED IN	Ch 67, 84

CR-34 · Addressing adds no information

CLAIM	A scheme that specifies *where* to look adds nothing to *what is there*; therefore the ceiling on any purely regulatory intervention is the latent repertoire.
(+1) SOURCE	CR-30 (targeting separable from editing) and CR-31 (activation without addition), jointly.
MEASURED	dCas9 binds without cutting; Yamanaka factors reprogramme without adding sequence. In both cases the intervention selects among what is present and adds nothing.
(-1) SOURCE	The memory-palace tradition (§6.2), and specifically its late Renaissance error: the belief that a palace mirroring the structure of the universe would confer understanding of the universe.
RECORDED	The technique, correctly; and the error, instructively.
ROLES	(+1) evidence, strong. (-1) precedent, ~1.6 bits, carrying a cautionary case rather than a supporting one.
C1	**PASS** — homomorphism.
C2	**PASS** — predicts a hard ceiling: nothing not already latent can be reached. This is falsifiable and it constrains the framework's own protocol more tightly than any external criticism would.
C3	**PASS** — it is the honesty clause of the addressing and latent-capability analyses (CCP-030, CCP-031) in one sentence.
0p	Integrates.
STATUS	**ESTABLISHED**
USED IN	Ch 62, 66, 67, 83, 84, 87

29.16.7 PART G — METHOD, NOTATION, AND THE OLD PROCEDURES

CR-35 · Cadence: periodic forcing of a leaky store

CLAIM	For a decaying store feeding a threshold, scheduling a fixed total input at short intervals raises the floor; intensity buys the peak, cadence buys the floor.
(+1) SOURCE	the storage law's contraction and DC-gain results (CCP-007); Cepeda, Pashler, Vul, Wixted & Rohrer, *Psychological Bulletin*, 2006 (quantitative synthesis of distributed practice); Ebbinghaus 1885 for the decay curve.
MEASURED	Spaced presentations outperform massed ones for the same total study, and the optimal gap grows with the retention interval — the model's own prediction that optimal `T` scales with `1/delta`. At `delta = 0.10`, `R = 1.0`: mean `Q = 10.000` for every interval, `Q_min` falling `10.000 -> 7.131 -> 1.476 -> 0.008` as `T` goes `1 -> 7 -> 30 -> 90`.
(-1) SOURCE	Fixed-cadence observances: the Rule of St Benedict (c. 530 CE, eight daily offices); Jewish thrice-daily prayer and the seven-day sabbath; Islamic *salat*; Vedic *sandhyavandanam*; Buddhist monastic daily and fortnightly cycles. Independence is low — the Abrahamic set shares a lineage and Near Eastern contact is continuous.
RECORDED	The schedule, the repair procedure for a lapsed office, and the doctrine that a short observance kept beats a long one abandoned. Also Rappaport (1999) on invariance as constitutive of ritual form.
ROLES	(+1) evidence, strong on both the theorem and the spacing effect. (-1) precedent, credited at approximately one tradition's weight, ~1.6 bits, because `c` is high.
C1	**PASS** — homomorphism; three of four structures map.

C2	**PASS** — optimal interval scales with the time constant; tested in the memory domain; holds.
C3	**PASS** on both sides.
0p	Integrates without either side lying. The framework does not claim liturgical hours were tuned for retention; that is unfalsifiable. It claims the schedule has the form the model recommends.
STATUS	**ESTABLISHED**
USED IN	Ch 2, 59, 61, 62, 85, 86

CR-36 · The method of loci is spatial storage with a favourable retention constant

CLAIM	Binding items to an ordered set of familiar places raises encoding efficiency and, more importantly, lowers the decay rate.
(+1) SOURCE	Maguire, Valentine, Wilding & Kapur, *Nature Neuroscience*, 2003; Dresler et al., *Neuron*, 2017.
MEASURED	2003: superior memorizers distinguished by spatial mnemonic strategy rather than general ability or brain structure, with engagement of spatial-memory regions. 2017: trained naive subjects showed large durable recall gains with connectivity changes. **Direction and qualitative finding asserted; effect sizes not quoted and not independently verified here.**
(-1) SOURCE	The classical rhetorical tradition; *Rhetorica ad Herennium* as the standard early source; transmission traced by Yates, *The Art of Memory*, 1966. Independence low — a single continuously copied Western lineage.
RECORDED	The full procedure: how many loci, how spaced, how lit, what makes an image memorable, how the walk is performed.
ROLES	(+1) evidence, and it carries the claim. (-1) precedent, ~1.6 bits, and it carries the procedure.
C1	**PASS** — homomorphism; the storage law's `eta`, `delta` and `C` all have counterparts in the tradition's own emphases.
C2	**PASS** — the advantage is a decay-rate advantage and compounds with retention interval. Illustrative: `eta 0.20 / delta 0.35` versus `eta 0.70 / delta 0.06` gives `3.5x` at day 0 and `612x` at day 14. **Parameters assumed, not measured; the compounding is the prediction.**
C3	**PASS** on both sides.
0p	Integrates completely.
STATUS	**ESTABLISHED**
USED IN	Ch 59, 62

CR-37 · A correspondence table is a category assignment

CLAIM	Correspondence systems are finite relations, and a correspondence table performs the mandatory precondition for applying the surplus functional.
(+1) SOURCE	The surplus functional's validity conditions (CCP-A02); the literal-reading rule of §6; the enumerations computed there.
MEASURED	Definitional and computational, not empirical. `N_eff = 1 + (N−1)u` cannot be evaluated until the `N` categories are named. Addressing: a flat 78-element set costs `log2(78) = 6.285` bits; the `22 + 4 x 14` decomposition costs `6.807` bits and is far cheaper to memorise, its components being independent.

(-1) SOURCE	Esoteric correspondence systems: the Kircher-arrangement Tree of Life (10 vertices, 22 edges); the 78-element tarot; planetary-metal-day tables. Dated and traced in the corpus's literal-reading audit.
RECORDED	A fixed, written, auditable category assignment with multiple retrieval keys per element.
ROLES	(+1): definitional, so the usual evidence/precedent framing does not apply — the claim is that the artefact *is* the object, which is checkable by inspection. (-1) precedent, ~1.6 bits, low independence.
C1	**PASS** — isomorphism, and this is one of very few entries in the register that reaches it.
C2	**PASS** — predicts that the systems have computable graph and set properties, which the corpus's literal-reading audit computed and printed.
C3	**PASS** — it supplies the category assignment the formalism requires.
0p	Integrates trivially, because the correspondence is definitional.
STATUS	**ESTABLISHED** as a reading. **REFUSED**, standing, is any claim that a correspondence carries efficacy, force, or physical consequence (standing refusal, §3.7).
USED IN	Ch 57, 62, 66

CR-38 · Gematria is a hash function

CLAIM	A letter-value scheme summed over a word is a map from strings to integers, which is what a hash function is.
(+1) SOURCE	Definition; the corpus's measurement of collision behaviour.
MEASURED	Computed by the corpus's literal-reading audit: on a 234,454-word list the scheme destroys 10.47 bits. Collisions are the point of a hash and are not evidence of significance.
(-1) SOURCE	Hebrew and Greek letter-numeral traditions, attested from antiquity; Arabic *abjad*.
RECORDED	The correspondence of letters to numbers and the practice of summing them.
ROLES	(+1): definitional and computational. (-1) precedent, ~1.6 bits.
C1	**PASS** — isomorphism.
C2	**PASS** — predicts a computable collision rate, which the corpus's literal-reading audit computed.
C3	**PASS** as a technical description.
0p	Integrates.
STATUS	**ESTABLISHED** as a description. **REFUSED** is any claim that a numerical coincidence between two words carries significance.
USED IN	Ch 57, 62

CR-39 · The essence law is a pure square law, and essence frequencies are not physical resonances

CLAIM	`f(n) = k n^2` with `k = 0.483425732988414 Hz`, and the resulting frequency is the resonance of the essence, not a physical resonance.
(+1) SOURCE	The author's *Effective Method of Sonic Chemistry* (2022); verified against every published value to 14 significant figures.

MEASURED	The collapse of the original recipe to a pure square law, and `k = (9/8)^2 / phi^2 = (81/64)/(phi+1)`, verified exactly. The verification is of internal consistency, not of any physical effect.
(-1) SOURCE	Pythagorean and later speculative-music traditions relating number to tone.
RECORDED	Ratio relations between tones, and the doctrine that numerical relation is the substance of harmony.
ROLES	(+1): internal verification only, not physical evidence. (-1) precedent, ~1.6 bits, and only for the ratio practice.
C1	**PASS** for ratio structure; **FAIL** for any claim of physical resonance.
C2	**PASS** — the odd-part theorem predicts exactly `ceil(N/2)` distinct pitch classes for an index set `1..N`, which is computable and was computed.
C3	**PASS** as a notation.
0p	Integrates only under the standing distinction.
STATUS	**POSTULATE** (the author's, badged). The distinction that essence frequencies are essence frequencies and not physical resonances is absolute and is restated wherever the law is used (§3.4). CR-27 is the reason the distinction is non-negotiable.
USED IN	Ch 29, 30, 32, 69

CR-40 · Staged process control: the ordering is the knowledge

CLAIM	The alchemical operations are unit operations, and the correct ordering of stages is itself substantial process knowledge.
(+1) SOURCE	Chemical engineering; the direct inheritance of distillation, sublimation, crystallisation and filtration, and of the apparatus — alembic, retort, *balneum mariae*.
MEASURED	Computed: `n` stages admit `n!` orderings, so specifying the correct one carries `log2(n!)` bits — `2.585` bits for 3 stages, `6.907` for 5, `12.299` for the seven-stage presentations, `28.835` for 12.
(-1) SOURCE	The alchemical corpus: calcination, dissolution, separation, conjunction, putrefaction, distillation, coagulation, in the seven-stage presentations, with longer and shorter lists elsewhere. Attested from the Hellenistic period through the early modern.
RECORDED	The sequence, the graded heats, the requirement of long digestion at low temperature, and the iterative diminishing-returns character of purification.
ROLES	(+1) evidence, decisive (the operations are still performed). (-1) precedent, and here it is unusually valuable: the corpus is the *record of the procedure*, which is exactly the payload §4.5 assigns the `–1` column.
C1	**PASS** — isomorphism for the operations themselves; they are the same operations.
C2	**PASS** — predicts that permuting stages degrades yield, which is testable and which is why the ordering carries information at all.
C3	**PASS**
0p	Integrates. And it illustrates survivorship bias B3 in its purest form: the part that was right is tacit skill and copies badly; the part that was wrong is text and copies well.
STATUS	**ESTABLISHED**
USED IN	Ch 62

CR-41 · Chemical transmutation of the elements

CLAIM	That base metal can be converted to gold by chemical operations.
(+1) SOURCE	Nuclear physics, applied.
MEASURED	Transmutation changes proton number and is a nuclear operation. Nuclear binding energy is of order `8 MeV` per nucleon; a covalent bond of order `4 eV`. **The ratio is `2,000,000` — six orders of magnitude (`log10 = 6.30`), and no furnace, reagent or duration closes it.** Rider: transmutation is real physics, performed in accelerators and reactors at costs making the product worthless as a commodity.
(-1) SOURCE	The alchemical corpus's compositional theory: the four elements and the three principles.
RECORDED	A compositional theory of matter, and the goal of transmutation. Envelope check: P4 fails — a failed transmutation is always attributable to incompleteness (T5), so failure was invisible and the filter was memorability-selecting.
ROLES	(+1) evidence, decisive against. (-1) precedent: 0 bits — this is precisely the profile of material §5.4 predicts will be preserved and be false.
C1	**FAIL** by scale (error E6, six orders of magnitude).
C2	**FAIL**
C3	**FAIL**
0p	Does not integrate.
STATUS	**REJECTED.** Retained in the register because it is the corpus's most instructive failure: the goal was not absurd, only unreachable by the means available, and the reason is now exactly computable.
USED IN	Ch 62

CR-42 · The doctrine of signatures

CLAIM	That the appearance of a plant indicates its medicinal use.
(+1) SOURCE	None; the doctrine has no measured support.
MEASURED	Nothing. The famous apparent hits — walnut and brain, lungwort and lung — are false positives produced by a rule that generates a resemblance for anything and is therefore never wrong in advance and never right by design.
(-1) SOURCE	Paracelsus; Giambattista della Porta, *Phytognomonica* (1588); the herbal tradition descending from them.
RECORDED	The doctrine, in detail, for centuries. Envelope check: P1 fails (small, slow effects); P2 fails (illness does not recur on demand); P3 passes (the resemblance is visible); P4 fails (delayed and confounded). Visible failure: none. Memorability: maximal.
ROLES	(+1): empty. (-1) precedent: 0 bits.
C1	**FAIL** — metaphor only.
C2	**FAIL** — the rule generates its own content and cannot be wrong in advance.
C3	**FAIL**
0p	Does not integrate.

STATUS	**REJECTED. The register's control: an item scoring maximum on memorability and minimum on every accuracy-selecting criterion, whose actual fate — preserved for centuries, and false — is exactly what the preservation model of §5.4 predicts.** Retained because it shows the model can be tested against a known answer.
USED IN	Ch 62, 87

29.16.8 PART H — THE WORKED ENTRY

The entry built from nothing in Section 7.6, in register format.

CR-43 · Religious fasting schedules and autophagic flux

CLAIM	Traditional fast durations fall within the window in which human autophagic flux rises materially.
(+1) SOURCE	Ohsumi's identification of the autophagy machinery; Nobel Prize in Physiology or Medicine, 2016.
MEASURED	The genes, the pathway, and its upregulation under nutrient deprivation in model systems. Not settled: the time course, magnitude and tissue distribution of fasting-induced autophagy in living humans under these schedules. This author asserts no settled quantitative answer.
(-1) SOURCE	Yom Kippur (~25 h, annual, 2000+ years); Ramadan (lunar month, dawn to sunset, 7th c. onward); Lent and Friday abstinence (4th c. onward); Ekadashi (fortnightly); Buddhist vinaya (no solid food after midday); North American vision-quest and Mesoamerican ritual fasting — the last two carrying the genuine independence.
RECORDED	Duration, timing, exclusions, manner of breaking, warning signs, and a reported change of state.
ROLES	(+1) evidence: strong for mechanism, weak-to-absent for human dose-response. (-1) precedent: partially independent, ~2 bits, attesting schedule and subjective state only.
C1	**PARTIAL** — weak homomorphism; 2 of 5 structures map (threshold, cycle).
C2	**PASS** — predicts a material rise in human autophagic flux within the 12-to-30 hour window and not substantially below it. Falsifiable; untested at this specificity.
C3	**PARTIAL** — a stated hypothesis on the evidence side; nothing new on the precedent side.
0p	Integrates narrowly: both describe a threshold-and-cycle structure on nutrient deprivation and agree on roughly where the threshold sits.
STATUS	**SPECULATIVE** — the bridge between religious fasting schedules and autophagic flux is speculative, and this is the sentence that marks it.
USED IN	Ch 61, 85

29.16.9 Register tallies, recomputed

Recomputed field by field from the entries above, and reported against the source's own counts in Section 11.5.

Quantity	Over the 42 entries CR-01 to CR-42	Over all 43 entries
ESTABLISHED (primary status)	32	32
SPECULATIVE (primary status)	2	3
REJECTED	6	6
POSTULATE (primary status)	2	2
ESTABLISHED with a speculative rider	4 (CR-04, CR-12, CR-31, CR-32)	4
ESTABLISHED with a REFUSED rider	2 (CR-37, CR-38)	2
ESTABLISHED with a POSTULATE rider	1 (CR-19)	1
Entries carrying a qualifier	14 of 42 = 33.3 %	15 of 43 = 34.9 %
C1 = PASS	21	21
C1 = PARTIAL	4	5
C1 = FAIL	7	7
C1 = N/A (no bridge proposed)	10	10
Bridges attempted (C1 graded)	32	33
C1 outright failure rate	**7/32 = 21.9 %**	**7/33 = 21.2 %**
Entries with an empty or void precedent column	12	12

The twelve entries with an empty or void precedent column are CR-06, CR-09, CR-10, CR-14, CR-16, CR-17, CR-21, CR-22, CR-26, CR-27, CR-30 and CR-33. Ten of them draw no bridge and carry `C1 = N/A`; the remaining two, CR-17 and CR-27, are graded `C1 = FAIL` and are therefore counted among the bridges attempted. **That is consistent, and it is the reason the twelve and the ten are different numbers.**

29.17 Appendix B Works named in the text without a bibliography key

The bibliographic database governing this corpus contains no entries for the following, and **no key has been attached to any of them anywhere in this paper.** They are listed with the details the source manuscript supplies so that a reader can locate them, and their absence is recorded as a gap in the corpus's apparatus rather than concealed (Section 3.6, limitation L-6). **Nothing in this list should be read as a citation; it is a statement of what is missing.**

On belief and its channels. Levine, Gordon and Fields (*The Lancet*, 1978) on naloxone reversal of placebo analgesia. Kaptchuk and colleagues (*PLoS ONE*, 2010) on open-label placebo in irritable bowel syndrome, and the subsequent open-label trials. Sisk, Burgoyne, Sun, Butler and Macnamara (*Psychological Science*, 2018) on the meta-analysis of growth-mindset interventions.

On mechanotransduction and the cell. Coste and colleagues (*Science*, 2010) on Piezo1 and Piezo2 as essential components of mechanically activated cation channels, and the 2021 Nobel Prize in Physiology or Medicine to Ardem Patapoutian, shared with David Julius. Tajik and colleagues (*Nature Materials*, 2016) on force transmission to the nucleus, chromatin stretching and transcriptional upregulation. Ibsen, Tong, Schutt, Esener and Chalasani (*Nature Communications*, 2015) on TRP-4 sonogenetics in *C. elegans*, and Duque and colleagues (2022) on hsTRPA1. The cochlear mechanotransduction and tip-link gating literature. Bernardi and

colleagues (*BMJ*, 2001) on respiration and baroreflex sensitivity during rosary and mantra recitation.

On the genome. Church, Gao and Kosuri (*Science*, 2012) on digital information storage in synthesised DNA. Zetsche and colleagues (*Cell*, 2015) on Cpf1/Cas12a, and Fonfara and colleagues (*Nature*, 2016) on its self-processing of pre-crRNA. Qi and colleagues (*Cell*, 2013) and Gilbert and colleagues (*Cell*, 2014) on catalytically dead Cas9 for sequence-specific transcriptional control. Takahashi and Yamanaka (*Cell*, 2006) on induced pluripotency, and the 2012 Nobel Prize in Physiology or Medicine to John Gurdon and Shinya Yamanaka. Mi and colleagues (*Nature*, 2000) on syncytin. Yoshinori Ohsumi's identification of the autophagy machinery and the 2016 Nobel Prize in Physiology or Medicine. The contemporary genomic-annotation literature behind the non-coding, transposable-element and endogenous retroviral fractions quoted in CR-32, whose figures are method-dependent and are quoted as approximate for that reason.

On memory and practice. Ebbinghaus (1885) on the retention decay curve. Cepeda, Pashler, Vul, Wixted and Rohrer (*Psychological Bulletin*, 2006), the quantitative synthesis of distributed practice. Maguire, Valentine, Wilding and Kapur (*Nature Neuroscience*, 2003) and Dresler and colleagues (*Neuron*, 2017) on the method of loci. Yates, *The Art of Memory* (1966). The *Rhetorica ad Herennium*.

On ritual, tradition and the old corpus. Rappaport, *Ritual and Religion in the Making of Humanity* (1999), on invariance as constitutive of ritual form. Giambattista della Porta, *Phytognomonica* (1588), and the Paracelsian doctrine of signatures. Horowitz and Puleo, *Healing Codes for the Biological Apocalypse* (1999), the source of the "Solfeggio" values rejected in Section 7.5. Guido of Arezzo's eleventh-century solmisation.

On physics named in the register. Heisenberg (1927) and the subsequent formalisation of the uncertainty relation beyond the entry already keyed here; the decoherence and environment-induced superselection literature; the von Neumann–Wigner interpretation; and the standard vibrational-spectroscopy range of 500 to 3000 cm^{-1} used in Section 7.5.

On the framework's own earlier work. The author's *Effective Method of Sonic Chemistry* (2022), the source of the essence law recorded in CR-39, and the earlier framework from which the three-state method and the three bridge criteria of Section 3.1 are adopted unchanged. **These are the author's own prior works and are named rather than keyed for the same reason: the database carries no entries for them.**

Chapter 30

The Cell as Receiver, the Channel and Its Capacity, and Addressing Without Editing: Adequate Bandwidth Into an Absent Decoder

Abstract. We compute the acoustic channel into a single cell and separate what the physics permits from what has been demonstrated. Air-to-tissue transmission is -29.9 dB; the pressure differential across a 10 um cell is 0.0816 per cent of peak at 20 kHz and 4.08 per cent at 1 MHz; and wavelength equals cell diameter only at 154 MHz, where attenuation confines the field to millimetres. The product of wavelength and 20 dB depth falls from 6160 to 0.0026 mm-cm across that range, closing acoustic addressing on physical grounds rather than on capacity. The binding term is the receiver's own bandwidth: mechanotransduction kinetics give a corner frequency near 10.6 Hz, so Shannon capacity is of order 70 to 106 bits per second and a 40-bit address takes about half a second. That result is used to eliminate an explanation rather than to support a claim — individually addressing the 3.65e6 cells in one voxel would take 23.93 days, a per-cell exclusive rate of 1.93e-5 bit/s, so the field is intrinsically broadcast. The Gabor limit dt*df >= 1/(4*pi) yields an optimal symbol rate R_max = 6.669448*B, cross-checked against Shannon at 20.034 dB. On the addressing side, naming one genomic position costs 32.53 bits, the PAM constraint costs 4.4465 nats of naming capacity, and a worked block is declared valid only at matcher tolerance d <= 2, where expected collisions are 0.624 against 11.47 at d = 3.

Keywords: mechanotransduction; acoustic impedance; channel capacity; receiver bandwidth; Gabor limit; genomic addressing; PAM constraint; collision analysis

Series: B. Engineering the Surplus **Paper:** CCP-030

30.1 1 Introduction

A living cell is a mechanical receiver. That is established physiology, it is not speculative, and it carries a Nobel Prize. It is also the exact size of the claim, and this paper is built so that the difference between *receiving force* and *receiving a message* is structural rather than rhetorical.

The question this paper answers is the engineer's question rather than the enthusiast's: **given that a cell transduces pressure, how much information can physically arrive at it, and**

what does the arithmetic then permit anyone to claim? The answer is computed in full, with every constant declared nominal at first use, and it is a surprise in both directions.

The channel is not the bottleneck. Air-to-tissue intensity transmission at normal incidence is `-29.9` dB, while the pressure amplitude just inside the tissue nearly doubles; the binding term downstream is neither of those but the receiver's own bandwidth. Taking mechanotransduction kinetics with a nominal 15 ms time constant, the corner frequency is 10.61 Hz, and Shannon capacity at 20 dB signal-to-noise is **70.65 bit/s** — rising to 106.0 bit/s at a 10 ms constant. **A 40-bit address, the size of a 20-nucleotide name, takes about half a second to deliver.** That result is used to *eliminate* an explanation rather than to support a claim: bandwidth is adequate, so "there is not enough capacity" is removed from the list of available explanations, and what remains is exposed.

The spatial resolution is catastrophic, and it fails on geometry rather than on bandwidth. In soft tissue at a nominal 1540 m/s the wavelength equals a 10 µm cell diameter only at **154 MHz**, where the depth at which one-way attenuation reaches 20 dB is 2.6 mm on the most generous attenuation model. The product of wavelength and 20 dB depth falls as `1/f^2`, from **6160 mm·cm at 100 kHz to 0.0026 mm·cm at 154 MHz**. At 1 MHz, taking a resolution voxel as `lambda^3` and a nominal density of `1e9` cells per cm^3, **3.65e6 cells share one voxel and every one of them receives the identical waveform.** Individually addressing them at 70.65 bit/s would take **23.93 days**, a per-cell exclusive rate of `1.93e-5` bit/s. **The acoustic field into tissue is intrinsically a broadcast**, and that is a property of the physics rather than of any particular design.

Energy is not the constraint either. Landauer's bound at 310 K permits `8.19e3` bit/s into a 10 µm cell at one pascal, more than a hundred times the receiver-limited capacity. Three intuitively appealing wrong explanations are therefore removed — not bandwidth, not energy, not thermodynamics — and the two that remain are spatial resolution, which is physical and severe, and **the absence of a demodulator, which is the open problem this paper hands to its successor** [Curzi, 2026y].

A second computed result comes out of putting two bounds side by side. A Gabor-limited tone-selection channel carries at most `R_max = 4 pi B log2(e)/e = 6.669448 B` bit/s, and Shannon's `C = B log2(1 + S/N)` equals that when `S/N = 2^6.669448 - 1 = 100.79`, which is **20.034 dB**. Below that ratio noise binds; above it, time–frequency resolution binds.

The third part of the paper takes up the problem the second one locates. If the acoustic field cannot resolve a cell, selectivity must come from somewhere with cellular resolution, and there is exactly one such layer: sequence. A 20-nucleotide name is a 40-bit address; naming one position in a mammalian genome on either strand requires `log2(2 x 3.1e9) = 32.5296` bits. **Targeting and editing are demonstrated to be separable functions**, so a system may name a locus with full specificity and do nothing to it. The protospacer-adjacent-motif requirement acts as an address-family constraint and costs **4.4465 nats — 6.415 bits — of nameable variety** for the T-rich family relative to unrestricted naming. And the decisive design number is not the address length but the matcher tolerance: a 20-mer address has an expected **0.624** genomic collisions at Hamming distance two and **11.47** at distance three, so a worked address block is declared valid only at `d <= 2`.

The counter-result is the paper's spine, and it is stated here rather than at the end. Every favourable number above is refused as support for the architecture it appears to serve. **Computing the capacity of a channel leading to a receiver does not create the receiver.** The standing constraint of this series is restated in every section that touches the subject: *there is no established mechanism by which a cell demodulates sequence-specific information from an acoustic signal.* Measuring that a room has excellent acoustics tells you nothing about whether anyone in it speaks the language.

Sections 2 and 3 give the hypotheses and the method, including the declared nominal constants, the analogy discipline that governs every borrowing, and an explicit disclosure of a gap in the corpus's bibliography that leaves the entire biological evidence base of this paper uncited. Section 4 characterises the cell as a receiver. Section 5 computes the channel. Section 6 specifies the addressing layer. Sections 7 and 8 collect the specifications and the named

failure modes. Section 9 works three complete specifications end to end, two of which fail. Sections 10 to 13 discuss, verify, limit and conclude.

30.2 2 Hypotheses

Five hypotheses, each stated so that it could be wrong, each with its falsifier. Two further claims are labelled as what they are rather than dressed as hypotheses.

H1 — The receiver, not the medium, sets the information rate into a cell. The bandwidth term in Shannon's formula is the corner frequency of the slowest stage that must resolve a symbol, not the carrier bandwidth. **Predicted:** substituting carrier bandwidth for receiver bandwidth inflates the computed capacity by three to five orders of magnitude, and the receiver-limited figure at mechanotransduction kinetics is of order tens of bits per second. **Falsified by:** an identified cellular stage that resolves symbols at carrier rates, or a demonstration that mechanotransduction kinetics do not bound the symbol rate. *(Result: **not falsified** — 70.65 bit/s at 10.61 Hz and 20 dB, against 6,658 bit/s at a 1 kHz medium bandwidth and `6.66e6` bit/s if the full 1 MHz carrier is substituted: inflation factors of 94.2 and `9.4e4`; see Section 5.7 and the correction in Section 9.4.)*

H2 — Acoustic addressing of individual cells fails on geometry, not on capacity. The frequency at which an acoustic wavelength resolves a cell is a frequency at which the wave cannot reach one. **Predicted:** the product of wavelength and 20 dB penetration depth falls as `1/f^2`, and every plausible attenuation exponent makes the conclusion worse rather than better. **Falsified by:** an attenuation model on which resolution and depth do not trade, or a non-acoustic mechanism supplying cell-scale acoustic resolution. *(Result: **not falsified** — 6160 to 0.0026 mm·cm between 100 kHz and 154 MHz, and exponents 1.1 and 1.5 both reduce the reachable depth further; see Section 5.4.)*

H3 — Capacity is adequate, and its adequacy eliminates an explanation rather than supporting a claim. If bandwidth were the obstacle, the architecture would fail for a reason that could be engineered around. **Predicted:** the computed capacity delivers a 40-bit address in under a second, and the Landauer bound exceeds the receiver-limited capacity by more than two orders of magnitude. **Falsified by:** a capacity computation returning a figure that cannot carry an address in a physiologically relevant time. *(Result: **not falsified** — 0.566 s for 40 bits at 20 dB; Landauer permits `8.19e3` bit/s at 1 Pa; see Sections 5.7 and 5.10. **The consequence is that the explanation for the architecture's failure must be sought elsewhere, and Section 6.9 states where.**)*

H4 — Targeting and editing are separable, so an addressing layer can be fully specific and completely inert. Specificity of address and modification of target are independent functions. **Predicted:** a catalytically inactivated nuclease retains full guide-directed binding specificity while performing no cleavage, and an architecture that introduces no protein and no nucleic acid cannot edit a genome. **Falsified by:** a demonstration that binding specificity requires catalytic activity. *(Result: **not falsified** — the separability is established in the cited literature; see Section 6.7. **The literature concerned carries no citation key in this paper, for the reason given in Section 3.7.**)*

H5 — Usable specificity is set by the matcher's tolerance and not by the address's length. Adding bits to a name is cheap; tightening the matching step is the decisive and expensive move. **Predicted:** expected genomic collisions for a 20-mer rise from 0.000352 at exact match to 11.47 at Hamming distance three, a factor of `3.3e4`,

while the address length is unchanged. **Falsified by:** a collision analysis in which tolerance is second-order to length. *(Result: **not falsified** — see Section 6.5, and the specification decision at `d <= 2` in Section 9.3.)*

Two claims here are not hypotheses.

That the leaky-integrator form describes cellular regulatory state is a modelling choice, badged wherever it appears (Section 4.7). It is a claim about the *shape* of an accumulation, not a claim that any cell obeys the storage law [Curzi, 2026a, Elaydi, 2005], and nothing in this paper tests it.

That there is no established mechanism by which a cell demodulates sequence-specific information from an acoustic signal is a statement about the state of the literature, not a theorem. It is a negative claim, it is stated with its scope, and Section 12 records exactly what would overturn it.

30.3 3 Method

30.3.1 3.1 What is established

Three statements used throughout this paper are established science. They are not postulates of this framework, they are not derived from anything in this corpus, and nothing about the framework is required for them to be true.

```
E1  MECHANICALLY GATED ION CHANNELS EXIST AND ARE IDENTIFIED.
    PIEZO1 and PIEZO2 are ion channels opened by mechanical force
    (Coste et al., Science 330:55–60, 2010). The 2021 Nobel Prize in
    Physiology or Medicine was awarded to David Julius and Ardem
    Patapoutian for discoveries of receptors for TEMPERATURE AND TOUCH.

E2  SOUND IS MECHANICAL.
    A sound wave is a propagating pressure and displacement disturbance
    in a material medium. Classical continuum mechanics.

E3  FORCE AT THE CELL SURFACE REACHES THE NUCLEUS AND CHANGES
    TRANSCRIPTION. Force applied at the cell surface transmits through
    the cytoskeleton, directly stretches chromatin, and upregulates
    transcription of a targeted reporter gene (Tajik et al., Nature
    Materials 15:1287–1296, 2016).
```

From E1 and E2 together: **a pressure wave incident on a cell can open mechanically gated channels, so a real, established pathway runs from acoustic energy to cellular signalling.** From E3 additionally: **mechanical input at the cell surface is an established input to gene expression.** Those two sentences are the whole of what this paper takes as given about biology. **E1 and E3 carry no citation key here** — see Section 3.7.

30.3.2 3.2 The standing constraint, stated first

The boundary is stated at the front of every section that touches the subject rather than buried in a caveat at the back:

> **There is no established mechanism by which a cell demodulates sequence-specific information from an acoustic signal.**

Read the qualifier carefully, because it does precise work. **The constraint does not say cells cannot hear.** They can, in the only sense that matters mechanically: they respond to pressure.

It does not say sound cannot change gene expression. It can, by E3 and by the general route of mechanotransduction into signalling cascades. It says something narrower and harder: **nothing in the literature identifies a molecular apparatus that takes an acoustic waveform and recovers from it a specified nucleotide sequence, or any other symbolic content whose meaning was chosen by a sender.**

That is a statement about a *demodulator*. Every telecommunications system has one: a radio has a mixer, a filter and a detector; a modem has a constellation decoder; the cochlea has a bank of mechanically tuned filters feeding a rate code. Each recovers a symbol stream from a waveform because a physical structure exists whose job is that recovery. **In the cell, the receiver front-end is documented and the demodulator is not.**

The reason to state it in Section 3 rather than only in the companion paper is that Section 4 is where the temptation is strongest. The mechanotransduction literature is genuinely striking, the prize is genuinely there, and a reader who has just been shown that force opens channels and that force stretches chromatin is one careless paragraph away from believing something the evidence does not support. **The slide is one sentence long, and the standing of the whole architecture depends on refusing to make it.**

30.3.3 3.3 Nominal constants, declared once

Every constant below is **nominal**: a conventional round figure used to set scale, not a measured constant of any particular tissue or preparation. Each is flagged nominal again at first use in the section that consumes it.

Quantity	Value used	Status
Speed of sound, soft tissue	`c = 1540` m/s	**nominal** [Rossing et al., 2002]
Density, soft tissue	`rho = 1050` kg/m³	**nominal**
Speed of sound, air	343 m/s	**nominal**
Density, air	1.204 kg/m³	**nominal**
Acoustic attenuation	`alpha = 0.5` dB/cm/MHz	**nominal**, and a rough average; published soft-tissue values span roughly 0.3 to 1.0
Frequency exponent of attenuation	`b = 1.0`	**nominal simplification**; real tissues run `f^1.0` to `f^1.5`, and the sensitivity is computed in Section 5.4 rather than assumed away
Cell diameter	`d = 10` µm	**nominal**
Nucleus diameter	6 µm	**nominal**
Cell density in soft tissue	`1e9` per cm³	**nominal, order of magnitude only**
Body temperature	`T = 310` K, `kT = 4.280e-21` J = `4.280` pN·nm	**standard**
Mean residue mass	110 Da	**nominal**, used for mass estimates from residue counts
Propagation model	plane wave, linear, no cavitation	**modelling choice**

The attenuation figure deserves particular care because everything downstream leans on it. `0.5` dB/cm/MHz is the conventional round number for soft tissue; bone and lung are far higher. Section 5.4 computes the sensitivity of the conclusions to the exponent explicitly, and every plausible exponent makes the conclusion worse rather than better, which is the direction that matters for a bound.

30.3.4 3.4 Analogy discipline: what licenses each borrowing

Every borrowing from physics, information theory or networking in this paper is labelled here, at first use, as exactly one of three things, and no later section may let a category-2 or category-3 borrowing collect the authority of a category-1 one.

Borrowing	Category	What licenses it
Acoustic impedance, wavelength, attenuation, radiation force (§4.6, §5.2–5.4)	**(1) derivation**	These are claims about a physical acoustic field in physical tissue, and continuum acoustics applies directly [Rossing et al., 2002, Beranek, 2004]. The premises are satisfied; the results are used as physical results.
Shannon capacity `C = B log2(1+S/N)` (§5.7)	**(1) derivation**	The theorem applies to any channel for which a bandwidth and a signal-to-noise ratio can be defined [Shannon, 1948, Shannon and Weaver, 1949, Cover and Thomas, 2006]. **What it licenses is an upper bound and nothing else**: it is an existence proof about codes, not a construction of a decoder, and Section 5.7 is written around that distinction.
The Gabor limit `dt df >= 1/(4 pi)` (§5.8, §5.9)	**(1) derivation, with an explicit disclaimer**	Classical Fourier duality [Gabor, 1946], applying to every wave including sound and carrying **no quantum content whatever**. The position–momentum relation [Kennard, 1927] is a fact about state preparation rather than measurement disturbance and is *not* invoked here; the corpus proves the acoustic bound by the same variational argument with `p = hbar k` deleted, Gaussians saturating and a Hann window costing 2.6 per cent [Curzi, 2026z].
The thermal floor and fluctuation–dissipation (§5.5)	**(1) derivation, with a declared validity regime**	The fluctuation–dissipation theorem [Callen and Welton, 1951] fixes the noise of any dissipative receiver at temperature `T`. **Its application at cellular apertures is outside the regime in which the aperture formula holds**, and Section 5.5 says so and carries two estimates rather than one.
Landauer's bound (§5.10)	**(1) derivation**	`kT ln 2` per irreversible bit operation [Landauer, 1961]; used only to show that energy is not the binding constraint. **This is thermodynamic entropy; the bits of Sections 5.7 and 6.2 are Shannon information.** The two are different objects with different units, and the distinction is stated wherever both appear.
The leaky integrator applied to cellular regulatory state (§4.7)	**(2) shared mathematical form, badged**	`Q_{t+1} = (1−delta)Q_t + eta S_t − C_t` is a first-order linear difference equation whose fixed point and contraction are theorems about the equation [Curzi, 2026a, Elaydi, 2005, Banach, 1922]. **No claim is made that a cell obeys the storage law**; the claim is that the same accumulation shape is a useful description, and it is badged at every use.

Borrowing	Category	What licenses it
The internet-addressing correspondence (§6.3–6.6)	**(2) shared structural form, scoped in the paragraph that uses it**	The correspondence is of **format and function** — a variable destination field, a validity constraint on address form, a framing delimiter, an explicit destination list — and it is stated field by field so a reader can check it. **It is not a claim that cells run a protocol stack**, and any extension beyond format is marked speculative in the sentence that extends it. The general design principles it draws on are engineering ones [Saltzer and Schroeder, 1975].
Requisite variety applied to the address family (§6.4)	**(2) shared mathematical form**	Only variety absorbs variety [Ashby, 1956, 1958]; an address family is a restriction on the variety of acceptable addresses, so restricting it reduces what can be named. The arithmetic is the same; no cybernetic claim about cells is made.
The framework's constant `k = (9/8)^2/phi^2 = 0.483425732988414` (§5.12)	**definition, with a postulate attached**	`k` is an exact ratio of exact quantities and is **defined**, so its precision is legitimate. **Attaching hertz to it is a separate and much stronger claim and is POSTULATED**, not derived; the essence frequencies are essence frequencies and not physical resonances. The standard critique of golden-section claims [Markowsky, 1992] is cited here deliberately and again wherever `phi` appears, and the underlying identity `phi^2 = phi + 1` is Euclidean [Euclid, 1956, Vajda, 1989].
The cochlea as an existence proof (§4.3)	**(3) analogy, tightly bounded**	The cochlea proves that biology *can* build a fine mechanical receiver. **It does not license any inference about ordinary cells in ordinary tissue**, and Section 4.3 enumerates the special conditions it enjoys and states that a cell in bulk tissue has none of them.

Most of the borrowings in this corpus are category 2, and category 2 is respectable. The failure mode this table exists to prevent is a category-2 or category-3 borrowing quietly collecting the certainty of a category-1 one. **The standing critique of physics imported into non-physical subjects is that formal machinery arrives without the conditions that license it** [Cartwright, 1999, Anderson, 1972]; **this table is the answer to that critique, run one borrowing at a time, and the badged postulates it produces are doing exactly the work Lakatos [1970] describes.**

30.3.5 3.5 The two-column apparatus, and what each column carries

The corpus runs a concordance apparatus on every substantive claim: an evidence column drawn from the peer-reviewed literature and a precedent column drawn from pre-modern textual traditions. **The refinement that governs this series must be restated at every use: the evidence column carries EVIDENCE and the precedent column carries PRECEDENT, and two sources agreeing does not double the evidence when only one of them is evidence** [Curzi, 2026w]. The same paper prices the asymmetry — a single traditional record is worth 1.585 bits against 9.966 for a replicated result — and computes the collapse of agreement between correlated sources.

That paper's rejection of the claim that a tone at 528 Hz repairs DNA binds this one directly. **This paper's own results derive from that rejection**: the wavelength of 2.9167 m against a 10 µm cell, the quantum-to-thermal ratio of `8.17e-11` at 310 K, and the 34.7-to-37.3-octave separa-

tion between the audible band and molecular vibrational modes [Curzi, 2026w] are the same three computations that Section 5.3 generalises across frequency. **Nothing in this paper may claim sequence-specific acoustic action on genomic material, because the framework refused that claim to others.**

Where a precedent item appears in this paper it is stated with its tradition, approximate date and transmission path, and it is credited in bits rather than summed with the evidence column. **Where the precedent column is empty, the entry says so rather than filling it.**

30.3.6 3.6 Identification, reflexivity, and the limits this paper inherits

Nothing in this paper estimates a social parameter, so the reflection problem does not bind its arithmetic. **It binds the framework the arithmetic is embedded in, and that is stated here rather than left to a reader.** The corpus's central formal object is a reflexive loop in which a group influences its members and the members constitute the group; that is a linear-in-means reflexive specification, and Manski [1993] proves the endogenous social effect is **not identified from observational data**, with Shalizi and Thomas [2011] establishing the same confounding for network data. **No remedy is adopted anywhere in this series** — not randomisation, not an instrument, not partial-population variation, and not a defended stipulation of the reference group [Brock and Durlauf, 2001] — **so every claim in this corpus that rests on the loop is a modelling position rather than an identified empirical result.**

The specific inheritance here is Section 4.7's storage-law reading of cellular regulatory state. **It is a modelling choice about form, it is badged as one, and it is not identified from anything measured in this paper.** Lucas [1976] applies with equal force to the framework's own parameters: a framework asserting that systems change under observation, and then treating its own `delta` and `eta` as constants, must say which. The position taken is narrow: **`delta` and `eta` appear here only in illustrative parameterisations with declared values, never as estimates**, so there is nothing to be biased; any later use that fits them to data inherits the critique and this paper does not protect it.

30.3.7 3.7 A gap in the bibliography, disclosed

The biological literature this paper describes — mechanically gated ion channels and their structure, cochlear mechanotransduction and its tip-link apparatus, force transmission to the nucleus and its transcriptional consequence, mechanosensitive transcriptional regulators, substrate-stiffness effects on lineage, sonogenetics, nucleotide data storage, guide-sequence specificity, self-processing effector arrays, protospacer-adjacent-motif dependence, catalytically dead nucleases and their use for transcriptional control, compact effectors, and mitochondrial base editing — has no corresponding cluster in the bibliographic database governing this corpus. Every such work is therefore named in the text with its journal, volume, page and year, and **without a citation key**. Attaching an unrelated key to a biological claim would be worse than the gap, because a reviewer in that field will check it and a mis-supporting citation destroys more than a missing one.

Appendix A lists the affected works. Section 12 records it as limitation L-1. **This is a defect of the corpus's bibliography rather than a claim that the works do not exist**, and it means that **the entire biological evidence base of this paper is unverifiable from the reference list**: a reader must go to the named sources directly. The same gap is disclosed in the neighbouring papers of this series [Curzi, 2026w,y] and in the sonification protocol [Curzi, 2026].

One consequence of the gap must be stated even though the gap itself is the defect. Each biological result named here is named as a single published finding, and the required context for any such citation is the measured replication base rate: large-scale replication returns roughly a third of original findings with effect sizes about halved [Open Science Collaboration, 2015], and most published findings in low-prior fields are false [Ioannidis, 2005]. **The results relied on here are among the most heavily replicated in their field — mechanotransduction carries a Nobel Prize and the addressing results are routine laboratory tools — but**

the reader is entitled to that base rate beside them, and the corpus's own evidential pricing puts a replicated result at 9.966 bits against 1.585 for an unreplicated traditional record [Curzi, 2026w]. **This paper does not weight the individual biological findings; it takes them as given and computes physics around them.**

One further item is named without a key and is a correction rather than a gap. The source manuscript attributes the thermal-noise floor to "Nyquist (1928)". The corpus's bibliography contains a Nyquist 1928 entry, but it is *Certain Topics in Telegraph Transmission Theory* — the sampling paper — and **not** the thermal-agitation paper that establishes Johnson–Nyquist noise. **The two are different papers published in the same year and attaching the available key here would be a mis-citation.** The thermal floor is therefore attributed in this paper to the fluctuation–dissipation theorem [Callen and Welton, 1951], which is the correct and available warrant, and Nyquist's thermal-agitation paper is named in Appendix A without a key.

30.3.8 3.8 Standing honesty clauses and refusals

- **Capacity is permission, not performance.** Every capacity figure in this paper is accompanied, in the same paragraph, by the statement that it is an upper bound on what a perfect decoder could recover and does not imply that any decoder exists.
- **Bandwidth is the receiver's, never the transmitter's.** Quoting carrier bandwidth as channel bandwidth inflates capacity by three to five orders of magnitude and is named as failure mode FM-C.2.
- **Nothing is delivered, therefore nothing is edited.** The architecture described in Section 6 contains no nuclease, introduces no protein and introduces no nucleic acid into any cell. **It cannot edit a genome. Cannot, not does not** — the safety property is structural, and a structural safety property is the only kind worth trusting, because it does not depend on anyone behaving well.
- **No clinical, medical or therapeutic claim is made anywhere in this paper**, and the pressures tabulated for capacity purposes are not recommendations, exposure guidance, or safety statements of any kind.
- **Uncertain figures are omitted, not guessed.** Where this author is not certain that a published source reports a specific number, the number is left out and the omission is stated. Section 4.5 does exactly that with a drive frequency, and the text is stronger for the omission than it would be for a guess.
- **Numerical coincidences are labelled or omitted.** `4^18 = 2^36`, so an 18-nucleotide address is exactly 36 bits, the same number as an octave transposition used elsewhere in the corpus. **That carries no content**: both systems are built on powers of two, so coincidences of this shape are guaranteed and informative about nothing.
- **Scale type.** Every quantity in this paper is a physical measurement on a ratio scale with a true zero — pressure, frequency, time, energy, bits — so the arithmetic performed on them is licensed. **That is not true of the psychological constructs elsewhere in the corpus**, where Michell [1997]'s objection applies and the conjoint conditions [Luce and Tukey, 1964, Krantz et al., 1971] have not been tested; the storage-law reading of Section 4.7 inherits that exposure and is badged accordingly.

30.4 4 The cell as a mechanical receiver

30.4.1 4.1 The receiver chain, stage by stage

An engineer handed an unknown receiver asks for the block diagram before asking what it can decode. The cell's, drawn as one would draw a radio front-end:

```
ACOUSTIC FIELD
    |
```

```
    |  (a) coupling: pressure, pressure GRADIENT, shear, radiation force,
    |      streaming, cavitation if present
    v
PLASMA MEMBRANE
    |
    |  (b) bilayer tension; local curvature; area strain
    v
MECHANICALLY GATED CHANNEL   <-- PIEZO1/2, TREK/TRAAK, MscL/MscS (bacterial),
    |                            TMC-containing MET complex (hair cells),
    |  (c) ion flux               TRP family members
    v
MEMBRANE POTENTIAL + Ca2+ TRANSIENT
    |
    |  (d) second messengers, kinase cascades
    v
CYTOSKELETON / FOCAL ADHESIONS / LINC COMPLEX
    |
    |  (e) direct force transmission, tension-dependent unfolding
    v
NUCLEAR ENVELOPE -> CHROMATIN
    |
    |  (f) chromatin stretch; transcription factor localisation
    v
TRANSCRIPTIONAL RESPONSE
```

Two features of this diagram set up the whole of Section 5.

First, there are two parallel paths from surface to nucleus, and they run at very different speeds. Path (c)–(d) is electrochemical: channel opening in microseconds to milliseconds, calcium transients in hundreds of milliseconds to seconds, transcriptional consequences in minutes. Path (e) is mechanical, propagating along a prestressed cytoskeletal network, and is argued to transmit faster and further than diffusive signalling (Wang, Tytell and Ingber, *Nature Reviews Molecular Cell Biology* 10:75, 2009; named without a key, Appendix A). **A receiver with two paths of very different latency has a complicated impulse response, and Section 5.6 shows that the slowest stage in the chain — not the acoustic medium — caps the information rate.**

Second, nowhere in this diagram is there a stage that assigns meaning to a waveform. Each stage is a transducer or an amplifier. There is no correlator, no matched filter tuned to a symbol alphabet, and no decision device. **That absence is the standing constraint of Section 3.2, drawn in block-diagram form.**

30.4.2 4.2 The identified transducer

Mechanically activated currents had been recorded in many cell types for decades before the responsible molecule was known in vertebrates. Coste and colleagues, using a mechanically stimulated cell line and a candidate-knockdown screen, identified Piezo1 and, by homology, Piezo2 as essential components of distinct mechanically activated cation channels (*Science* 330:55–60, 2010); the 2021 Nobel Prize in Physiology or Medicine was awarded jointly for discoveries of receptors for temperature and touch. **This is not a fringe result pressed into service by a framework with an agenda; it is a canonical result of modern physiology.** It is also, per Section 3.7, cited here without a key.

The architecture explains the transduction mechanism. Cryo-electron microscopy shows PIEZO1 as a trimer with three long curved blade-like arms radiating from a central pore module; the blades bow the surrounding bilayer into a dome, and the membrane-dome model proposes that flattening the dome under membrane tension is what opens the pore — **the channel is gated by the area it can gain by straightening.**

Sizes, computed from residue count at a nominal mean residue mass of 110 Da. **This is an estimate from residue count, not a measured mass:**

```
mouse Piezo1                2521 residues
monomer, estimated          ~277 kDa
trimer, estimated           ~832 kDa  (~0.83 MDa)
```

Published cryo-EM work reports the trimer at roughly 0.9 MDa; **the estimate above should be read as an order check, not as a measurement.**

The gating physics matters more than the mass. If the channel is opened by bilayer tension `T` acting through an in-plane area change `dA`, the work available is `E = T dA`. Computed at body temperature with `kT = 4.280e−21` J `= 4.280` pN·nm at 310 K:

membrane tension `T` (mN/m)	`dA` for 1 kT (nm²)	`dA` for 5 kT (nm²)	energy at `dA` = 100 nm² (kT)
0.5	8.560	42.800	11.68
1.0	4.280	21.400	23.36
3.0	1.427	7.133	70.09
10.0	0.428	2.140	233.64

Read the right-hand column and the point is made: a channel with a large in-plane area change is an enormously sensitive tension sensor, because the energy scale it must beat is only a few kT. A conformational change of a hundred square nanometres at one millinewton per metre delivers of order twenty kT — decisive against thermal fluctuation. **The tension values are illustrative parameters chosen to span the physiologically discussed range; they are not measured constants of the protein, and the table is an energy-scale calculation rather than a characterisation.**

Excised-patch and reconstitution studies indicate the channel is intrinsically gated by bilayer tension rather than requiring an intact cytoskeletal tether (Cox et al., *Nature Communications*, 2016; Syeda et al., *Cell Reports*, 2016; Appendix A). **This matters for the acoustic question, because it means a stimulus that changes membrane tension can in principle act on the channel without a specialised accessory structure — and it matters for Section 4.6, because changing membrane tension is precisely what an ordinary sound field at cellular scale is bad at.**

Precedent, priced. The idea that the living body is a tuned structure rather than an inert one is recorded in the Latin curriculum for a thousand years before any instrument could test it: Boethius's *De institutione musica* (c. 500 CE) divides music into *musica mundana*, *musica humana* and *musica instrumentalis*, and *musica humana* is explicitly the proportion of the body itself. **That is precedent at approximately one tradition's weight, about 1.6 bits on the corpus's scale [Curzi, 2026w]. It records that the conclusion was reachable without a mechanism. It is not evidence, and every evidential claim in this section rests on the measured column.** Boethius carries no citation key here (Appendix A).

30.4.3 4.3 The cochlea, as an existence proof and nothing more

If the question is whether biology can build a mechanical receiver of extraordinary quality, the question is closed, and anatomy closed it long before molecular biology did.

The mammalian cochlea contains on the order of 3,500 inner and 12,000 outer hair cells — roughly 15,500 mechanoreceptors, **a nominal figure** — arrayed tonotopically along a basilar membrane of roughly 35 mm. Human hearing spans about 20 Hz to 20 kHz, which is

```
log2(20000 / 20) = 9.97 octaves
35 mm  / 9.97 octaves = 3.51 mm per octave
3500 IHC / 9.97 octaves = 351 inner hair cells per octave
```

Three hundred and fifty transducers per octave, across ten octaves, in a structure the size of a pea. That is the density of a well-designed filter bank [von Helmholtz, 1885, Plomp and Levelt, 1965].

The transduction apparatus is finer still. Hair-cell stereocilia are joined by tip links — fine extracellular filaments running from the tip of a shorter stereocilium to the side of its taller neighbour — and deflection tensions the link, opening the transduction channel directly. The kinetics are fast enough for the channel to be gated by force without an intervening second messenger, and the compliance change associated with gating is the observation from which the gating-spring model takes its name. **The identity of the pore-forming subunit remains an active argument, and this paper reports that as an open question rather than a settled one.** All the works concerned are named in Appendix A without keys.

Now the numbers, because they are why the cochlea belongs here at all. At the nominal threshold of hearing, 0 dB SPL, the sound pressure is 20 µPa and the intensity in air is

```
I = p^2 / (2 rho c) = (20e-6)^2 / (2 * 1.204 * 343) = 4.843e-13 W/m^2
```

Over a tympanic membrane of nominal area 55 mm² that is a delivered power of `P = 4.843e-13 x 55e-6 = 2.664e-17` W, and at 1 kHz the energy arriving per cycle is

```
E = P / f = 2.664e-20 J = 6.22 kT   (at 310 K)
```

Six kT per cycle, spread over the whole eardrum, is the entire energy budget of audible threshold. The middle ear then concentrates it: the area ratio between tympanic membrane and stapes footplate is roughly 55 mm² to 3.2 mm², about 17.2, and the ossicular lever adds roughly 1.3, for a nominal pressure gain of `17.2 x 1.3 = 22.3 = 27.0` dB. **That gain is what makes the air-to-fluid transition survivable, and it is the biological solution to exactly the impedance-mismatch problem Section 5.2 computes.**

Even after the gain, the mechanical displacement at threshold is of order 0.3 nm at the hair bundle. The work done against a gating spring of nominal stiffness 1 mN/m:

bundle displacement	gating-spring work (`E = 0.5 k x^2`, `k` = 1 mN/m)	in units of `kT` (310 K)
0.3 nm	4.500e-23 J	0.0105
1.0 nm	5.000e-22 J	0.1168
3.0 nm	4.500e-21 J	1.0514

At threshold the single-cycle mechanical work is roughly one hundredth of the thermal energy scale. A naive receiver could not detect it: the signal is buried a hundredfold below the noise on any single measurement. The ear detects it anyway, by the two classic routes — coherent averaging over many cycles, which improves signal-to-noise as the square root of the number integrated, and active mechanical amplification supplied by the outer hair cells. The general question of how close biological sensors run to physical limits is an old one, and the cochlea is its central example; that literature is named in Appendix A.

Two engineering lessons follow, and both are used again in Section 5.

Lesson one: a receiver beats the thermal floor by integration time and by active gain, not by wishing. The leaky integrator is exactly the right object [Curzi, 2026a, Gerstner and Kistler, 2002, Lapicque, 1907, Usher and McClelland, 2001]. Integration buys sensitivity and costs bandwidth, and the exchange rate is the Gabor limit [Gabor, 1946, Curzi, 2026z].

Lesson two, and it bounds the whole section: the cochlea is a purpose-built organ occupying a specialised, impedance-matched, actively amplified, mechanically isolated cavity, with a dedicated afferent nerve. A fibroblast in the middle of a tissue has none of that. Citing the cochlea as proof that *cells in general* hear finely is the same error as citing a radio telescope as proof that a paperclip receives radio. **The cochlea proves buildability. It does not prove that the build is present elsewhere.**

30.4.4 4.4 Force to the nucleus, and force to transcription

Does mechanical input at the surface reach the genome? It does, and the demonstration is direct: local force applied to the cell surface through integrin-bound magnetic beads produced, in the same experiment, stretching of a chromatin region and upregulation of transcription from a targeted reporter (Tajik et al., *Nature Materials* 15:1287–1296, 2016). **This is mechanical input to gene expression, published, direct, and not mediated by a diffusible second messenger in the reported pathway.**

It does not stand alone. The surrounding literature includes work on mechanotransduction at a distance and the physical coupling of extracellular matrix to nucleus through the cytoskeleton and the LINC complex; the shuttling of transcriptional co-activators to the nucleus as a function of mechanical cues including matrix stiffness and cell geometry (Dupont et al., *Nature* 474:179, 2011); and the finding that the elastic modulus of the substrate directs mesenchymal stem cell lineage specification (Engler, Sen, Sweeney and Discher, *Cell* 126:677, 2006) — **the stiffness of what a cell is standing on changes what the cell becomes.** All are named in Appendix A without keys.

Taken together this is a large, replicated body of work. **The claim that mechanical force changes gene expression is not a frontier claim; it is a textbook claim.**

And here is the boundary, drawn precisely where it belongs. All of the above is *amplitude* signalling. The cell responds to how much force, applied where, for how long, in what pattern of stiffness. **In no case in this literature does the cell recover a symbol that a sender chose.** Force is a scalar field; chromatin responds to it; there is no demonstrated stage that maps a waveform onto a sequence.

Precedent, priced. The general doctrine that structure at one scale is expressed at another, and the classical medical doctrine that regimen alters the body's constitution, record that outside-to-inside determination was a durable idea. **They supply no mechanism, no magnitude and no evidence, and the entire evidential weight here sits in the measured column** [Curzi, 2026w]. What the modern work adds is that "environment writes into the organism" is now a mechanistic statement with molecular detail where it was formerly an analogical one. **The gain from the precedent column is historical, not evidential.**

30.4.5 4.5 Sonogenetics: what it actually demonstrated

Sonogenetics is the closest existing work to "use sound to control cells", and it must be reported accurately rather than enthusiastically.

Neurons in *Caenorhabditis elegans* expressing the TRP-4 channel were activated by low-pressure ultrasound, producing behavioural responses (Ibsen, Tong, Schutt, Esener and Chalasani, *Nature Communications* 6:8264, 2015). **As reported, the effect required microbubbles in the medium to amplify the stimulus — a detail that is central rather than incidental, and that is stated here because it constrains what the result can be used to argue. The exact drive frequency reported is not restated here: where this author is not certain of a published figure, the figure is omitted rather than guessed.** The approach was later extended to mammalian cells by expressing a human channel and demonstrating ultrasound-evoked activation at megahertz frequencies (Duque et al., *Nature Communications* 13:600, 2022). **Again the sensitising element is an expressed transgene: the cell was made ultrasound-responsive by putting a particular channel into it.**

What sonogenetics establishes, stated exactly:

```
S1  Ultrasound can activate a specific, chosen channel in a living animal or
    cell, with sufficient specificity that cells expressing the channel respond
    and neighbouring cells largely do not.

S2  The specificity comes from WHICH CHANNEL IS PRESENT, not from what the sound
    says. It is receiver-side selectivity by molecular identity -- exactly
```

```
    analogous to a radio band selected by which crystal is soldered in.

S3  In at least the 2015 C. elegans work, amplification by microbubbles was
    required as reported.
```

S2 is the sentence to carry forward. Sonogenetics is addressing by receiver identity, not addressing by message content. That is a real and useful architecture — Section 6 shows that molecular addressing is the only layer in this whole architecture with cell-scale spatial resolution — **but it is not demodulation, and it must not be described as if it were. A sonogenetic system carries, at most, one bit per stimulus epoch to the cells that possess the transgene: on, or off.**

30.4.6 4.6 The honest mechanical limit: why a sound field is a poor cell-scale stimulus

This section exists because the analysis would be dishonest without it.

A cell is very much smaller than an audible wavelength. In soft tissue at a nominal 1540 m/s:

frequency	wavelength in tissue	wavelength / 10 µm cell
20 Hz	77 m	7.70e6
20 kHz	0.077 m	7,700
1 MHz	1.54 mm	154
10 MHz	154 µm	15.4
154 MHz	10 µm	1.0

The mechanically relevant consequence is that at ordinary frequencies **the cell sits inside a region of essentially uniform pressure.** The fractional pressure difference across a cell of diameter `d` is approximately `k d` with `k = 2 pi / lambda`:

frequency	`k d` for `d` = 10 µm	differential pressure across the cell
20 Hz	8.16e-7	0.0000816 % of peak
20 kHz	8.16e-4	0.0816 %
1 MHz	0.0408	4.08 %
10 MHz	0.408	40.8 %
154 MHz	6.283	628 % (multiple wavelengths across the cell)

A cell is, to good approximation, an incompressible bag of water. **Uniform pressure on an incompressible body produces almost no membrane tension, and membrane tension is what gates the channel.** What actually generates tension from an acoustic field is the *non-uniform* part: pressure gradients, shear at interfaces of differing impedance, acoustic streaming, radiation force, and — at higher intensities — cavitation, **which is why the sonogenetics work reached for microbubbles.**

Acoustic radiation force on a single absorbing cell can be estimated. Taking a cell radius of 5 µm (volume `5.236e-16` m³), the nominal soft-tissue attenuation of 0.5 dB/cm at 1 MHz converted to an amplitude attenuation coefficient of 5.756 Np/m, and absorbed power `P = 2 alpha I V` with force `F = P/c`:

peak pressure	intensity (W/m²)	absorbed power (W)	radiation force
100 Pa	3.092e-3	1.864e-17	1.21e-8 pN
1 kPa	3.092e-1	1.864e-15	1.21e-6 pN
10 kPa	3.092e+1	1.864e-13	1.21e-4 pN
100 kPa	3.092e+3	1.864e-11	1.21e-2 pN
1 MPa	3.092e+5	1.864e-9	1.21 pN

Compare that to the force scale of gating: **doing 1 kT of work over a 4 nm conformational swing requires 1.07 pN; 5 kT requires 5.35 pN.**

At a megapascal of peak pressure the acoustic radiation force on a single cell is of the same order as the force needed to do one channel's worth of gating work — and at kilopascal pressures it is six orders of magnitude below it. That single comparison explains the shape of the entire sonogenetics literature: why effects are sought at high frequency and high pressure, why microbubbles or gas vesicles are so often involved, and why the field is hard. **It is also the clearest available answer to a reader who asks whether ordinary audible sound at ordinary levels mechanically gates channels deep in tissue. On these numbers, by the direct radiation-force route, it does not come close.**

This is stated here, in the section arguing that the cell *is* a receiver, deliberately. **A claim is worth more when the analysis that makes it also computes the case against it.**

30.4.7 4.7 The cell as a leaky integrator: a badged model-form claim

The corpus's central identity is the first-order accumulation

```
Q_{t+1} = (1 − delta) Q_t + eta S_t − C_t
```

and its parameters, not its form, are what change between scopes [Curzi, 2026a]. At cellular scope the reading is:

term	cellular interpretation
`Q`	durable regulatory state: chromatin configuration, methylation pattern, stable protein levels, cytoskeletal prestress
`S`	this period's signalling input, including mechanical input
`eta`	the fraction of signalling that becomes durable regulatory state rather than a transient
`delta`	reversal: mark turnover, protein degradation, dilution by division
`C`	metabolic and proteostatic cost of holding the state
`h`	headroom: `eta ln N − delta Q − C`

This is a claim about model form and not about physics, and it is badged as such here as it is everywhere in the corpus. **The cell is not asserted to obey the storage law**; the assertion is that the same first-order accumulation *shape* is a useful description, useful because it makes the right qualitative predictions and forbids the wrong ones. It is a **category-2 borrowing** in the sense of Section 3.4, and Section 3.6 records that it is not identified from anything measured here.

Two predictions are worth spelling out, computed with `N = 4` (an illustrative four-category input set), `eta = 0.4`, `C = 0.1`. **All three parameters are assumed, not measured.**

`delta`	`Q_inf = (eta ln 4 − C)/delta`	time constant (periods)	half-life (periods)
0.02	22.726	50.0	34.31
0.10	4.545	10.0	6.58
0.30	1.515	3.3	1.94

Prediction one: a transient stimulus leaves a transient trace. At `delta = 0.3` the half-life of any deposit is under two periods. **Any protocol proposing that a single exposure produces a permanent cellular change is proposing that `delta` is near zero for the relevant state variable — an empirical claim about mark stability that should be stated and tested rather than assumed.**

Prediction two: success consumes headroom.

stored state `Q`	`delta` = 0.02	`delta` = 0.10
0	h = +0.4545	h = +0.4545
2	h = +0.4145	h = +0.2545
5	h = +0.3545	h = -0.0455
10	h = +0.2545	h = -0.5455

At `delta = 0.10` the system goes headroom-negative between `Q = 2` and `Q = 5`: past that point the maintenance burden of the state already held exceeds what the input can supply, and **no arrangement of the input geometry prevents decline** [Curzi, 2026a]. A differentiated cell holding a large, expensive, stable regulatory state is, in this description, a low-headroom system — **which is a formal restatement of the observation that differentiated cells are hard to reprogram, and is taken up in earnest by the companion paper** [Curzi, 2026y]. **It is a restatement, not evidence for the observation.**

30.4.8 4.8 What the precedent column preserved, read as engineering

Three items are worth recording, **strictly as precedent and priced in bits** [Curzi, 2026w]. All are named without citation keys (Appendix A).

The Indian doctrine of *shabda* and *nada*. Vedic and later Indian metaphysics treats sound as constitutive rather than incidental, and the grammarian Bhartṛhari's *Vākyapadīya* (c. 5th century) develops a technical theory in which meaning-bearing sound has a structure distinct from its acoustic realisation. **As precedent this is the oldest sustained attempt on record to distinguish a signal's physical carrier from its content — which is, formally, the carrier/payload distinction of Section 6.9.** That is a genuine structural correspondence and it is worth recording. **It is not evidence that either the metaphysics or the mechanism is correct.**

The Chinese *lü* pitch standards. The twelve *lü* pipes, discussed in the *Lüshi Chunqiu* (3rd century BCE) and later sources, tied pitch standards to calendar and statecraft. **As precedent this records the idea that a system's structure and its tuning are the same problem.** It should be recorded together with an honest note, because the honesty is the useful part: the associated *houqi* practice, in which buried pitch-pipes charged with ash were watched for the ash to be expelled at the arrival of the seasonal *qi*, is a recorded attempt at an *experiment* that was disputed within the tradition and has no modern replication. **A tradition that ran an experiment and could not make it work is a more instructive precedent than one that never tried — and a recorded null on the precedent side is not evidence for anything on the measured side.**

Boethius on *musica humana*, entered at Section 4.2.

Against all three, the standing rule: **precedent tells you the idea was findable; only the measured column tells you whether it is true** [Curzi, 2026w].

30.4.9 4.9 The stopping point

ESTABLISHED	Cells possess identified, prize-recognised, mechanically gated ion channels. Sound is mechanical. Therefore a real pathway runs from a pressure wave to a cellular signal.
ESTABLISHED	Force at the cell surface reaches the nucleus, stretches chromatin, and changes transcription.
ESTABLISHED	Ultrasound can activate a chosen, expressed channel with receiver-side selectivity.
NOT ESTABLISHED	Any mechanism by which a cell demodulates sequence-specific information from an acoustic signal.
COMPUTED LIMIT	At cellular scale an acoustic field is nearly uniform; radiation force on a single cell reaches the single-channel gating force scale only at roughly megapascal pressures.

The cell is a receiver. It is not, on any published evidence, a decoder.

30.5 5 The channel and its capacity

Section 4 established that a cell is a mechanical receiver. This section asks the engineer's next question, which is the only question that can settle an argument: **how much information can physically arrive at it?**

That question has had a formal answer since 1948. Shannon's channel-capacity theorem bounds the rate at which information can be transmitted over a noisy channel with arbitrarily small error probability, and the bound depends on exactly two things: the bandwidth available and the signal-to-noise ratio [Shannon, 1948, Shannon and Weaver, 1949]. Both are computable for a sound wave arriving at a cell in soft tissue.

An honest capacity bound is the most valuable thing this analysis can contain, whatever the bound turns out to be, and a number that comes out unfavourable is worth more than a paragraph that avoids the calculation. The result is stated at the front so that nobody has to read to the end to find the verdict:

THE CHANNEL IS NOT THE BOTTLENECK.	At the cell's own receiver bandwidth and a modest signal-to-noise ratio, the computed capacity is of order tens of bits per second. A forty-bit address takes about half a second.
THE SPATIAL RESOLUTION IS CATASTROPHIC.	At 1 MHz, roughly 3.65 million cells share one acoustic resolution voxel. Every one of them receives the same bits. The channel is a BROADCAST.
THE DEMODULATOR DOES NOT EXIST.	Capacity is an upper bound on what a perfect decoder could recover. Nothing in the literature identifies a decoder.

Capacity is permission, not performance. Shannon's theorem says a code exists which approaches the bound. It says nothing whatever about whether the receiver in question implements one. **That distinction is the intellectual core of this section and it is the reason the section can be quantitative and honest at the same time.**

30.5.1 5.1 The three bounds that govern

```
B1  SHANNON CAPACITY        C = B log2(1 + S/N)          bits per second
    C is the supremum of rates at which information can be sent with
    arbitrarily small error. B is bandwidth in Hz; S/N is signal power to
    noise power in the same band.

B2  THE GABOR LIMIT         dt df >= 1/(4 pi) = 0.079577
    Classical Fourier duality. Applies to every wave including sound and
    carries NO quantum content.

B3  THE THERMAL FLOOR       fluctuation-dissipation; noise power ~ 4 kT R B
    Any dissipative receiver at temperature T carries an irreducible noise of
    this form. At 310 K, kT = 4.280e-21 J = 4.280 pN.nm.
```

The bounds are B1 [Shannon, 1948], B2 [Gabor, 1946] and B3 [Callen and Welton, 1951]. **None of them is a postulate of this framework**, and to them must be added two propagation facts that set the parameters rather than being inequalities: the acoustic impedance step at any boundary, and frequency-dependent attenuation in tissue.

The standing constraint, restated: *there is no established mechanism by which a cell demodulates sequence-specific information from an acoustic signal.* **This section computes a channel capacity, and a channel capacity is not a mechanism.** Computing that a copper wire can carry a gigabit per second tells you nothing about whether the object at the far end is a modem or a doorstop. **The whole value of the computation is that it gives the size of the pipe, and thereby removes "the pipe is too small" from the list of available explanations, leaving the actual explanation exposed.**

30.5.2 5.2 The impedance step: what gets in

Acoustic impedance is `Z = rho c`. Computed at the nominal constants of Section 3.3:

```
Z_air    = 1.204 * 343   =        413.0 Pa.s/m
Z_tissue = 1050  * 1540  = 1.6170e+06   Pa.s/m
ratio    = 3915.5
```

At normal incidence the intensity transmission coefficient is `T_I = 4 Z1 Z2 / (Z1 + Z2)^2 = 1.021e-3 = -29.91` dB, and the pressure transmission coefficient is `t_p = 2 Z2 / (Z1 + Z2) = 1.99949 = +6.02` dB.

Both are correct and they point in opposite directions. Ninety-nine point nine per cent of the incident intensity reflects at an air–tissue boundary, while the pressure amplitude just inside the tissue nearly doubles. The apparent paradox resolves because particle velocity collapses by the same factor that pressure gains, and intensity is their product.

Which figure matters depends on what the receiver responds to. Mechanically gated channels respond to force, hence to pressure, **so the pressure figure is the operative one and it is the generous one. This paper uses the generous figure deliberately: a bound argued on the most favourable available assumption is a bound worth having.**

Worked, for an airborne 94 dB SPL source (1.0024 Pa in air):

```
I_air     = p^2/(2 rho_a c_a)  = 1.2165e-03 W/m^2
I_tissue  = I_air * T_I        = 1.2421e-06 W/m^2
p_tissue  = sqrt(2 rho c I)    = 2.0042 Pa
```

This is also the exact problem the middle ear solves. Section 4.3 computed the nominal ossicular pressure gain at 22.3, or 27.0 dB. **Biology built a matching transformer, because the impedance step is the first and largest loss in the chain and is unavoidable without one.**

30.5.3 5.3 Wavelength against the cell, and why acoustic addressing fails

Wavelength in soft tissue, computed at `c = 1540` m/s (nominal):

frequency	wavelength	wavelength / 10 µm cell
20 Hz	77 m	7.70e6
200 Hz	7.7 m	7.70e5
2 kHz	0.77 m	7.70e4
20 kHz	0.077 m	7,700
100 kHz	15.4 mm	1,540
1 MHz	1.54 mm	154
3 MHz	513 µm	51.3
10 MHz	154 µm	15.4
20 MHz	77 µm	7.7
50 MHz	30.8 µm	3.08
154 MHz	**10 µm**	**1.00**
1 GHz	1.54 µm	0.154

The frequency at which the wavelength equals a cell diameter is exactly `f = c/d = 1540 / 10e-6 = 1.540e8` Hz `= 154` MHz.

Now take an acoustic resolution voxel as nominally `lambda^3` — **a deliberately optimistic convention, since real focused-beam resolution is worse than a wavelength laterally** — and count the cells inside it at a nominal `1e9` cells per cm³:

frequency	`lambda^3`	cells per voxel
20 kHz	4.57e5 mm³	4.57e11
1 MHz	3.652 mm³	3.65e6
10 MHz	3.65e-3 mm³	3.65e3
50 MHz	2.92e-5 mm³	29.2
100 MHz	3.65e-6 mm³	3.65
154 MHz	1.00e-6 mm³	1.00

At one megahertz, three and a half million cells occupy a single resolution element and every one of them receives exactly the same waveform. The acoustic channel into tissue is not a point-to-point link. It is a broadcast.

That single line reorganises the architecture, and it is why Section 6 exists. **Selectivity at cellular scale cannot come from the acoustic field, because the field cannot resolve a cell without going to frequencies at which it cannot reach one.** Selectivity must come from somewhere else, and the only candidate with the required resolution is molecular addressing.

30.5.4 5.4 Attenuation, and the trade that closes the door

Under the nominal law `alpha = 0.5 f_MHz` dB/cm, one-way attenuation:

frequency	1 cm	5 cm	10 cm	20 cm
20 kHz	0.01 dB	0.05 dB	0.10 dB	0.20 dB
100 kHz	0.05	0.25	0.50	1.00
1 MHz	0.50	2.50	5.00	10.00
3 MHz	1.50	7.50	15.00	30.00

frequency	1 cm	5 cm	10 cm	20 cm
10 MHz	5.00	25.00	50.00	100.00
30 MHz	15.00	75.00	150.00	300.00
100 MHz	50.00	250.00	500.00	1000.00
154 MHz	77.00	385.00	770.00	1540.00

Define `d20` as the depth at which one-way attenuation reaches 20 dB — a factor of ten in pressure, a hundred in intensity. Then:

frequency	`lambda`	`d20`	product `lambda x d20`
100 kHz	15.4 mm	400 cm	6160 mm·cm
1 MHz	1.54 mm	40 cm	61.6 mm·cm
10 MHz	154 µm	4 cm	0.616 mm·cm
100 MHz	15.4 µm	0.4 cm	0.00616 mm·cm
154 MHz	10 µm	0.26 cm	0.0026 mm·cm

The product falls as `1/f^2`. Resolution and depth are not merely in tension; they trade against each other at the square of the frequency. Ten times finer resolution costs a hundred-fold in reachable volume. **This is the most consequential number here for anyone imagining a system that addresses individual cells acoustically at depth.**

Sensitivity to the attenuation model, computed because the conclusion must not depend on the convenience of a round exponent:

exponent `b` in `alpha = 0.5 f^b`	`d20` at 10 MHz	at 100 MHz	at 154 MHz
1.0	4.000 cm	0.400 cm	0.260 cm
1.1	3.177 cm	0.252 cm	0.157 cm
1.5	1.265 cm	0.040 cm	0.021 cm

Every plausible exponent makes the conclusion worse, not better. The nominal linear law is the most generous of the three, and it is the one used throughout.

30.5.5 5.5 The thermal noise floor: two estimates, both flagged

Noise is where honest capacity analyses are won or lost, so two independent estimates are given with the validity regime of each stated, rather than picking whichever is convenient.

Estimate one: radiation-resistance thermal noise at an aperture. For a receiving aperture of area `A` in a medium of impedance `rho c`, in the regime where the aperture is large compared with a wavelength, the radiation resistance is approximately `rho c A` and the fluctuation–dissipation theorem [Callen and Welton, 1951] gives a mean-square thermal pressure `p_rms = sqrt(4 kT rho c B / A)`. Computed at 310 K in soft tissue:

aperture diameter	area	B = 100 Hz	B = 1 kHz	B = 1 MHz
1 µm	7.854e-13 m²	1.877 Pa	5.937 Pa	187.7 Pa
5 µm	1.964e-11	0.3755	1.187	37.55
10 µm	7.854e-11	0.1877	0.5937	18.77
20 µm	3.142e-10	0.0939	0.2969	9.387
100 µm	7.854e-09	0.0188	0.0594	1.877

aperture diameter	area	B = 100 Hz	B = 1 kHz	B = 1 MHz
5.5 mm (eardrum scale)	2.376e-05	3.41e-4	1.08e-3	3.41e-2

The scaling is the lesson: thermal pressure noise goes as one over the square root of aperture area. Small receivers are noisy receivers. A 10 µm aperture is 70 times noisier in pressure than a 5.5 mm one at the same bandwidth. **That is a general design law and it is why the ear is the size it is.**

The honest caveat, stated rather than buried. The `rho c A` radiation resistance holds for `k a >> 1`, and at cellular scale in the audible and low-megahertz band `k a << 1` — Section 4.6 computed `k d = 4.08e-2` at 1 MHz for a 10 µm cell. In that regime the radiation resistance is much smaller than `rho c A`, so the formula overstates the dissipation and therefore overstates the noise; **but the same small radiation resistance also weakens the coupling of *signal* into the receiver, so signal and noise fall together and the signal-to-noise ratio does not simply improve. A rigorous treatment requires the fluctuation–dissipation theorem applied to the actual mechanical impedance of the cell, which this paper cannot state with confidence.** The figures above are therefore a reference calculation with a declared validity regime, **not a characterisation of a cell.**

Estimate two: Brownian force noise on the channel itself, which is nearly regime-independent because it concerns the immediate viscous environment of the protein. For an object of radius 5 nm in water (`eta = 1e-3` Pa·s), Stokes drag gives `gamma = 6 pi eta r`:

```
gamma  = 9.425e-11 kg/s
F_th   = sqrt(4 kT gamma B)  = 4.017e-14 N = 40.2 fN   at B = 1 kHz
```

Against the gating scale of Section 4.6 — **1.07 pN does 1 kT of work over a 4 nm swing** — a 40 fN thermal force is about twenty-five times smaller. **The channel is not thermally drowned; it is thermally hovering, close enough to the floor that the receiver's own integration time matters.** That is precisely the cochlea's situation, and it is why the cochlea integrates and amplifies.

30.5.6 5.6 The receiver's own bandwidth: the term that binds

This is the step most treatments of the subject skip, and it determines the answer.

The bandwidth `B` in Shannon's formula is not the bandwidth of the transmitter or of the medium. **It is the bandwidth over which the receiver can distinguish successive states.** A megahertz carrier delivered to a receiver whose output cannot change faster than ten times a second carries one bit per tenth of a second, not one bit per microsecond.

Cellular receiver stages have measured or estimated time constants. Converting each to a corner frequency `f_c = 1/(2 pi tau)`:

stage	time constant `tau` (nominal)	corner frequency `f_c`
cochlear MET channel activation	~20 µs	7,957.75 Hz
fast mechanotransduction generally	~100 µs	1,591.55 Hz
PIEZO1 inactivation	~10 ms	15.92 Hz
PIEZO1 inactivation	~15 ms	10.61 Hz
calcium transient	~1 s	0.1592 Hz
transcriptional response	~30 min	8.84e-5 Hz

All time constants above are nominal figures used to set scale. They are not asserted as measured constants of any particular preparation, and channel inactivation in particular is known to depend on membrane potential, isoform and preparation.

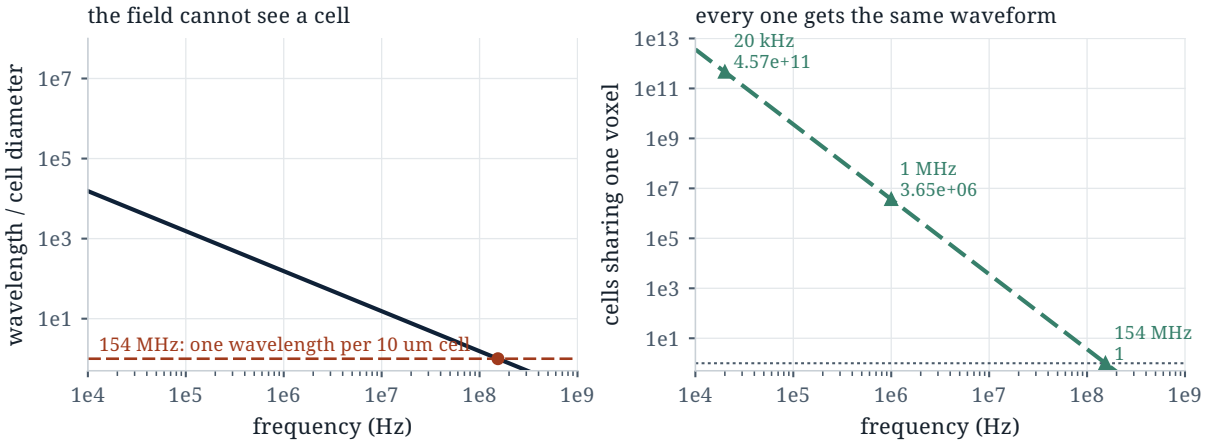

Figure 30.1: **The wavelength resolves a cell only at 154 MHz, and until then the field is a broadcast to millions.** Left: wavelength in soft tissue at a nominal 1540 m/s against a 10 µm cell diameter, with the crossing at 154 MHz marked. Right: cells sharing one `lambda^3` resolution voxel at a nominal `1e9` cells per cm³, falling from `4.57e11` at 20 kHz to 1.00 at 154 MHz; the marked point at 1 MHz is the `3.65e6` cells of Section 5.3. Plotted as small multiples because a length and a count share no scale, and on logarithmic axes because both span eleven orders of magnitude. Computed from the nominal constants of Section 3.3; generated by `figs/src/CCP-030_fig01.py`.

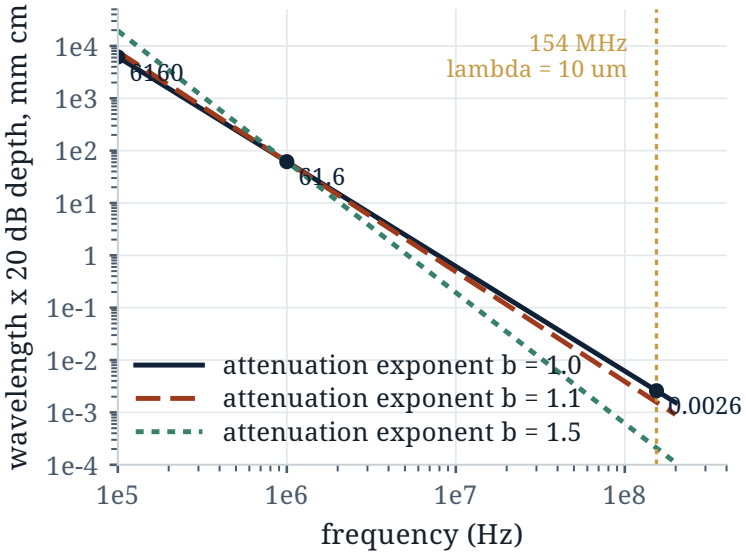

Figure 30.2: **Resolution and depth trade at the square of the frequency, and every plausible attenuation exponent makes it worse.** The product of wavelength and 20 dB one-way depth falls from 6160 mm·cm at 100 kHz to 0.0026 mm·cm at 154 MHz, a straight line of slope −2 on logarithmic axes, under the nominal `b = 1.0` attenuation law. The two lower curves recompute `d20` under `b = 1.1` and `b = 1.5`; at 154 MHz the 20 dB depth falls from 0.260 cm to 0.157 cm and 0.021 cm respectively. The vertical marker is the 154 MHz frequency at which the wavelength first resolves a 10 µm cell. Computed from the nominal attenuation law of Section 3.3; generated by `figs/src/CCP-030_fig02.py`.

This table is the engineering pivot. Whatever the acoustic field is doing at megahertz rates, the cell's own transducer is a low-pass filter — which is the leaky integrator at cellular scope, with `1 − delta` as the pole [Curzi, 2026a, Oppenheim et al., 1996, Horowitz and Hill, 2015]. **A single-pole low-pass stage is the most ordinary object in control engineering** [Åström and Murray, 2008], **and the fixed-gain recursive estimator it is adjacent to is equally standard** [Kalman, 1960]; **naming that is a category-2 borrowing and nothing more.** The signalling stage is slower still, and the transcriptional stage slower by five further orders of magnitude.

30.5.7 5.7 The capacity calculation

`C = B log2(1 + S/N)` evaluated at each receiver stage, for three signal-to-noise ratios, with the time to deliver a 40-bit payload — the size of a 20-nucleotide address, Section 6.2 — at the 20 dB column:

receiver stage	`B` (Hz)	`C` at 10 dB	`C` at 20 dB	`C` at 30 dB	40 bits at 20 dB
transcriptional (~30 min)	8.84e-5	3.06e-4 bit/s	5.89e-4 bit/s	8.81e-4 bit/s	67,944 s (18.9 h)
calcium transient (~1 s)	0.1592	0.551	1.059	1.586	37.75 s
PIEZO1 (~15 ms)	10.61	36.67	70.65	105.8	0.5662 s
PIEZO1 (~10 ms)	15.92	55.01	106.0	158.6	0.3775 s
fast MET (~100 µs)	1,591.6	5,506	1.060e4	1.586e4	3.775 ms
cochlear MET (~20 µs)	7,957.8	2.753e4	5.298e4	7.932e4	0.755 ms

For completeness, the same calculation with bandwidth set by the *medium* rather than by the receiver, using the aperture-noise estimate of Section 5.5 at a 10 µm aperture and `B` = 1 kHz, `p_noise` = 0.5937 Pa:

signal pressure	intensity (W/cm²)	SNR (dB)	capacity (bit/s)
0.1 Pa	3.09e-13	-15.47	40.4
1 Pa	3.09e-11	+4.53	1,940
100 Pa	3.09e-07	+44.53	14,792
10 kPa	3.09e-03	+84.53	28,080
1 MPa	3.09e+01	+124.53	41,368

Note the shape of that second table. Capacity grows only logarithmically in signal pressure: a ten-thousandfold increase between 100 Pa and 1 MPa buys a factor of 2.8. This is the same logarithmic ceiling that governs `ln N` in the surplus law [Curzi, 2026], appearing again in a completely different subject because it is the same mathematics. **You cannot shout your way to a fast channel.**

The result, stated plainly. Taking the honest, receiver-limited figure — the cell's own mechanotransduction bandwidth of about 10 to 16 Hz, at a signal-to-noise ratio of 20 dB — the channel capacity into a single cell is of order 70 to 106 bits per second, and a 40-bit address would take about half a second to deliver.

Three things it does and does not mean.

It means the pipe is adequate. Half a second for an address is not a limitation. If the only problem were bandwidth, this architecture would work. **"There is not enough capacity"**

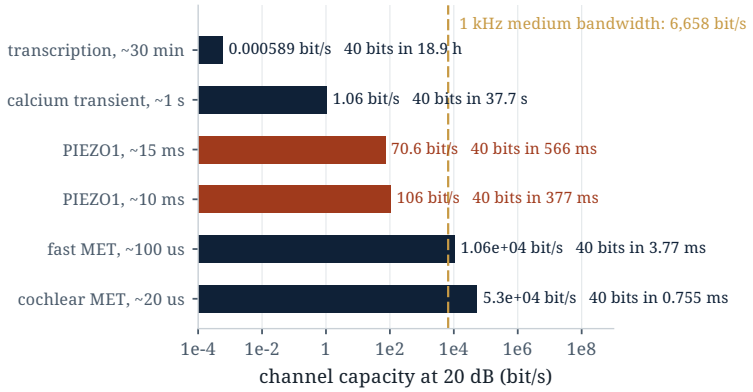

Figure 30.3: **The receiver's own kinetics, not the medium, set the rate — and the range across stages is nine orders of magnitude.** Shannon capacity `C = B log2(1 + S/N)` at 20 dB for the six receiver stages of Section 5.6, with the time to deliver a 40-bit address annotated. The two mechanotransduction rows give 70.65 and 106.0 bit/s, delivering the address in 0.566 s and 0.378 s; the transcriptional stage would need 18.9 hours. Substituting a 1 kHz medium bandwidth instead returns 6,658 bit/s, marked, an inflation of 94.2 times; substituting a full 1 MHz carrier returns `6.66e6` bit/s, a factor of `9.4e4`. Computed from the nominal time constants of Section 5.6; generated by `figs/src/CCP-030_fig03.py`.

is hereby removed from the list of explanations, and removing a wrong explanation is real progress.

It means the pipe is shared. At 1 MHz, `3.65e6` cells occupy one voxel and receive identical bits. If each cell in one voxel needed its own distinct 40-bit address:

```
40 bits * 3.6523e6 cells = 1.4609e8 bits
at 70.65 bit/s           = 2.0678e6 s = 23.93 days
```

Twenty-four days to individually address the cells in a single voxel, and that assumes the addressing worked at all. The per-cell exclusive rate at 1 MHz is `1.93e-5` bit/s. **Broadcast is not a limitation of the design; it is a property of the physics, and the only escape is receiver-side selectivity — which is Section 6.**

It does not mean anything is decoded. Shannon's theorem is an existence proof: for any rate below `C` there exists a code achieving arbitrarily small error. **It does not construct the code, it does not construct the decoder, and it makes no claim that any particular physical system implements either. A channel capacity of 70 bits per second into a cell is a statement about the channel. There is no established mechanism by which a cell demodulates sequence-specific information from an acoustic signal, and computing the capacity of the channel leading to a receiver does not create the receiver.** Measuring that a room has excellent acoustics tells you nothing about whether anyone in it speaks the language.

30.5.8 5.8 The Gabor limit at cellular timescales

The Gabor limit is `dt df >= 1/(4 pi) = 0.079577` [Gabor, 1946]. **It is classical, it applies to every wave including sound, it is the same Fourier mathematics as the position–momentum relation with no quantum content, and it is measurable on an oscilloscope** [Curzi, 2026z]. Applied at the timescales of Section 5.6:

observation window `dt`	minimum frequency resolution `df`
1 µs	79,577.5 Hz
10 µs	7,957.75 Hz
100 µs	795.775 Hz
1 ms	79.5775 Hz
5 ms	15.9155 Hz
15 ms	5.30516 Hz
100 ms	0.795775 Hz
1 s	0.0795775 Hz
60 s	0.00132629 Hz
1 hour	2.21049e-5 Hz

Read this against the receiver stages and a structural fact appears. **A hair cell integrating over 100 µs cannot have a frequency resolution better than 796 Hz — at a 1 kHz carrier that is a quality factor of about 1.26, which is barely a filter at all.** The cochlea's actual frequency selectivity is far sharper, and the resolution of the apparent contradiction is that the cochlea does *not* make its decision in 100 µs: the mechanical filter integrates over many cycles and the active amplification narrows the tuning further. **Sharpness in frequency is bought with time, at the Gabor exchange rate, and there is no other currency.**

Conversely, a slow receiver has extraordinary potential frequency resolution:

stage	window	best possible `df`	quality factor at a 1 kHz carrier
hair-cell MET	100 µs	795.8 Hz	1.26
PIEZO1	15 ms	5.31 Hz	188
calcium integration	1 s	0.0796 Hz	1.26e4
transcription	30 min	4.42e-5 Hz	2.26e7

A transcriptional response integrating over half an hour could in principle discriminate frequencies to forty-four microhertz. **Nothing is known to use that resolution, and stating a theoretical capability is not stating that anything realises it** — but the number belongs in the record, because it shows that the slow end of the cell is the *high-resolution* end in frequency, which is the opposite of most readers' intuition.

30.5.9 5.9 The Gabor bound as a rate bound, and the crossover with Shannon

There is a second, less familiar way to use the Gabor limit, and it produces a clean number.

Suppose the channel carries information by choosing one of `M` distinguishable tones inside a bandwidth `B`, holding each for a symbol time `dt`. For the tones to be distinguishable they must be separated by at least `df = B/M`, and Gabor requires `df >= 1/(4 pi dt)`. Therefore `M <= 4 pi B dt`, and the information rate is `R = log2(M)/dt = log2(4 pi B dt)/dt`. Differentiating and setting to zero puts the optimum at `4 pi B dt = e`, so

```
dt*    = e / (4 pi B)
R_max  = 4 pi B log2(e) / e  =  6.669448 * B    bits per second
```

A Gabor-limited tone-selection channel carries at most about 6.67 bits per second per hertz of bandwidth. Computed instances:

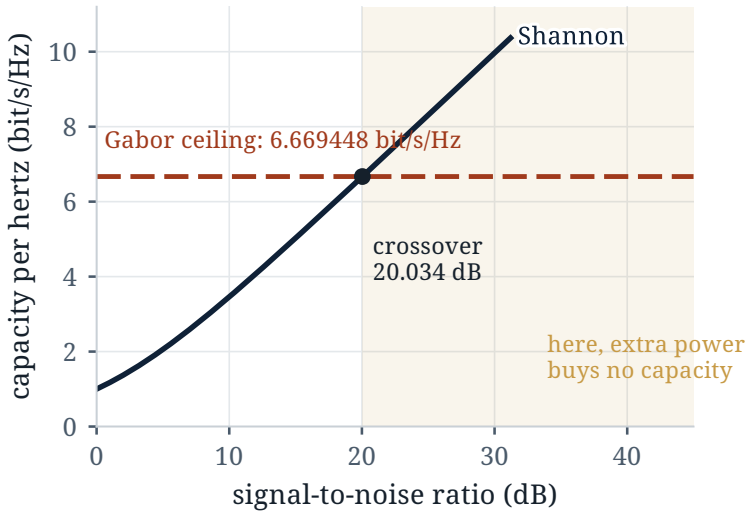

Figure 30.4: **Two bounds cross at 20.034 dB, and which one binds depends on which side you are.** Capacity per hertz of bandwidth: Shannon's `log2(1 + S/N)` rising with signal-to-noise ratio, against the Gabor tone-selection ceiling of a constant 6.669448 bit/s/Hz. They meet exactly at `S/N = 2^6.669448 − 1 = 100.79`, which is 20.034 dB; below it noise binds and above it time–frequency resolution binds. The shaded region is where extra power no longer buys capacity. Computed from the two closed forms of Sections 5.7 and 5.9; generated by `figs/src/CCP-030_fig04.py`.

bandwidth `B`	optimal symbol time `dt*`	`R_max`
20 kHz	10.82 µs	1.334e5 bit/s
1 MHz	216.3 ns	6.669e6 bit/s
10 MHz	21.63 ns	6.669e7 bit/s
154 MHz	1.405 ns	1.027e9 bit/s

And now the cross-check that makes the result trustworthy. Shannon's `C = B log2(1 + S/N)` equals `6.669448 B` when `log2(1 + S/N) = 6.669448`, that is

```
S/N = 2^6.669448 − 1 = 100.79 = 20.034 dB
```

The Gabor-limited tone channel and the Shannon capacity agree exactly at a signal-to-noise ratio of 20.034 dB. Below that ratio Shannon binds and noise is the limiting factor; above it, Gabor binds and time–frequency resolution is. **That crossover is a genuinely useful design number and, so far as this author is aware, it is not a standard textbook figure — it falls straight out of putting the two bounds side by side.** The practical reading: **20 dB signal-to-noise is the point past which spending more power stops buying capacity and bandwidth must be bought instead.**

30.5.10 5.10 Energy is not the constraint

Landauer's principle sets the minimum energy to erase one bit at `kT ln 2` [Landauer, 1961], which at 310 K is `2.967e-21` J. **This is thermodynamic entropy; the bits of Section 5.7 are Shannon information, and the two are different objects brought together only for a bound.** Computing the acoustic power delivered to a 10 µm cell (area `7.854e-11` m²) and dividing:

pressure	intensity (W/m²)	power on cell	Landauer-limited bits/s
1 Pa	3.092e-7	2.429e-17 W	8.19e3
100 Pa	3.092e-3	2.429e-13 W	8.19e7
10 kPa	3.092e+1	2.429e-9 W	8.19e11
1 MPa	3.092e+5	2.429e-5 W	8.19e15

Even at one pascal — a pressure comparable to the thermal floor at that aperture — the thermodynamic bound permits eight thousand bits per second, more than a hundred times the receiver-limited capacity. Energy is not scarce in this problem. That is worth stating because "there is not enough energy" is another intuitively appealing wrong explanation, and it is now also removed.

Three explanations removed, then: not bandwidth, not energy, not thermodynamics. What remains is spatial resolution, which is catastrophic and physical, and the absence of a demodulator [Curzi, 2026y].

30.5.11 5.11 What the cell could do about noise, and what it costs

The receiver's one classical defence against a poor signal-to-noise ratio is coherent averaging. Averaging `n` cycles improves amplitude SNR as `sqrt(n)`:

cycles averaged	SNR gain
1	0 dB
10	5 dB
100	10 dB
1e4	20 dB
1e6	30 dB

Twenty decibels of gain costs ten thousand cycles of integration, and by the Gabor limit those cycles are time no longer available for the next symbol. **The exchange is not optional and it is not negotiable**, and it is the same exchange the corpus has been making since the storage law: **integration buys retention and costs responsiveness** [Curzi, 2026a]. The leaky integrator with a small `delta` averages well and reacts slowly; with a large `delta` it reacts fast and remembers nothing. **There is one dial.**

30.5.12 5.12 The essence ladder under the Gabor constraint

The corpus's essence law is `f(n) = k n^2` with `k = 0.483425732988414` Hz, and — **restating the absolute honesty clause — the output is an essence frequency, not a physical resonance. No claim is made that any material, molecule, element or person physically resonates at these values.** `k` is a **defined** constant, exactly `(9/8)^2 / phi^2`, so its precision is legitimate; **attaching hertz to it is a separate and stronger claim and is POSTULATED** (Section 3.4), and the standard scepticism about golden-section claims is cited alongside it [Markowsky, 1992].

With that badge on, the Gabor limit imposes a computable rendering constraint. Adjacent essence indices are separated by `f(n+1) − f(n) = k(2n + 1)`, so the minimum window needed to resolve index `n` from index `n+1` is `dt >= 1/(4 pi k (2n+1))`:

index `n`	`f = k n^2` (Hz)	gap to `n+1` (Hz)	minimum window `dt` (s)
1	0.483426	1.450277	0.054871
2	1.933703	2.417129	0.032922
3	4.350832	3.383980	0.023516
4	7.734812	4.350832	0.018290
5	12.085643	5.317683	0.014965
6	17.403326	6.284535	0.012662
7	23.687861	7.251386	0.010974
8	30.939247	8.218237	0.009683
9	39.157484	9.185089	0.008664
10	48.342573	10.151940	0.007839
11	58.494514	11.118792	0.007157
12	69.613306	12.085643	0.006584

The bottom of the essence ladder cannot be rendered faster than about 55 milliseconds per symbol without smearing index 1 into index 2, and the constraint relaxes as `1/(2n+1)` up the ladder. Octave transposition multiplies both `f` and `df` by the same factor [Shepard, 1982], so transposing up by `j` octaves divides every entry in the last column by `2^j` — **the ratio structure is preserved exactly, which is the whole point of transposition** — and the successor paper uses this table directly when specifying rendering speed [Curzi, 2026y,?].

Note that the maximum symbol rate implied at the bottom of the ladder, about 18 symbols per second, sits inside the 10 to 16 Hz receiver bandwidth of Section 5.6. **That is a coincidence of scale, not a mechanism, and it is stated as a coincidence.**

30.6 6 Addressing without editing

Section 5 located the problem exactly. An acoustic field in tissue is a broadcast: at one megahertz some 3.65 million cells share a single resolution voxel and every one receives the identical waveform. **Selectivity at cellular scale cannot come from the sound. It has to come from somewhere else.**

There is exactly one layer in biology with the required resolution, and it is not acoustic, not optical and not spatial. **It is sequence.** A twenty-nucleotide string is a forty-bit name, and forty bits is enough to name any position in a mammalian genome with room to spare. Molecular recognition of that name is base-paired, essentially digital, and specific to a resolution no field can approach.

This section is about the name, and only the name. Its subject is the guide spacer read as a routing header rather than as a molecule; the correspondence between that header and the addressing layer of an internet protocol, stated field by field; the demonstrated separability of *targeting* from *editing*; and the consequence that follows:

Nothing is delivered, therefore nothing is edited. The architecture is non-invasive by construction, not by restraint.

That is a claim about architecture rather than about ethics or intention. A system that contains no nuclease cannot cut; a system in which no protein and no nucleic acid is introduced into any cell cannot modify a genome, whatever its operator wishes. **The safety property is structural, and a structural safety property is the only kind worth trusting, because it does not depend on anyone behaving well.** The general principle — that a system's security should rest on its design rather than on the goodwill or ignorance of those who handle it — is the oldest rule in the field [Kerckhoffs, 1883, Saltzer and Schroeder, 1975], and the corpus states it as a structural property elsewhere [Curzi, 2026].

And the standing constraint applies here with full force: *there is no established mechanism by which a cell demodulates sequence-specific information from an acoustic signal.* **An addressing scheme is not a delivery mechanism, and this section does not supply one.**

30.6.1 6.1 What is established

Four statements here are established molecular biology, none of which depends on this framework and none of which is a postulate. **All four are cited without keys, per Section 3.7; the sources are named in Appendix A.**

```
E1  A GUIDE'S SPECIFICITY LIVES IN A SHORT VARIABLE SEGMENT.
    The spacer -- ~20 nt for SpCas9, ~23 nt for Cas12a -- determines which
    genomic sequence is recognised. The remainder of the guide is invariant
    scaffold.

E2  TARGETING AND EDITING ARE SEPARABLE FUNCTIONS.
    Catalytically dead Cas9 (D10A + H840A) binds its target and does not cut.
    Fused to effectors it represses or activates transcription. THIS IS THE
    PROOF THAT BINDING A LOCUS AND CHANGING A LOCUS ARE DIFFERENT OPERATIONS.

E3  Cas12a PROCESSES ITS OWN GUIDE ARRAY.
    Cas12a cleaves its own precursor CRISPR RNA array without requiring
    tracrRNA or host RNase III.
    CONSEQUENCE: ONE TRANSCRIPT CAN CARRY MANY ADDRESSES.

E4  A PROTOSPACER-ADJACENT MOTIF CONSTRAINS WHICH ADDRESSES ARE VALID AT ALL.
    SpCas9 requires an NGG motif; Cas12a requires a T-rich motif, canonically
    TTTV. A target lacking the correct motif is not engaged regardless of how
    well the spacer matches.
```

From E2 alone the central architectural claim follows: **addressing is a separable function. A system may name a locus with full specificity and do nothing to it.**

What this section does not claim, stated as a block because the honesty clauses are absolute and because this is where a careless reader is most likely to over-read:

```
N1  NO CLAIM THAT DNA IS EDITED, ALTERED, OR DAMAGED. The architecture described
    here contains no nuclease, introduces no protein, and introduces no nucleic
    acid into any cell. It cannot edit. Not "does not"; CANNOT.

N2  NO CLINICAL, MEDICAL OR THERAPEUTIC CLAIM. None. No trials, no controlled
    observation, no demonstrated physiological effect.

N3  NO CLAIM THAT AN ADDRESS DELIVERED ACOUSTICALLY IS RECEIVED, RECOGNISED, OR
    ACTED UPON.

N4  NO CLAIM THAT ANY CAPABILITY HAS BEEN CONFERRED ON ANY CELL.

N5  THE PROTOCOL CORRESPONDENCE IS A CORRESPONDENCE OF FORMAT, NOT AN ASSERTION
    THAT CELLS RUN A PROTOCOL STACK. Any extension beyond format is marked
    SPECULATIVE in the sentence that extends it.
```

30.6.2 6.2 The address, sized

A nucleotide is two bits. Therefore:

spacer length	address space `4^L`	bits
12 nt	1.678e7	24
16 nt	4.295e9	32
17 nt	1.718e10	34
18 nt	6.872e10	36
20 nt (SpCas9)	**1.0995e12**	**40**
23 nt (Cas12a)	**7.0369e13**	**46**
25 nt	1.126e15	50
32 nt	1.845e19	64

For comparison, computed: an IPv4 address is 32 bits (`4.2950e9` addresses) and an IPv6 address is 128 bits (`3.4028e38`). **A 20-nucleotide spacer is a 40-bit address — wider than IPv4 by 8 bits, a factor of 256** — and a 23-nucleotide spacer at 46 bits is 16,384 times the IPv4 space. **The comparison is not decorative; it is the right way to size the naming problem, and it immediately answers whether the address is long enough.**

How long does it need to be? The human haploid genome is about `3.1e9` base pairs. Counting start positions on both strands:

```
candidate positions = 2 * 3.1e9 = 6.200e9
bits to name one    = log2(6.200e9) = 32.5296 bits = 16.26 nt
```

Sixteen and a quarter nucleotides would suffice to name every position in the genome exactly once. The 20-nucleotide spacer over-provisions by 3.74 nucleotides — 7.47 bits, a factor of 177. That over-provision is not waste; it is error margin, and Section 6.5 computes exactly what it buys.

30.6.3 6.3 The addressing correspondence, stated field by field

The correspondence is one of *format and function*, and it is stated field by field so that a reader can check it rather than admire it. **It is a category-2 borrowing** (Section 3.4).

```
INTERNET PROTOCOL                    GUIDE FORMAT
---------------------------------    ---------------------------------
destination address                  SPACER (20 nt / 40 bits, SpCas9)
  names WHERE the packet goes          names WHICH LOCUS is recognised

address family (AF_INET / AF_INET6)  PAM (NGG for SpCas9, TTTV for Cas12a)
  a validity constraint on the         a validity constraint on the target:
  address form; a well-formed          a locus without the correct motif is
  address in the wrong family is       not engaged regardless of spacer
  not routable                         match

header framing / delimiters          DIRECT REPEAT (19-20 nt in Cas12a)
  marks packet boundaries              marks address boundaries within the
                                       array; the self-processing site

multicast destination list           MULTI-SPACER crRNA ARRAY
  one transmission, many               one transcript, many spacers, each
  recipients                           cleaved out to address a locus

payload                              ENCODED DATA (base-4)
  the content, distinct from the       distinct from the address
```

```
  address

routing table lookup                  BASE PAIRING + MOTIF RECOGNITION
  the physical act of matching          the physical act of matching
```

What the correspondence is not. It is not a claim that cells implement a protocol stack, that there is a transport layer, or that anything is acknowledged, retransmitted or checksummed, and it licenses no inference about behaviour not independently demonstrated. **Where this paper extends the correspondence past format — to talk about "delivery" or "reception" — the extension is speculative and is marked speculative in the sentence that makes it.** The value of the correspondence is that it supplies the right vocabulary for a real structural fact: **specificity is carried in a short, variable, separable field, and the rest of the construct is invariant. The internet protocol specifications themselves carry no citation key here** (Appendix A).

30.6.4 6.4 The motif as an address-family constraint

Of all the rows in that table, motif-as-address-family survives the hardest scrutiny, because the correspondence is functional rather than visual.

An IPv6 address presented to an IPv4-only socket is not routed: it is not that the destination is unreachable, but that the address is *not of a form the machinery accepts*. Similarly, a genomic sequence perfectly complementary to a spacer but not followed by the required motif is not engaged; the protein requires the motif to initiate DNA unwinding, and without it recognition does not proceed. **The constraint is on the form of the address, imposed by the machinery, independent of whether the address is otherwise correct. That is precisely what an address family is.**

The constraint is quantitatively severe:

```
P(NGG at a random position)   = 1/16          = 0.0625
P(TTTV at a random position)  = (1/4)^3 * 3/4 = 0.011719  = 1 in 85.33

targetable positions, SpCas9 NGG  : 3.8750e8 of 6.2000e9
targetable positions, Cas12a TTTV : 7.2656e7 of 6.2000e9

mean spacing between NGG sites  = 16.00 bp
mean spacing between TTTV sites = 85.33 bp
```

One position in sixteen is addressable under NGG; one in eighty-five under the canonical T-rich motif. Address-family choice is therefore a design decision with a hard cost: choosing the T-rich family reduces the reachable address space by a factor of 5.33 relative to NGG.

There is a genuine correspondence to the law of requisite variety [Ashby, 1956, 1958]: **only variety absorbs variety, and an address family is exactly a restriction on the variety of addresses the system will accept.** Restricting the family reduces what can be named. **That is not a defect of the biology; it is what makes the recognition step tractable**, and the same logic explains why routing tables are hierarchical.

Precedent, priced. The Confucian doctrine of *zhengming*, the rectification of names (*Analects* XIII.3) — if names are not correct, language is not in accordance with the truth of things, and affairs cannot be carried on to success — records that "the validity of the name is a precondition of the operation, prior to the operation's own correctness" was arrived at independently and preserved for two and a half millennia. **It supplies no mechanism and no evidence**, and every evidential claim here rests on the measured column [Curzi, 2026w]. Named without a key (Appendix A).

30.6.5 6.5 Routing collisions: what the extra bits buy

An address that names more than one destination is a routing collision. In this domain the collision has a name in the literature — off-target binding — and it can be computed exactly.

Expected number of exact matches of a random spacer in the human genome:

spacer length	expected exact genomic matches
12 nt	369.55
16 nt	1.4436
20 nt	5.6389e-3
23 nt	8.8107e-5

At 16 nt the expected number of matches is about 1.44 — the address is right at the edge of ambiguity. At 20 nt it is 0.0056, comfortably unique. That is what the four nucleotides between 16 and 20 bought: 8 bits, a factor of 256 in collision margin (`1.4436 / 5.6389e-3 = 256.0`).

But exact matching is not the operative condition, because base pairing tolerates mismatches. The honest calculation counts the *Hamming ball*: all sequences within `d` substitutions of the intended address. For a 20-mer over a four-letter alphabet the ball sizes are `C(20,d) 3^d`:

`d`	sequences at exactly distance `d`	cumulative ball size	expected genomic hits, motif-constrained
0	1	1	0.000352
1	60	61	0.021498
2	1,710	1,771	0.624152
3	30,780	32,551	11.471923
4	392,445	424,996	149.780999
5	3,767,472	4,192,468	1,477.548130

where the per-site expectation base is `6.2e9 x (1/16) / 4^20 = 3.5243e-4`.

A 20-nucleotide address that tolerates three mismatches has roughly eleven and a half expected matches in the human genome instead of one. That single number explains the entire off-target literature, explains why mismatch tolerance is the dominant engineering concern in the field, and demonstrates a general law of addressing worth stating in its own right:

An address system's usable specificity is set not by the length of the address but by the tolerance of the matching step. Adding bits to the name is cheap; tightening the matcher is the expensive and decisive move.

An internet engineer will recognise this as the reason longest-prefix matching and exact-match forwarding behave so differently. It is also Goodhart's law wearing molecular clothes [Goodhart, 1975, Campbell, 1979]: **a matcher scored on *finding* targets rather than on *not finding wrong ones* will drift toward tolerance.**

30.6.6 6.6 The self-processing array as a multicast destination list

This is the strongest single item in the section, and it is worth being precise about why.

Cas9 does not process its own guide array; maturation of its CRISPR RNA involves tracrRNA and host RNase III. **Cas12a does**: it is a single RNA-guided endonuclease requiring only a crRNA, and the same enzyme also cleaves the direct repeats within a multi-spacer array to liberate individual mature guides.

Read as a data format, that is a specific and recognisable object:

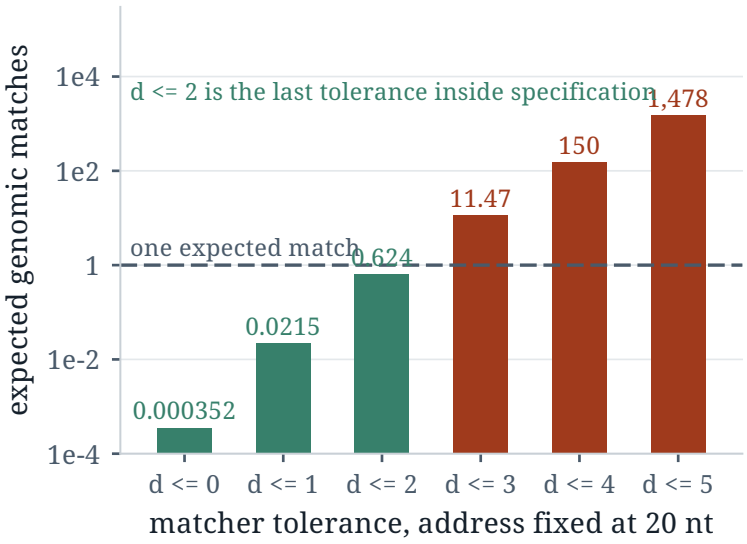

Figure 30.5: **Specificity is set by the matcher, not by the address.** Expected genomic matches for a fixed 20-nucleotide address as the matcher's mismatch tolerance rises, computed from the Hamming-ball sizes `C(20,d) 3^d` against a per-site base of `6.2e9 x (1/16) / 4^20`. The address length never changes; the expected collision count rises from 0.000352 at exact match to 11.47 at `d = 3`, a factor of 32,551 — exactly the ratio of the Hamming-ball sizes. The horizontal line at one expected match is the specification boundary, and the last tolerance below it is `d = 2` at 0.624 — which is why the worked block of Section 9.3 is declared valid only there. Computed from the closed form of Section 6.5; generated by `figs/src/CCP-030_fig05.py`.

```
5'--[DR]--[spacer 1]--[DR]--[spacer 2]--[DR]--[spacer 3]-- ... --3'

DR      = direct repeat: a delimiter, and the site at which the enzyme
          cleaves. FUNCTIONALLY A FRAME MARKER.
spacer  = one destination address.
```

One transcript. Many addresses. Self-delimiting. Processed by the same machine that uses the addresses. That is formally a packet with a multicast destination list, and the correspondence is structural rather than decorative because the framing is a real, enzymatically recognised feature of the molecule and not something an author drew on top of it.

The format arithmetic, computed with a **nominal** 19 nt direct repeat and a **nominal** 23 nt spacer:

```
per-address unit  = 19 + 23 = 42 nt
header overhead   = 19/42   = 45.24 %
address payload   = 46 bits per address
framing           = 38 bits per address
```

addresses in array	transcript length	address bits	framing bits
1	42 nt	46	38
2	84 nt	92	76
4	168 nt	184	152
8	336 nt	368	304
10	420 nt	460	380

addresses in array	transcript length	address bits	framing bits
20	840 nt	920	760

Forty-five per cent framing overhead is high by network standards — IPv4's minimum header is 20 bytes against a payload typically hundreds — **and the reason is instructive: this is a format optimised for reliable self-delimiting cleavage rather than for efficiency, which is the correct trade when a framing error is catastrophic and bandwidth is free.** Repeat lengths vary by ortholog; the 19 nt figure is nominal and used for scale.

For comparison, IPv4's multicast allocation is `224.0.0.0/4`, which is `2^28 = 268,435,456` group addresses. **A self-processing array is a different kind of multicast — an explicit destination *list* rather than a group *identifier* — and the distinction is worth keeping, because a list scales linearly in transcript length while a group identifier does not scale at all.** A 20-address array costs 840 nucleotides; a group address costs 28 bits. **Explicit lists are simple and expensive; group identifiers are cheap and require infrastructure. Biology chose the list, and biology has no routers.**

Precedent, priced. The Alexandrian *Pinakes* of Callimachus (3rd century BCE) was a catalogue physically separate from the scrolls, in which each work was named and located. **It records independent arrival at the structural insight this section needs — the catalogue is not the book; the address is a distinct object from the content, and a single object may carry many addresses. It is not evidence about molecules and supplies no mechanism** [Curzi, 2026w]. Named without a key (Appendix A).

30.6.7 6.7 The separability of targeting from editing

If a reader takes one result from this section, it should be this one.

The nuclease activity of Cas9 resides in two domains. Mutating one residue in each produces a protein that retains full RNA-guided DNA binding and has no cleavage activity. That dead nuclease was used to block transcription by steric interference, and the approach was later extended to genome-scale repression and activation by fusing effector domains, so that binding a promoter *increases* transcription.

Bind a locus. Change its expression. Cut nothing.

That sentence is the load-bearing result, and its architectural consequence is that **specificity of address and modification of target are independent functions, and the first can be present in full while the second is entirely absent. Addressing is not a weakened form of editing. It is a different operation, and it was shown to be a different operation by deleting the editing and finding that the addressing still worked.**

Two clarifications, both required.

First, those systems are still delivered. In every experiment concerned, a protein and a guide RNA were introduced into cells. **The architecture described here introduces neither**, and the result is cited as *proof of a principle* — that targeting and editing separate — and not as a description of what this architecture does.

Second, the honest limit: even a catalytically dead nuclease changes something. It occupies a locus, and occupancy has consequences — that is the entire point of transcriptional interference and activation. **It does not change *sequence*, which is the claim**, and the distinction between changing sequence and changing expression is exactly the distinction between this section and the editing literature. **Nothing in this architecture does either, because nothing is delivered.**

Precedent, priced, and this is where the gap between the columns is at its widest anywhere in the series. The "true name" doctrine in its widest form — the Egyptian narrative of Isis and the secret name of Ra, the Kabbalistic treatment of divine names, the insistence of the Solomonic grimoire tradition on exact naming as the operative variable — **records independent arrival at the idea that precision of the name, rather than force applied, determines**

whether an operation engages its target. It supplies no mechanism, no magnitude, and no evidence whatever about molecules. Presenting it as evidence would be the exact fault the two-column refinement forbids [Curzi, 2026w]. **Say so rather than smoothing it over.**

A footnote on wildcards, offered because it is genuinely apt. Roman ritual formulae included the hedge *sive deus sive dea* — "whether god or goddess" — used when the correct name of a locality's deity was not known. **That is, formally, a wildcard address issued under name-uncertainty, and the tradition recorded it as a recognised practice rather than an embarrassment.** It is precedent, it is not evidence, and its engineering lesson is real: **a system that must address under name-uncertainty needs an explicit underspecified-address form, and one that lacks it will get silent misrouting instead.**

30.6.8 6.8 The mitochondrial address family, corrected

A separate address family for mitochondrial targets is genuinely necessary. **The reason usually given in casual discussion is wrong, and correcting it is more useful than repeating it.**

The wrong reason: "mitochondrial DNA needs a smaller, more compact editor." Compactness is a real virtue of the hypercompact effectors — roughly 70 kDa, reported from huge phages — **but compactness is a *delivery* virtue.** Computed, with a nominal mean residue mass of 110 Da:

protein	residues	estimated mass	estimated CDS	fraction of a 4.7 kb AAV payload
SpCas9	1,368	~150.5 kDa	4,104 bp	87.3 %
AsCas12a	1,307	~143.8 kDa	3,921 bp	83.4 %
compact effector	~636 (est)	~70 kDa	~1,909 bp	40.6 %

The mass ratio is about 2.15, and the coding-sequence difference is what decides whether an editor and its regulatory elements fit in a viral vector. That is a real and important engineering fact — and it is irrelevant to this architecture, because this architecture delivers nothing and therefore has no packaging limit to fit inside. Citing compactness as a reason for a mitochondrial address family here would be borrowing a constraint the system does not have.

The right reason: mitochondria are not a reliable destination for guide RNA. RNA import into mammalian mitochondria has been studied for decades and remains contested; whatever the resolution, the field's operative position is that it is not reliable enough to build a targeting system on. **The decisive evidence is what the field did about it: it invented protein-only editors.** A split bacterial cytidine deaminase fused to TALE DNA-binding proteins was described explicitly as *CRISPR-free* mitochondrial base editing. **A field does not build an entirely separate, guide-RNA-free targeting chemistry unless the guide-RNA route is unavailable.** That is an argument from *engineering behaviour* rather than from a single measurement, and it is stated as one.

The addressing arithmetic closes the point:

```
human mtDNA (reference sequence)  = 16,569 bp
positions, both strands           = 33,138
bits to name one uniquely         = log2(33138) = 15.0162 bits = 7.51 nt
expected exact matches of a random 20-mer in mtDNA = 3.0139e-8
over-provision of a 20-nt address for mtDNA = 4^20 / 33138 = 3.3180e7

address bits actually required:
    nuclear        32.53 bits
    mitochondrial  15.02 bits
```

```
difference     17.51 bits
```

A 20-nucleotide address over-specifies a mitochondrial target by a factor of thirty-three million. Address length is not the mitochondrial problem — reachability is. In network terms this is a routing problem rather than a naming problem: the destination network is not reachable by the available transport, and no amount of address precision fixes an unreachable network. **The separate address family exists because the transport differs, which is exactly why address families exist in networking.**

30.6.9 6.9 Payload, and the reason there is not one here

Arbitrary digital data can be encoded in nucleotide sequence at the natural rate of two bits per base, and a volume of order 5.27 megabits has been stored and recovered. **That is the payload side of the correspondence and it is entirely real: base-4 encoding of arbitrary content in sequence is a demonstrated technology.** Named without a key (Appendix A).

The format is therefore complete in principle:

```
[ ADDRESS: spacer, 20–23 nt, 40–46 bits ]
[ FAMILY CONSTRAINT: motif, validity gate ]
[ FRAMING: direct repeat, self-delimiting ]
[ PAYLOAD: base-4 encoded content, arbitrary length ]
```

And here is where this paper must stop. A well-formed packet is not a delivered packet. The format above can be constructed on a computer and rendered as audio; Section 5 shows the acoustic channel has ample capacity to carry it and no ability to resolve a single cell. **What does not exist, anywhere in the literature, is the receiving side: there is no established mechanism by which a cell demodulates sequence-specific information from an acoustic signal.**

Nothing is delivered, therefore nothing is edited. Both halves of that sentence are the same fact stated twice. **The architecture's safety and the architecture's open problem are the *same* structural property, and any account claiming the first while quietly disowning the second is incoherent.** This paper claims both, in the same breath, and the successor paper examines the second without flinching [Curzi, 2026y].

30.6.10 6.10 The storage law at the addressing layer

A brief note on how this connects to the corpus's spine, **badged as the model-form claim it is** (Section 3.4).

In storage-law terms an addressing scheme is an `eta` device: it does not supply input `S`; it determines what fraction of a given input reaches a durable structure rather than dissipating [Curzi, 2026a]. **A broadcast with no addressing has, for any specific target, `eta` near zero — the input is spent on 3.65 million cells to reach one.** Addressing raises `eta` by concentrating the same `S` where it can convert.

That reading yields one checkable design consequence, computed with the surplus law's own arithmetic [Curzi, 2026]:

```
an address family restricts the reachable set.
SpCas9 NGG:  reachable fraction 1/16    ->  ln(6.2e9/16)     = 19.77 nats
Cas12a TTTV: reachable fraction 1/85.33 ->  ln(6.2e9/85.33)  = 18.10 nats
unrestricted:                               ln(6.2e9)        = 22.55 nats
```

Choosing the T-rich address family costs 4.4465 nats of nameable variety relative to unrestricted addressing, and 1.67 nats relative to NGG. In bits that is 6.415 — **the address family throws away about six and a half bits of the genome's nameable space in exchange for a**

tractable recognition step. That is the price of requisite variety at the recognition layer [Ashby, 1958], **and whether it is a good trade depends on whether the six bits contained anything needed, which is an empirical question about the target list and not a matter of preference.**

A note on which quantity this is. `ln(6.2e9)` is the logarithm of a count of positions, not an effective count of anything. **Where the corpus uses an effective count it uses `N_eff = 1 + (N-1)u`, which is a linear interpolation between 1 and `N`, is the framework's own construction, and is not a Hill number** [Curzi, 2026]; `1/HHI` and `exp(H)` are Hill numbers of orders two and one and are the grounded objects the literature supports [Hill, 1973, Jost, 2006]. **No effective count appears in this section**, and the distinction is stated so that a reader does not import one.

30.7 7 Specifications

Numbered, checkable requirements. **The three groups replace the source manuscript's chapter-keyed numbering: SP-R for the receiver, SP-C for the channel, SP-A for addressing.**

30.7.1 7.1 SP-R — the receiver

SP-R1. Mechanotransduction is cited as fact, not as analogy. Established physiology may be stated flatly; do not hedge it and do not decorate it.

SP-R2. The standing constraint appears in every document citing SP-R1, verbatim: *there is no established mechanism by which a cell demodulates sequence-specific information from an acoustic signal.* It appears in the same document, not in a linked appendix.

SP-R3. Receiver and decoder are never conflated. "Receives force" and "receives a message" are different claims with different evidence. Any sentence containing both must be rewritten.

SP-R4. Sonogenetics is described as **receiver-side selectivity**: state that specificity derives from which channel is expressed, and state the reported reliance on microbubble amplification. Do not describe it as acoustic messaging.

SP-R5. The cochlea is cited as an existence proof of buildability only. It proves that biology *can* build a fine mechanical receiver and licenses no inference about ordinary cells in ordinary tissue.

SP-R6. Mechanical constants carry their nominal flag at first use in any document: sound speed, attenuation, tissue density, eardrum area, hair-cell counts, and all channel kinetic time constants (Section 3.3).

SP-R7. Energy-scale arguments are stated in units of kT. `kT = 4.280e-21` J `= 4.280` pN·nm at 310 K. **Any claimed mechanical effect must be shown against that scale or declared unquantified in the same sentence.**

SP-R8. The uniform-pressure limit is disclosed. Any claim of acoustic action on cells states the `k d` fraction at the frequency used and names the non-uniform mechanism it relies on — gradient, shear, streaming, radiation force, or cavitation.

SP-R9. No clinical, medical or therapeutic claim. Absolute.

SP-R10. No claim that genomic sequence is edited, altered or damaged. Absolute.

SP-R11. Concordance blocks state column roles explicitly. **A block without the roles stated is void.**

SP-R12. Uncertain figures are omitted, not guessed, and the omission is stated.

30.7.2 7.2 SP-C — the channel

SP-C1. Every capacity claim states `B`, `S/N` and the noise model. A capacity figure without all three is void, and the noise model's validity regime is stated with it.

SP-C2. Bandwidth is the receiver's, not the transmitter's. Use the corner frequency of the slowest stage that must resolve the symbol.

SP-C3. Nominal constants are flagged at first use, and **sensitivity to the attenuation exponent is shown, not assumed away** (Section 5.4).

SP-C4. Spatial resolution is reported as cells per voxel, not as wavelength. "`3.65e6` cells share one voxel at 1 MHz" is the honest statement; "1.54 mm resolution" conceals it.

SP-C5. The broadcast property is disclosed. Any design using an acoustic field at or below about 10 MHz states that all cells within a voxel receive identical signal, and names the non-acoustic mechanism supplying selectivity or states that there is none.

SP-C6. Capacity is never presented as mechanism. Every capacity result is accompanied in the same document by: *capacity is an upper bound on what a perfect decoder could recover; it does not imply that any decoder exists.*

SP-C7. The standing constraint appears verbatim in every document computing a capacity into tissue.

SP-C8. Gabor is applied to every timed spectral design. Any specification of symbol rate and frequency spacing shows the product `dt df` and shows it satisfies `>= 0.079577`.

SP-C9. The 20.03 dB crossover is the design point. Below it, buy signal; above it, buy bandwidth. Power spent above the crossover to increase capacity is wasted.

SP-C10. Logarithmic returns are stated where they bite. A 10,000-fold pressure increase from 100 Pa to 1 MPa buys a factor of 2.80 in capacity. **Never promise linear gain in a quantity that grows logarithmically.**

SP-C11. No clinical, medical or therapeutic claim. **The pressures tabulated for capacity purposes are not recommendations, exposure guidance, or safety statements of any kind.**

SP-C12. No claim that genomic sequence is edited or altered. This section concerns transmission only.

30.7.3 7.3 SP-A — the addressing layer

SP-A1. The address is a header, never a molecule, in this architecture. Text must not describe the spacer as something present in, delivered to, or synthesised by a cell. It is a name computed on a computer.

SP-A2. Nothing is delivered; state it as a structural property. "No protein and no nucleic acid is introduced into any cell; the architecture therefore cannot edit a genome." **Cannot, not does not.**

SP-A3. No claim that genomic sequence is edited, altered or damaged. Absolute.

SP-A4. No clinical, medical or therapeutic claim. Absolute.

SP-A5. The standing constraint appears verbatim in every document using this format.

SP-A6. Every address publishes its collision analysis. Required fields: spacer length; address space `4^L`; expected exact genomic matches; Hamming ball sizes to `d = 3`; expected hits at `d = 3` under the applicable motif constraint. **An address without this analysis is not specified, it is merely written down.**

SP-A7. Every address declares its address family, naming the motif, its per-position probability, and the resulting reachable-site count. NGG `= 1/16`; TTTV `= 1/85.33`.

SP-A8. The separability result is cited for separability only, with the delivery caveat: every citation states that those systems were delivered into cells and that this architecture delivers nothing.

SP-A9. The mitochondrial family is justified by reachability, not compactness. Compactness is a delivery virtue and is irrelevant where nothing is delivered.

SP-A10. The protocol correspondence is scoped in the same paragraph that uses it. It is a correspondence of format and function; any extension beyond format carries the word *speculative* in the sentence that extends it.

SP-A11. Concordance blocks state column roles. **Permitted verbs for the precedent column: records, preserves, arrived at independently. Forbidden: confirms, corroborates, verifies, proves.**

SP-A12. Numerical coincidences are labelled as such or omitted. `4^18 = 2^36`, so an 18-nucleotide address is exactly 36 bits, the same number as an octave transposition used in genomic audio. **This coincidence carries no content**; it is an artefact of both systems using powers of two, and any text implying otherwise is void.

30.8 8 Failure modes

Each fault carries a clinical signature, a diagnostic, and a fix.

30.8.1 8.1 FM-R — faults of the receiver argument

FM-R.1 · The one-sentence slide. *Signature:* a paragraph establishes mechanotransduction correctly and the next sentence begins "and therefore cells can receive information from sound." **The word "information" has changed meaning between the sentences: in the first it meant a physical influence, in the second a chosen symbol.** *Fix:* ban the unqualified word at the join. Write "physical influence" or "symbolic content" and the slide becomes visible immediately, because "cells can receive symbolic content from sound" is obviously an unsupported claim in a way that the equivocal version is not.

FM-R.2 · The cochlea generalisation. *Signature:* hair-cell sensitivity figures — 0.3 nm displacement, sub-kT energies — quoted in support of a claim about ordinary cells. *Fix:* every citation of cochlear performance is immediately followed by the enumerated special conditions — impedance-matched middle ear at 27 dB nominal gain, active amplification, dedicated afferent innervation, isolated fluid-filled cavity, purpose-built gating apparatus — **and by the statement that a cell in bulk tissue has none of them.**

FM-R.3 · The uniform-pressure omission. *Signature:* a design claims mechanical action on cells from an audible-band field and never computes `k d`. *Diagnostic:* at 20 kHz, `k d` for a 10 µm cell is `8.16e-4` — the pressure differential across the cell is under a tenth of a per cent of peak. **If the mechanism is "pressure squeezes the cell", the design is describing an effect roughly a thousand times smaller than it thinks.** *Fix:* SP-R8, then size the named non-uniform mechanism against the 1.07 pN / 4 nm gating scale.

FM-R.4 · The energy-free claim. *Signature:* a proposed effect on a cell stated with no energy or force figure at all. *Why it is fatal:* cells sit in a bath at 310 K where every degree of freedom carries 4.28 pN·nm. **An effect that cannot be sized against kT is not an effect; it is a hope.** *Fix:* SP-R7.

FM-R.5 · Precedent laundered as evidence. *Signature:* a precedent entry described with verbs like "confirms", "corroborates" or "independently verifies", or two columns summed into "multiple lines of evidence". *Fix:* SP-R11, and a test with teeth — **delete the precedent row and ask whether the argument's *evidential* standing changed. If it did, the argument was resting on precedent** [Curzi, 2026w].

FM-R.6 · The sonogenetics overread. *Signature:* sonogenetics cited as "controlling cells with sound", with the transgene and microbubble requirements dropped. *Fix:* SP-R4. **The honest one-line summary is: ultrasound can turn on a channel you put there.**

FM-R.7 · The permanence assumption. *Signature:* a protocol assumes a single exposure produces a lasting cellular change, with no statement of the decay rate of the state variable. *Diagnostic:* this is an unstated assumption that `delta` is near zero. At `delta = 0.3` per period the half-life is 1.94 periods; at `delta = 0.02` it is 34.3. **Three orders of magnitude of protocol design hang on a parameter nobody measured.** *Fix:* name the state variable, cite or measure its turnover, and state the implied `delta` and half-life before any durability claim.

FM-R.8 · The prize borrow. *Signature:* the Nobel Prize invoked in a context where the claim being supported is not the claim the prize was awarded for. *Why it is corrosive:* it is the strongest available citation and misusing it costs the document its credibility with exactly the readers who can check. *Fix:* **state the citation with its scope attached, every time — the prize was awarded for the discovery of receptors for temperature and touch. It supports E1 and it supports nothing about symbolic content.**

FM-R.9 · The fabricated figure. *Signature:* a specific published number appears without the author having verified it, because a specific number reads better than a qualitative statement. *Fix:* SP-R12. **Section 4.5 does exactly that with a drive frequency, and the text is stronger for the omission than it would be for a guess.**

30.8.2 8.2 FM-C — faults of the channel argument

FM-C.1 · Capacity mistaken for mechanism. *Signature:* a document computes a favourable capacity and concludes that transmission occurs; the tell is the word "therefore" immediately after a capacity figure. **Shannon's theorem is an existence proof about codes, not about hardware: its converse forbids exceeding C, and nothing in it *permits* reaching C in any particular physical system.** *Fix:* SP-C6, applied literally — paste the disclaimer into the same paragraph as the number. **If the argument collapses when the sentence is added, the argument was the fault.**

FM-C.2 · Transmitter bandwidth substituted for receiver bandwidth. *Signature:* a 1 MHz carrier is quoted and `B = 1e6` goes into the capacity formula. *Diagnostic:* compare the two computed tables of Section 5.7. At 20 dB the receiver-limited figure at mechanotransduction kinetics is 70.65 bit/s; **at a 1 kHz medium-set bandwidth it is 6,658 bit/s, a factor of 94.2, and if the full 1 MHz carrier is substituted it is `6.66e6` bit/s, a factor of `9.4e4`.** *Fix:* SP-C2. **The source manuscript states this comparison with a different figure, and the discrepancy is reported in Section 9.4 rather than silently harmonised.**

FM-C.3 · The resolution mirage. *Signature:* a design proposes to address individual cells acoustically and quotes a wavelength without quoting a depth. *Diagnostic:* the `lambda d20` product falls as `1/f^2`; at 154 MHz the 20 dB depth is 2.6 mm on the most generous attenuation model and 0.21 mm on an `f^1.5` model. *Fix:* **always publish the pair — resolution *and* reachable depth, with the attenuation exponent stated.**

FM-C.4 · The undisclosed broadcast. *Signature:* a protocol describes acoustic delivery "to the target cells" with no statement of how non-target cells in the same voxel are excluded. *Diagnostic:* at 1 MHz there are `3.65e6` cells in the voxel. **If the protocol has no receiver-side selectivity, its true addressee count is the voxel population.** *Fix:* SP-C5.

FM-C.5 · The noise model borrowed from the wrong regime. *Signature:* `p_rms = sqrt(4 kT rho c B / A)` used at cellular apertures without stating that it assumes `k a >> 1`. *Why it matters in both directions:* used naively it overstates the noise and makes a design look worse than it is; **corrected naively, by shrinking the radiation resistance without also shrinking the signal coupling, it makes the design look far better than it is — and the second error is the dangerous one.** *Fix:* SP-C1; where a rigorous impedance model is unavailable, say so and carry both estimates, as Section 5.5 does.

FM-C.6 · The power escalation. *Signature:* a design responds to insufficient capacity by proposing higher amplitude. *Diagnostic:* from 100 Pa to 1 MPa — four orders of magnitude in pressure, eight in intensity — capacity rises from 14,792 to 41,368 bit/s, a factor of 2.80. **Above the crossover the return is logarithmic and the cost is quadratic in pressure.** *Fix:* SP-C9.

FM-C.7 · The Gabor violation. *Signature:* a specification lists both a symbol rate and a frequency spacing whose product is below 0.079577. *Diagnostic:* **the specification is not merely ambitious; it is describing something that cannot exist.** Two tones separated by `df` cannot be distinguished in a window shorter than `1/(4 pi df)`, on any equipment, ever. *Fix:* compute `dt df` for every pair; Section 5.12 shows the worked case, 54.9 ms minimum at index 1.

FM-C.8 · The quantum import. *Signature:* the Gabor limit described as a quantum effect, or `hbar` appearing in an acoustic calculation. **Gabor's relation is classical Fourier duality and**

contains no quantum content at all [Gabor, 1946, Curzi, 2026z]. *Why it is fatal to credibility:* importing quantum language into an acoustics problem signals to any physicist reading that the rest of the document should not be trusted. *Fix:* state the relation as `dt df >= 1/(4 pi)`, note that it is the same Fourier mathematics as the position–momentum relation without the quantum content, and stop.

FM-C.9 · The unstated nominal. *Signature:* 0.5 dB/cm/MHz appears without the word "nominal" and without a sensitivity check. *Fix:* SP-C3 and the sensitivity table of Section 5.4. **Every plausible exponent makes the depth conclusion worse, which means the conclusions are robust to the assumption in the direction that matters.**

30.8.3 8.3 FM-A — faults of the addressing argument

FM-A.1 · The address treated as an agent. *Signature:* a sentence in which the spacer *does* something — "the guide finds the locus" — in a context where no guide molecule exists. *Fix:* SP-A1. **Permitted verbs: names, designates, specifies. Forbidden: finds, seeks, binds, targets, used transitively of a physical event.**

FM-A.2 · Editing vocabulary imported with the citation. *Signature:* sources are cited and the surrounding prose acquires "editing", "knock-in", "correction" or "repair". *Why it is fatal:* **it converts an architecture whose entire claim is *nothing is edited* into a document that appears to claim editing. A single stray verb can invert the safety property in a reader's mind.** *Fix:* SP-A3, plus a mechanical check — grep the document for *edit, cut, cleave, knock, correct, repair*, and confirm each occurrence describes the cited literature and is explicitly excluded from the architecture.

FM-A.3 · The collision analysis omitted. *Signature:* an address published as a bare 20-mer. *Diagnostic:* without the Hamming analysis the address's real specificity is unknown — 0.000352 expected hits at `d = 0` against 11.47 at `d = 3`. **The address is either essentially unique or thirty-two-thousand-fold ambiguous depending entirely on a matcher tolerance that was never stated.** *Fix:* SP-A6, in full, for every published address.

FM-A.4 · The motif forgotten. *Signature:* an address designed without its address family stated. *Diagnostic:* fifteen positions in sixteen have no NGG. **A well-formed address to a non-addressable position is the exact molecular analogue of an IPv6 literal handed to an IPv4 socket: not unreachable, but malformed.** *Fix:* SP-A7.

FM-A.5 · Compactness cited as the mitochondrial reason. *Signature:* effector mass offered as the justification for a separate mitochondrial address family. **Compactness matters for packaging into a delivery vector; this architecture has no delivery vector, so it has no packaging limit, so the virtue is real and inapplicable.** *Fix:* SP-A9.

FM-A.6 · The protocol-stack overreach. *Signature:* the correspondence extended to acknowledgements, retransmission, checksums, sessions or congestion control. *Diagnostic:* ask which molecule performs the function; **if the answer is a shrug, the sentence is an analogy that has escaped its enclosure.** *Fix:* SP-A10.

FM-A.7 · Precedent laundered as evidence. *Signature:* the true-name doctrine, *zhengming* or the Alexandrian catalogue described with verbs like "confirms" or "anticipates the discovery of". *Why this section is especially exposed:* **the precedents here are unusually apt, and aptness is exactly what makes the laundering tempting.** *Fix:* SP-A11, and the deletion test of FM-R.5.

FM-A.8 · The numerological slide. *Signature:* a numerical coincidence presented as though it carried meaning; the canonical example is `4^18 = 2^36`. *Why it is a coincidence and nothing else:* both systems are built on powers of two, so coincidences of this shape are guaranteed and carry no information about either. **A framework that cannot say "this is a coincidence" out loud will eventually be unable to say anything.** *Fix:* SP-A12.

FM-A.9 · The silent wildcard. *Signature:* a system permits underspecified addresses without an explicit wildcard form, so ambiguity is expressed as tolerance rather than as a declared wildcard. *Why it matters:* **the failure is silent misrouting, the worst class of addressing failure**

because nothing reports it. *Fix:* require every address to be either fully specified or explicitly marked as a declared wildcard with its expected match count computed under SP-A6.

30.9 9 Results: three specifications worked end to end

Three complete specifications are worked here against the requirements of Section 7. **Two of them fail, and both failures are reported in the same plain language a success would get.** None of the three involves a laboratory, a subject, or a cell: each is arithmetic on a proposed design, and the arithmetic is the result.

30.9.1 9.1 An audible-band installation, evaluated and relocated

The proposal. A treatment room in which a subject is exposed to an audible-band programme at 85 dB SPL delivered through air by loudspeakers. The proposal document contains the sentence *"mechanotransduction (Nobel 2021) provides the pathway by which the programme reaches the cell."*

Step 1 — what arrives at the tissue surface. 85 dB SPL in air is a pressure amplitude of `p = 20e-6 x 10^(85/20) = 0.3557` Pa. Air and soft tissue are grossly mismatched:

```
Z_air    = 1.204 * 343  =     413.0 Pa.s/m
Z_tissue = 1050  * 1540 = 1.617e6   Pa.s/m      ratio = 3915.5
T_I = 4 Z1 Z2 / (Z1 + Z2)^2 = 1.021e-3 = -29.9 dB
```

Ninety-nine point nine per cent of the incident intensity is reflected at the skin. The pressure transmission coefficient is `2 Z2/(Z1+Z2) = 1.9995`, so the pressure amplitude just inside the tissue is essentially doubled to about 0.711 Pa while the intensity collapses. **Both facts are correct and they are not in tension; they are what an impedance step does.** For mechanotransduction the relevant quantity is force, so the pressure figure is carried forward, **and it is the more generous of the two.**

Step 2 — what that pressure does to a cell. Taking the programme's dominant energy at 1 kHz, `lambda = 1540/1000 = 1.54` m and `k d = 2 pi x 10e-6 / 1.54 = 4.08e-5`, so the pressure differential across the cell is about 0.004 per cent of 0.711 Pa, or `dp = 2.90e-5` Pa. At 0.711 Pa the intensity is `p^2/(2 rho c) = 1.56e-7` W/m²; the attenuation coefficient at 1 kHz is a thousandfold smaller than the 1 MHz value used in Section 4.6 under the nominal linear law, so the absorbed power in a 523.6 µm³ cell is negligible and the resulting radiation force is many orders of magnitude below a femtonewton. **Against the gating scale — 1.07 pN to do 1 kT of work over a 4 nm swing — the proposal's stated mechanism is short of its own requirement by a margin too large to close by any adjustment of level within the audible band.**

Step 3 — the thermal floor. At a 10 µm aperture and a 1 kHz receiver bandwidth, `p_noise = sqrt(4 kT rho c B / A) = 0.594` Pa. **The signal available at the cell, 0.711 Pa, is of the same order as the thermal noise at that aperture — an SNR of about 1.6 dB.** The programme is not below the floor, **but it is not meaningfully above it either, and nothing about a barely-above-noise scalar pressure supports the transmission of chosen content.**

Step 4 — the verdict. The proposal fails **SP-R3** (receiver/decoder conflation), **SP-R8** (uniform-pressure disclosure), **SP-R7** (no energy-scale statement) and **SP-R2** (standing constraint absent), and commits **FM-R.1** and **FM-R.8**. The rewritten sentence that passes:

> *Mechanically gated ion channels establish that pressure is a real input to cellular signalling; the 2021 Nobel Prize was awarded for the discovery of receptors for temperature and touch. At the levels and frequencies used in this installation, the computed pressure differential across a 10 µm cell is `4.08e-5` of peak and the radiation force is far below the ~1 pN scale of channel gating; we therefore make no claim of direct mechanical action on cells. There is no established mechanism*

by which a cell demodulates sequence-specific information from an acoustic signal. The installation's claimed effects are auditory and psychological, and they are stated and tested as such.

That rewrite loses nothing the proposal could actually support, and it gains the only thing that matters: a reader who checks the arithmetic will find it correct.

Step 5 — what the exercise establishes. The installation is not condemned; it is *relocated*. Its effects, if any, belong to the chain running ear → auditory system → expectation → physiology, which is a real chain with an identified channel, and which is exactly what the corpus's own belief postulate means by *grounded in truth*: **belief acts through a channel, and the channel must exist — the postulate's own forbidding clause is that zero channel gain implies zero effect for any strength of belief** [Curzi, 2026ab]. **The cell is a receiver. In this installation it is not the receiver being used. Saying so costs the proposal nothing it was entitled to and saves it from a claim it could not defend.**

30.9.2 9.2 An acoustic link, evaluated and corrected by a factor of 885

The proposal. An acoustic link intended to deliver a 20-nucleotide address — 40 bits — to cells in a 1 cm³ region at 4 cm depth, specifying a 5 MHz carrier, a peak pressure of 500 kPa at focus, and a symbol scheme of 16 tones spaced 40 kHz apart, each held for 10 µs. It claims a delivery time of 100 µs.

Step 1 — does the carrier reach the depth? Under the nominal linear law `alpha = 0.5 x 5 = 2.5` dB/cm, one-way loss at 4 cm is 10.0 dB. Under `f^1.1` the coefficient is 2.937 dB/cm and the loss 11.75 dB; under `f^1.5` it is 5.59 dB/cm and 22.36 dB. **Verdict: the depth is reachable, with a loss between 10.0 and 22.4 dB depending on the exponent. The proposal must state which exponent it assumed. It did not** — FM-C.9.

Step 2 — what is the spatial resolution, in cells?

```
lambda   = 1540 / 5e6 = 308 um
lambda^3 = 2.92e-2 mm^3
cells per voxel at 1e9 cells/cm^3 = 2.92e4 cells
```

Twenty-nine thousand cells share one resolution element. The 1 cm³ region contains `1000 / 2.92e-2 = 3.42e4` voxels, so the design can distinguish about thirty-four thousand locations, each containing about twenty-nine thousand cells. **Verdict: the delivery is a broadcast to blocks of `2.9e4` cells, and the proposal did not disclose it** — FM-C.4, SP-C5.

Step 3 — does the symbol scheme satisfy Gabor?

```
dt = 10 us,  df = 40 kHz
dt * df = 1e-5 * 4e4 = 0.400      required: >= 0.079577
0.400 >= 0.0796  ->  PASSES, with a margin of 5.03x
```

Verdict: the symbol scheme is physically realisable, and this is the part of the proposal that was done correctly — which should be said. At the Gabor optimum for the 640 kHz occupied bandwidth, `R_max = 6.669448 x 6.4e5 = 4.268e6` bit/s against the proposal's actual `log2(16)/10 µs = 4.0e5` bit/s: **the scheme runs at about 9.4 per cent of its Gabor ceiling, which is conservative and defensible.**

Step 4 — what is the actual capacity, at the receiver? The proposal's 100 µs for 40 bits implies `4.0e5` bit/s, and that figure uses the *transmitter's* symbol rate. Applying SP-C2, the receiving stage is mechanotransduction at a nominal `tau = 15` ms, so `f_c = 1/(2 pi x 0.015) = 10.61` Hz. At 500 kPa focal pressure attenuated 10 dB to 4 cm, the pressure at target is `5e5 x 10^(-10/20) = 1.5811e5` Pa; against aperture thermal noise at a 10 µm receiver in a 10.61 Hz band, `p_noise = 6.115e-2` Pa, the SNR is `20 log10(1.5811e5 / 6.115e-2) = 128.25` dB. **Capacity is logarithmic in SNR, so:**

```
C = 10.61 * log2(1 + 10^12.825) = 10.61 * 42.60 = 452.04 bit/s
40 bits in 88.5 ms
```

Verdict: the proposal is wrong by a factor of 885 in delivery time — 88.5 ms, not 100 µs. The error is entirely FM-C.2. **Note also that an SNR of 128 dB bought only a factor of about 6 in capacity over the 20 dB case, exactly as SP-C10 warns.**

Step 5 — the fatal objection, which is none of the above. Every number so far is a design correction, and the proposal can be rewritten to state its exponent, disclose its broadcast property, and correct its delivery time by three orders of magnitude. **None of that saves it. There is no established mechanism by which a cell demodulates sequence-specific information from an acoustic signal.** The 16-tone scheme presupposes a receiver that can distinguish sixteen frequencies and map them onto a symbol alphabet; **nothing in the mechanotransduction literature identifies such a receiver.** The cell's transducer is a low-pass amplitude device with no demonstrated frequency-discriminating front-end at the required selectivity and no demonstrated mapping from any spectral feature to a nucleotide symbol.

The capacity calculation was worth doing anyway, and this is the point of the whole analysis. It establishes that the failure is not one of bandwidth (452 bit/s is ample), not one of energy (the Landauer bound permits `2.05e14` bit/s at that pressure), and not one of thermodynamics. **The failure is located precisely: the receiver has no demodulator. That is a well-specified, falsifiable gap** [Curzi, 2026y], **and it is a far more useful thing to know than a vague sense that the idea is difficult.**

Step 6 — the rewritten specification.

```
ACOUSTIC LINK, HONEST SPECIFICATION
carrier             5 MHz
attenuation model   alpha = 0.5 f^1.0 dB/cm/MHz, NOMINAL; sensitivity to
                    b = 1.1 and b = 1.5 tabulated: 10.0 / 11.75 / 22.36 dB
                    one-way at 4 cm
spatial resolution  lambda = 308 um; lambda^3 = 2.92e-2 mm^3;
                    2.92e4 cells per voxel at 1e9 cells/cm^3 NOMINAL
delivery mode       BROADCAST to voxel populations. No acoustic mechanism
                    supplies cell-level selectivity. Selectivity, if any,
                    must be receiver-side.
symbol scheme       16 tones, 40 kHz spacing, 10 us hold.
                    dt.df = 0.400 >= 0.079577. Gabor PASSES, margin 5.03x.
                    Rate is 9.4% of the Gabor ceiling for the occupied band.
channel capacity    Receiver-limited. B = 10.61 Hz (NOMINAL kinetics).
                    C = 452 bit/s. 40 bits in 88.5 ms.
energy              Not limiting. Landauer bound at this pressure permits
                    ~2.05e14 bit/s; the shortfall is 11 orders of magnitude
                    in the permissive direction.
DECODER             NONE IDENTIFIED. Capacity is an upper bound on what a
                    perfect decoder could recover; it does not imply that any
                    decoder exists. There is no established mechanism by which
                    a cell demodulates sequence-specific information from an
                    acoustic signal.
claims made         Transmission arithmetic only. No clinical, medical or
                    therapeutic claim. No claim that DNA is edited or altered.
```

That specification is publishable. The original was not — and the difference is entirely a matter of stating what was computed and what was not.

30.9.3 9.3 An address block, specified completely and inert by construction

The problem. Specify a complete address block for a hypothetical target list of four nuclear loci and one mitochondrial locus, using the self-processing array format, and state exactly what has and has not been done. **This exercise builds a *format*. No molecule is synthesised, nothing is delivered, and no biological claim of any kind is made.**

Step 1 — choose the address family and pay for it. Canonical T-rich motif:

```
P(TTTV) = (1/4)^3 * (3/4) = 0.011719 = 1 in 85.33
reachable positions = 6.2000e9 * 0.011719 = 7.2656e7
mean spacing between addressable sites = 85.33 bp

ln(6.2e9)         = 22.5478 nats     unrestricted naming
ln(6.2e9 / 85.33) = 18.1013 nats     under TTTV
cost              =  4.4465 nats = 6.415 bits
```

Choosing this family throws away 6.415 bits of nameable genome in exchange for a recognition step that works. Stated, paid, moving on.

Step 2 — size the addresses. At a nominal 23 nt spacer: address space `4^23 = 7.0369e13`, address width 46 bits, required for genome uniqueness 32.53 bits, **over-provision 13.47 bits, a factor of `1.135e4`.**

Step 3 — collision analysis, per SP-A6. Computed for the 20-mer case and reported as the conservative bound, **since a 23 nt address is strictly better and a specification should not claim more margin than it has verified.** The per-site base under the NGG constraint is `6.2e9 x (1/16) / 4^20 = 3.5243e-4`:

matcher tolerance	ball size	expected genomic hits
exact (`d = 0`)	1	0.000352
`d <= 1`	61	0.021498
`d <= 2`	1,771	0.624152
`d <= 3`	32,551	11.471923
`d <= 4`	424,996	149.780999

Specification decision: the block is declared valid only for a matcher with tolerance `d <= 2`, where the expected collision count is 0.624 — under one. At `d = 3` the block would name eleven and a half places on average, **which is not an address; it is a neighbourhood.**

Note what just happened: the specification was constrained by the matcher, not by the address. That is Section 6.5's law in operation.

Step 4 — build the array as a multicast packet. Four nuclear addresses at a nominal 19 nt direct repeat:

```
per-address unit = 19 + 23 = 42 nt
total transcript = 4 * 42  = 168 nt
address bits     = 4 * 46  = 184 bits
framing bits     = 4 * 38  = 152 bits
header overhead  = 152 / (184 + 152) = 45.24 %
```

One hundred and sixty-eight nucleotides carries four fully specified destinations, self-delimited, in a format the enzyme itself is documented to parse.

Step 5 — the mitochondrial address, handled honestly.

```
mtDNA positions, both strands = 33,138
bits required for uniqueness  = 15.02 bits = 7.51 nt
```

```
a 23-nt address provides      = 46 bits
over-provision                = 30.98 bits = factor 2.1e9
```

The address is over-provisioned by a factor of two billion. Naming is not the problem, and no change of address length touches the actual problem, which is that the destination is not reachable by the transport this format assumes (Section 6.8). **The mitochondrial target is therefore placed in a separate address family with its own declared transport**, and is not merged into the nuclear array, because merging would produce an address that is well-formed and unroutable. **Compactness is not used as the justification** — SP-A9.

Step 6 — the complete block.

```
ADDRESS BLOCK, HONEST SPECIFICATION

format             self-processing crRNA array
address family     TTTV. P = 0.011719 per position. Reachable sites
                   7.2656e7 of 6.2000e9. Variety cost 4.4465 nats
                   (6.415 bits) relative to unrestricted naming.
address width      23 nt = 46 bits. Space 4^23 = 7.0369e13.
                   Genome requires 32.53 bits; over-provision 13.47 bits.
matcher tolerance  VALID ONLY FOR d <= 2. Expected collisions:
                   d=0: 0.000352 | d<=1: 0.0215 | d<=2: 0.624
                   d<=3: 11.47 -- OUT OF SPECIFICATION.
array              4 nuclear addresses. 168 nt. 184 address bits,
                   152 framing bits, 45.24 % header overhead.
5th target         MITOCHONDRIAL. SEPARATE ADDRESS FAMILY, separate declared
                   transport. Reason: reachability, NOT compactness.
payload            Base-4 encoded content at 2 bits/nt. Length arbitrary.

WHAT HAS BEEN DONE A format has been specified and its collision, family and
                   framing arithmetic computed.
WHAT HAS NOT       Nothing synthesised. Nothing delivered. No protein and no
                   nucleic acid introduced into any cell. NOTHING IS EDITED,
                   AND THE ARCHITECTURE CANNOT EDIT.
OPEN PROBLEM       There is no established mechanism by which a cell
                   demodulates sequence-specific information from an
                   acoustic signal.
CLAIMS             None clinical, medical or therapeutic. None biological.
                   This is a routing specification.
```

Step 7 — what the exercise establishes. The addressing layer is **fully specifiable, fully computable, and completely inert.** Every number above was computed; none required a laboratory; none touched a cell.

That inertness is the point. A design whose addressing layer is a pure computation is a design whose addressing layer cannot harm anyone, cannot be misused into editing, and can be published, audited and criticised in the open by anyone with a computer. **An architecture that delivers nothing has not removed anyone's ability to decline, because it has not reached them at all** — which is simultaneously its strongest safety property and its most serious unsolved problem, **and the two are the same fact.** The corpus's standing refusal to move a harm through a discovered gap in a scheme, and its concession that the case where a feedback loop runs through another person's will is an unsettled seam, bound what may be claimed here [Curzi, 2026].

30.9.4 9.4 A discrepancy in the source, reported rather than harmonised

One figure in the source manuscript does not reproduce, and it is reported here rather than quietly corrected. The source's diagnostic for the transmitter-bandwidth fault states that "at

20 dB SNR the medium-limited figure at 1 kHz bandwidth is `1.06e4` bit/s" against a receiver-limited 70.65 bit/s, "an inflation factor of about 150".

Recomputing: `C = B log2(1 + 100)` with `log2(101) = 6.6582` gives `1000 x 6.6582 = 6,658` bit/s at a 1 kHz bandwidth, not `1.06e4`. The figure `1.060e4` is the *fast mechanotransduction* row of the receiver table at `B = 1591.6` Hz — `1591.6 x 6.6582 = 10,597` — and `10,597 / 70.65 = 150.0` is exactly the source's stated ratio. **The arithmetic is correct and the label is wrong: the comparison is between two receiver stages, one of which is described as the medium.**

The corrected figures, which this paper uses throughout:

```
receiver-limited, tau = 15 ms   B =   10.61 Hz   C =     70.65 bit/s
receiver-limited, tau = 100 us  B = 1591.6  Hz   C = 1.0597e4  bit/s   ratio 150.0
medium-set, B = 1 kHz                            C = 6.658e3   bit/s   ratio  94.2
full 1 MHz carrier substituted                   C = 6.658e6   bit/s   ratio 9.4e4
```

None of the paper's conclusions changes. The point of the diagnostic — that substituting a bandwidth other than the binding receiver stage inflates capacity by orders of magnitude — holds at 94.2, at 150.0 and at `9.4e4` alike. **The correction is printed because a reader recomputing `1000 x 6.6582` would otherwise find a discrepancy and have no way to tell whether the error was in the label or in the physics.**

30.10 10 Discussion

30.10.1 10.1 What follows

The most transferable result is methodological: computing a favourable number and then refusing to use it. Three explanations for why acoustic control of cellular content does not work are eliminated here — bandwidth, energy and thermodynamics — and eliminating them is the whole contribution, because it leaves the two that remain in plain view. **A field advances by removing wrong explanations at least as much as by supplying right ones** [Platt, 1964, Popper, 1959]. **The demand this paper is built to meet is Meehl [1967]'s: a directional prediction in a soft science is nearly costless, so a method must make point predictions with numbers in them or it is not being tested at all. Sections 5.3, 5.4, 5.7 and 6.5 are the answer — five computed ratios, each of which could have come out otherwise.**

The receiver-bandwidth result generalises well beyond this subject. Any analysis of a channel terminating in a slow transducer has the same structure: the medium's bandwidth is irrelevant and the transducer's corner frequency is everything. **The inflation factor from substituting one for the other is about 150 in the comparison of Section 5.7 and roughly `1e5` at full carrier bandwidth**, and that error is not exotic — it is the default error.

The resolution–depth trade is a hard physical constraint with an exponent. `lambda d20` falling as `1/f^2` is the reason no purely acoustic scheme addresses individual cells at depth, and stating it as a product rather than as two separate quantities is what makes the impossibility visible. **The corpus reaches structurally parallel results elsewhere whenever apparent multiplicity collapses onto a single effective unit: a five-house network measures 3.819710 effective jurisdictions naively and 1.000000 effective blocs once the coordinating perimeter is treated as one, giving `h = -0.500000`** [Curzi, 2026]. **The `3.65e6` cells in one acoustic voxel are the same arithmetic: a large naive count and an effective count of one addressee.**

A third parallel is worth naming because it shows the same denomination trick at work elsewhere in the corpus. A branch of a forecast is scored 0-3 for the steepness of each step, summed to a resistance `R`, and weighted as `1/2^R`, so a three-point difference in steepness is a factor of eight in expectation [Curzi, 2026]. **That is the same operation as putting capacity, energy and resolution on one logarithmic scale and reading off which term dominates.**

And the addressing law is the most portable single sentence here. *Usable specificity is set by the tolerance of the matcher, not by the length of the address.* It holds for genomic addresses, for network forwarding, for record reconciliation, and for any system that matches a

name against a store. **The corpus's own canonical-form work is the same result in another domain: comparing entries on a canonical form with an independent byte-hash witness takes a reconciliation false-break rate from 40.0 per cent to 0.0 per cent at a 40 per cent manipulation rate** [Curzi, 2026] — **a tightened matcher, not a longer name.**

30.10.2 10.2 What does not follow

It does not follow that anything is decoded. Capacity is an upper bound on what a perfect decoder could recover. **Nothing in this paper identifies a decoder, and Section 12 states exactly what would.**

It does not follow that the storage-law reading of cellular state is true. It is a model-form claim, badged, and the corpus's own treatment of the contraction mapping is the bound to read alongside it: **a human life is not a metric space, nobody has measured the relevant contraction modulus, and the theorem therefore transfers as shape rather than as guarantee** [Curzi, 2026]. The same discipline applies one scale down.

It does not follow that the essence ladder describes anything physical. `k` is a defined constant; the hertz attachment is a postulate; the frequencies are essence frequencies and not resonances (Section 5.12). **The corpus's own analysis of the related width statistic is the sharpest available bound: a statistic invariant under relabelling does not even determine the object it is computed from, which formally blocks any inference from it to a physical or psychological state** [Curzi, 2026].

It does not follow that precedent supports any of this. Every precedent item in Sections 4.2, 4.8, 6.4, 6.6 and 6.7 is credited at one to three bits against six to twenty for the measured column, and **the columns are never summed** [Curzi, 2026w].

And it does not follow that a favourable capacity makes the architecture safe. The safety property is that nothing is delivered, and it is structural. **If anything were ever delivered, the safety property would be gone and the capacity figure would become a liability rather than a curiosity.**

30.10.3 10.3 Relation to the surrounding literature

The information-theoretic core is standard [Shannon, 1948, Shannon and Weaver, 1949, Cover and Thomas, 2006, Hartley, 1928] and the time–frequency bound is classical Fourier analysis [Gabor, 1946]. **The one place where this paper puts two standard results together to get a number that is not standard is Section 5.9's crossover at 20.034 dB**, and it is offered as a design point rather than as a discovery.

The thermal treatment rests on fluctuation–dissipation [Callen and Welton, 1951] and the energetic floor on Landauer [Landauer, 1961]. **Where the corpus reaches for physics beyond that it is bounded by its own analysis of the speculative margin, which reports that decoherence suppresses coherences as `rho_01(t) = rho_01(0) exp(-t/tau)` and changes no diagonal element — converting a superposition into something that looks classical without solving measurement** [Curzi, 2026aa]. **No quantum content is imported into any acoustic calculation here, and FM-C.8 exists to keep it out.**

The leaky-integrator reading of a transducer has a century-old precedent in exactly the domain it is applied to [Lapicque, 1907, Gerstner and Kistler, 2002, Usher and McClelland, 2001], and the first-order difference equation's properties are textbook [Elaydi, 2005, Oppenheim et al., 1996, Horowitz and Hill, 2015, Banach, 1922]. **That precedent supports the *shape*; it does not support the corpus's particular parameterisation, and Section 4.7 says so. The cleanest physical instance of the same shape is acoustic and is worth naming here: reverberation is an exponential decay with a measurable time constant** [Sabine, 1922, Schroeder, 1965], **which is the storage law's own `delta` in a medium where it can actually be measured.**

A structurally parallel concentration result appears elsewhere in the corpus on a different axis. A constructed maturity stack of 37.0/11.0/7.0/16.5/15.5/13.0 per cent gives a time-axis

concentration index of 0.222050, an effective spread of 4.50 buckets and 55.0 per cent refinancing within three years, against a flat ladder's 0.1667, 6.00 and 50.0 per cent [Curzi, 2026]. **The arithmetic of "many nominal units, few effective ones" is the same arithmetic as the acoustic voxel, and noticing that it recurs is the corpus's own claim rather than an argument for any of it.**

On the addressing side the relevant general literature is engineering rather than biological: open design and least privilege [Saltzer and Schroeder, 1975], disclosure as a structural property [Kerckhoffs, 1883, Curzi, 2026], and the measurement-corruption warnings that explain why a matcher scored on finding targets drifts toward tolerance [Goodhart, 1975, Campbell, 1979]. **The biological literature that actually carries the claims is named in Appendix A and carries no keys, for the reason in Section 3.7 — which is the single largest defect in this paper's apparatus.**

Finally, two standing corpus-level cautions apply here as everywhere. **The surplus functional's logarithmic form is underdetermined by the evidence:** a sub-linear power law [Latané, 1981] and `n log n` [Briscoe et al., 2006] fit the same qualitative facts, and the strongest available warrant for a logarithm is dynamical rather than perceptual [Peters and Gell-Mann, 2016]. **And no scaling or heavy-tail claim is made anywhere in this paper**, so the distribution-fitting procedure such a claim would require [Clauset et al., 2009] does not apply; the two power laws that do appear — `lambda d20 ~ 1/f^2` and radiation force quadratic in pressure — **have exponents defined by the physics, not estimated from data.**

30.11 11 Verification

30.11.1 11.1 Dimensional audit

Every quantity, its dimension, its unit, and its epistemic status. `[1]` denotes dimensionless.

Symbol	Dimension	Unit	Status
`p`	`[M L^-1 T^-2]`	Pa	**measured / specified** input pressure
`Z = rho c`	`[M L^-2 T^-1]`	Pa·s/m	**derived** from nominal `rho` and `c`
`T_I`, `t_p`	`[1]`	none	**derived** transmission coefficients
`I`	`[M T^-3]`	W/m²	**derived**: `p^2/(2 rho c)`
`lambda`	`[L]`	m	**derived**: `c/f`
`f`	`[T^-1]`	Hz	**specified**
`k = 2 pi/lambda`	`[L^-1]`	m⁻¹	**derived**
`k d`	`[1]`	none	**derived**, the fractional pressure differential
`alpha`	`[L^-1]`	dB/cm	**nominal**, and frequency-dependent
`d20`	`[L]`	cm	**derived** from `alpha`
`lambda d20`	`[L^2]`	mm·cm	**derived**; the product that falls as `1/f^2`
`kT`	`[M L^2 T^-2]`	J, or pN·nm	**standard**: `4.280e-21` J at 310 K
`T` (tension)	`[M T^-2]`	mN/m	**assumed** in the illustrative gating table
`dA`	`[L^2]`	nm²	**assumed** in the same table

Symbol	Dimension	Unit	Status
`B`	`[T^-1]`	Hz	**derived** from a **nominal** time constant, `f_c = 1/(2 pi tau)`
`S/N`	`[1]`	none (dB when logged)	**derived**
`C`	`[T^-1]`	bit/s	**derived. The bit is Shannon information [Jaynes, 2003] and is dimensionless; the rate carries `[T^-1]`**
`dt df`	`[1]`	none	**derived**; the Gabor product, dimensionless as a time times a frequency
`R_max/B`	`[1]`	bit/s/Hz	**derived**: `4 pi log2(e)/e = 6.669448`
address bits	`[1]`	bit	**derived**: `log2` of a count of positions
nats	`[1]`	nat	**derived**: `ln` of a count. `1 nat = log2(e) = 1.442695 bit`
`Q`, `eta`, `delta`, `C_cost`	see below	—	**modelling choice** (Section 4.7)

Does the storage law balance? `Q_{t+1} = (1-delta)Q_t + eta S_t - C_t` balances only if `eta` `S` and `C` carry the dimension of `Q` per period. **In Section 4.7 `Q` is "durable regulatory state" and has no operational unit at all**; `delta` is per period and dimensionless in magnitude, `S` is dimensionless in the illustrative parameterisation, and `eta` therefore carries `[Q]` directly. **The equation balances by stipulation of the units rather than by measurement of them, and that is said here rather than left implicit. `Q` at cellular scope is a placeholder with no instrument behind it**, and Section 12 records the consequence.

Where a quantity has no operational unit, that is said. Every physical quantity in Sections 4.6, 5 and 6 is on a ratio scale with a true zero and the arithmetic performed on it is licensed. **`Q` is not**, and the psychological constructs elsewhere in the corpus are not [Michell, 1997, Luce and Tukey, 1964]. The typology being applied is Stevens's [Stevens, 1946], and the operation that separates the licensed cases from the stipulated ones is division by a quantity with a true zero.

30.11.2 11.2 The postulates

Six postulates. Each is atomic, checkable alone, and carries its status. **Where a postulate could be dropped and the result still follow, it has been dropped.**

P1 — Soft tissue has `c = 1540` m/s, `rho = 1050` kg/m³, and attenuation `alpha = 0.5 f_MHz` dB/cm with exponent 1.0. *Status:* **NOMINAL CONSTANTS**, conventional round figures rather than measurements of any tissue. Section 5.4 computes the sensitivity, and **every alternative exponent moves the conclusion in the same direction.**

P2 — A cell is 10 µm in diameter and soft tissue holds `1e9` cells per cm³. *Status:* **NOMINAL, ORDER OF MAGNITUDE ONLY.** The voxel occupancy of Section 5.3 is linear in this figure, so an order-of-magnitude error moves `3.65e6` to between `3.65e5` and `3.65e7` — **and changes no conclusion, because all three are broadcasts.**

P3 — An acoustic resolution voxel is `lambda^3`. *Status:* **MODELLING CHOICE, and a deliberately optimistic one**, since real focused-beam resolution is worse than a wavelength laterally. **The optimism is in the direction unfavourable to this paper's conclusion, which is why it is adopted.**

P4 — Shannon's capacity theorem and the Gabor limit hold. *Status:* **CITED** [Shannon, 1948, Gabor, 1946]. **Both are theorems, and the Gabor bound is independently derived within this corpus** [Curzi, 2026z].

P5 — The receiver's bandwidth is the corner frequency of the slowest stage that must resolve a symbol, `f_c = 1/(2 pi tau)`. *Status:* **DEFINITION**, plus **NOMINAL** time constants. It carries no empirical weight of its own; it is the identification that makes the capacity figure a statement about a cell rather than about a loudspeaker.

P6 — A nucleotide carries two bits and the human haploid genome is about `3.1e9` base pairs. *Status:* **DEFINITION** and **CITED FACT** respectively; the genome figure is a standard round number and the bit count is `log2(4)`.

Two postulates considered and dropped. An earlier form of the capacity argument assumed a specific noise model at the cell. It is not needed: **the receiver-limited capacity of Section 5.7 is dominated by `B`, and the conclusion "the pipe is adequate" holds at every SNR in the table, from 10 dB to 30 dB.** An earlier form also assumed a specific coupling efficiency from field to membrane tension; **it is not needed either, because Section 4.6's conclusion is stated as a ratio against the gating scale and the ratio is six orders of magnitude at kilopascal pressures.**

30.11.3 11.3 The compounding chain

```
P1          -> L1   lambda(f) = 1540/f; at f = 1e6, lambda = 1.54 mm       ARITHMETIC
P1 + P2     -> L2   f at which lambda = 10 um is 1540/1e-5 = 1.540e8 Hz    ARITHMETIC
P3 + P2     -> L3   cells per voxel = lambda^3 * 1e9 per cm^3
                    at 1 MHz: (1.54e-3 m)^3 = 3.652e-9 m^3 = 3.652 mm^3
                    x 1e6 cells/mm^3 = 3.652e6                            ARITHMETIC
P1          -> L4   d20(f) = 20 / (0.5 f_MHz) cm; at 154 MHz, 0.2597 cm    ARITHMETIC
L1 + L4     -> R3   lambda x d20: 6160 mm.cm at 0.1 MHz, 0.0026 at 154 MHz
                    and the product falls as 1/f^2 exactly                 ARITHMETIC
P5          -> L5   tau = 15 ms -> f_c = 1/(2 pi 0.015) = 10.6103 Hz       ARITHMETIC
P4 + L5     -> R1   C = 10.6103 * log2(1 + 100) = 10.6103 * 6.6582
                    = 70.646 bit/s                                         ARITHMETIC
R1          -> R1b  40 bits / 70.646 = 0.56620 s                           ARITHMETIC

                    = 23.93 days; per-cell rate 70.646/3.6523e6
                    = 1.934e-5 bit/s                                       ARITHMETIC
P4          -> R5   R_max/B = 4 pi log2(e)/e = 12.56637 x 1.442695 / e
                    = 18.13106 / 2.718282 = 6.669448                       ARITHMETIC
R5 + P4     -> R5b  Shannon equals Gabor when log2(1+S/N) = 6.669448,
                    so S/N = 2^6.669448 - 1 = 100.79 = 20.034 dB           ARITHMETIC
P6          -> R6a  log2(2 x 3.1e9) = log2(6.2e9) = 32.5296 bits           ARITHMETIC
P6          -> R6b  ln(6.2e9) - ln(6.2e9/85.3333) = ln(85.3333)
                    = 4.44653 nats = 6.4152 bits                           ARITHMETIC
P6          -> R6c  ball(20,2) = 1 + 60 + 1710 = 1771;
                    1771 x 3.5243e-4 = 0.62415 expected hits               ARITHMETIC
P6          -> R6d  ball(20,3) = 1771 + 30780 = 32551;
                    32551 x 3.5243e-4 = 11.4718 expected hits              ARITHMETIC
```

Three checks a reviewer can redo in a minute: `1540/10e-6 = 1.54e8`; `1/(2 pi x 0.015) = 10.6103`; and `2^6.669448 = 101.79`, so `S/N = 100.79`. Everything in R1, R3, R4 and R5 follows from those and from the nominal constants of P1, P2 and P5.

What the chain does not establish. It does not establish that any cell responds to any particular acoustic stimulus. It does not establish that a decoder exists. **And R1's status depends entirely on P5's nominal time constant: at 10 ms the capacity is 106.0 bit/s and at 1 s it is 1.06 bit/s, so the figure is a scale, not a measurement**, which is why Section 5.7 prints the whole table rather than one number.

30.11.4 11.4 The verification instance, worked

The smallest instance exercising the whole chain is the crossover of Section 5.9, because it uses both bounds and nothing else.

```
Gabor tone channel:   M <= 4 pi B dt,  R = log2(M)/dt
maximise:             d/d(dt) [ log2(4 pi B dt)/dt ] = 0
                      =>  ln(4 pi B dt) = 1  =>  4 pi B dt = e
                      =>  dt* = e/(4 pi B)
substitute:           R_max = log2(e) / (e/(4 pi B)) = 4 pi B log2(e)/e

numerically:          4 pi = 12.566371
                      log2(e) = 1.4426950
                      12.566371 x 1.4426950 = 18.131060
                      18.131060 / 2.7182818 = 6.6694480

Shannon equals it when  log2(1 + S/N) = 6.6694480
                        1 + S/N = 2^6.6694480 = 101.7900
                        S/N = 100.7900 = 10 log10(100.79) = 20.0342 dB
```

Status: **ARITHMETIC** on a **DEFINITION** (the tone-selection scheme) and a **CITED** theorem. **A reader with a calculator can confirm every figure, and the agreement of two independently derived bounds at a single ratio is the strongest internal check in the paper.**

30.11.5 11.5 Limits, asymptotics, and the domain of validity

Limit	Behaviour	Reading
`f -> 0`	`lambda -> infinity`, `k d -> 0`, cells per voxel `-> infinity`	the field is perfectly uniform and perfectly non-selective; the audible band is here
`f -> 154` MHz	`lambda -> d`, cells per voxel `-> 1`	**the only frequency at which the field resolves a cell**, and `d20 = 2.6` mm
`f -> infinity`	`d20 -> 0` as `1/f`, `lambda d20 -> 0` as `1/f^2`	resolution is bought at a quadratic price in reachable volume; **the door closes**
`S/N -> 0`	`C -> 0`	no signal, no capacity; correct
`S/N -> infinity`	`C ~ B log2(S/N)`, unbounded but logarithmic	**shouting never buys a fast channel**; the 100 Pa $\rightarrow$ 1 MPa case buys 2.80×
`B -> 0`	`C -> 0`	**a receiver that cannot change state carries nothing, whatever the medium does**
`tau -> 0`	`f_c -> infinity`, `C -> infinity`	an infinitely fast transducer; no biological stage approaches it

Limit	Behaviour	Reading
`A -> 0` (aperture)	`p_noise -> infinity` as `A^-1/2`	**small receivers are noisy receivers**; the formula's own regime fails first (Section 5.5)
`d -> 0` (matcher tolerance)	expected hits `-> 3.52e-4`	a perfect matcher; the address is essentially unique
`d -> 20`	ball `-> 4^20`, hits `-> 3.875e8`	**a matcher with total tolerance names every addressable position**, which is the reductio of FM-A.3
`delta -> 0` in Section 4.7	no decay; state persists forever	**a pathology, not an ideal** — nothing decays out of the stock [Curzi, 2026a]

Two domain restrictions follow and are stated as restrictions. The aperture noise formula of Section 5.5 is valid only for `k a >> 1` and is used at cellular scale where `k a << 1`; it is therefore a reference calculation with a declared regime rather than a characterisation, and **the paper carries two estimates rather than pretending one suffices.** And the `lambda^3` voxel convention of P3 is optimistic; **real lateral resolution is worse, so the true cells per voxel exceed the figures given.**

30.11.6 11.6 Invariance, and how far each claim has been tested

The resolution–depth product's `1/f^2` scaling is invariant under the attenuation coefficient's magnitude and not under its exponent. Doubling `alpha` halves `d20` at every frequency and leaves the exponent untouched; changing the exponent from 1.0 to 1.5 changes the product's slope from `-2` to `-2.5`. **Tested at three exponents (1.0, 1.1, 1.5) and at three frequencies (10, 100, 154 MHz): nine points, all moving the conclusion in the same direction. Nine points, not a proof.**

The Gabor–Shannon crossover is invariant under everything. `6.669448` is `4 pi log2(e)/e`, a pure number with no physical constant in it, so the 20.034 dB crossover holds for any wave, any medium and any bandwidth. **That is the strongest invariance claim in the paper and it is an identity rather than a sample.**

The capacity figure is not invariant and is not claimed to be. It scales linearly in `B` and logarithmically in `S/N`, and `B` rests on a nominal time constant that varies by isoform and preparation. **The invariant statement is the ordering — receiver bandwidth dominates medium bandwidth by orders of magnitude — and only that ordering is asserted.**

The address arithmetic is invariant under genome size to within a logarithm. A tenfold error in `3.1e9` moves `log2(6.2e9) = 32.53` bits by `log2(10) = 3.32` bits, **which changes no verdict about a 40-bit or 46-bit address.**

30.11.7 11.7 Model comparison, audited against what proper model comparison requires

No model is fitted anywhere in this paper and no parameter is estimated from data. That makes several standard requirements inapplicable rather than unmet, **and the distinction is drawn explicitly here rather than used as cover.**
